
1) Things to note from supplemental Figure 2:
   1) Closing schools, restaurants and bars dropped the infection rate about four fold, seemingly a combination of the individual effects of closing bars and closing schools seen in states that ordered those separately.
   2) The effect of closing schools eateries is as strong here, at a time when daily new infections were close to a thousand, as they were in other states with daily new infection rates in the tens, supporting the idea that the proportional effect of a particular mandate is about the same whether implemented early or late.
   3) As with other states, opening the economy stopped the decline in infections. Opening in stages resulted in staged increases in slope.
   4) Mandating masks had no apparent immediate effect during the lockdown, as the previous mandates had already sent infection rates into decline. However, when the state opened up, it did not return to the post-school closing doubling rate of 5.9 days, as was seen in states that had not required masks (Figure 3), but instead to the lower rates that resulted from late-post-opening mask mandates. Thus, like the effect of closing schools, the effect of mandating masks seems to last as long as the mandate is in place.

Widespread use of face masks in public may slow the spread of SARS CoV-2: an ecological study

Abstract

Background

The reasons for the large differences between countries in the sizes of their SARS CoV-2 epidemics is unknown. Individual level studies have found that the use of face masks was protective for the acquisition and transmission of a range of respiratory viruses including SARS CoV-1. We hypothesized that population level usage of face masks may be negatively associated SARS CoV-2 spread.

Methods

At a country level, linear regression was used to assess the association between COVID-19 diagnoses per inhabitant and the national promotion of face masks in public (coded as a binary variable), controlling for the age of the COVID-19 epidemic and testing intensity.

Results

Eight of the 49 countries with available data advocated wearing face masks in public – China, Czechia, Hong Kong, Japan, Singapore, South Korea, Thailand and Malaysia. In multivariate analysis face mask use was negatively associated with number of COVID-19 cases/inhabitant (coef. -326, 95% CI -601- -51, P=0.021). Testing intensity was positively associated with COVID-19 cases (coef. 0.07, 95% CI 0.05-0.08, P<0.001).

Conclusion

medRxiv preprint doi: https://doi.org/10.1101/2020.03.31.20048652; this version posted April 6, 2020. The copyright holder for this preprint

Whilst these results are susceptible to residual confounding, they do provide ecological level support to the individual level studies that found face mask usage to reduce the transmission and acquisition of respiratory viral infections.

Background

SARS CoV-2, the viral cause of COVID-19, has spread rapidly to over 190 countries [1]. There has, however, been remarkable variation in how extensively it has spread and in the national responses to this spread [1, 2]. For example, although the virus is thought to have first emerged in China, European countries such as Italy and Spain have reported roughly 30-fold higher number of infections per capita than China [1, 2]. Understanding the reasons underpinning this heterogeneity in spread is crucial to ongoing prevention efforts. The cornerstones of prevention efforts have included extensive testing, contact tracing and isolation and various forms of social distancing/quarantining [3, 4]. Whilst there have been important differences in how these were implemented in different countries, arguably the most striking difference in approach has been in the use of universal face masks in public. Whereas a number of predominantly Asian countries have promoted this practice, the World Health Organization (WHO) and most European and North American countries have not promoted this strategy [5, 6]. The head of the Chinese Center for Disease Control and Prevention has stated that the biggest mistake that Europe and the US were making in tacking COVID-19 was their failure to promote the widespread usage of face masks in public [7]. The WHO argues against universal face mask use based on a lack of evidence to support the practice, as well as a concern that using face masks will provide users with a false sense of security which may result in poorer hand hygiene and hence increased transmission [3, 5, 8]. The US Centers for Disease Control and Prevention does not recommend that people who are well wear a face mask to protect themselves from respiratory diseases, including COVID-19 [5]. In fact, the US Surgeon General stated that facemasks “are not effective in

medRxiv preprint doi: https://doi.org/10.1101/2020.03.31.20048652; this version posted April 6, 2020. preventing (the) general public from catching coronavirus" and urged people to stop buying face masks [5].

Advocates of universal usage of face masks point to four types of evidence. Firstly, SARS CoV-1 and -2 are spread mainly through contact- and droplet- but also through airborne-transmission [6, 9]. Detailed environmental and epidemiological investigations from the large Amoy Gardens outbreak of SARS CoV-1 revealed that airborne transmission played an important role in the outbreak [10, 11]. Likewise in vitro studies demonstrate that SARS CoV-2 can be aerosolized and remain viable in the air in this form for at least 3 hours [12]. Although viral viability was not assessed, air samples from hospital rooms and toilets used by COVID-19 patients as well as from a crowded entrance to a department store tested positive for SARS CoV-2 [13]. Even if we discount the evidence of airborne transmission, face masks could play a major role in reducing droplet and possibly contact (via reduced digital-oral interactions) transmission. The second type of evidence is that from epidemiological studies showing that masks do provide this protective effect. One systematic review on the efficacy of face masks to prevent influenza, found evidence that face masks were effective in preventing the transmission to others and weaker evidence that they prevented influenza acquisition [14]. Likewise, a systematic review and metanalysis in health care workers found that mask wearing was associated with a lower incidence of clinical respiratory infections [15]. A Cochrane review of different physical measures to prevent the acquisition of respiratory viruses found face masks to be the most effective of all measures investigated - including social distancing [16]. The results were similar for studies limited to SARS CoV-1 transmission, with the authors concluding: 'wearing a surgical mask or a N95 mask is the measure with

medRxiv preprint doi: https://doi.org/10.1101/2020.03.31.20048652; this version posted April 6, 2020. It is made available under a CC-BY-NC-ND 4.0 International license .

the most consistent and comprehensive supportive evidence' [16]. Thirdly, there is increasing evidence that a large proportion of SARS CoV-2 transmission occurs from pauci- or asymptomatic individuals. An estimated 30% of infections are truly asymptomatic and 80% mild infections [17]. Evidence is also mounting that infected individuals are infectious prior to the onset of symptoms [18]. Taken together these findings provide an explanation for why epidemiological studies have found that nondocumented infections were the infection source for 79% of documented cases in Wuhan, China [18]. In this setting limiting masks to confirmed infections is far less likely to have an impact on transmission than universal use. The key argument for universal use is thus preventing transmission and a secondary argument is preventing acquisition [7, 9].

These considerations provided the motivation for the current analysis where we assessed if there was ecological level evidence that countries that promoted face mask usage in public had a lower number of COVID-19 diagnoses per capita.

Methods

Dependent variable:

The *cumulative number of cases of COVID-19* infection per million inhabitants on 29 March 2020 per country. This data was obtained from the European Centre for Disease Prevention and Control (ECDC) data repository: https://www.ecdc.europa.eu/en/geographical-distribution-2019-ncov-cases

Independent variables:

medRxiv preprint doi: https://doi.org/10.1101/2020.03.31.20048652; this version posted April 6, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. It is made available under a CC-BY-NC-ND 4.0 International license .

Universal face mask. A binary variable equal to 1 or 0 according to whether or not national policies promote the wearing of face masks in public regardless of symptoms. Countries were classified according to a narrative review of official national documents and other sources (STable 1).

Testing intensity. Cumulative number of nucleic acid amplification SARS CoV-2 tests conducted per country per million inhabitants up till 29 March 2020. This data was extracted from the Wikipedia COVID-19 testing site on 29 March 2020: https://en.wikipedia.org/wiki/COVID-19_testing

Age of epidemic. The date the first case of COVID-19 was diagnosed in each country. This was measured in days after the first COVID-19 case was officially reported in China (10 January 2020). This data was obtained from the ECDC data repository on 29 March 2020: https://www.ecdc.europa.eu/en/geographical-distribution-2019-ncov-cases

Data analysis

Linear regression was used to analyze the association between the independent and dependent variables. We controlled for the fact that SARS CoV-2 epidemic is at different stages in different countries via two methods. Firstly, the 'age of the epidemic' variable was included in all analyses. Secondly, we only included countries with at least 500 cumulative cases and countries whose first case was reported before 7 March 2020. Countries with missing data were dropped from the analyses. The analysis was performed in STATA version 16 (Stata Corp, College Station, Tx). Although Hong Kong is a part of China it was included as a separate data point in

medRxiv preprint doi: https://doi.org/10.1101/2020.03.31.20048652; this version posted April 6, 2020. keeping with its population size and relative autonomy as regards public health responses. Because Czechia was the only country to introduce universal face masks late in the epidemic (18 March 2020), we repeated the analyses excluding Czechia [19, 20].

Results

Forty-nine countries were found with complete data, epidemics older than 7 March 2020 and more that 500 cases/million inhabitants (STable 1). Large variations were evident in the number of COVID-19 cases per million inhabitants (median 158, interquartile range [IQR] 20-486), testing per million (median 1723, IQR 307-4802) and the date of the first case (median 24 February, IQR 28 January – 28 February; STable 1). Only 8 of these countries advocated wearing face masks in public – China, Czechia, Hong Kong, Japan, Singapore, South Korea, Thailand and Malaysia. These countries tended to have older epidemics. Seven of the 8 were in the group of countries with the 10 oldest epidemics (STable 1).

In multivariate analysis face mask use was negatively associated with number of COVID-19 cases (coef. -326, 95% CI -601- -51, P=0.021; Table 1). Testing intensity was positively associated with COVID-19 cases (coef. 0.07, 95% CI 0.05-0.08, P<0.001).

Repeating the analyses excluding Czechia strengthened the association between COVID-19 cases and face mask usage slightly (STable 2).

Discussion

medRxiv preprint doi: https://doi.org/10.1101/2020.03.31.20048652; this version posted April 6, 2020. The copyright holder for this preprint

In this ecological study we found that countries that promoted widespread face mask usage had lower cumulative numbers of COVID-19 diagnosed after controlling for testing intensity and age of the epidemic. It is important to note that this association may be entirely explained by unmeasured confounders. For example, if countries promoting universal face masking also conducted more effective contact tracing and isolation than other countries and this was responsible for the slower spread, our study design would have falsely attributed this effect to using face masks. We did not have accurate data to control for these confounders. We did however control for testing intensity which is an important potential confounder. We also controlled for the age of the epidemic which is an obvious independent determinant of the size of the epidemic. A further limitation of our study was that we were unable to quantitate the intensity of face mask use per country. This resulted in a rather crude binary classification of face mask usage per country.

At this albeit early phase of the pandemic it is important to explore why the virus has spread more extensively in many European countries than China and neighboring countries where the outbreak appeared to have commenced. This is difficult in the absence of data that quantitates national competency in terms of the various components of successful national COVID-19 response plans. Narrative reviews of the features that resulted in the success of countries such as China, Hong Kong, Japan, Singapore and Taiwan have noted a number of common features. These include: rapid response, extensive testing, contact isolation and the widespread usage of face masks in public [4, 21].

There are a number of countries in Western European such as Italy that have conducted intensive screening, contact tracing, isolation, social distancing and widespread lockdowns and yet have amongst the largest COVID-19 epidemics in the world [2]. A striking omission from this response-list if we compare it to the responses in China and other Asian countries with lower COVID-19 incidence is that the widespread use of face masks in public was not promoted. The only European country to adopt this strategy was Czechia, and it did so at a relatively late stage in the epidemic [19, 20]. Early indications suggest that despite higher testing rates than the average for western European countries, the number of new infections is lower in Czechia [1]. Future studies will however be crucial to evaluate the impact of this intervention in Czechia and elsewhere. These studies may benefit from including data from Taiwan and Macau where use of face masks in public has been high and the cumulative number of infections has remained so low that they did not meet the 500 case threshold for inclusion in this study (Taiwan 283 and Macau 34 cumulative cases as of 29 March) [1].

It is likely that a single intervention is not sufficient to suppress the spread of COVID-19 [2]. The safest approach in the middle of this epidemic may be to introduce the full package of interventions that have been proven to work in Asian countries and then scale back according to new findings [3, 9]. Our analysis provides further evidence that this package should include widespread usage of face masks in public. Currently the only European country that can be considered to be doing this is Czechia.

Association of County-Wide Mask Ordinances with Reductions in Daily CoVID-19 Incident Case Growth in a Midwestern Region Over 12 Weeks

Enbal Shacham, PhD,[1] Stephen Scroggins, MSc, [1,3] Matthew Ellis, PhD(c), MPE; [1] Alexander Garza, MD, MPH[2]

[1]College for Public Health and Social Justice, Saint Louis University

[2]SSM Health, St. Louis, MO

[3]Sinquefield Center for Applied Economic Research, Saint Louis University

Abstract

Importance: This study assessed the longitudinal impact of new COVID-19 cases when a mask ordinance was implemented in 2 of a 5-county Midwestern U.S. metropolitan region over a 3-month period of time. Reduction in case growth was significant and reduced infection inequities by race and population density.

Objective: The objective of this study was to assess the impact that a mandatory mask wearing requirement had on the rate of COVID-19 infections by comparing counties with a mandatory policy with those neighboring counties without a mandatory masking policy.

Design: This was a quasi-experimental longitudinal study conducted over the period of June 12-September 25, 2020.

Setting: This study was a population-based study. Data were abstracted from local health department reports of COVID-19 cases.

Participants: Raw cases reported to the county health departments and abstracted for this study; census-level data were synthesized to address county-level population, income and race.

Intervention(s) (for clinical trials) or Exposure(s) (for observational studies): The essential features of this intervention was an instituted mask mandate that occurred in St. Louis City and St. Louis County over a 12 week period.

Main Outcome(s) and Measure(s): The primary study outcome measurement was daily COVID-19 infection growth rate. The mask mandate was hypothesized to lower daily infection growth rate.

Results: Over the 15-week period, the average daily percent growth of reported COVID-19 cases across all five counties was 1.81% (±1.62%). The average daily percent growth in incident COVID-19 cases was similar between M+ and M- counties in the 3 weeks prior to implementation of mandatory mask policies (0.90% [±0.68] vs. 1.27% [±1.23%], respectively, p=0.269). Crude modeling with a difference-in-difference indicator showed that after 3 weeks of mask mandate implementation, M+ counties had a daily percent COVID-19 growth rate that was 1.32 times lower, or a 32% decrease. At 12 weeks post-mask policy implementation, the average daily COVID-19 case growth among M- was 2.42% (±1.92), and was significantly higher than the average daily COVID case growth among M+ counties (1.36% (±0.96%)) (p<0.001). A significant negative association was identified among counties between percent

medRxiv preprint doi: https://doi.org/10.1101/2020.10.28.20221705; this version posted November 20, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

growth of COVID-19 cases and percent racial minorities per county ($p<0.001$), as well as population density ($p<0.001$).

Conclusions and Relevance: These data demonstrate that county-level mask mandates were associated with significantly lower incident COVID-19 case growth over time, compared to neighboring counties that did not implement a mask mandate. The results highlight the swiftness of how a mask ordinance can impact the trajectory of infection rate growth. Another notable finding was that following implementation of mask mandates, the disparity of infection rate by race and population density was no longer significant, suggesting that regional-level policies can not only slow the spread of COVID-19, but simultaneously create more equal environment.

Key Points

Question: How are local mask ordinances associated with growth of COVID-19 cases among adjacent counties?

Findings: Ecological longitudinal analysis reveals a significant slowing of daily COVID-19 case growth after mask ordinance implementation among counties.

Meaning: Local-level policy of mask ordinances are shown to be an effective COVID-19 mitigation strategy even within locations of diverse populations.

Introduction

COVID-19 has claimed over 210,000 lives in the U.S.[1] While urgent policies have been implemented to reduce COVID-19 infections throughout the pandemic, there has been significant variability across state and local governments. In particular, due to the difficulty in maintaining social distancing guidelines and in an attempt to allow the economy to recover by opening businesses, some elected officials have issued mask mandates for the public to reduce COVID-19 transmission. Research has demonstrated the effectiveness of masks in preventing the spread of infectious diseases through airborne droplets,[2] yet the majority of a community would need to be masked in order to reduce infection rates. Several governors have avoided state-level mandates by rationalizing that within-state variations of COVID-19 infection rates call for more localized public health policymaking than state-wide orders.[3]

While studies found mask policies to be effective in reducing infection growth rates early in the pandemic, there is an urgent need to know how the impact of such policy persists over time; in addition, the impact on unequal infection rates such as higher rates reported among African-American/Black and Hispanic/Latinx populations.[1] Mask wearing has transitioned to a politically nuanced behavior, and this has been particularly true in the region surrounding the Midwestern city of St. Louis, providing a natural experiment to understand the longitudinal impact of a variable mask mandate policies has on county-level changes in incident CoVID-19 rates over a 12-week period.

Methods

This ecological study evaluated the effects of a public mask mandate on the daily cumulative case growth of COVID-19 infections among five neighboring counties within the metropolitan statistical area of Saint Louis, Missouri: City of St. Louis, St. Louis County, Jefferson County, Saint Charles County, and Franklin County. The study period included a three-week period prior

medRxiv preprint doi: https://doi.org/10.1101/2020.10.28.20221705; this version posted November 20, 2020. No reuse allowed without permission.

to the implementation of a mandatory mask order in St. Louis City and County on July 3, 2020, and a 12-week post-implementation period, for a total of 15 weeks.

Outcome of Interest

The primary outcome of interest was the cumulative daily percent change of reported COVID-19 cases by county. Daily incident COVID-19 cases were sourced from publicly available data provided by the Missouri Department of Health and Senior Services.

Primary Predictor and Covariates

Presence of a mask ordinance was the primary predictor of interest. Among the five counties, two implemented a mask ordinance during the study period for individuals entering public indoor spaces; the City and County of Saint Louis[4] (M+), with three counties having no such mandate during the study period (M-).

As COVID-19 infections occur more often among areas with higher county-level population density per square mile, higher proportion of residents identifying as non-white, and lower median annual household income,[25,6] these variables were included from the 2018, 5-year American Community Survey to control for variations in COVID-19 case growth.

Statistical Analysis

Data were constructed with daily percent changes in COVID-19 cases as a function of time (daily) and location (county), with 530 unique observations from June 12, 2020 to September 25, 2020. The average percent change in cases per day was calculated across M+ and M- counties to understand the pattern of COVID-19 growth throughout the study period. Kendal's tau-b rank correlation test was employed to identify associations among county-level demographics and percent daily growth of COVID-19 cases.

A difference-in-difference (DID) framework was employed to evaluate the effect of mask ordinances on percent daily growth in COVID-19 prevalence. Specific to this study, a DID estimator (δ) was calculated using binary dummy variables for both treatment (M+ or M-) at time (prior to mask ordinance implementation and after implementation). The calculated DID estimator was then applied to a linear probability model to determine the effects of a mask ordinance on COVID-19 case growth. Four adjusted models were constructed, accounting for county-level characteristics, each at 3 week intervals past the implementation date.

Statistical analyses were completed using R 4.0 software with significance determined at $\alpha = 0.05$.

Results

Over the 15-week period, the average daily percent growth of reported COVID-19 cases across all five counties was 1.81%(±1.62%). A total of 44,294 cases were reported throughout this period among a total estimated population of just over 2,000,000 residents, which is approximately one-third of the population within the state of Missouri.

The average daily percent growth in incident COVID-19 cases was similar between M+ and M- counties in the 3 weeks prior to implementation of mandatory mask policies (0.90%[±0.68] vs. 1.27%[±1.23%], respectively, p=0.269) (Figure 1). Prior to the mandate implementation a there was no association between percent growth of COVID-19 cases and percent racial minorities, population density, nor median income per county.

At 12 weeks post-implementation, the average daily COVID-19 case growth among M- was 2.42%(±1.92), significantly higher than the average daily COVID case growth among M+ counties (1.36%[±0.96%], p<0.001).

In adjusted linear probability models (Table 1), the mask mandate was found to be significantly associated with slowing the reported growth of daily COVID-19 cases across the study period.

medRxiv preprint doi: https://doi.org/10.1101/2020.10.28.20221705; this version posted November 20, 2020. No reuse allowed without permission.

From 3 weeks pre-policy to 3 weeks post-policy, M+ counties had a daily average COVID-19 growth rate of 44% less than M- counties (1.08/2.44). At week 6, 9, and 12 assessments, modeling revealed a continuing significant reduction in COVID-19 cases in counties with mask mandates. From pre-policy to 12 weeks post-policy (Figure 2), M+ counties had a daily average COVID-19 growth rate of 40% less than of M- counties (0.47/1.16). Using the DID linear probability equation, a counterfactual line is estimated, indicating probable growth of counties with mask mandate had a mask mandate not been implemented. Within the adjusted models, accounting for the DID estimator, proportion non-white population and population density were negatively associated with increased daily growth rate, yet median income did not contribute significantly to any of the calculated models.

Discussion

This longitudinal study demonstrates that the implementation of county-level mask mandates lowered incident COVID-19 case growth over time, compared to neighboring counties with no such mask mandate. Importantly, the results highlight the swiftness of such impact, with significant effects seen at just 3 weeks post-implementation. As time progressed, this impact was slightly reduced, possibly due to the arbitrary political borders of counties and states, which do not necessarily constrain transmission as mobility across mask mandate and non-mandated regions occurs. Although broader state or national mandatory mask ordinances would likely have a significant reduction in COVID-19 infections, in their absence, support for governors and elected officials to minimize the interactions across these borders may be beneficial.

Furthermore, implementation of a mask mandate may have reduced the unequal burden on African American/Black and Hispanic/Latinx individuals, as well as areas with higher population density. COVID-19 has highlighted the impact and swiftness of racial and ethnic inequities through higher rates of COVID-19 morbidity and mortality among non-white communities. In particular, many individuals were unable to abide by stay-at-home orders that protected middle

and high-income communities as a result of “essential” employment in grocery stores, health care support positions, and public transportation. These jobs, often lacking PPE and paid sick leave, are more often filled by people of color, living in higher population density and lower socioeconomic areas.[7] The mask policy that was enacted in many communities may have provided a more equal approach to reducing COVID-19 infections, as it occurred in St. Louis, Missouri.

Background	Healthcare workers (HCWs) and other essential workers are at risk of occupational infection during the COVID-19 pandemic. Several infection control strategies have been implemented. Evidence shows that universal masking can mitigate COVID-19 infection, though existing research is limited by secular trend bias.
Aims	To investigate the effect of hospital universal masking on COVID-19 incidence among HCWs compared to the general population.
Methods	We compared the 7-day average incidence rates between a Massachusetts (USA) healthcare system and Massachusetts residents statewide. The study period was from 17 March (the date of first incident case in the healthcare system) to 6 May (the date Massachusetts implemented public masking). The healthcare system implemented universal masking on 26 March, we allotted a 5-day lag for effect onset and peak COVID-19 incidence in Massachusetts was 20 April. Thus, we categorized 17–31 March as the pre-intervention phase, 1–20 April the intervention phase and 21 April to 6 May the epidemic decline phase. Temporal incidence trends (i.e. 7-day average slopes) were compared using standardized coefficients from linear regression models.
Results	The standardized coefficients were similar between the healthcare system and the state in both the pre-intervention and epidemic decline phases. During the intervention phase, the healthcare system's epidemic slope became negative (standardized β: −0.68, 95% CI: −1.06 to −0.31), while Massachusetts' slope remained positive (standardized β: 0.99, 95% CI: 0.94 to 1.05).
Conclusions	Universal masking was associated with a decreasing COVID-19 incidence trend among HCWs, while the infection rate continued to rise in the surrounding community.
Key words	Hospital; infection control; infectious disease; personal protective equipment; SARS-CoV-2.

Introduction

COVID-19 is an occupational risk for healthcare workers (HCWs) essential to maintaining health and hospital systems [1]. Evidence supports HCWs' infection risk due to direct exposure to co-workers, patients and contaminated environments [2]. Accumulating research suggests that optimal infection control strategies, including personal protective equipment (PPE), can minimize the risk of SARS-CoV-2 transmission to HCWs [3,4]. Among now established mitigation measures, universal masking is thought to be one of the most effective means to protect HCWs. However, existing evidence of universal masking efficacy is largely based on self-comparison results (i.e. comparing pre- and post-masking phases) [5] instead of comparing HCWs with a reference population, and thus

Key learning points

What is already known about this subject:

- Healthcare workers are occupationally exposed to SARS-CoV-2.
- Protecting healthcare workers and other essential workers is important to maintain healthcare and other essential businesses.
- Optimal personal protective equipment use can minimize workers' risk of being affected by COVID-19.

What this study adds:

- Additional evidence that universal masking is associated with decreased incident COVID-19 infections among healthcare workers.
- Universal masking in the healthcare setting protects healthcare workers.

What impact this may have on practice or policy:

- Timely universal masking policy should be implemented and maintained in healthcare settings during the COVID-19 pandemic.
- Our study indirectly supports universal masking with procedure masks or similar medical masks by other essential workers and within indoor businesses when social distancing and ventilation may be inadequate.

subject to secular trend bias. Therefore, we conducted this study to investigate the effect of universal masking in a Massachusetts (USA) healthcare system, using the statewide population as a comparison group.

Methods

This time-series study examined the daily COVID-19 incidence trends among the Massachusetts statewide population and the HCWs of a Massachusetts community healthcare system that tested symptomatic employees since the initial outbreak. The statewide data were derived from the Massachusetts Department of Public Health [6]. More than 95% of the system's HCWs (4449 out of 4673) resided within Massachusetts, almost all in the seven counties of the greater Boston area, which are also home to 84% of the statewide population [7]. The HCW cohort of the healthcare system and related ethical statement are described in our previous paper [8]. In the present study, the total number of HCW incident cases is different due to a longer observation period. We calculated 7-day moving average COVID-19 incidence to smooth daily fluctuation. Each incident case was assigned the date when that HCW called the occupational health 'hotline' for triage. For state population cases, we assigned the reported date.

We defined the study period as from 17 March 2020, when the first case in the healthcare system was identified, to 6 May 2020. The study period was divided into three phases: pre-intervention (17–31 March), intervention (1–20 April) and epidemic decline (21 April to 6 May). Date cut-offs were determined as follows. First, the healthcare system implemented universal masking on 26 March and we allowed five more days for the policy to take effect based on the average COVID-19 incubation period. The policy included securing N95s for all direct-care staff managing confirmed/suspect COVID-19 patients and providing procedure masks to all other clinical and non-clinical staff. Second, Massachusetts reached the peak of COVID-19 incidence on 20 April (Figure 1), and the effects of universal masking are more detectable when the surrounding community secular trend is increasing. Finally, Massachusetts implemented a statewide masking policy on 6 May.

We built linear regression models to investigate the temporal trends for each cohort's 7-day average incidence within each of the three phases. Standardized beta coefficients and 95% confidence intervals (95% CIs) were calculated and presented to account for the different scales between the healthcare system and the state. The analyses were performed using R software (version 3.6.3) and SAS software (version 9.4, SAS Institute).

Results

During the study period, incident cases in the healthcare system and the state were 142 and 75 493, respectively. Pre-intervention, both the healthcare system and the state had strong increasing trends in the 7-day average COVID-19 incidence (Figure 1; Table 1) with overlapping slopes (0.96 (0.80 to 1.13) and 0.99 (0.92 to 1.07), respectively). While the temporal trend among Massachusetts residents kept increasing with a similar slope in the intervention phase (0.99 (0.94 to 1.05)), that of the healthcare system decreased and was negative (−0.68 (−1.06 to −0.31)). During epidemic decline, following the states' pandemic peak, both populations' incidence showed overlapping negative slopes (−0.90 (−1.19 to −0.60) and −0.99 (−1.07 to −0.92)) (Figure 1; Table 1).

Discussion

Our study provides additional evidence of the protective effect of universal masking in healthcare settings. The HCW's epidemic curve was flattened, and in fact, demonstrated a decreasing daily incidence trend after

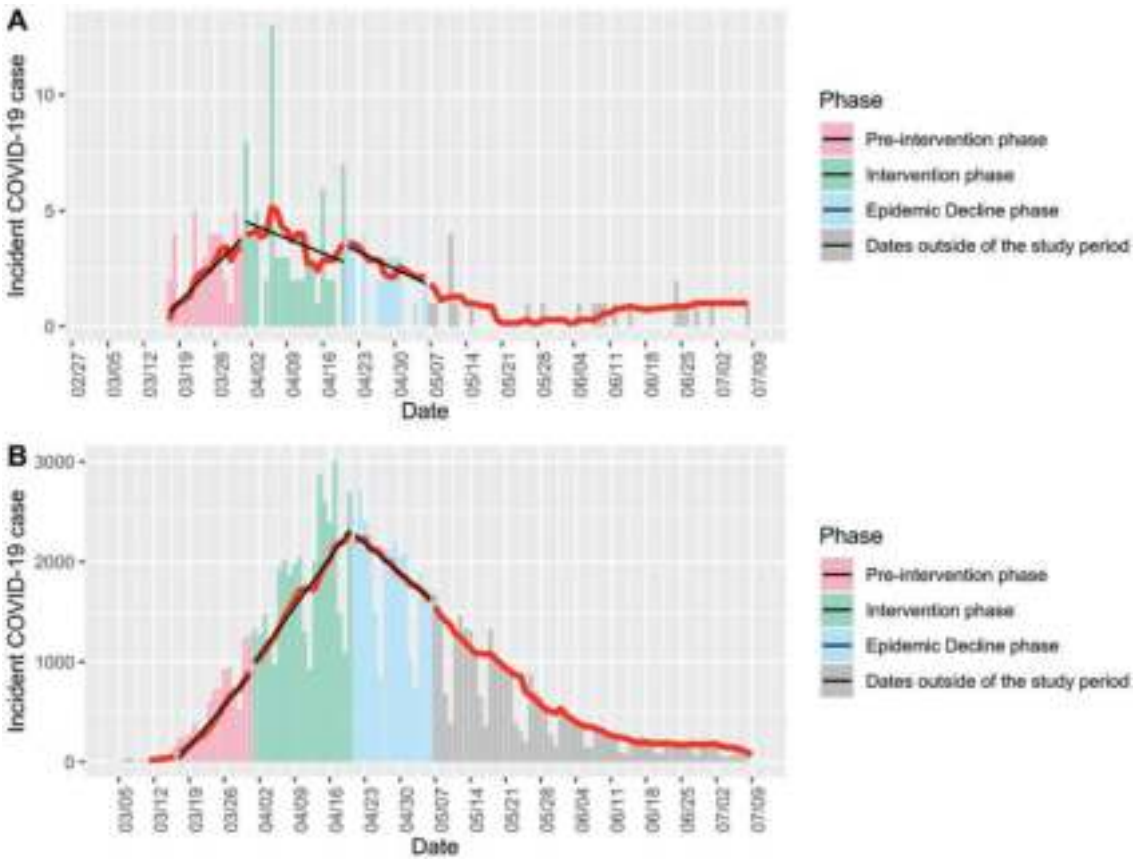

Figure 1. Temporal distribution of COVID-19 incidence among the (A) healthcare system employees and (B) Massachusetts residents statewide. Bars indicate the absolute number of daily cases. The red line denotes the 7-day average of new cases. The black lines show linear regression slopes in each specific phase. The phases were categorized based on the implementation date of universal masking policy by the healthcare system (pre-intervention phase, 17–31 March; intervention phase, 1–20 April; epidemic decline phase, 21 April to 6 May).

Table 1. The standardized beta coefficients of 7-day average COVID-19 incident cases regressed on days during the three study phases

	Pre-intervention phase (17–31 March)	Intervention phase (1–20 April)	Epidemic decline phase (21 April to 6 May)
The healthcare system	0.96 (0.80 to 1.13)	−0.68 (−1.06 to −0.31)	−0.90 (−1.19 to −0.60)
Massachusetts statewide	0.99 (0.92 to 1.07)	0.99 (0.94 to 1.05)	−0.99 (−1.07 to −0.92)

Beta coefficient (95% CI) derived from linear regression models in each phase.

implementing universal masking, while the statewide infection rate continued to increase during the same time period. The findings are in agreement with a recently published study using HCW self-comparison [5], finding a significant decrement in the SARS-CoV-2 positivity rate after the implementation of universal masking. We confirmed this effect by including a comparison group, eliminating potential secular trend bias that limits before and after time-series studies.

Evidence supports that PPE can prevent HCWs from being infected [9]. Two studies conducted in Wuhan, China investigated 278 and 420 front-line HCWs with optimal PPE protection from different healthcare systems, respectively, and reported no infections [3,10]. In contrast, 10 out of 213 HCWs without appropriate masking protection sustained nosocomial infection [10]. In accordance with the existing evidence [5], our results further support masking's protective effects from the perspective of hospital infection prevention.

The current study has several strengths such as the use of a comparable reference group, a validated outcome and a distinct intervention. Nonetheless, there are some limitations. First, the current study is limited by the small sample size of HCWs, the short intervention period and individual HCW compliance with the masking policy and PPE use were not measured. The relatively small sample size during the post-intervention, epidemic decline period prevented us from detecting potential additional effects of universal masking, as statewide incidence was also strongly decreasing. In part, this was likely due to

the increased use of masks within the community for grocery shopping and similar activities. Therefore, additional larger-scale studies of masking are warranted. Second, the 5-day interval assumed for the policy to take effect was not precise, but reasonable because the median lag time between symptom development and infection is 5 days [11]. Finally, there could be unmeasured confounding, such as improved social distancing, hand hygiene and isolation of COVID-19 patients. However, we found significant differences between incidence curves, with HCWs' changing from positive to negative slopes shortly after universal masking, which is unlikely to be entirely biased.

In conclusion, our results suggest that universal masking significantly mitigates COVID-19 incidence in the healthcare setting, which may be applicable to other essential workers and indoor businesses.

Mask-Wearing During the COVID-19 Pandemic

Abstract

Background
Masks have been widely recommended as a precaution against COVID-19 transmission. Several studies have shown the efficacy of masks at curbing droplet dispersion in lab settings. Using individual response data from the Imperial College London — YouGov personal measures survey, this study investigates reported mask use and its association with the spread of COVID-19.

Methods
We examine the association of reported mask-wearing in a population within a country with the growth rate of active cases COVID-19 cases. The analysis uses country-wide data from weekly surveys of individuals' mask-wearing behavior in public places, as well as other concurrently implemented non-pharmaceutical interventions, mobility changes, new cases of COVID-19 data and other control variables. The mask-wearing data were obtained from the Imperial College — YouGov multi-country survey of people's personal habits before and during COVID-19. Because mask-wearing showed substantial variation across countries and over time, we use a reduced form econometric model to relate population-wide changes in mask-wearing to the growth rate in COVID-19.

Results
The results indicate that reported mask-wearing could play an important role in mitigating the growth of COVID-19. Widespread mask-wearing within a country associates with an expected 7% (95% CI: 3.94% — 9.99%) decline in the growth rate of daily active cases of COVID-19 in the country. This daily decline equates to an expected 88.5% drop in the growth of daily active cases over a 30-day period when compared to zero percent mask-wearing, all else held equal. The decline in daily growth rate due to the combined effect of reported mask-wearing, reduced social mobility, and non-pharmaceutical interventions averages 28.1% (95% CI: 24.2%-32%). These estimates remain robust across multiple sensitivity analyses.

Conclusions
Face mask usage as a preventative measure against the transmission of COVID-19 varies widely across countries. This observational study uses data from 24 countries and finds that reported face mask usage associates with a decline in new COVID-19 cases. Even though the model controls for a large variety of variables that affect spread, and we run a number of robustness checks, it remains possible that some of the decline associated with face masks is related to confounding variables not included in the model. In summary, due to the confounding variables and the variations in the type of mask and its usage, randomized control trials of mask usage in populations are needed to determine the true effect of mask–wearing on mitigating the transmission of infectious respiratory diseases.

1. Introduction

In response to the COVID-19 pandemic, multiple countries curbed the spread of the disease by enforcing strict policy measures such as lockdowns and shelter-in-place orders [1]. The non-pharmaceutical interventions (NPIs) included closures of school, restaurants, bars, retail outlets and other non-essential businesses, as well as shelter-in-place policies and the prohibition of large gatherings (e.g., limited to 10 people) [2]. These institutional measures aimed to reduce the exposure of susceptible individuals to symptomatic and asymptomatic infected individuals by decreasing social mobility (e.g., going out to movies, concerts and restaurants, assembling in large groups) and encouraging social distancing. (e.g., 1m-2m physical distancing) [3,4].

Unlike the widespread and proactive implementation of lockdowns and physical distancing measures, the usage of masks varied widely across countries. Some countries quickly adopted guidelines for mask usage (e.g., Malaysia, Singapore, Taiwan, and Thailand) while others did not recommend using face mask unless sick [5,6,7]. Indeed, the World Health Organization updated its mask-wearing guidelines only on June 5, 2020 [8], to recommend that "The general public should wear non-medical masks where there is widespread transmission and when physical distancing is difficult, such as on public transport, in shops or in other confined or crowded environments.". Due to these changing guidelines and uneven implementations, mask-wearing varied dramatically across countries and over time [9].

Multiple studies have investigated the impact of various governmental NPIs [3,10,11,12], that encourage physical distancing and the wearing of face masks [13,14,15]. In each case they find that NPIs, physical distancing, and face mask usage reduce the transmission of COVID-19. However, the interventions, government policies, and individual measures seldom act in isolation. Treating these measures in isolation could lead to under- or over-estimation of their effectiveness at reducing the spread of the disease, biasing the assessments of the measure's impact. In this study, we investigate the association of population-wide mask-wearing with the number of COVID-19 cases, concurrent with other individual and institutional measures. Specifically, we expand on the current stream of research by simultaneously considering the effects of NPIs and social mobility along with a population's reported usage of face masks in public places in a reduced-form econometric model (see examples in [3] and [10]). Using data from 24 countries, we identify the effect of each measure by exploiting the country-wise differences in the (1) percentage of the population who report wearing a face masks in public places (YouGov Survey Data [9]), (2) social mobility across multiple categories such as Parks and Transit Locations (using Google Mobility Reports [16]) and NPI implementations (using CoronaNet-Project [1])

2. Methods

This study is a cross-sectional analysis of the effects of personal and governmental measures across 24 countries on mitigating COVID-19 disease spread. The data used in this study were collected from February 21, 2020 to July 8, 2020, representing 139 days of data for each country. All analysis presented in this paper uses publicly available data. Subsequently, we first present the data and then the model-based analysis.

medRxiv preprint doi: https://doi.org/10.1101/2020.09.11.20192971; this version posted September 13, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

Key Variables of Interest

Mask-Wearing: Survey data released by the Institute of Global Health Innovation (IGHI) at Imperial College London and YouGov [9] provide reported mask-wearing across multiple countries. The survey covers 26 countries (as of July 8, 2020), with around 21,000 people interviewed each week. We restrict our analysis to 24 countries, because two countries – China and Hong Kong – do not have publicly available data on the social mobility dimensions we control for in this study. The data present global insights on people's reported behavior in response to COVID-19. The dataset provides the percentage of population in each country who report to wear a mask in public places. Because these surveys were conducted at an interval of several days, we interpolate (linearly) to estimate the percentage of the population that would wear masks in public spaces for days when the data were unavailable (Figure 1). We use the significant variation of mask-wearing across countries to measure the association of people reporting mask wearing and the spread of COVID-19.

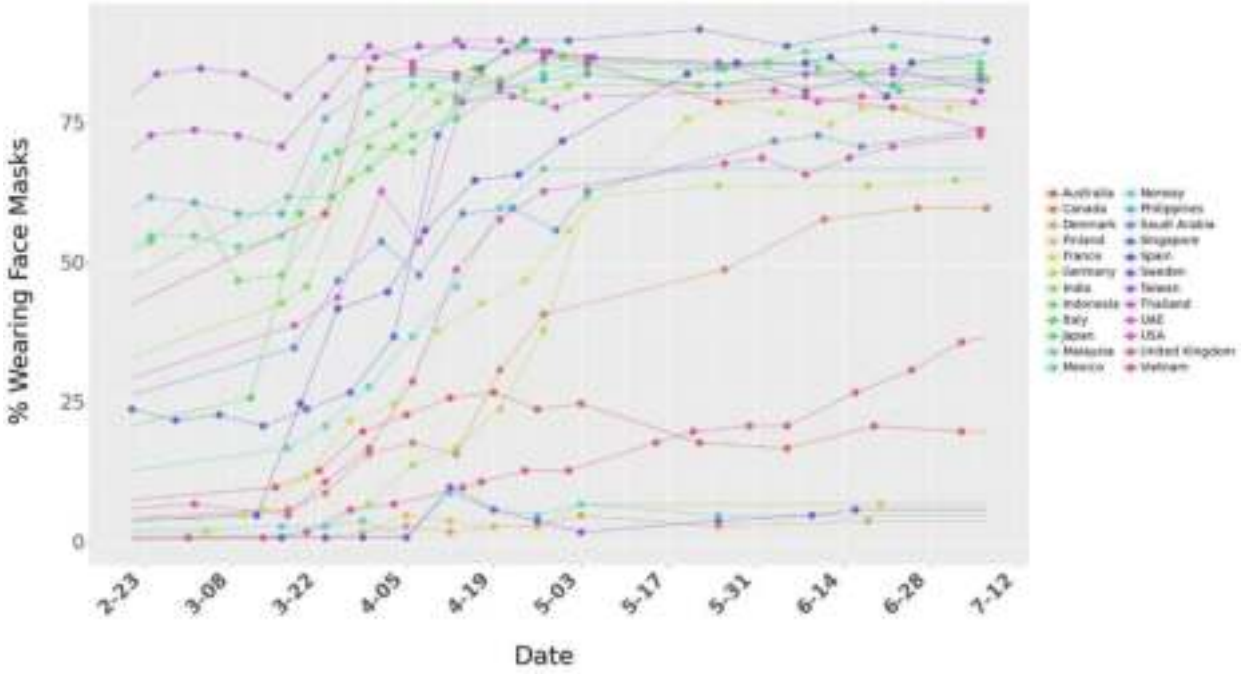

Figure 1. Percentage of people who say they are wearing a face mask in public spaces

Social Mobility: Google Community Mobility Reports provide data on relative mobility changes with respect to an internal baseline across multiple categories namely, retail and recreation, groceries and pharmacies, parks, transit stations, workplaces, and residential (Figure 2). A summary for the community mobility is shown in Table S2 in the Supplement. Apart from the Google Mobility reports, we also utilize mobility data from Apple to test the robustness of the model to different measures of mobility. We note that neither Google nor Apple provide absolute measures of mobility, but rather present relative changes with respect to benchmarks they use internally. Finally, drops in mobility could be driven by both individual actions (e.g., cautious behavior) as well as institutional actions due to NPIs enacted by governments. To control for mobility declines due to institutional actions, we also include country-specific interventions enacted both nationally and provincially.

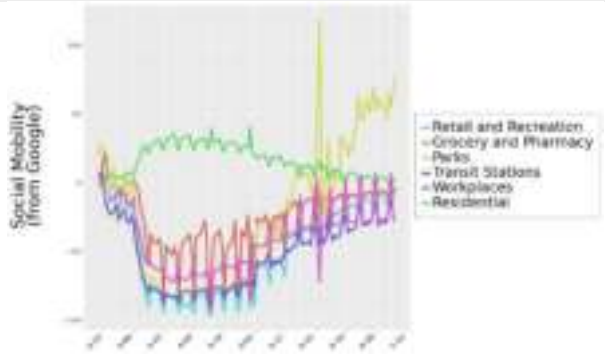

Figure 2 (a) Social Mobility for Italy from Google Community Mobility Reports

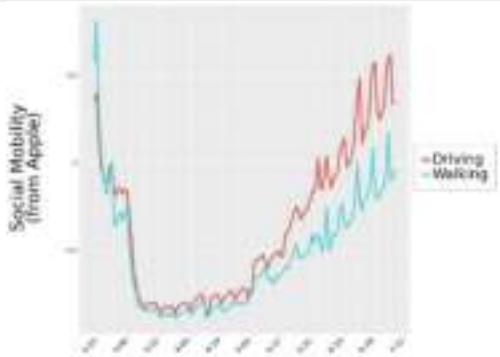

Figure 2 (b) Social Mobility for Italy from Apple Community Mobility Reports

Figure 2. Social mobility from Google Mobility Reports and Apple Mobility Reports for Italy. Social mobility for all the 24 countries is shown in Figure S8 in Supplementary.

Non-Pharmaceutical Interventions: Governments across the 24 countries enforced different policies to control the spread of COVID-19. Prior research has shown that these policies played a significant role in reducing human to human physical contacts and led to a slowdown in the spread of the disease. However, these policies were implemented in different ways, some nationally, some provincially. We use data from COVID-19 Government Response Event Dataset [1] to control for government policies in estimating the effect of masks. Figure S10 lists the types and counts of national and provincial government policies implemented across the 24 countries we consider in this study. The dataset contains 5,816 entries on policies at National and Provincial level. Finally, inclusion of these interventions helps control for some of the observed drops in mobility that are not necessarily associated with individual actions but by the presence of institutional policies. Detailed information about the interventions are included in the Supplement (Section S2.5).

Covariates

Because the data span multiple countries and weeks, we include time and country fixed effects in the model. The model controls for country-level heterogeneity using fixed-effects, where the variable for a country assumes a value of one if the data considered are specific to that country, and zero otherwise. This allows for control of country-level characteristics that are not in the model and helps reduce the errors due to omitted variables in our analysis. In addition to country-level differences, we also control for time-based differences (e.g., people are more aware and cautious over time) by incorporating time-fixed effects, where the variable $Week_t$ takes a value of 1 if the data are from week 't' (where t =1 in the first week for a given country in the data). In addition, we control for each country's testing capability (Figure 3a) by accounting for the total number of daily tests in the country. Finally, we also control for actions people take to educate themselves by including the Google Trends (Figure 3b) data for the search term 'coronavirus'.

Figure 3. Number of COVID-19 Tests and Google Trends (per thousand people) for Italy. Data for all the 24 countries is shown in Figure S13 and Figure S14 respectively in Supplementary.

Outcome Variable

Data for the number of active daily cases in each country were obtained from the Johns Hopkins University School of Public Health [17]. We use a seven-day moving average of cumulative confirmed cases and cumulative recovered cases to compute daily active cases and daily growth rate. The dataset aggregates this information across multiple national, state, and local health departments within each country. The daily growth rate is then related, by means of a reduced-form econometric model, to the independent variables described earlier. We describe the derivation in the Supplement (Section S1.1). We illustrate the daily cases and growth rate for one country, Italy, in Figure 4.

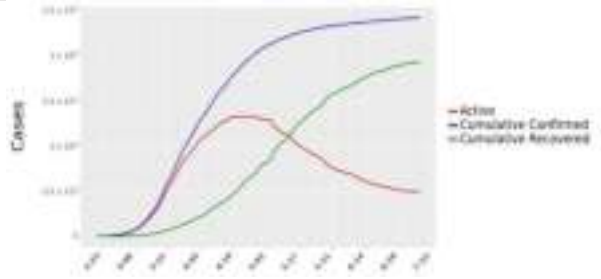

Figure 4 (a) CoVID-19 Cases in Italy.

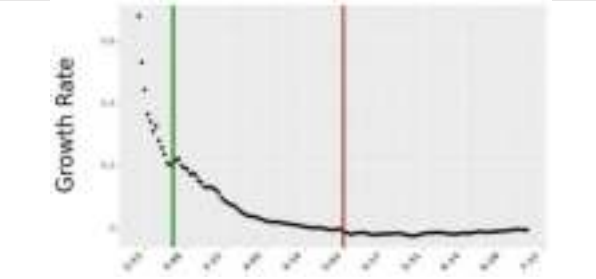

Figure 4 (b) Growth rate in Italy.

Figure 4. Daily Active cases and growth rate in Active cases for Italy. Vertical green line in (b) shows the start of data collection for Italy. Vertical red line in (b) shows the end of 60 days of data collection for Italy. Data for all the 24 countries is shown in Figure S6 and Figure S7 respectively in the Supplement.

Analysis

A reduced form econometrics model was used to relate the growth rate of daily active infections to the independent variables described earlier. Similar models have been used by [3] to determine the effect of anti-contagion policies on the spread of COVID-19. In brief, the model assumes that the daily growth rate (ratio of active infections today to active infections the day before) is affected by the institutional measures such as NPIs as well as individual measures such as social mobility and mask-wearing. The covariates listed above help control for other factors

medRxiv preprint doi: https://doi.org/10.1101/2020.09.11.20192971; this version posted September 13, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

It is made available under a CC-BY-ND 4.0 International license .

that could affect growth over time. Because the epidemiological parameters for new diseases such as COVID-19 might not be well understood, reduced form techniques allow for the estimation of the impact of governmental and personal measures to help contain the spread of the virus. The model we use initializes when a country reaches 20% of peak new cases as observed by July 8, 2020 to filter out the high variation in growth rates when the number of cases is very low at the beginning of the pandemic. For robustness, we also test other starting times in the Supplement and find results in line with the ones presented here. The Supplement also provides further details about the methodological approach as well as information on the model formulation used.

We provide some brief notes on the operationalization of the independent variables and the model initialization below:

1. Responses to the survey about mask-wearing are subject to biases. For example, individuals might overestimate the efficacy of their mask or their wearing pattern. To alleviate some of these concerns, we compute the natural log of the mask-wearing variable to discount its impact on the growth of cases. This transformation yields a curve that grows at a slower rate as the values of mask-wearing increase, thereby diminishing the impact of higher levels of mask-wearing. We also test for other functional forms (square-root and linear) and present those results in the Supplement (Table S7).
2. Due to the high correlation across the different mobility data categories obtained from Google, we only include *Mobility: Parks* and *Mobility: Transit Stations* in the model. Because we are interested in determining the impact of mobility in general, the two mobility variables suffice in capturing the individual's movement patterns during this time. In Supplement S3.4, we present results including other types of mobility, and also run the model with Apple Mobility data in the place of Google Mobility Reports.
3. The CoronaNet dataset from [1] collected information on all the government policies introduced by different countries across the world. They categorized the policies into 19 different policy-types. We use their categorization in the model. From February 21, 2020 to July 8, 2020, we check if a policy p was implemented in a country j on day t. If the policy was implemented, we assign a value of 1 to $s_{j,t,p}$, where s represents the level of policy coverage. If the policy was introduced at a provincial level, we $s_{j,t,p}$ by the population of the state. Because several policies were introduced at the same time or close together, they too suffered from collinearity issues. To minimize multicollinearity issues, we choose only a specific set of policies to include in the analysis. The Supplement (Section S2.5) discusses this selection mechanism.
4. Due to uncertainty of the lag in COVID-19 incidences and the difficulties in detection during the early days of the disease (Woloshin et al 2020), similar to prior research we tested the focal model across multiple lag periods (*shift*) from zero to 14 days and for different initialization thresholds (*th*) for each country (zero percent to 20% of a country's peak daily cases). We chose the best *shift* and *th* values using a k-fold cross-validation process (k=5). The chosen model had the highest maximum likelihood estimate of the data as well as the lowest prediction error. We discuss this procedure in the Supplement (Section S4.1). The results presented in the next section correspond to a model with a shift of nine days and a *th* of 20% of peak new cases by July 12, 2020. Finally, the model was estimated on 1,422 observations across 24 countries, averaging 60 observations per country. We restrict our analysis to the first 60 days. However, we test

medRxiv preprint doi: https://doi.org/10.1101/2020.09.11.20192971; this version posted September 13, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

It is made available under a CC-BY-ND 4.0 International license .

the robustness of the findings for other lengths of data. This allows for greater variation in mask usage within the data.

In the next section, we describe our results and their policy implications.

3. Results

The results indicate that individual (mask-wearing, social mobility) and institutional measures (NPIs) could play a role in mitigating the growth of COVID-19. The estimates from the focal reduced form model for these measures and their corresponding confidence intervals are shown in Figure 5. The full table of results, along with results for all robustness checks are provided in Supplement (Section 3). We first list the results of the key measures we consider and then discuss their implications.

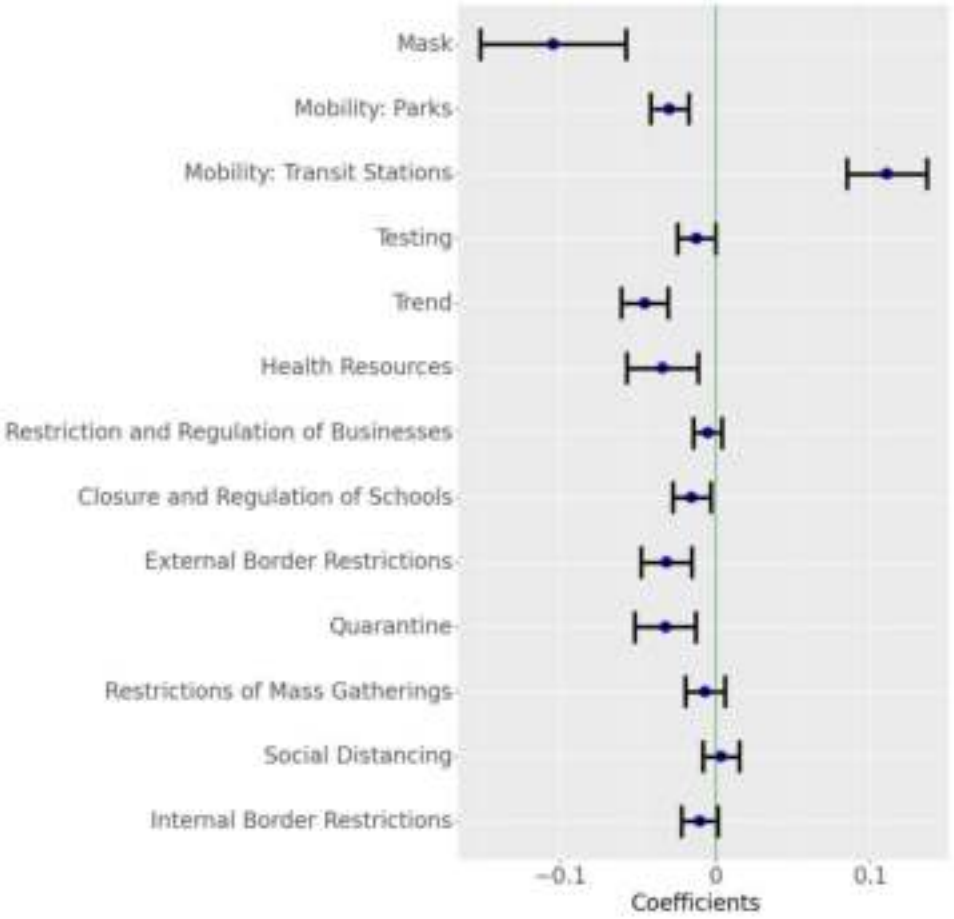

Figure 5. Parameter estimates for the Growth rate model. The blue dot indicates the point estimates and the horizontal lines indicate 95% confidence interval around the estimate (Masks transformed as ln(1+mask)). Results for different transformations of Mask and other covariates is shown in Figure S16.

Masks. The model finds that a reported mask wearing of 100% is associated with an average 7% (95% CI: 3.94% — 9.99%) drop in daily COVID-19 cases. While this daily effect appears small over a 30 day period, 100% reported mask-wearing leads to approximately 88.5% (95% CI:

medRxiv preprint doi: https://doi.org/10.1101/2020.09.11.20192971; this version posted September 13, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

It is made available under a CC-BY-ND 4.0 International license .

68.7% — 89.2%) decline in active cases when compared to the situation where 0% of the people report wearing masks (all else remaining the same across the two scenarios). Modifying the functional form of the mask variable did not appreciably change the association. For example, in the linear model, masks are associated with an average 8.69% (95% CI: 5.63% — 11.66%) drop in daily growth rate and for the square root model the expected daily drop in growth rate was 7.89% (95% CI: 4.81% — 10.87%). The stability of the results seems to indicate that mask-wearing can potentially play a significant role in mitigating the spread of the disease. Figure 6 plots the ratio of active cases under different proportions of respondents who claim to wear masks as against no mask wearing.

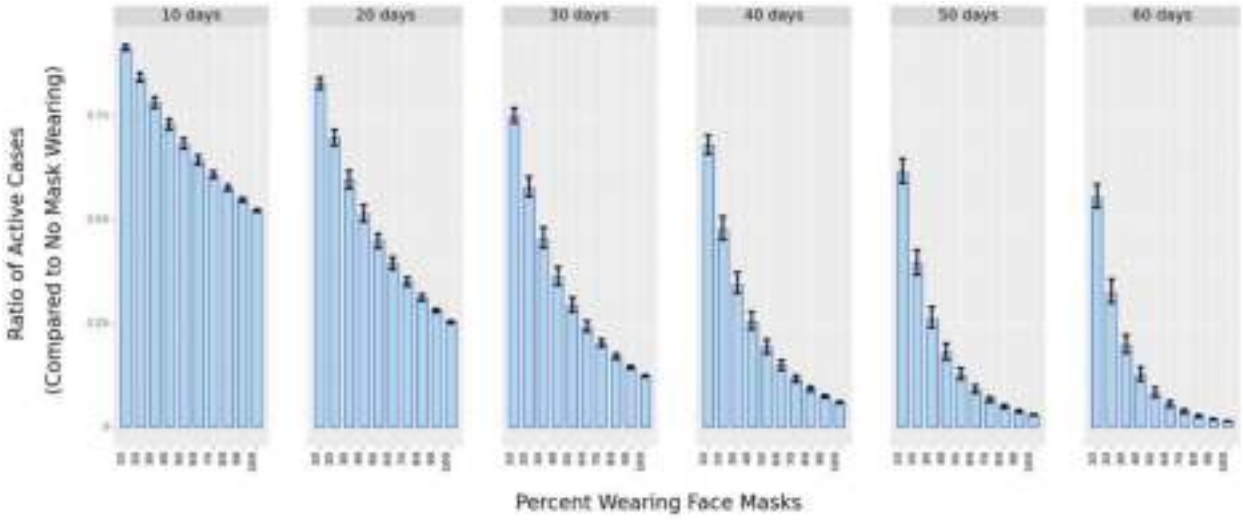

Figure 6. Ratio of Active cases under different percentage of mask wearing in public spaces as compared to 0 mask wearing over different periods (in days) . The shaded bars represents in ratio while the black vertical lines represent the 25th and 75th percentile of the ratio (from simulations using Krinsky-Robb method)

Mobility and NPIs. As expected, the model finds that a rise in mobility links with a rise in the number of cases. Specifically, the selected mobility variables associate with a combined 8.1% (95% CI: 5.6% - 10.6%) drop in daily case numbers. Similarly, we find that the implementation of NPIs also associate with a drop in daily growth rates across countries. After accounting for mobility declines, the NPI measures 'Quarantine, 'External Border Restrictions,' and 'Closure and Regulation of Schools' link with the highest declines in the growth of cases. Overall, all NPIs included in the model led to a decrease in the growth rate of COVID-19. This finding confirms multiple studies that investigated the effects of NPIs at limiting the spread of COVID-19 [10,18]. Overall, we find that if the NPIs were enacted uniformly across the whole country, then the combined association of the NPIs with the decline of growth in daily cases of COVID-19 would average 13% (95% CI: 9.2% - 16.2%). We determine the combined effect using the Krinsky-Robb method, a Monte Carlo simulation used to draw samples from a multivariate normal distribution. Supplement S3.1 provides more details on this method.

Control Functions and Robustness Checks

Due to nearly concurrent enactments and blanket coverage of policies and precautionary behaviors within countries, the individual (e.g., masks, limiting mobility) and institutional (NPIs)

medRxiv preprint doi: https://doi.org/10.1101/2020.09.11.20192971; this version posted September 13, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

It is made available under a CC-BY-ND 4.0 International license .

measures correlate in time. This precludes causal identification of each measure's individual effect on disease mitigation. In other words, because mask-wearing, mobility reductions, and NPIs occur at similar times, their effects are intertwined and difficult to determine separately. For some variables such as mobility and NPIs, we lack the necessary data to fully control for some of these issues. In the case of mask-wearing, even though we cannot eliminate the simultaneity, we attempt to reduce the effects of confounding variables by employing control functions [19]. In addition, [20] note that control functions make the intervention exogenous in a regression equation. To create a control function, we use country mortality data for SARS, H1N1, and MERS to predict the propensity of mask-wearing in each country (see Supplement S4.5.2 for more details). Next, we compute the control function by determining the predicted mask-wearing residuals (Predicted Mask-Wearing minus Actual Stated Mask-Wearing), allowing for better identification of the effect of reported mask-wearing on COVID-19 case numbers.

Using this procedure, we find that if 100% of the population claimed to wear masks, then mask-wearing relates with an average 4.95% (95% CI: 2.26% — 7.53%) drop in daily growth rate (nine days later), when compared to zero percent reported mask-wearing. While we are careful to note that this estimate could still be affected by confounding variables, this result lends further support to the estimate presented earlier. In summary, widespread mask-wearing could lead to a significant decline in the growth of COVID-19.

To help determine the accuracy of the results we run several robustness checks (see Supplement S4):

(1) We vary the lag period (*shift*) from 0 to 14 days. The results show that the estimates of the individual and institutional measures are relatively stable.
(2) We also vary the length of time we consider in the analysis. The model considered 60 days of data for each country. We vary this to estimate the model on 35, 45, 55, 65, 75 and 85 days of data. We find that the results remain consistent to these changes.
(3) We replace Google mobility data with Apple mobility data. The model estimates remain robust to this change.
(4) We vary the functional form of how mask-wearing relates to the growth of COVID-19. The results do not vary appreciably with respect to this to this change.
(5) We also test the robustness of the analysis by modifying the data using exponential smoothing. Specifically, for any day *t*, the focal model in Equation (1) ignores the value of the independent variables from days *t-shift+1* to t (discussed in Figure S1). In the model we use for the robustness check, we do not ignore values between *t-shift* and *t* and use exponential smoothing to average the intervening data. Finally, we also modify the interpolation method from linear (current) to quadratic. We find that the results are stable to all these modifications.

The Supplement details all the robustness checks and simulations as well as their results.

4. Discussion

Over the past few months, several studies have investigated the efficacy of masks at minimizing droplet dispersion [21,22] and the potential consequences of their use [14,23] in the general population. Although no randomized control trial on the efficacy of face mask usage in the general population exists, [15,14] provide compelling evidence for the use of face masks through a systematic review of the multiple observational studies and the evidence thus far. Both studies project that the use of face masks reduces the transmission of disease. While the type of face mask as well as the timing and length of use can affect its efficacy, its use as a precautionary principle has been strongly advised [24]. Despite this preponderance of evidence, face mask use, in the US remains controversial [25,26]. Additionally, as observed in the data, even in countries where masks do not face similar headwinds and as support for mask usage gathers further evidence, face mask use is not as common place (e.g., Denmark, Norway, Sweden, Finland, Australia), even as a precautionary principle.

This study links the growth in active cases of COVID-19 in a country, to a population's reported wearing of face masks in public places over time. The model also includes other measures that could simultaneously impact the growth of the disease as face mask usage changes over time. After accounting for these measures and controlling for other covariates, the results indicate that reported face mask use is associated with a decline in the growth of COVID-19. More precisely, if 100% of the population claimed to wear masks, then mask-wearing is associated with an average 7% decline in the growth of COVID-19. This association persists across multiple robustness checks and model formulations. A decline of 7% corresponds to an 88.5% drop in the number of active cases 30 days later. Taken together with the other measures (mobility changes, NPIs), the combined association obtained via the Krinsky-Robb method of individual and institutional measures on the decline in the daily growth of COVID-19 is 28.1% (95% CI: 24.2%-32%).

Limitations

This study has several limitations. First, countries enacted multiple NPIs simultaneously. This precludes us from identifying the effectiveness of NPIs separately. Second, the mobility data provided by Google and Apple are only indicative of the relative changes from a benchmark, so their association with disease spread should be interpreted with precaution.

Third, even though we consider multiple NPIs and mobility measures and control for population-wide awareness, testing, and country and time differences, there could be several variables that we do not or cannot include due to the lack of data. For example, one of the NPIs we consider relates to health announcements (e.g., handwashing, coughing into one's elbow, etc.). However, the model only notes the NPI and not the adoption of these practices in the general population. While some data (e.g. sale of soap, cleansers, etc.) could approximate this, multiple confounding variables still exist and thus limit the extent to which we can apply any causal interpretation of the results. We attempt to provide better insights using a control function approach, however, stop short of making causal claims.

medRxiv preprint doi: https://doi.org/10.1101/2020.09.11.20192971; this version posted September 13, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

It is made available under a CC-BY-ND 4.0 International license .

Fourth, our analysis was conducted at the country level due to data restrictions. However, mask usage, mobility changes as well as the implementation of NPIs most likely vary within the country. Nevertheless, the analyses in this study are helpful at understanding the practical implementation of mask usage policy within a country.

Finally, we rely on the accuracy of data collected by third parties. Inconsistencies in testing, reporting, and recording of the data could lead to errors in the results obtained. Additionally, mask-types and mask-wearing patterns could vary across countries, individuals, and over time. This limitation affects all observational COVID-19 population-based studies. Randomized control trials of mask usage in populations are needed to determine the true effect of mask–wearing on mitigating the transmission of infectious respiratory diseases.

5. Conclusions

The population-wide usage of face masks as a preventative measure against the transmission of COVID-19 varies widely across countries. Using data from 24 countries, this study finds that reported face mask usage associates with a decline in the growth rate of COVID-19. Even though we control for multiple variables that could affect spread and include multiple robustness checks, it remains possible that some of the decline associated with face masks may be related with other confounding variables not included in our model.

Abstract

Universal masking the health care setting and in the community to contain the spread of SARS-CoV-2 has been recently recommended by the WHO, but supporting data are rare. The City of Jena was the first community in Germany to issue an order on mandatory public masking. Here, we report the development of the number of novel infections in our hospital and in the city of Jena after implementation of universal masking in our hospital and the city.

Introduction

There are only a few studies on universal masking during the flu season in hospitals (Esposito et al. 2020), and, to the best of our knowledge, there are no studies investigating the efficacy of universal masking in healthy individuals to prevent SARS-CoV-2 transmissions. At least, for seasonal human corona virus infection, it was shown that exhaled droplets with a diameter of ≤5 µm containing viral particles can completely be withheld by surgical masks when worn by an infected person (Leung et al. 2020). Arguments against universal masking include a global supply shortage of medical masks, the insufficient filtration of alternative cloth masks compared to medical masks (MacIntyre et al. 2015), a false sense of protection by wearing a mask that may result in failing to maintain physical distance from others, and the risk imposed by incorrect usage of masks by non-trained carriers, *e.g.* transmitting pathogens from contaminated hands to the mask. Here, we report effects of universal masking that were observed after implementation of (*i*) mandatory universal masking in the Jena University Hospital (JUH) and (*ii*) of mandatory community masking in the city of Jena.

Impact of hospital-wide universal masking

The JUH is a tertiary academic hospital with about 1,400 beds and 5,600 employees providing care for about 53,000 inpatients per year. The first detected COVID-19 case in Jena was a physician returning from Austria. Upon his return, he immediately reported to the hospital occupational health department, was tested and isolated at home on 11th March

2020. On 16th March, a nurse that had returned from skiing in Northern Italy became the source of the first nosocomial outbreak involving four patients and two health care workers (HCW). Consequently, extensive screening was conducted on 1,311 HCW – representing one third of the total work force in direct patient care- between 11th March and 12th May resulting in 31 positive cases until 19th March, approximately one week after the first confirmed case (***Figure 1***). As a consequence, mandatory masking for all personnel involved in patient care was implemented on 20th March. Continued routine staff screening revealed only four HCWs tested positive between 20th March and 12th May. This corresponds to a substantial drop in the rate of new infections among HCWs from 10.1% (31 of 306 screened HCW in this period) before to 0.4% (4 of 1,005 HCW screened in this period) after implementation of universal masking. In addition, a strict containment system was introduced on 5th April, which included placing all patients in single rooms upon admission and SARS-CoV-2 screening regardless of their admitting chief complaint. Thereafter, HCW screening did not reveal any further positive case.

Impact of community-wide universal masking

Jena is the second largest city in Thuringia, Germany, with approximately 111,400 inhabitants. Despite thorough contact tracing and isolation of confirmed COVID-19 positive cases by the authorities, a rapid increase in numbers was observed after patient zero (***Figure 1***). The governmental containment (closing of stores, schools, kindergartens, churches etc.) together with social distancing measures was strictly implemented on 20th March in Jena and four days later in the entire Federal State of Thuringia. As novel infections continued to occur, Jena authorities were the first in Germany to introduce universal community-wide masking*, i.e.* mandatory covering of the mouth and nose in public buildings and public transport accepting also cloth masks or scarfs. On 24th April, a state-wide recommendation for community-wide masking in combination with first relaxations of the strict lockdown was issued.

medRxiv preprint doi: https://doi.org/10.1101/2020.09.02.20187021; this version posted September 3, 2020. The copyright holder for this preprint

We also assessed the effectiveness of mandatory community-wide masking in Jena in comparison with the nearby city of Erfurt (***Figure 1***). Both cities exhibit a similar university as well as socioeconomic structure. Erfurt introduced masking four weeks after Jena, simultaneously with the first relaxation of the lockdown measures.

As shown in ***Figure 1,*** there were no new COIVD-19 cases in Jena five days after implementation, which is in line with the average incubation time of SARS-CoV-2. While in Erfurt, COVID-19 continued to spread and only ceased after the same community-wide masking was imposed.

We are aware that mere association is not causation and that our conclusions are limited by the observational nature of the data. However, it is uncertain whether an ethically sound trial on the controversial issue of mandatory community-wide masking will ever be performed. Therefore, our observations support the notion to implement universal masking in both health care as well as community settings as considering the ensuing reduced infection-rates. Given the risk-benefit ratio, we consider universal masking combined with social distancing as a suitable measure to contain the spread of SARS-CoV-2.

Abstract

Interrupted time series analyses (ITSA) were performed to measure the impact of social distancing policies (instituted 22/03/2020) and subsequent mandatory masking in the community (instituted 04/05/2020) on the incidence and effective reproductive number (Rt) of COVID-19 in São Paulo State, Brazil. Overall, the impact of social distancing both on incidence and Rt was greater than the incremental effect of mandatory masking. Those findings may reflect either a small impact of face masking or the loosening of social distancing after mandatory use of masks.

Text

São Paulo state reported the first case of COVID-19 in Brazil, on 25 February 2020 [1]. While this manuscript is being written (as of 23 August 2020), the number of laboratory-confirmed cases in Brazil approaches 3 million, with circa 115 thousand deaths (https://covid.saude.gov.br/). Circa 20.5% of both cases and deaths occurred in São Paulo, Brazil's most populous state (44 million inhabitants). Geographic modeling[2] and ecological analyses[3] documented patterns of disease spread from the metropolitan area, where 39 cities harbor 21 million inhabitants, to the remaining 606 municipalities located in the inner areas of the state.

To contain the spread of SARS-Cov-2, The government of São Paulo decreed the closure of non-essential services and the restriction of public transport from 22 March. Even though evidence for the effectiveness of that measure in preventing deaths and intensive care units (ICU) admissions was reported[4], data on its impact in the inner areas of the state is still lacking. Furthermore, a second decree from May 4th made the use of face masks in community settings mandatory.

Out study was a natural experiment using ecological approach. We aimed at analyzing the impact of both control measures cited above on daily incidence rates (per 100,000 inhabitants) and daily estimates of the effective reproductive number (R_t) of laboratory-confirmed COVID-19 cases in the metropolitan and inner areas of São Paulo State. Daily incidence from 1 March through 4 July were obtained from São Paulo State Epidemiological Surveillance Center database (www.cve.saude.sp.gov.br), and population data for year 2020 was recovered from the São Paulo State Foundation for Data Analysis (SEADE, https://www.seade.gov.br/). The time series of cases was used to estimate R_t, as described by Wallinga & Lipsitch[5].

medRxiv preprint doi: https://doi.org/10.1101/2020.08.23.20180273; this version posted August 25, 2020. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY-NC-ND 4.0 International license .

Interrupted time series (ITS) analysis[6] was performed using STATA 14 (Statacorp, College Station, TX), with models that included both successive interventions (social distancing [#1] and universal masking [#2]). Those models fitted linear trends for each period (pre-intervention #1, between interventions, and post-intervention #2). Both immediate impact and sustained changes in trends were assessed.

Results are presented in **Table 1** and **Figure 1**. Social distancing had immediate beneficial impact on incidence in all the state, but trend changes were significant only for inner municipalities. As symmetric result was detected for R_t: overall immediate impact, but sustained trend changed only in the metropolitan area. The incremental impact of universal masking was not immediate, but a significant change downwards in incidence trends was generally detected. As for the R_t, only an immediate impact in inner municipalities was statistically significant.

São Paulo state did not experience a lockdown in the strict sense of the word. Instead, the March 22nd decree attempted to induce social distancing by closing non-essential services (e.g., stores) and restricting public transport (subway, metropolitan railways, and buses). ITS analysis demonstrates a variable but generally beneficial impact of that measure. This is in agreement with previous reports and modeling predictions[4,7]. The incremental benefit of mandatory universal masking was subtle, with impact on incidence rates but not on daily R_t series. This finding contrasts with recent reports from the US [8].

As with all analyzes of natural experiments, our study is subject to confounding bias. The most important is the gradual loosening of restrictive policies (the so-called São Paulo Plan, available at https://www.saopaulo.sp.gov.br/planosp/). Briefly, those measures, initiated in 1 June 2020 were slowly and heterogeneously applied. The State was divided in 22 administrative areas, which could open 0 to 40% of non-essential services, depending on standards of COVID-19 incidence and mortality, availability and occupation of Intensive Care Unit beds.

medRxiv preprint doi: https://doi.org/10.1101/2020.08.23.20180273; this version posted August 25, 2020. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY-NC-ND 4.0 International license .

Municipalities were also allowed to implement additional restrictive measures, as aspect which increased the heterogeneity of the preventive policies. Recommendations changed every two weeks, depending on novel epidemiological data. To assess that slowly applied, geographically heterogeneous and time-varying strategy was beyond the scope of this study. Also, the continuous rise in population mobility (as detected from movement of mobile phones and reported in the São Paulo Government homepage, https://www.saopaulo.sp.gov.br/coronavirus/) was not included in our models, since we had access only to incomplete data. Also, the increasing availability of laboratory testing may have influenced our findings. However, as previously reported, that increase was greater during the first months of pandemics in Brazil, so they were expected to underestimate the impact of the first intervention [9]. Even though those aspects might confound the impact of nonpharmaceutical measures, they are real life phenomena inherent to studies of effectiveness (as opposed to efficacy).

Another limitation of our study was its ecological approach. Obviously, we did not assess the impact of staying at home or using cloth masks on individual risks of being infected by SARS-Cov-2. Our main objective was to study the collective impact of governmental policies.

A systematic review of nonpharmaceutical measures to prevent COVID-19, based solely on observational studies, concluded that social distancing, use of masks and eye protection were beneficial [10]. Unfortunately, those results are limited by the heterogeneity of settings (healthcare and community) and of interventions. The analysis of benefits from use of masks is particularly challenging. Previous studies point to an expected greater efficacy of N95 respirators and surgical masks than that of cloth and/or homemade masks. It is worth noting that a recent systematic review with meta-analysis or randomized clinical trials found general protective impact of face masks [11]. However, protection was greater in healthcare settings than in the community. Also, the included studies assessed influenza and other respiratory

medRxiv preprint doi: https://doi.org/10.1101/2020.08.23.20180273; this version posted August 25, 2020. The copyright holder for this preprint

viruses, and most of them tested surgical masks. Therefore, inferences have been largely based on analogy, and the benefits of cloth masks are far from straightforward.

In conclusion, we found that governmental strategies based on nonpharmaceutical intervention were generally effective in slowing the evolution of pandemics in São Paulo State, Brazil. The effectiveness was greater for the first intervention (social distancing), with some incremental impact of mandatory use of face masks. Those findings may reflect either a small impact of face masking or the loosening of social distancing after mandatory use of masks. Either way, they contribute for directing public policies against COVID-19 in Brazil and other countries, in a period when the world is still far from achieving control of the current pandemics.

Face Masks, Public Policies and Slowing the Spread of COVID-19: Evidence from Canada*

Abstract

We estimate the impact of mask mandates and other non-pharmaceutical interventions (NPI) on COVID-19 case growth in Canada, including regulations on businesses and gatherings, school closures, travel and self-isolation, and long-term care homes. We partially account for behavioral responses using Google mobility data. Our identification approach exploits variation in the timing of indoor face mask mandates staggered over two months in the 34 public health regions in Ontario, Canada's most populous province. We find that, in the first few weeks after implementation, mask mandates are associated with a reduction of 25 percent in the weekly number of new COVID-19 cases. Additional analysis with province-level data provides corroborating evidence. Counterfactual policy simulations suggest that mandating indoor masks nationwide in early July could have reduced the weekly number of new cases in Canada by 25 to 40 percent in mid-August, which translates into 700 to 1,100 fewer cases per week.

1 Introduction

When government policies to stem the spread of COVID-19 were introduced in early 2020, the best available evidence supporting them was provided by studies of previous epidemics, epidemiological modeling, and case studies (OECD, 2020). Even when the efficacy of a given precaution in reducing COVID-19 transmission has been established, significant doubts regarding the usefulness of specific policy measures may persist due to uncertainty regarding adherence to the rules and other behavioral responses. For example, even though several observational studies, mostly in medical setting, have shown that face masks reduce the transmission of COVID-19 and similar respiratory illnesses (see Chu et al. (2020) for a comprehensive review), a face mask mandate may not be effective in practice if it fails to increase the prevalence of mask wearing (compliance), or if it leads to increased contacts due to a false sense of security. It is therefore important to directly evaluate and quantify the relationship between various policy measures and the rate of propagation of COVID-19.

The low cost and high feasibility of mask mandates relative to other containment measures for COVID-19 has generated keen interest worldwide for studying their effectiveness. This attention has been compounded by substantial variation, across jurisdictions and over time, in official advice regarding the use of masks. Figure B1 in the Appendix plots self-reported mask usage in select countries (Canada, United States, Germany and Australia) in the left panel, and across Canadian provinces in the right panel. The figure shows large differences in mask usage, both across countries and within Canada.[1]

We estimate and quantify the impact of mask mandates and other non-pharmaceutical interventions (NPI) on the growth of the number of COVID-19 cases in Canada. Canadian data has the important advantage of allowing two complementary approaches to address our objective. First, we estimate the effect of mask mandates by exploiting within-province geographic variation in the timing of indoor face mask mandates across 34 public health regions (PHUs) in Ontario, Canada's most populous province with a population of nearly 15 million or roughly 39% of Canada's population (Statistics Canada, 2020). The advantage of this approach is that it exploits variation over a relatively small geographic scale (PHU), holding all other province-level policies or events constant. In addition, the adoption of indoor face mask mandates in these 34 sub-regions was staggered over approximately two months, creating sufficient intertemporal policy variation across the PHUs.

[1]We show mask usage for the U.S. and Germany because related work by Chernozhukov et al. (2020) and Mitze et al. (2020) studies the effect of mask mandates in these countries respectively. We show Australia as an example of a country which did not mandate mask usage, except for Melbourne in late July. See Hatzius et al. (2020) for more cross-country comparisons of mask usage.

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. Second, we evaluate the impact of NPIs in Canada as a whole, by exploiting variation in the timing of policies across the country's ten provinces. By studying inter-provincial variation, we are able to analyze the impact of not only mask mandates, but also other NPIs, for which there is little or no variation across Ontario's PHUs (regulations on businesses and gatherings, schooling, travel and long-term care). In addition, our province-level data include both the closing period (March-April) and the gradual re-opening period (May-August), providing variation from both the imposition and the relaxation of policies.

Our panel-data estimation strategy broadly follows the approach of Chernozhukov, Kasahara and Schrimpf (2020), hereafter CKS (2020), adapted to the Canadian context. We allow for behavioural responses (using Google Community Mobility Reports geo-location data as proxy for behaviour changes and trends), as well as lagged outcome responses to policy and behavioral changes. Our empirical approach also allows current epidemiological outcomes to depend on past outcomes, as an information variable affecting past policies or behaviour, or directly, as in the SIR model framework.

We find that, in the first few weeks after their introduction, mask mandates are associated with an average reduction of 25 to 31% in the weekly number of newly diagnosed COVID-19 cases in Ontario, holding all else equal. We find corroborating evidence in the province-level analysis, with a 36 to 46% reduction in weekly cases, depending on the empirical specification. Furthermore, using survey data, we show that mask mandates increase self-reported mask usage in Canada by 30 percentage points, suggesting that the policy has a significant impact on behaviour. Jointly, these results suggest that mandating indoor mask wear in public places is a powerful policy measure to slow the spread of COVID-19, with little associated economic disruption at least in the short run.[2]

Counterfactual policy simulations using our empirical estimates suggest that mandating indoor masks nationwide in early July could have reduced weekly new cases in Canada by 25 to 40% on average by mid-August relative to the actually observed numbers, which translates into 700 to 1,100 fewer cases per week.

We also find that the most stringent restrictions on businesses and gatherings observed in our data are associated with a decrease of 48 to 57% in weekly cases, relative to a lack of restrictions. The business/gathering estimates are, however, noisier than our estimates for mask mandates and do not retain statistical significance in all specifications; they appear driven by the smaller provinces and the re-opening period (May to August). School closures and travel restrictions are associated with a large decrease in weekly case growth in the

[2]Hatzius et al. (2020) estimate that a national mask mandate in the USA could replace alternative restrictions costing 5% of GDP.

closing period. Our results on business/gathering regulations and school closure suggest that reduced restrictions and the associated increase in business or workplace activity and gatherings or school re-opening can offset, in whole or in part, the estimated effect of mask mandates on COVID-19 case growth, both in our sample and subsequently.

An additional contribution of this research project is to assemble, from original official sources only, and make publicly available a complete dataset of COVID-19 cases, deaths, tests and policy measures in all 10 Canadian provinces.[3] To this end, we constructed, based on official public health orders and announcements, time series for 17 policy indicators regarding face masks, regulations on businesses and gatherings, school closures, travel and self-isolation, and long-term care homes.

Our paper relates most closely to two recent empirical papers on the effects of mask mandates using observational data.[4] CKS (2020) and Mitze et al. (2020) study the effect of mask mandates in the United States and Germany, respectively. CKS (2020), whose estimation strategy we follow, exploit U.S. state-level variation in the timing of mask mandates for employees in public-facing businesses, and find that these mandates are associated with 9 to 10 percentage points reduction in the weekly growth rate of cases. This is substantially smaller that our estimates, possibly because the mask mandates that we study are much broader: they apply to all persons rather than just employees, and most apply to all indoor public spaces rather than just businesses. Mitze et al. (2020) use a synthetic control approach and compare the city of Jena and six regions in Germany that adopted a face mask policy in early to mid April 2020, before their respective state mandate. They find that mandatory masks reduce the daily growth rate of cases by about 40%.

Our paper has several advantages compared to the above two papers. First, we exploit both regional variation within the same province (like Mitze et al., 2020) and provincial variation in the whole country (like CKS, 2020), and find similar results, which strengthens the validity of our findings. Second, we show that self-reported mask usage has increased after introducing mask mandates. We view this "first-stage" result on mask usage as informative, as the effectiveness of any NPI or public policy critically depends on the compliance rate. Moreover, this result mitigates possible concerns that the estimated mask mandate effect on COVID-19 case growth may be caused by factors other than mask policy. Third, a key

[3] All data are available for download at https://github.com/C19-SFU-Econ. The COVID-19 cases, deaths and tests data that we collected and use in this paper incorporate all official ex-post revisions as of mid-August, unlike data from the Government of Canada COVID-19 website or other aggregator websites.

[4] Howard et al. (2020), a comprehensive review of the medical literature, stresses that "no randomized controlled trial (RCT) on the use of masks as source control for SARS-CoV-2 has been published." It is unlikely that an RCT on masks' effectiveness against COVID-19 will be feasible or ethical during the pandemic.

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. difference between our paper and CKS (2020) is that we evaluate the effect of *universal* (or *community*) mandatory indoor mask wearing for the public rather than the effect of mandatory mask wearing for *employees only*.[5] While other factors such as differences in mask wear compliance between Canada and the U.S. may contribute to the different estimated magnitude of the policy impact, our results suggest that more comprehensive mask policies can be more effective in reducing the case growth rate.

Other Related Literature

Abaluck et al. (2020) discuss the effectiveness of universal adoption of homemade cloth face masks and conclude that this policy could yield large benefits, in the \$3,000–\$6,000 per capita range, by slowing the spread of the virus. The analysis compares countries with pre-existing norms that sick people should wear masks (South Korea, Japan, Hong Kong and Taiwan) and countries without such norms.[6]

In the medical literature, Prather et al. (2020) argue that masks can play an important role in reducing the spread of COVID-19. Howard et al. (2020) survey the medical evidence on mask efficiency and recommend public use of masks in conjunction with existing hygiene, distancing, and contact tracing strategies. Greenhalgh et al. (2020) provide evidence on the use of masks during non-COVID epidemics (influenza and SARS) and conclude that even limited protection could prevent some transmission of COVID-19. Leung et al. (2020) study exhaled breath and coughs of children and adults with acute respiratory illness and conclude that the use of surgical face masks could prevent the transmission of the human coronavirus and influenza virus from symptomatic individuals. Meyerowitz et al. (2020) present a recent comprehensive review of the evidence on transmission of the virus and conclude that there is strong evidence from case and cluster reports indicating that respiratory transmission is dominant, with proximity and ventilation being key determinants of transmission risk, as opposed to direct contact or fomite transmission.

Our paper also complements recent work on COVID-19 policies in Canada. Mohammed et al. (2020) use public opinion survey data to study the effect of changes in mask-wear policy recommendations, from discouraged to mandatory, on the rates of mask adoption and public trust in government institutions. They show that Canadians exhibit high compliance with mask mandates and trust in public health officials remained consistent across time. Yuksel et al. (2020) use an outcome variable constructed from Apple mobility data along

[5] Lyu and Wehby (2020) provide suggestive evidence that community mask mandates are more effective than employees-only mandates.

[6] The authors report average daily case growth rate of 18% in countries with no pre-existing mask norms vs. 10% in countries with such norms. On a weekly basis, this translates to a reduction of 49 log points ($100(\log(1.18^7) - \log(1.1^7))$) in case growth, or 39% reduction in weekly cases.

with weather data and lagged COVID-19 cases or deaths as dependent variables to study compliance with social distancing measures.

2 Data

We use three main data sources, respectively for epidemiological variables, NPI and mask mandates, and behavioral responses. The time period is from the start of detected community transmission in Canada in March to mid-August, 2020.

We located and accessed the original official sources to collect a complete dataset of COVID-19 cases, deaths, tests and policy measures in all ten Canadian provinces.[7] In addition, our data include cases and policy measure indicators for each of the 34 public health units (PHUs) in Ontario. A detailed description is provided in the data source files shared at the project's Github webpage.

Implementation dates of NPIs and other public policies were collected from government websites, announcements, public health orders and staged re-opening plans collected from their official sources. In the national data, the raw policy measures data contain the dates or enactment and relaxation (if applicable) of 17 policy indicators including: mandatory mask wear; closure and re-opening of retail and non-essential businesses, restaurants, recreation facilities, and places of worship; school closures; limits on events and gatherings; international and domestic travel restrictions and self-isolation requirements; restrictions on visits and staff movement in long-term care homes. All policy indicator variables are defined in Table C1 in the Appendix.[8] Since many of these indicators are highly correlated with each other, we combine them into five policy aggregates in the empirical analysis (see Table A17 and Section 3.2). In the Ontario PHU data, the implementation dates of mask mandates and the relaxation dates of policies for businesses and gatherings vary across PHUs. Decisions about the former were made at the PHU level, while decisions about the latter were made by the province, which classified PHUs into three groups, with some exceptions.

Regarding behavioral responses, we use the Google COVID-19 Community Mobility Reports, which summarize daily cellphone geo-location data for each province as indices calculated relative to the median value for the same day of the week in the five-week baseline

[7]The provinces differ in the ease of accessibility of their official time series of COVID-19 cases, deaths and test numbers. In some cases, we located and used the hidden json sources feeding the public dashboard charts. In few instances in which data were not available, we used the numbers reported in the daily provincial government announcements. All COVID-19 outcome data sources are referenced and web-linked in Appendix Table C3.

[8]Additional survey data on mask usage is described and used in Section 4.4.

period January 3 to February 6, 2020.[9] In Ontario, these location data are available for each of the 51 first-level administrative divisions (counties, regional municipalities, single-tier municipalities and districts).[10]

3 Empirical method

We follow the approach of CKS (2020), but modify and adapt it to the Canadian context. The empirical strategy uses the panel structure of the outcome, policy and behavioral proxy variables, and includes lags of outcomes as information, following the causal paths suggested by the epidemiological SIR model (Kermack and McKendrick, 1927). Specifically, we estimate the effect of policy interventions on COVID-19 outcomes while controlling for information and behaviour. In contrast to CKS (2020) and Hsiang et al. (2020), who study variation in NPIs across U.S. states or across countries, our identification strategy exploits policy variation at the sub-provincial level (Ontario's PHUs) in addition to cross-province variation, and our data captures both the closing down and gradual re-opening stages of the epidemic.

3.1 Estimation strategy

The main data used in our empirical analysis are summarized below; Section 3.2 describes the variables in detail. Everywhere i denotes province for national analysis, and health region (PHU) for Ontario analysis, and t denotes time measured in days.

1. Outcomes, Y_{it} – growth rate of weekly cases or deaths.

2. Information, I_{it} – lagged outcomes, i.e. past levels or growth rate of cases (or deaths). We also consider a specification that includes the past cases/deaths and case/death growth at the national level as additional information variables.

3. Behavioral responses, B_{it} – Google mobility data capturing changes in people's geolocation relative to a baseline period in January-February.

4. Policy/NPIs, P_{it} – for the national analysis, five policy aggregates by province and date; for the Ontario analysis, two policy variables (mask mandates and regulation on business and gathering) by PHU and date.

[9] The reports are available for download at https://www.google.com/covid19/mobility/.

[10] Each of these divisions is either entirely (in most cases) or predominantly located within a single PHU. In cases where a PHU corresponds to multiple divisions, 2016 Census population counts were used as weights to compute the PHU's mobility index.

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

5. Controls, W_{it} – province or PHU fixed effects, growth rate of weekly new COVID-19 tests, and a time trend.

To assess and disentangle the impact of NPIs and behavioral responses on COVID-19 outcomes, we estimate the following equation:

$$Y_{it} = \alpha B_{it-l} + \pi P_{it-l} + \mu I_{it} + \delta_Y W_{it} + \varepsilon_{it}^Y \tag{1}$$

where l denotes a time lag measured in days. Equation (1) models the relationship between COVID-19 outcomes, Y_{it}, and lagged behaviour, B_{it-l}, lagged policy measures, P_{it-l} and information (past outcomes), $I_{it} = Y_{it-l}$. For case growth as the outcome, we use $l = 14$. For deaths growth as the outcome, we use $l = 28$.[11] The choice of these lags is discussed in Appendix D.

By including lagged outcomes, our approach allows for possible endogeneity of the policy interventions P_{it}, that is, the introduction or relaxation of NPIs based on information on the level or growth rate of cases or deaths. Also, past cases may be correlated with (lagged) government policies or behaviors that may not be fully captured by the policy and behaviour variables.

In Appendix Table A18, we also report estimates of the following equation:

$$B_{it} = \beta P_{it} + \gamma I_{it} + \delta_B W_{it} + \varepsilon_{it}^B \tag{2}$$

which models the relationship between policies P_{it}, information, I_{it} (weekly levels or growth of cases or deaths) and behaviour, B_{it}. It is assumed that behaviour reacts to the information without a significant lag. We find strong correlation between policy measures and the Google mobility behavioral proxy measure.

Equation (1) captures both the direct effect of policies on outcomes, with the appropriate lag, as well as the potential indirect effect on outcomes from changes in behaviour captured by the changes in geo-location proxy B_{it-l}. In Appendix Tables A19 and A20, we also report estimates of equation (1) without including the behavioral proxy, that is, capturing the total effect of policies on outcomes. Since our estimates of the coefficient α in equation (1) are not significantly different from zero, the results without controlling for the behavioral proxy are very similar to those from estimating equation (1).

[11] Our lag for deaths is one week longer than that used by CKS (2020). The difference is due to additional evidence from the medical literature and the construction of the weekly variables (see Appendix D).

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

3.2 Variables and descriptive analysis

Outcomes. Our main outcome of interest is the growth rate of weekly new positive COVID-19 cases as defined below.[12] We use weekly outcome data to correct for the strong day-of-the-week effect present in COVID-19 outcome data.[13] Weekly case growth is a metric that can be helpful in assessing trends in the spread of COVID-19, and it is highlighted in the World Health Organization's weekly epidemiological updates (see, for example, World Health Organization (2020)).

Specifically, let C_{it} denote the cumulative case count up to day t and define ΔC_{it} as the weekly COVID-19 cases reported for the 7-day period ending at day t:

$$\Delta C_{it} \equiv C_{it} - C_{it-7}.$$

The weekly case (log) growth rate is then defined as:

$$Y_{it} = \Delta \log(\Delta C_{it}) = \log(\Delta C_{it}) - \log(\Delta C_{it-7}), \tag{3}$$

that is, the week-over-week growth in cases in region i ending on day t.[14] The weekly death growth rate is defined analogously, using cumulative deaths data.

Policy. In the Ontario analysis, we exploit regional variation in the timing of indoor mask mandates staggered over two months in the province's 34 regions ("public health units" or PHUs). Figure 1 displays the gradual introduction of mask mandates across the 34 PHUs in Ontario. The exact implementation dates of the mask mandates are reported in Table C2. Mandatory indoor masks were introduced first in the Wellington-Dufferin-Guelph PHU on June 12 and last in the Northwestern PHU on August 17.[15]

[12] We also report results using the growth rate of deaths as supplemental analysis in Section 4.6.

[13] Figures B9 and B10 in the Appendix respectively display the weekly and daily cases, deaths and tests in each Canadian province over time. There are markedly lower numbers reported on weekends or holidays.

[14] To deal with zero weekly values, which mostly occur in the smaller regions, as in CKS (2020), we replace log(0) with -1. We also check the robustness of our results by adding 1 to all ΔC_{it} observations before taking logs, by replacing log(0) with 0, and by using population weighted least squares; see Tables A5 and A8.

[15] There is no PHU-wide mask mandate in Lambton as of August 31, but its main city, Sarnia, enacted a mask mandate on July 31.

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. Figure 1: Ontario - mask mandates over time

Notes: There are a total of 34 public health units (PHU) in Ontario. See Table C2 for the exact date of mask mandate implementation in each PHU.

In the province-level analysis, we assign numerical values to each of the 17 policy indicators listed in Table C1 in Appendix C. The values are on the interval [0,1], with 0 meaning no or lowest level of restrictions and 1 meaning maximal restrictions. A policy value between 0 and 1 indicates partial restrictions, either in terms of intensity (see more detail and the definitions in Table C1) or by geographical coverage (in large provinces). The numerical values are assigned at the daily level for each region (PHU or province, respectively for the Ontario and national results), while maintaining comparability across regions.

Many NPIs were implemented at the same time, both relative to each other and/or across regions (especially during the March closing-down period), which causes many of the policy indicators to be highly correlated with each other (see Appendix Table A4). To avoid multi-collinearity issues, we group the 17 policy indicators into 5 policy aggregates via simple averaging: (i) *travel*, which includes international and domestic travel restrictions and self-isolation rules; (ii) *school*, which is an indicator of provincial school closure; (iii) *business/gathering*, which comprises regulations and restrictions on non-essential businesses and retail, personal businesses, restaurants, bars and nightclubs, places of worship, events,

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

gyms and recreation, and limits on gathering; (iv) *long-term care (LTC)*, which includes NPIs governing the operation of long-term care homes (visitor rules and whether staff are required to work on a single site) and (v) *mask* which takes value 1 if an indoor mask mandate has been introduced, 0 if not, or value between 0 and 1 if only part of a province has enacted such policy.[16]

The five policy aggregates are constructed at the daily level and capture both the closing-down period (an increase in the numerical value from 0 toward 1) and the re-opening period (decrease in the numerical value toward zero). In comparison, the policy indicators compiled by Raifman (2020) for the USA used in CKS (2020) are binary "on (1)"/"off (0)" variables.[17] For consistency with the weekly outcome and information variables and the empirical model timing, we construct the policy aggregates P_{it}^{j} used in the regressions (where j denotes policy type) by taking a weekly moving average of the raw policy data, from date $t-6$ to date t.

Figure 2 plots the values of the 5 policy aggregates over time for each of the 10 provinces. Travel restrictions, school closures (including Spring and Summer breaks) and business closures were implemented in a relatively short period in the middle of March. There is some variation in the travel policy aggregate since some Canadian provinces (the Atlantic provinces and Manitoba) implemented inter-provincial domestic travel or self-isolation restrictions in addition to the federal regulations regarding international travel. Restrictions on long-term care facilities were introduced more gradually. In the re-opening period (May-August), there is also more policy intensity variation across the provinces, especially in the business and gatherings category, as the different provinces implemented their own re-opening plans and strategies. Mask mandates were first introduced in Ontario starting from June in some smaller PHUs and early July in the most populous PHUs such as Toronto, Ottawa and Peel (see Appendix Table C2). In Quebec, indoor masks were mandated province-wide on July 18. Nova Scotia and Alberta's two main cities implemented mask mandates on July 31 and August 1, respectively.

[16] We do not use provincial declarations of emergency in our analysis as they are mostly legal tools enabling other restrictions rather than restrictions *per se*.

[17] The daily numerical values for each of the 17 basic policy indicators and the 5 policy aggregates for each province and date are available on the project's Github repository.

There are two empirical challenges specific to our Canadian context and data. The first challenge is the presence of small provinces and sub-regions with very few COVID-19 cases or deaths. In Section 4.3, we perform a number of robustness checks using different ways of handling the observations with very few cases (in particular zero cases). The second data limitation is that there are only 10 provinces in Canada and 34 public health units in Ontario, unlike the 51 U.S. jurisdictions in CKS (2020). To account for the resulting small number of clusters in the estimation, we compute and report wild bootstrap standard errors and p-values, as proposed by Cameron et al. (2008).[18] On the flip side, our data has the advantage of a longer time horizon (March to August) and non-binary, more detailed policy variables compared to Raifman et al. (2020).

Behaviour proxy. We follow CKS (2020) and other authors in interpreting the location change indices from the Google Community Mobility reports as proxies for changes in people's behaviour during the pandemic, keeping in mind that location is only one aspect of behaviour relevant to COVID-19. The general pattern in the data (see Figure B3) shows sharply reduced frequency of recorded geo-locations in shops, workplaces and transit early in the pandemic (March), with a subsequent gradual increase back toward the baseline (except for transit), and a flattening out in July and August.

Several of the six location indicators (retail, grocery and pharmacy, workplaces, transit, parks and residential) are highly correlated with each other (see Tables A1 and A2) and/or contain many missing observations for the smaller provinces. To address these data limitations and the possible impact of collinearity on the estimation results, we use as proxy for behavioral changes the simple average of the following three mobility indicators: "retail", "grocery and pharmacy" and "workplaces". To be consistent with the weekly outcome variables and to mitigate day-of-week behavioural variation, we construct the Behaviour proxy B_{it} by taking a weekly moving average of the $\frac{1}{3}$ (retail + grocery and pharmacy + workplaces) data, from date $t-6$ to date t.[19,20] As a result, our empirical analysis uses weekly totals (for cases, tests and deaths) or weekly moving averages (for policies and the behaviour proxy) of all variables recorded on daily basis.[21]

[18] Alternative methods for computing the standard errors are explored in Section 4.3.

[19] We drop the "transit", "parks", and "residential" location indicators because, respectively, 10.6%, 13.7%, and 2.8% of the observations are missing in the provincial data, and 20.7%, 52.1%, and 11.1% are missing in the Ontario data. The "transit" and "residential" variables are also highly correlated with the three indicators we include in our aggregate behaviour proxy B_{it}. Furthermore, the "parks" indicator does not have clear implication for COVID-19 outcomes.

[20] In the Ontario analysis, 1.4% of the B_{it} values are imputed via linear interpolation.

[21] In estimation equation (1), we take moving average from date $t-14$ to date $t-20$ for policies and behaviour when the outcome is weekly case growth, and from date $t-28$ to date $t-34$ if the outcome is

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. Tables A3 and A4 display the correlation between our behaviour proxy B_{it} and the five NPI policy aggregates P_{it}^{j}. Importantly, the behaviour proxy and mask mandate variables are not highly correlated, suggesting that the effect of mask mandates on COVID-19 outcomes should be independent of location behaviour changes.

Information. We use the weekly cases and case growth variables defined above, ΔC_{it} and Y_{it}, to construct the information variables I_{it} in equation (1). Specifically, we use as information the lagged value of the weekly case growth rate Y_{it-l} $(= \Delta \log(\Delta C_{it-l})$ and the log of past weekly cases, $\log(\Delta C_{it-l})$. We also use the lagged provincial (Ontario analysis) or national (Canada analysis) case growth rate and log of weekly cases as additional information variables in some specifications. A two-week information lag $l = 14$ is used in the baseline results. In the supplementary regressions using the death growth rate as the outcome, we use information on past deaths and a four-week lag (see Section 4.6).

Control variables. In all regressions, we control for region fixed effects (PHU or province) and the weekly COVID-19 tests growth rate $\Delta \log(\Delta T_{it})$, where T_{it} denotes cumulative tests in region i until date t and ΔT_{it} is defined analogously to ΔC_{it} above. We include a time trend: our baseline uses a cubic polynomial in days, but we also report results with no time trend and with week fixed effects. Robustness checks also include news or weather variables as controls (see Section 4.3).

Time period. We use the period May 15 to August 13 for the analysis with Ontario PHU level data and the period March 11 to August 13 for the national analysis with provincial data. The end date reflects data availability at the time of empirical analysis and writing. The start date for the Ontario sample (May 15) is approximately two weeks after the last restrictive measures were implemented and four weeks before the first mask mandate was introduced in Ontario. Robustness checks with different initial dates (May 1, June 1 and June 15) are reported in Section 4.3, with our results remaining stable. The initial date for the national sample (March 11) was chosen as the first date on which each province reported at least one COVID-19 test (so that cases could be potentially reported). Again, alternative initial dates are explored in Section 4.3.

deaths growth. Alternative lags are explored in Section 4.3.

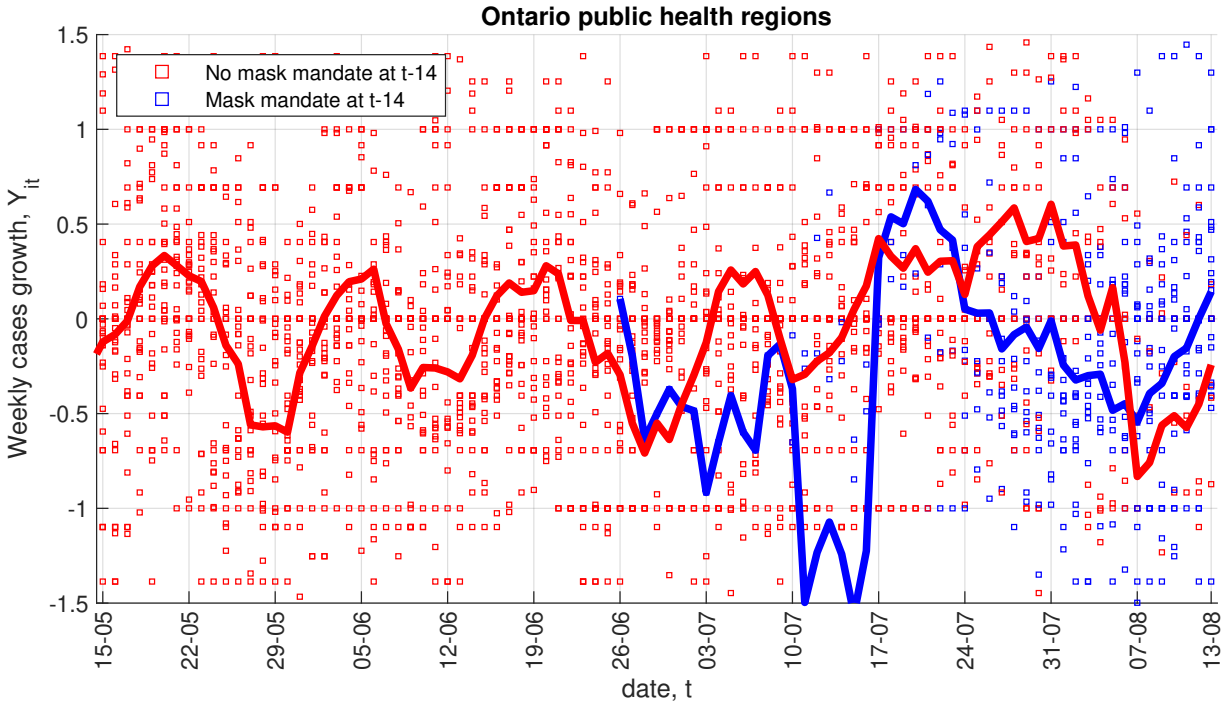
4 Results

4.1 Mask mandates in Ontario public health regions

We start with a simple graphical illustration of the effect of mask mandates on COVID-19 cases growth. Figure 3 displays the average log case growth, $Y_{it} = \Delta \log(\Delta C_{it})$ in Ontario PHUs with or without mask mandates. It shows that, on average, the PHUs with a mask mandate two weeks prior have lower case growth than the PHUs without a mask mandate two weeks prior.

Figure 3: Ontario - mask mandates and weekly case growth



Notes: The figure plots the average log weekly case growth $\Delta\log(\Delta C)$ in the PHUs with mask mandate (blue) vs. without (red) mask mandate 14 days prior.

Table 1 shows the estimates of equation (1), in which we control for other policies, behaviour and information, as explained in Section 3.1.[22] We report wild bootstrap p-values clustered at the PHU level to account for the small number of clusters.[23] The odd-numbered

[22]Mask mandates and regulations on business and gatherings vary at the PHU level. Long-term care policy changed only province-wide. The other policies (schooling and travel) do not vary during the sample period and hence are omitted from the regressions with Ontario PHU data.

[23]Table A6 in the Appendix reports alternative standard error specifications: regular clustering at the PHU level (Stata command "cluster"), wild bootstrap standard errors clustered at the PHU level, and wild

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. columns in Table 1 use lagged cases and lagged cases growth at the PHU level as information; the even-numbered columns also include lagged cases and lagged case growth at the province level as additional information variables. In the tables, *Variable*_14 indicates a 14-day lag of *Variable*.

We present estimates of equation (1) from three specifications that handle possible time effects differently. Columns (1) and (2) in Table 1 are the most basic specifications, without including a time trend. The estimates in columns (1) and (2) suggest that, controlling for behavioural changes, mandatory indoor face masks reduce the growth rate of infections by 29–32 log points ($p < 0.05$), which is equivalent to a 25–28% reduction in weekly cases.[24]

In order to control for potential province-wide factors affecting the spread of COVID-19 such as income support policies or adaptation to the pandemic over time (so-called COVID fatigue), we also estimate (1) with a cubic time trend in days from the beginning of the sample, in columns (3) and (4) of Table 1, and with week fixed effects, in columns (5) and (6). Columns (3)-(6) show that our estimates of the mask mandate policy remain robust to the inclusion of a cubic time trend or week fixed effects. The results indicate that, depending on the specification, mask mandates are associated with a reduction of up to 38 log points in weekly case growth or, equivalently, a 31% reduction in weekly cases. The magnitude of the mask policy estimate is not very sensitive to whether lagged province-level data are included as additional information.

The results in Table 1 suggest that indoor mask mandates can be a powerful preventative measure in the COVID-19 context. Our estimates of the mask mandate impact across Ontario's PHUs are equivalent to a 25–31% reduction in weekly cases. This estimate is larger than the 9–10% reduction estimated by CKS (2020) for the U.S. One possible explanation is that Ontario's mask policy is more comprehensive: we evaluate the effect of *universal* indoor mask-wearing for the public rather than the effect of mask wearing for *employees only* in CKS (2020). Differences in the compliance rate may also contribute to this difference; we discuss this potential channel in Section 4.4.

The results in Table 1 also show a statistically significant negative association between information (log of past cases, log(ΔC)_14) and current weekly case growth ($p < 0.01$ in all specifications), indicating that a higher level of cases two weeks prior is correlated with lower current case growth. While B_{it} allows for behavioural responses to information, the negative estimate on log(ΔC)_14 in Table 1 suggests that our location-based proxy does not capture

bootstrap standard errors clustered by both PHU and date. Our results are robust to alternative ways of calculating standard errors.

[24] Using equation (3), a coefficient of x translates into a $1-\exp(x)$ reduction in weekly cases $\Delta C_{it}/\Delta C_{it-7}$.

Notes: The sample time period is May 15 to August 13, 2020. P-values from wild bootstrap (cgmwildboot) standard errors clustered by public health unit (PHU) with 5000 repetitions are reported in the square brackets. Mask_14, Business/gathering_14, Behaviour_14, $\Delta\log(\Delta C)$_14, and $\log(\Delta C)$_14 are measured at the PHU level, while Long-term care_14, $\Delta\log(\Delta PC)$_14, $\log(\Delta PC)$_14, and $\Delta\log(\Delta T)$ are measured at the province level. PC denotes provincial total cases. ***, ** and * denote 10%, 5% and 1% significance level respectively. Missing values (1.3% of all observations) for Behaviour proxy_14 are imputed via linear interpolation.

important aspects of behaviour, such as frequent hand-washing or physical distancing. In fact, our coefficient estimate on the behavioral proxy B_{it} is very close to zero (both in Table

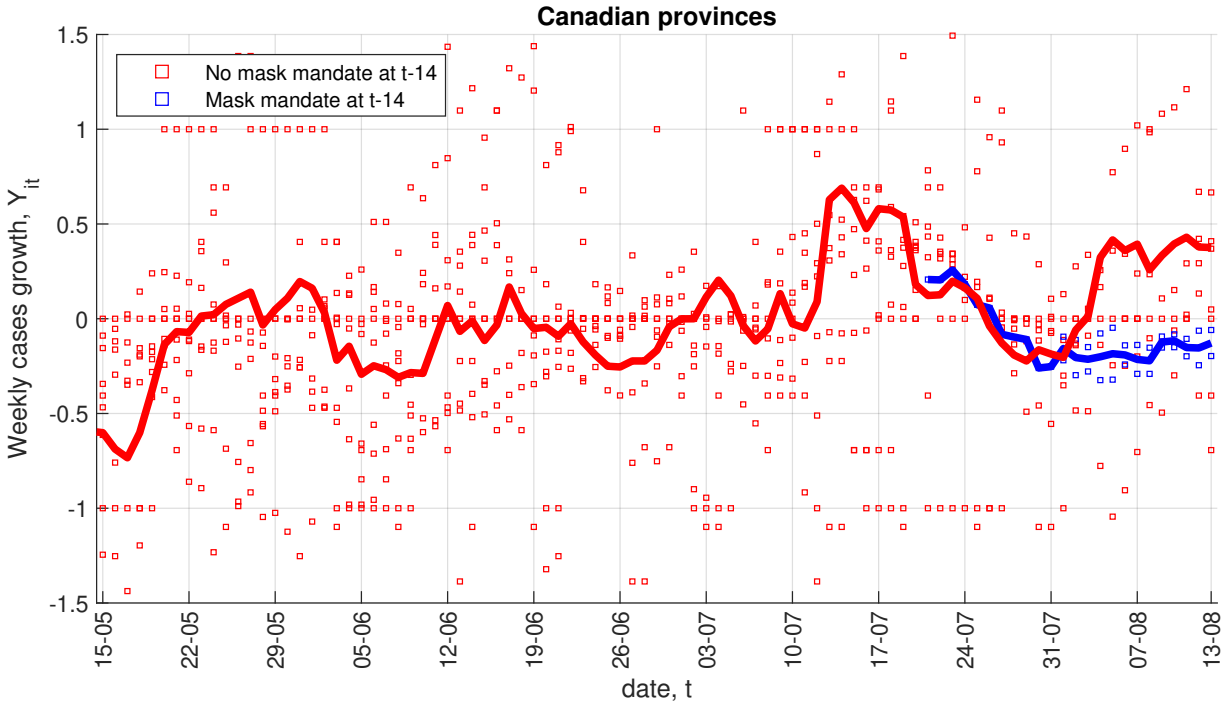
medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

1 and in Section 4.2's province-level results), unlike in CKS (2020).[25] In Appendix Table A18, we find strong contemporaneous correlations between the policy measures, log cases, and the Google mobility behavioral proxy from estimating equation (2). This suggests that the information (lagged cases) and the lagged policy variables included in equation (1) may absorb lagged behavioral responses proxied by B_{it-l} or other latent behavioral changes not captured by B_{it-l}.

4.2 Province-level results

We next evaluate the impact of NPIs on COVID-19 cases growth in Canada as a whole by exploiting variation in the timing of policies across the 10 provinces. Here, we examine NPIs for which there is no variation across Ontario's PHUs (i.e., schooling, travel, and LTC) in addition to mask mandates. Also, provincial data contain variation in the timing of policy changes in both the closing and re-opening phases, allowing us to study both the imposition and relaxation of restrictions.

Figure 4: Canada - mask mandates and weekly case growth



Notes: The figure plots the average weekly case growth $\Delta \log(\Delta C)$ in the provinces with mask mandate (blue) vs. without mask mandate (red) 14 days prior.

[25] We also tried including each location change measure separately and the results are similar (not shown).

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

As in the Ontario analysis, we begin with a graphical illustration of mask mandates and COVID-19 case growth across Canadian provinces, in the period March 11 to August 13, 2020. Figure 4 plots the average log weekly case growth in the provinces with vs. without mask mandates. While mask mandates are implemented relatively late in our sample period, average case growth in the provinces with a mask mandate (Ontario and Quebec) diverged from the average case growth in the provinces without a mandate begin roughly four weeks after the mandates are imposed.[26]

Table 2 displays the estimates of equation (1) for weekly case growth, along with wild bootstrap p-values, clustered at the province level (see Table A9 for other methods of computing the standard errors). The odd-numbered columns use lagged cases and lagged case growth at the provincial level as information while the even-numbered columns include in addition lagged cases and case growth at the national level as additional information variables.

As in the Ontario analysis, we present in Table 2 estimates from three specifications: no time trend (columns (1)-(2)), including cubic time trend in days (columns (3)-(4)) and including week fixed effects (columns (5)-(6)). The most robust result is the estimated effect of mask mandates: they are associated with a large reduction in weekly case growth of 45 to 62 log points, which is equivalent to a 36 to 46% reduction in weekly cases across the different specifications. The estimates are statistically significantly different from zero in all cases, with a p-value of less than 0.001 in columns (1)-(4). It is reassuring that these results regarding mask mandates are consistent with the Ontario analysis in the previous section.

Table 2 further shows that restrictions on businesses and gatherings are associated with a reduction in the weekly case growth of 65 to 85 log points or, vice versa, that relaxing business/gathering restrictions is associated with higher case growth. The estimate is equivalent to a 48 to 57% decrease in weekly cases in our sample period. The business/gathering estimates are, however, more noisy than our estimates for mask mandates and do not retain statistical significance in the specifications with week fixed effects ($p = 0.15$ and 0.14). Tables A8 and A15 further suggest that the results on business and gathering NPIs are driven by the smaller provinces and the re-opening period (May to August). Still, these results suggest that lowered restrictions and the associated increase in business/workplace activity or gatherings can be an important offsetting factor for the estimated effect of mask mandates on COVID-19 case growth, both in our sample and in the future.

We also find that school closures (the School_14 variable in Table 2) can be negatively

[26]Figure 4 assumes a July 7 mask mandate implementation date for Ontario (when its most populous PHU, Toronto, adopted a mask mandate, along with Ottawa), and July 18 for Quebec (province-wide mandate).

Notes: The time period is March 11 to August 13, 2020. P-values from wild bootstrap (cgmwildboot) standard errors clustered by province with 5000 repetitions are reported in the square brackets. ***, ** and * denote 10%, 5% and 1% significance level respectively. NC denotes national total cases.

associated with case growth. However, the estimates are statistically significant from zero only in the specifications with cubic time trend (columns (3) and (4)). As seen in Figure

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. No reuse allowed without permission.

2, provincial school closures occurred in a very short time interval during March, so we may lack statistical power to separately identify its effect from other NPIs (especially the travel-related). Hence, we interpret this result with caution.

As in Table 1, the level of past cases, $\log(\Delta C)$, is negatively and statistically significantly associated with current weekly case growth in columns (1)-(4).

Since the specification with cubic time trend in Tables 1 and 2 allows for possible non-monotonic aggregate time trends in case growth in a parsimonious way, we choose it as our baseline specification with which to perform robustness checks in the next section. Robustness checks with the other specifications are available upon request.

4.3 Robustness

Policy collinearity

A possible concern about our data for the national analysis is that some NPIs (e.g. international travel restrictions or closing of schools) were implemented within a very short time interval.[27] Thus, we may lack enough regional variation to distinguish and identify the separate effect of each policy.[28] Collinearity could also affect the standard errors and the signs of the estimated coefficients.

To check robustness with respect to potential collinearity in the NPI policies, Tables A7 and A10 report estimates from our baseline specification, omitting one policy at a time, for Ontario and Canada respectively. First, it is reassuring that the mask mandate estimates are hardly affected by omitting any of the other policies. This is expected since mask mandates were imposed during a period where other NPIs changed little (see Figure 2). Similarly, the effects of business/gathering regulations and school closures in Table A10 are not sensitive to omitting other policies one at a time, which suggests that there is sufficient statistical power and variation to identify them in the national analysis.

Treatment of zero weekly cases

Another concern for our empirical strategy is that the usual formula for our dependent variable, $\Delta \log(\Delta C_{it})$, cannot be applied when the weekly case total ΔC_{it} is zero. We follow CKS (2020) and replace ln(0) with -1 in our baseline specifications in Tables 1 and 2. We now check the robustness of our estimates to alternative treatments of zero weekly cases.

For easier comparison, the first two columns in Table A5 repeat columns (3) and (4)

[27] For example, Table A4 shows a correlation of 0.61 between the Travel and School policy aggregates.

[28] Aggregating the 17 basic policy indicators into five groups mitigates this issue. Here, we test whether any remaining collinearity poses a problem.

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

from Table 1 for Ontario.[29] Our main results on mask mandates across Ontario PHUs are robust to replacing log(0) with 0 and to adding 1 to all ΔC_{it} observations before taking logs, as shown in columns (3)-(6) of Table A5. Another way to mitigate the issue of PHUs with very few cases is to estimate a weighted least squares regression where PHUs are weighted by population. Columns (7) and (8) in Table A5 show that the resulting mask estimate has a slightly smaller magnitude and, due to the reduced effective sample size, weaker statistical significance.

Similarly, Table A8 shows that our province-level estimates, in particular for mask mandates, are also robust to the same manipulations as above.[30] In columns (9) and (10) of Table A8, we restrict the sample to only the largest 4 provinces (British Columbia, Ontario, Quebec and Alberta), which have only 0.3% (2 out of 624) zero observation cases. Again, the estimated mask effects are little changed.

Alternative dates

Figure B4 shows that our estimates and confidence intervals for the effect of mask mandates in the Ontario baseline regressions do not vary much by the initial date of the sample. Similarly, Figure B5 shows that, in the national analysis, our results about mask mandates and business/gathering restrictions are also robust to alternative sample start dates.

Alternative lags

We explore alternative time lags, either shorter or longer in duration, centered around the baseline value of 14 days. Figure B6 (with Ontario data) and Figure B7 (with province-level data) plot the estimates and confidence intervals from the baseline regressions and show that our mask effect estimates remain fairly consistent for different lags.

Omitted variables

Our behaviour proxy variable (Google geo-location trends) likely misses some aspects of behaviour relevant for COVID-19 transmission. One factor that may meaningfully impact behaviour is weather. For example, good weather could entice more people to spend time outside, lowering the chance of viral transmission. Columns (3) and (4) in Table A11 report national estimates with lagged weather variables (daily maximum and minimum temperatures and precipitation for the largest city in each province[31]) as additional regressors. Our NPI estimates, in particular mask mandates, are little changed from the baseline results in columns (1) and (2).

[29] 535 out of 3,094 observations (17%) had to be replaced.

[30] 230 out of 1,560 observations (15%) had to be replaced.

No reuse allowed without permission.

Another possible concern is that our information variables, lagged cases and lagged case growth, may not fully capture the information based on which people react or adjust their behaviour, possibly affecting the observed weekly case growth. Columns (5) and (6) in Table A11 add a national-level "news" variable to the baseline specification. The news variable is defined as the number of daily search results from a news aggregator website (*Proquest Canadian Newsstream*) for the terms "coronavirus" or "COVID-19" (see Appendix C for more details). In column (6), the lagged news variable approaches the 10% significance level ($p = 0.103$). Our estimates on masks and business/gathering remain very close to those in the baseline.

4.4 Self-reported mask usage

The effectiveness of any NPI or public policy crucially depends on whether it affects behaviour. In this section, we use self-reported data on mask usage to examine whether mask mandates indeed increase mask use in Canada ("first-stage" analysis).

We use data from the YouGov COVID-19 Public Monitor, which includes multiple waves of public opinion surveys fielded regularly since early April in many countries.[32] Here, we focus on inter-provincial comparison within Canada. Our variable of interest is based on responses to the question "Thinking about the last 7 days, how often have you worn a face mask outside your home (e.g. when on public transport, going to a supermarket, going to a main road)?" The answer choices are "Always", "Frequently", "Sometimes", "Rarely", and "Not at all". We create a binary variable taking value 1 if the response is "Always" and 0 otherwise, as well as another variable taking value of 1 if the respondent answered either "Always" or "Frequently" and 0 otherwise.

We begin with a simple illustration of self-reported mask usage in Canada from April to August 2020. Figure B2 plots the average self-reported mask usage (the response "Always") in the provinces with and without mask mandates.[33] The figure clearly shows that self-reported mask usage is higher, by up to 50 percentage points, in the provinces with a mask mandate than in the provinces without mask mandates. Since Figure B2 does not account for compositional changes in the data, we formally estimate equation (2), using self-reported mask usage as the behavioral outcome.[34]

[32] The YouGov data can be accessed at: https://yougov.co.uk/covid-19.

[33] As on Figure 4, we use July 7 as the mask mandate implementation date in Ontario.

[34] Since mask usage is reported only for specific dates within each survey wave, we use our mask policy variable daily values for these same dates instead of the weekly moving average.

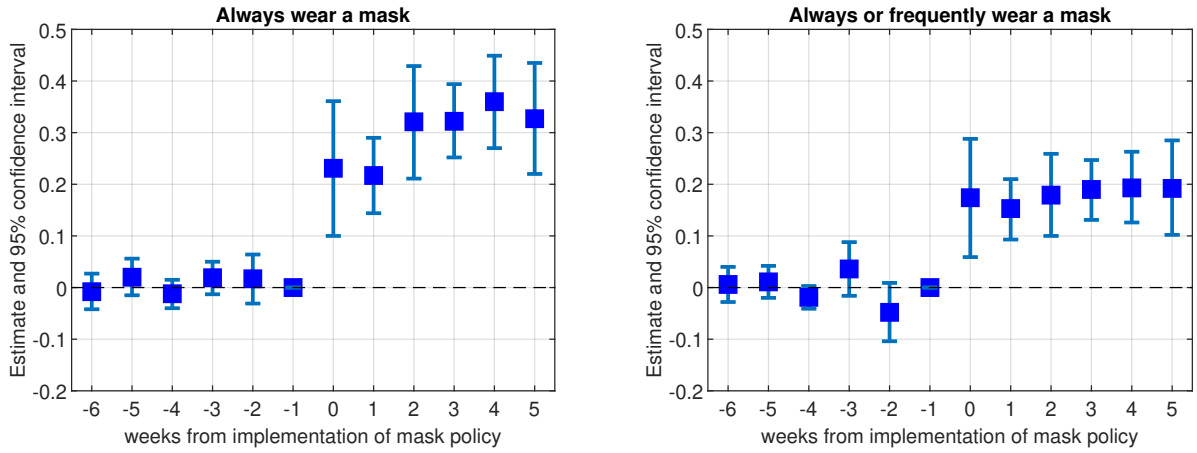
Figure 5: Event Study of Self-reported Mask Usage – Canada



Notes: The data source is YouGov. The outcome is a binary variable taking value 1 if the respondent respectively answered "Always" (in the left panel) or "Always" or "Frequently" (in the right panel) to "Thinking about the last 7 days, how often have you worn a face mask outside your home?" The figure plots the estimates from a version of equation (2) where the mask policy variable is replaced by the interaction of the variables corresponding to being in the treatment group (imposed mask mandate) and a series of dummies for each week, ranging from 6 weeks before the mask mandate to 6 weeks after ($T = -6$ to $+5$, where $T = 0$ is the mandate implementation date). The reference point is 1 week before the implementation ($T = -1$). Wild bootstrap (cgmwildboot) standard errors clustered by province with 5000 repetitions are used to construct the confidence intervals. Sample weights are used.

Figure 5 shows a graphical event study analysis on mask mandates and changes in mask usage. The event study approach is appropriate for the mask usage outcome variable, since the policy impact is expected to be immediate, unlike the other outcomes we study, for which any impact is expected to occur with a lag and we use weekly totals or moving averages. We replace the mask policy variable in equation (2) by the interaction of variables corresponding to being in the treatment group (i.e. under a mask mandate), and a series of dummies for each week, ranging from 6 weeks before the mask mandate to 5 weeks after the mask mandate ($T = -6$ to $+5$, where $T = 0$ is the implementation date of the mask mandate). The reference point is one week before the implementation of the mask mandate ($T = -1$), and we use the same y-axis scale on both panels.

The left and right panels of Figure 5 present the results from the event study analysis for the "Always" and "Always" or "Frequently" mask usage answers, respectively. We make several observations. First, neither panel shows a pre-trend – the estimates are close to zero before the mask mandates. This addresses the potential concern that provinces that implemented mask mandates may have had a different trend in mask usage than provinces that did not. Second, the effect of mask mandates on mask usage is immediate: an increase

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. of roughly 20 percentage points as soon as the mask policy is implemented at ($T = 0$). Third, the effect appears persistent rather than transitory, since mask usage after $T = 0$ does not revert to its level before $T = 0$.

without time trend, including cubic time trend (in days), and including week fixed effects. Our preferred specification with cubic time trend, column (4) of Table 3, shows that mask mandates are associated with 31.5 percentage point increase in self-reported mask usage ($p < 0.001$), from a base of self-reported mask usage without mask mandate of 29.8%.[35,36]

These "first-stage" results show that mask mandates exhibit significant compliance in Canada and establish a basis for the significant impact of mask mandates on the spread of COVID-19 that we find. That said, given that mask mandates do not change everyone's behaviour, our estimates in Tables 1 and 2 represent intent-to-treat effects. The full effect of the entire population shifting from not wearing to wearing masks is likely significantly larger.[37]

There is a heated debate on whether community use of masks may create a false sense of security that reduces adherence to other preventive measures. We also investigate this question using YouGov survey data. As Tables A13 and A14 indicate, we find no evidence that mask mandates in Canada have had an offsetting effect on other preventive measures such as hand washing, using sanitizer, avoiding gatherings, and avoiding touching objects in public during the period we study. On the contrary, mask mandates may slightly increase social distancing in one out of the eight precaution categories (avoiding crowded areas) ($p < 0.10$).[38]

4.5 Counterfactuals

We evaluate several counterfactuals corresponding to replacing the actual mask policy in a province or Canada-wide with a counterfactual policy, including absence of mask mandate.

Letting t_0 be the implementation date of a counterfactual policy, we set the counterfactual weekly case count, ΔC_{it}^c, equal to ΔC_{it} for all $t < t_0$. For each date $t \geq t_0$, using the definition of Y_{it} from (3), we then compute the counterfactual weekly cases, ΔC_{it}^c and the counterfactual

[35]Similarly, in Table A12, column (4) shows that "Always" or "Frequent" mask usage increases by 21.5 percentage points. The finding that the increase in mask usage among the "Always" respondents is larger than among the "Always" or "Frequent" respondents is consistent with some people switching from wearing masks "frequently" to "always."

[36]Hatzius et al. (2020) document that state mask mandates in the US increased mask usage roughly by 25 percentage points in 30 days. The compliance with mask mandates may differ across countries or regions based on social norms, peer effects, political reasons or the consequences of noncompliance (e.g., fines).

[37]If we take the increase of about 30 percentage points in reported mask usage induced by mask mandates at face value, the full effect of mask wearing (treatment-on-the-treated effect) would be roughly triple our estimates. It could be larger still if there is desirability bias in answering the mask usage survey question, so that the actual increase in mask use may be smaller than our estimate.

[38]Consistent with this result, Seres et al. (2020) find that wearing masks increased physical distancing based on a randomized field experiment in stores in Germany.

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. case growth rate, Y_{it}^c, as follows:

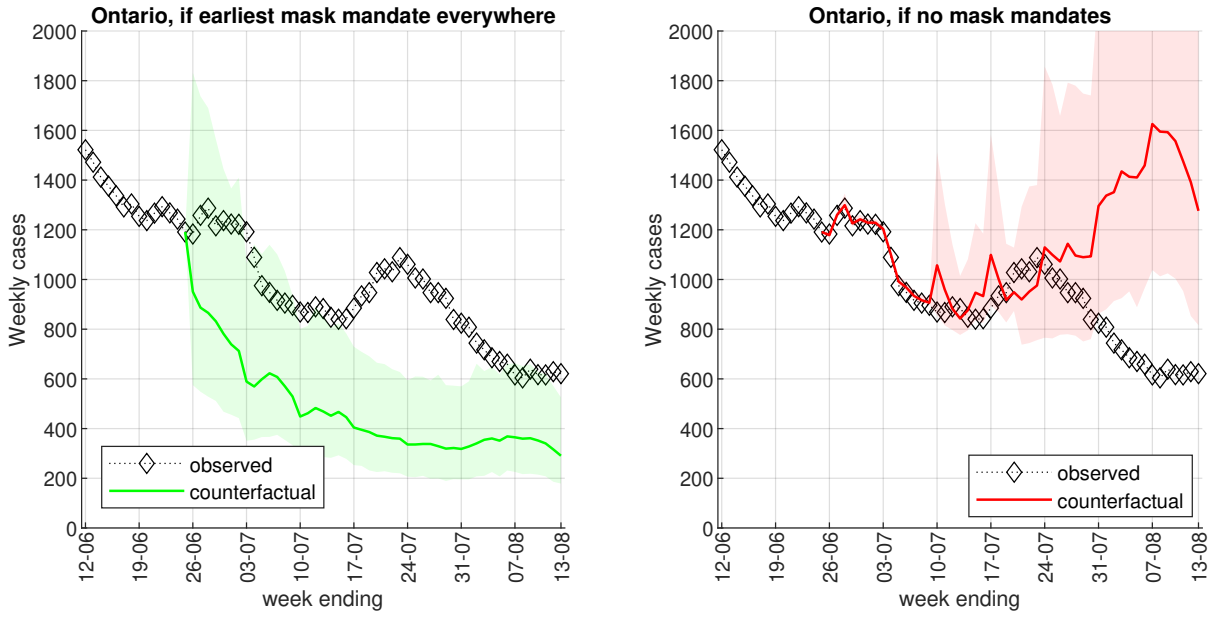
$$\Delta C_{it}^c = \exp(Y_{it}^c)\left(\Delta C_{it-7}^c\right) \text{ and}$$

$$Y_{it}^c = \hat{Y}_{it} + \beta_{Mask_14}\left(\text{Mask}^c_14 - \text{Mask_14}\right) + \beta_{log_dC_14}\left(\ln(\Delta C_{it-14}^c) - \ln(\Delta C_{it-14})\right),$$

where $\hat{Y}_{it}$ is the regression-fitted value of weekly case growth; β_{Mask_14} is the coefficient estimate on the mask mandate variable Mask_14 in baseline specification (4) in Table 1 or 2, depending on the counterfactual; Mask^c_14 is the counterfactual mask policy (e.g. different implementation date, wider geographic coverage or absence of mask mandate); and $\beta_{log\Delta C_14}$ is the coefficient estimate (-0.227 or -0.209) on lagged cases log(ΔC)_14 in Table 1 or 2, column 4. The coefficient $\beta_{log\Delta C_14}$ adjusts the counterfactual case growth rate for the negative statistically significant association between the weekly case total two weeks prior and time-t case growth. This effect may be due to people being more careful when they perceive the risk of infection to be higher or less careful vice versa.

Figure 6: Counterfactuals - Ontario public health regions



Notes: The left panel assumes that mask mandates were adopted in all PHUs on June 12 (date of the first mask mandate in ON). The right panel assumes that mask mandates were not adopted in any PHU. We use the mask estimate (-0.376) from column (4) of Table 1.

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. Figures 6, 7 and 8 show results from two counterfactual policy evaluations. The first exercise, depicted in the left-hand side panel of the figures, assumes that masks are adopted everywhere at the earliest date observed in the data. Specifically, Figure 6 considers the counterfactual of all Ontario PHUs adopting mask mandates on June 12, while Figures 7 and 8 assume that all provinces adopt a mask mandate on July 7.[39]

Using our mask policy estimate from Table 1, Figure 6 shows that an earlier face mask mandate across Ontario PHUs could have lead to an average reduction of about 300 cases per week as of August 13, holding all else equal. For Canada as a whole, a nation-wide adoption of mask mandates in early July is predicted to reduce total cases per week in the country by 700 to 1,100 cases on average as of August 13, depending on whether we use the more conservative mask estimate (-0.376) from column (4) of Table 1 (see Figure 7) or the larger estimate (-0.613) from column (4) of Table 2 (see Figure 8). In all cases, the indirect feedback effect via $\beta_{log\Delta C_14}$ (lagged cases as information) starts moderating the decrease in cases two weeks after the start of the counterfactual mask policy.

In the right-hand side panel of Figures 6, 7 and 8, we perform the opposite exercise, namely assuming instead that mask mandates were *not* adopted in any Ontario PHU or any Canadian province. Our estimates imply that the counterfactual absence of mask mandates would have led to a large increase in new cases, both in Ontario and Canada-wide, especially when using the larger mask coefficient estimate from Table 2 (see Figure 8).

Finally, in Figure B11 in the Appendix, we also evaluate the counterfactual in which British Columbia and Alberta, the third and fourth largest Canadian provinces by population, adopt province-wide mask mandates on July 15. The results, using the Mask_14 estimate from Table 2, suggest a reduction of about 300 cases per week in each province by mid-August.

The counterfactual simulations assume that all other variables, behaviour and policies (except the mask policy and $t-14$ cases) remain fixed, as observed in the data. This is a strong assumption, but it may be plausible over the relatively short time period that we analyze. Moreover, the counterfactuals assume that regions without a mask mandate would react in the same way, on average, as the regions that imposed a mandate. Therefore, these results should be interpreted with caution and only offer a rough illustration and projection of the estimated effect of mask mandates on COVID-19 cases.

[39] June 12 is the date of the earliest mask mandate in Ontario. For the national analysis, July 7, the effective date for Toronto and Ottawa, is considered Ontario's first significant date of mask mandate enactment: PHUs with earlier mandates account for less than 10% of Ontario's population.

4.6 Additional analysis

Closing and re-opening sub-periods

We investigate whether policy impact varied in different phases of the pandemic by splitting the full sample period into two sub-periods: "closing" (March 11 to May 14) and "re-opening" (May 15 to August 13). The dividing date of May 15 (referring to the NPIs in place around May 1) was chosen because very few policies were relaxed before May 1, and very few non-mask policies were tightened after May 1 in our sample period (see Figure 2).

In Table A15, we report estimates and wild bootstrap standard errors using our baseline specification with cubic time trend, separately for the closing and re-opening periods. We find that the imposition of school closures and travel restrictions early in the closing period is associated with a very large subsequent reduction in weekly case growth, as can be also seen on Figure B8 – the average observed log growth rate of cases $\Delta \log(\Delta \text{C})$ falls from 2.4 (ten-fold growth in weekly cases) to -0.4 (33% decrease in weekly cases) between March 15 and April 5. Long-term care restrictions are also associated with reduced case growth two weeks later during the March to May closing period. We interpret these results with caution, however, since many of these policy measures and restrictions were enacted in a brief time interval during March and there is not much inter-provincial variation (see Figure 2). No mask mandates were present in the closing period.

In the re-opening period, our results in Table A15 are in line with our full-sample results for mask mandates and business/gathering regulations (Table 2), with slightly larger coefficient estimates and less statistically significant p-values, possibly due to the smaller sample. Travel and school closures are not statistically significant in the re-opening period. This is unsurprising: relaxation of travel policies was minor and endogenous (only re-open to safe areas within Canada), and the schools that re-opened (in parts of Quebec and, on a part-time basis, in British Columbia) did so on voluntary attendance basis, yielding smaller class sizes.

Deaths

We also examine the weekly death growth as an outcome. We only have access to disaggregated deaths data at the province level (not at PHU levels in Ontario). We thus estimate regression equation (1) using $Y_{it} = \Delta \log(\Delta D_{it})$ for each province i as the dependent variable. In addition, we use a 28-day lag for the policy, behaviour proxy, and information variables to reflect the fact that deaths occur on average about two weeks after case detection; see Appendix D for details and references.[40]

[40] In Table 4, *Variable*_28 denotes the *Variable* lagged by 28 days.

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. No reuse allowed without permission.

Table 4 reports the estimates from the same specifications as those for case growth in Table 2. In all specifications, mask mandates are associated with a large reduction in the observed weekly deaths growth rate four weeks later (more than 90 log points, or equivalently more than 60% reduction in weekly deaths). These results are larger than our case growth results, but consistent with them given the substantial uncertainty. See also Figure B12, which plots the average weekly death growth in the provinces without a mask mandate four weeks prior vs. that for Ontario, the only province with mask mandate four weeks prior in our sample period.

The robustness checks in Table A16, however, show that, unlike for case growth, the mask mandate estimates in Table 4 are not robust to weighing by population or to restricting the sample to the largest 4 provinces. This suggests that the estimated effect is largely driven by observations from the small provinces, which have a disproportionately larger number of zero or small weekly death totals.[41] Furthermore, given the 28-day lag, there are only 9 days with observations (from Ontario only) for which the mask mandate variable takes value of 1. Due to these serious data limitations, the relation between mask mandates and COVID-19 deaths in Table 4 is suggestive at best, and we urge caution in interpreting or extrapolating from these results.

That said, our main findings about the growth in cases may have implications about future growth in deaths, particularly if the affected demographics become less skewed toward the young in later periods.

[41] 205 out of the 1,470 observations (14%) had log(0) replaced by -1.

5 Conclusion

The wearing of face masks by the general public has been a very contentious policy issue during the COVID-19 pandemic, with health authorities in many countries and the World Health Organization giving inconsistent or contradictory recommendations over time. "Conspiracy theories" and misinformation surrounding mask wear abound in social media, fuelled by some individuals' perception that mask mandates constitute significant restrictions on individual freedoms. Given the absence of large-scale randomized controlled trials or other direct evidence on mask effectiveness in preventing the spread of COVID-19, quantitative observational studies like ours are essential for informing both public policy and the public opinion.

We estimate the impact of mask mandates and other public policy measures on the spread of COVID-19 in Canada. We use both within-province and cross-province variation in the timing of mask mandates and find a robust and significantly negative association between mask mandates and subsequent COVID-19 case growth – 25 to 46% average reduction in weekly cases in the first several weeks after adoption, depending on the data sample and empirical specification used. These results are supported by our analysis of survey data on compliance with the mask mandates, which show that the mandates increase the proportion of reporting as always wearing a mask in public by around 30 percentage points. However, our sample period does not allow us to determine whether their effect lasts beyond the first few weeks after implementation. We conclude that mask mandates can be a powerful policy tool for at least temporarily reducing the spread of COVID-19.

Mask mandates were introduced in Canada during a period where other policy measures were relaxed, as part of the economy's re-opening. Specifically, we find that relaxed restrictions on businesses or gatherings are positively associated with subsequent COVID-19 case growth – a factor that could offset and obscure the health benefits of mask mandates. Past case totals were also found to matter for subsequent COVID-19 outcomes, suggesting that riskier behaviour based on favourable lagged information may limit how low mask mandates and other restrictions – short of a lockdown – can push the number of new cases.

We have deliberately abstained from studying the direct economic impacts of COVID-19, focusing instead on the unique features of the Canadian data for identifying the effect of NPIs, in particular mask mandates, on COVID-19 case growth. Future research combining epidemiological finding with the economic benefits and costs of various public policies or restrictions would enrich the ongoing policy debate and provide further guidance.

cubic time trend	X	X	X	X	X	X	X	X

Notes: The time period is May 15 to August 13, 2020. P-values from wild bootstrap (cgmwildboot) standard errors clustered by public health unit (PHU) with 5000 repetitions are reported in the square brackets. Columns (1) and (2) repeat columns (3) and (4) from Table 1. We drop each policy at at time in columns (3)-(8). ***, ** and * denote 10%, 5% and 1% significance level respectively.

Cubic trend	X	X	X	X	X	X	X	X	X	X
Weighted	No	No	No	No	No	No	Yes	Yes	No	No

Notes: The time period is March 11 to August 13, 2020. P-values from wild bootstrap (cgmwildboot) standard errors clustered by province with 5000 repetitions in the square brackets. Columns (1) and (2) repeat columns (3) and (4) from Table 2 where we replace log(0) with -1. Columns (3) and (4) replace log(0) with 0, and columns (5) and (6) add 1 to all ΔC_{it} observations. Columns (7) and (8) report results from a weighted least squares regression with the province populations as weights. Finally, columns (9) and (10) restrict the sample to only the largest 4 provinces (BC, ON, QC, and AB) which have only 0.3% zero observation cases. ***, ** and * denote 10%, 5% and 1% significance level respectively.

Notes: The time period is March 11 to August 13, 2020. P-values from wild bootstrap (cgmwildboot) standard errors clustered by province with 5000 repetitions are reported in the square brackets. Columns (1) and (2) repeat columns (3) and (4) from Table 2. Columns (3) and (4) report estimates with lagged weather variables as additional controls. Columns (5) and (6) add a "news" variable to the baseline specification (see Appendix C for more details). ***, ** and * denote 10%, 5% and 1% significance level respectively.

individual characteristics	X	X	X	X	X	X
province fixed effects	X	X	X	X	X	X
cubic time trend (days)			X	X		
week fixed effects					X	X

Notes: The time period is April 2 to August 13, 2020. P-values from wild bootstrap (cgmwildboot) standard errors clustered by province with 5000 repetitions are reported in the square brackets. NC denotes national total cases. The data source is YouGov. The outcome is a dummy which takes one for the respondent who answers "Always" or "Frequently" to the survey question "Thinking about the last 7 days, how often have you worn a face mask outside your home?" Sample weights are used. Individual characteristics include a gender dummy, dummies for each age (in years), dummies for each household size, dummies for each number of children, and dummies for each employment status. ***, ** and * denote 10%, 5% and 1% significance level respectively.

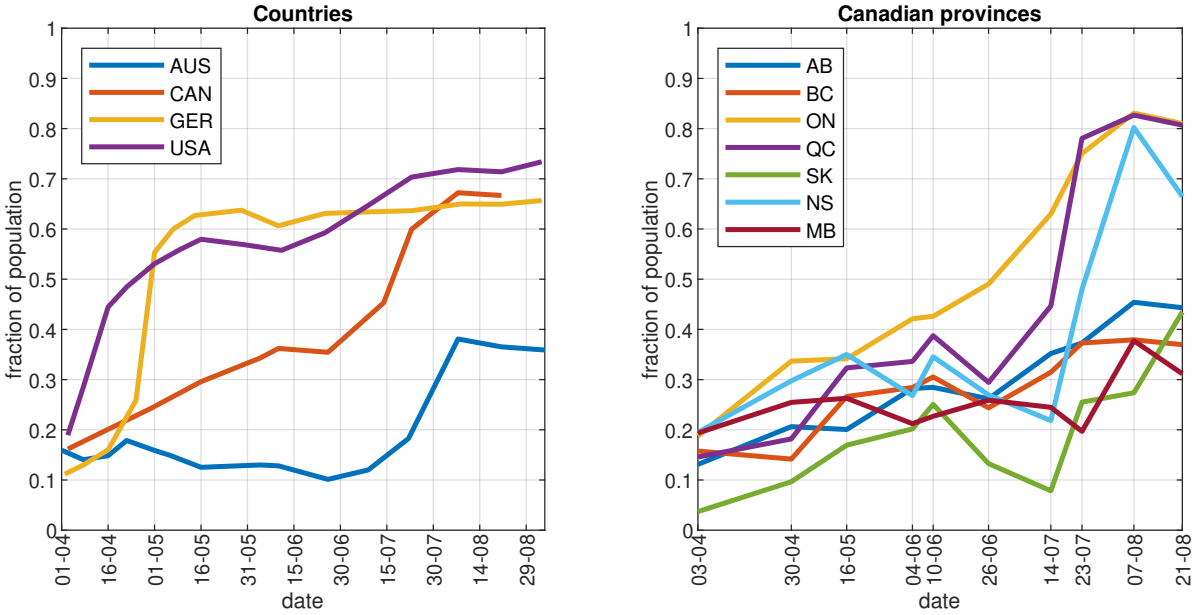
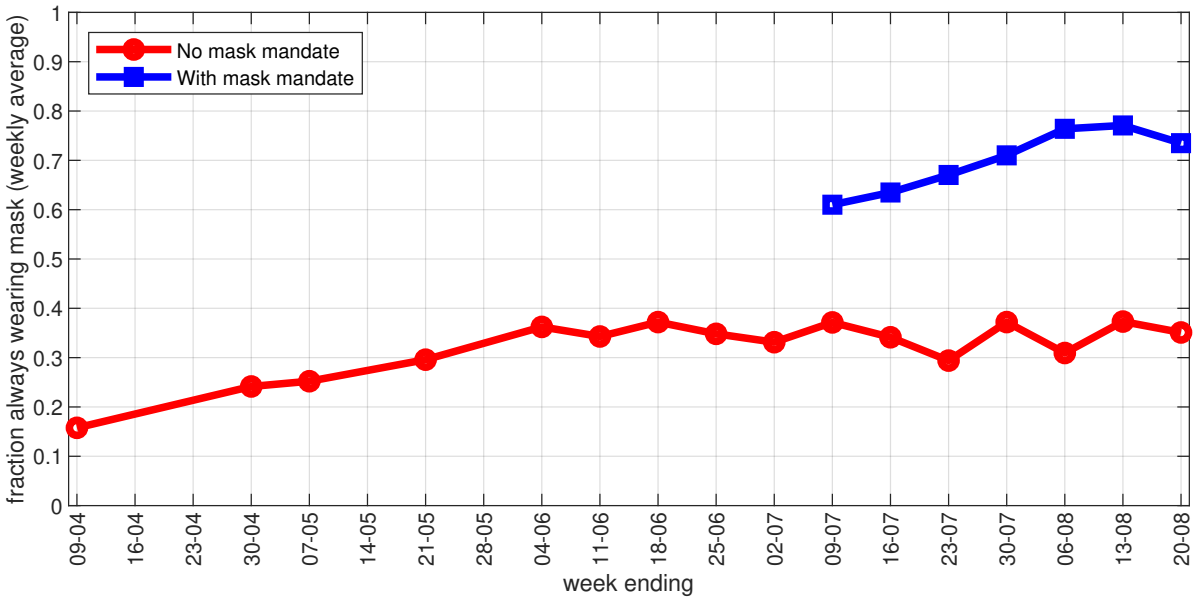
Appendix B. Additional Figures

Figure B1: Self-reported mask usage in selected countries and Canadian provinces



Notes: The data source is YouGov. The outcome equals 1 if the respondent answered "Always" to the question "Worn a face mask outside your home" and 0 otherwise. The sample weights are used to construct the country and provincial averages.

Figure B2: Canada - mask mandates and self-reported mask usage



Notes: The data source is YouGov. The figure plots the average self-reported mask usage by week (the fraction of respondents who answered "Always" to the survey question "Worn a face mask outside your home") in the provinces with vs. without mask mandates. Sample weights used to compute the averages.

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. Figure B4: Ontario - different initial dates

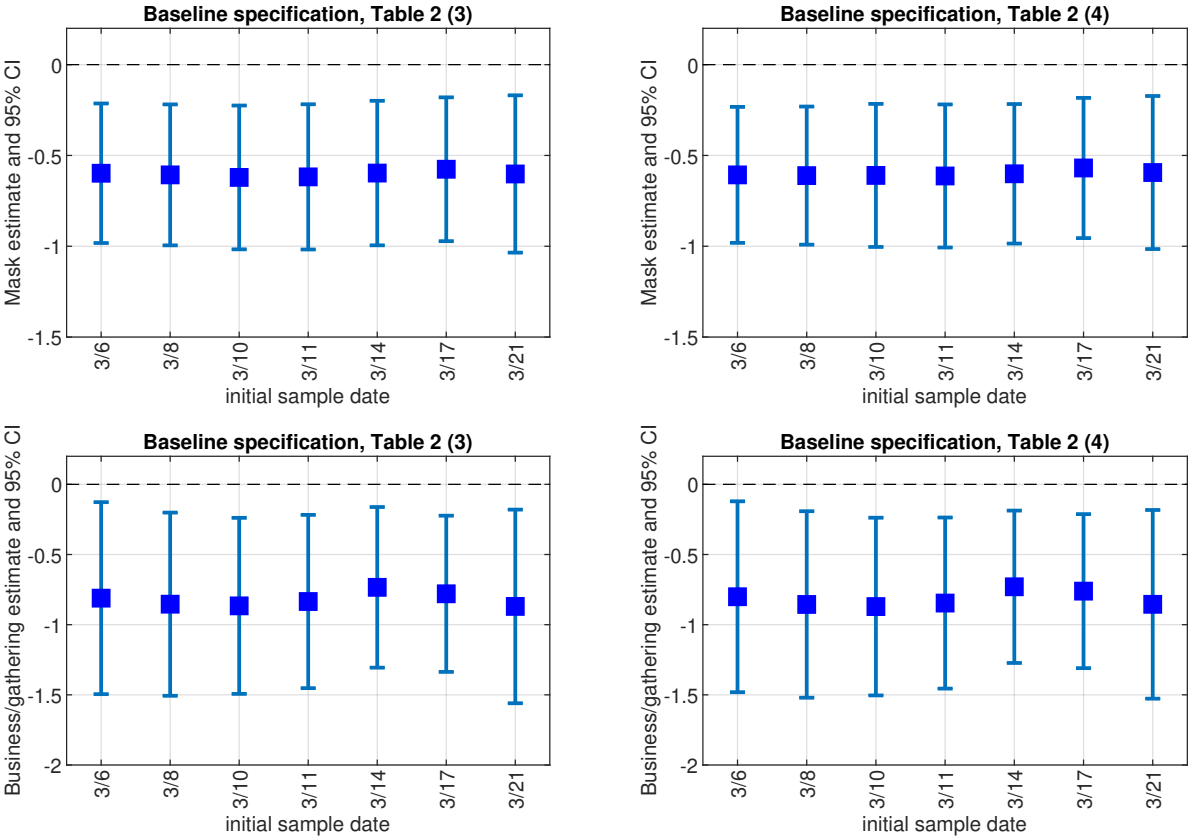
Notes: We plot the coefficient estimates on mask policy, with 95% confidence intervals, from equation (1), for different initial dates of the sample. The initial sample date in the baseline specifications reported in Table 1 is May 15. The left panel corresponds to baseline column (3) in Table 1, the right column corresponds to column (4) in Table 1.

Figure B5: Canada - different initial dates



Notes: We plot the coefficient estimates on mask policy, with 95% confidence intervals, in the upper panel and the estimates on business/gathering policy in the lower panel, from equation (1) for different initial dates of the sample. The initial date in our baseline specification (Table 2) is March 11. The left panels correspond to column (3) in Table 2; the right panels correspond to column (4) in Table 2.

Appendix C. Definitions and data sources

Table C1: Policy indicators and aggregates

Non-Essential Travel	
restrictions - international	1: travelers that are neither citizens nor residents 0.5: same as 1, but US citizens allowed
restrictions - inter-provincial	1: residents of all other provinces 0.5: residents of some other provinces
self-isolation - international	1: required (by provincial or federal government) 0.5: recommended (by provincial or federal government)
self-isolation - inter-provincial	1: required of residents of all other provinces 0.5: required of residents of some other provinces, or recommended
Primary and Secondary Schools	
schools closed	1: no classes (includes Spring and Summer breaks) 0.5: part-time classes; 0: classes in session
Business and Gathering Regulations	
non-essential and retail business personal services business restaurants bars and nightclubs places of worship events and gatherings recreation, gyms and parks	0: no or lowest restrictions; 1: strictest restrictions; values between 0 and 1: partial restrictions
indoor gatherings maximum	1: no gathering allowed; $x \in [0.5, 1]$: limit of $100(1-x)$ $x \in [0, 0.5]$: limit of $25/x$
Long-Term Care (LTC) Regulations	
visiting restrictions	1: no visits (with limited exceptions such as end of life) 0.5: number of visitors restricted
single-site work requirement[1]	1: requirement in effect 0.5: requirement with explicit later implementation deadline
Mandatory Masks	
indoor public places[2]	1: mask mandate in effect; 0: no mandate
provincial declaration of emergency	1: in effect; 0: not in effect

Notes: 1. We do not consider recommendations or requirements limited to outbreak facilities. 2. We do not consider limited mask mandates such as applying only to transit or personal service establishments.

Table C3: Canada COVID-19 official data sources

Province	Cases	Deaths	Tests
Alberta (AB)	link	link	link
British Columbia (BC)	link	link	link
Ontario (ON)	link	link	link
Quebec (QC)	link	link	link
Saskatchewan (SK)	link[1]	link	link
Nova Scotia (NS)	link	link	link
Manitoba (MB)	link	link	link[2]
Newfoundland and Labrador (NL)	link[1]	link	link
New Brunswick (NB)	link	link	link
Prince Edward Island (PE)	link	link	link

Notes: 1. Saskatchewan and Newfoundland and Labrador do not revise their posted data series. We made data adjustments based on subsequent revisions announced in government bulletins; 2. The Manitoba tests numbers were manually collected from the COVID-19 provincial government bulletins.

Weather – we downloaded historical weather data for the largest city in each province from the Weather Canada website. The data provide daily information on 11 variables: maximum temperature (C), minimum temperature (C), mean temperature (C), heating degree-days, cooling degree-days, total rain (mm), total snow (cm), total precipitation (mm), snow on the ground (cm), direction of maximum wind gust (tens of degrees), and speed of maximum wind gust (km/h). We only use the temperature and precipitation data in Table A11 as possible factors determining outside vs. inside activity.

News – we collected data from *Proquest Canadian Newsstream*, a subscription service to all major and small-market daily or weekly Canadian news sources. We recorded the number of search results for each day from Feb 1, 2020 to Aug 20, 2020 by searching the database for the keywords "Coronavirus" or "COVID-19". We only counted the results with source listed as "newspaper" since other sources, such as blogs or podcasts, tend to duplicate the same original content.

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. Table C4: YouGov Survey Questions

Survey item	Question
i12_health_2	Washed hands with soap and water
i12_health_3	Used hand sanitiser
i12_health_6	Avoided going out in general
i12_health_12	Avoided small social gatherings (not more than 2 people)
i12_health_13	Avoided medium-sized social gatherings (between 3 and 10 people)
i12_health_14	Avoided large-sized social gatherings (more than 10 people)
i12_health_15	Avoided crowded areas
i12_health_20	Avoided touching objects in public (e.g. elevator buttons or doors)

Notes: the data source is YouGov. Possible responses to each survey item are "Always", "Frequently", "Sometimes", "Rarely", and "Not at all". For Table A13, we create a binary variable taking value 1 if the response is "Always" and 0 otherwise. For Table A14, we create a binary variable taking value of 1 if the respondent answered either "Always" or "Frequently" and 0 otherwise.

All data used in the paper are available at https://github.com/C19-SFU-Econ/data.

Appendix D. Lags Determination

As discussed in Section 3.1, we assume a lag of 14 days between a change in policy or behaviour and its hypothesized effect on weekly case growth, and a lag of 28 days between such a change and its effect on weekly death growth.

First, we consider the lag between infection and a case being reported. As most identified cases of COVID-19 in Canada are symptomatic, we focus on symptomatic individuals. For most provinces cases are listed according to the date of report to public health. In provinces where the dates instead refer to the public announcement, we shifted them back by one day, as announcements typically contain the cases reported to public health on the previous day. The relevant lag therefore has two components:

1. Incubation period: Most studies suggest an average incubation period of 5-6 days (e.g. 5.2 days in Li et al. (2020), 5.5 days in Lauer et al. (2020), 5.6 days in Linton et al. (2020), 6.4 days in Backer et al. (2020)).

2. Time between symptoms onset and reporting of the case to public health: the Ontario data contain an estimate of the symptom onset date ("episode date") for each case. For our sample period the average difference between the date of report and the episode date is 4.8 days (median: 4 days) including only values from 1 to 14 days, and 6.3

medRxiv preprint doi: https://doi.org/10.1101/2020.09.24.20201178; this version posted September 25, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

days (median: 5 days) including only values from 2 to 28 days. We assume that the lags in Ontario and in other provinces are similar, and use a value of 5-6 days between symptom onset and report to public health authorities.

Adding these together implies that the typical lag between infection and a positive case being reported to public health is around 11 days.

Second, we consider the effect of weekly averaging on the appropriate lag for our analysis. Suppose a policy or behavioural change starts on date t, impacting the daily growth in infections between dates $t-1$ and t and in each subsequent day. Then, assuming a lag of 11 days between infection and case reporting, case counts C are affected from date t+11 onward. Our outcome variable $\Delta \log(\Delta \mathrm{C})$ thus would react to the original policy or behavioral change on date $t+11$. The change is complete on $t+23$, when the week from $t+17$ to $t+23$ is compared to the week from $t+10$ to $t+16$. The midpoint of the change is $t+17$.

Choosing a lag of l days implies that the policy/behaviour variable phases in from $t+l$ to $t+l+6$. To match the midpoint of this phase-in to the midpoint of the change in the outcome variable, we set $l=14$. The chosen lag matches the lag used by other authors who study COVID-19 policy interventions, e.g., CKS (2020). We explore sensitivity to alternative lags in Section 4.3.

With respect to deaths, our data are, in most cases, backdated (revised by the authorities ex-post) to the actual date of death. The medical literature suggests that the mean time from symptom onset to death is around 19 days (20 days in Wu et al. (2020), 17.8 days in Verity et al. (2020), 20.2 days when accounting for right truncation in Linton et al. (2020), 16.1 days in Sanche et al. (2020), etc.), that is, two weeks longer than our estimate of the time from symptom onset to reporting of a positive test result. We correspondingly set the lag used in our analysis of the death growth rate (Section 4.6) to 28 days.

Abstract

Identification of biomedical and socioeconomic predictors for the number of deaths by COVID-19 among countries will lead to the development of effective intervention. While previous multiple regression studies have identified several predictors, little is known for the effect of mask non-wearing rate on the number of COVID-19-related deaths possibly because the data is available for limited number of countries, which constricts the application of traditional multiple regression approach to screen a large number of potential predictors. In this study, we used the hypothesis-driven regression to test the effect of limited number of predictors based on the hypothesis that the mask non-wearing rate can predict the number of deaths to a large extent together with age and BMI, other relatively independent risk factors for hospitalized patients of COVID-19. The mask non-wearing rate, percentage of age ≥ 80 (male), and male BMI showed Spearman's correlations up to about 0.8, 0.7, and 0.6 with the number of deaths per million from 22 countries from mid-March to mid-June, respectively. The observed number of deaths per million were significantly correlated with the numbers predicted by the lasso regression model including four predictors, age ≥ 80 (male), male BMI, and mask non-wearing rates from mid-March and late April to early May (Pearson's coefficient = 0.918). The multiple linear regression models including the mask non-wearing rates, age, and obesity-related predictors explained up to 79% variation of the number of deaths per million. Furthermore, 56.8% of the variation of mask non-wearing rate in mid-March, the strongest predictor of the number of deaths per million, was predicted by age ≥ 80 (male) and male BMI, suggesting the confounding role of these predictors. Although further verification is needed to identify causes of the national differences in COVID-19 mortality rates, these results highlight the importance of the mask, age, and BMI in predicting the COVID-19-related deaths, providing a useful strategy for future regression analyses that attempt to contribute to the mechanistic understanding of COVID-19.

Introduction

There have been considerable differences in the number of deaths by COVID-19 among countries. Western countries (Europe and the United States), in particular, have been suffered from the high number of deaths and the high death rate compared to East Asian countries. Several regression studies have identified predictors, or candidates for true risk factors, for the difference among countries such as age, obesity, and previous BCG vaccination (Jeet et al., 2020; Bellali, Chtioui, & Chahed, 2020; Leung, Bulterys, & Bulterys, 2020; Squalli, 2020; Knittel & Ozaltun, 2020). However, it is important to continue characterizing novel and known predictors under various biomedical and socioeconomic contexts for potential future intervention to counteract with the ongoing COVID-19 pandemic.

Leffler et al. (2020) used the issued dates for each government's mandates or recommendations for face mask wearing as a predictor in their analysis. By their multivariable linear regression, duration of infection in the country, duration of wearing masks, and percentage of the population over age 60 significantly predicted each country's COVID-19 mortality rate. Also, a systematic review and meta-analysis identifying 172 observational studies indicated that face mask use could result in a large reduction in risk of COVID-19 (Chu et al., 2020). These findings, along with the big difference in face mask wearing rates between Western and other East Asian countries, suggest that the importance of mask wearing rate can be a significant predictor for the number of deaths by COVID-19. However, to our knowledge, there has been no analytical studies including the face mask wearing rate in regression models. This is possibly because the common regression approach uses a large number of samples and predictors to achieve the high prediction rates. The mask wearing rate is available only for limited number of countries.

Other studies identified age, BMI, and male sex as provisional and relatively independent risk factors for hospitalized patients of COVID-19 (Palaiodimos et al., 2020). In 5279 patients with laboratory confirmed COVID-19 patients in New York City, age is the strongest risk factor associated with hospital admission, while the critical illness after admission was associated with age, heart failure, BMI >40, and male sex (Petrilli et al., 2020). Docherty et al. (2020) reported using data from 20133 patients admitted to hospital with COVID-19 in the United Kingdom that independent risk factors are increasing age, male sex, and chronic comorbidity, including obesity.

In this study, we employed the hypothesis-driven regression approach to identify predictors for the number of deaths by COVID-19 across countries based on the hypothesis that the mask non-wearing rate can predict the number of deaths to a large extent together with age and BMI, other relatively independent risk factors for hospitalized patients of COVID-19. This approach uses limited number of a priori determined predictors based on a certain hypothesis. The hypothesis-driven regression is especially useful in providing biological insights related to the association with small number of samples, while the implication is restricted to the hypothesis, and has been used in various fields of research (Klein et al., 2013; Sabuncu et al., 2016; Carriedo et al., 2020). Based on the results we discussed the cultural factors for the observed difference among countries, which may have lowered

the number of COVID-19-related deaths in East Asian countries.

Methods

Data collection

All data was collected from publicly available secondary sources. Analyses in the present study included UK, France, Italy, USA, Spain, Mexico, Germany, Malaysia, Canada, Sweden, China, Saudi Arabia, India, Indonesia, Philippines, Norway, Finland, Japan, Denmark, Australia, Singapore, and Thailand. These countries were chosen because of the availability for mid-March mask-wearing data. The face mask wearing rates in mid-March (3/9-18) 2020 and late April to early May (4/26-5/1) 2020 across countries were derived from "% of people in each country who say they are: Wearing a face mask when in public spaces" in Smith (2020). Total COVID death per million were obtained from Ritchie (2020). BMI data was obtained from Global Status Report on Noncommunicable Diseases 2014. 5 Oct. 2015, www.who.int/nmh/publications/ncd-status-report-2014/en/. Population percent by age data was obtained from Kose et al. (2020).

Data analysis

R version 3.6.2 was used for all statistical analyses. Pearson's and Spearman's correlations were calculated by cor and cor.test fuctions. Lasso regression was used to find potential effects of predictors on the number of deaths per million (Tibshirani, 2011). Multiple linear regression models were built using the lm function.

Results

Spearman's correlations

We first calculated Spearman's correlations between the number of deaths per million from various dates and parameters related to the mask non-wearing rate, age, and obesity (Fig. 1). The correlation coefficients between the number of deaths per million and mask non-wearing rates (both mid-March and late April to early May) showed time-dependent increases, reaching the apparent plateau in early May. The mask non-wearing rate in mid-March generally showed higher correlation coefficients than those that determined in late April to early May. The highest correlation of 0.79 was observed between the mid-March mask non-wearing rate and the number of deaths per million on June 6, 2020 ($P = 6.865e-06$).

Age-related predictors were also highly correlated with the number of deaths per million with Spearman's correlation coefficients of up to ~0.68. In both sexes, correlation coefficients were lower in younger age groups (age 65–69) compared to those of higher age groups, and the highest

medRxiv preprint doi: https://doi.org/10.1101/2020.06.22.20137745; this version posted June 23, 2020. The copyright holder for this preprint

correlations were found in age ≥ 80 groups. In contrast to the mask non-wearing rate, correlations between the number of deaths and age-related predictors were highest in mid-May and decreased thereafter.

In general BMI showed lower correlations with the number of deaths per million with a clear sex-dependent difference. Male BMI was more closely associated with the number of deaths per million than female BMI.

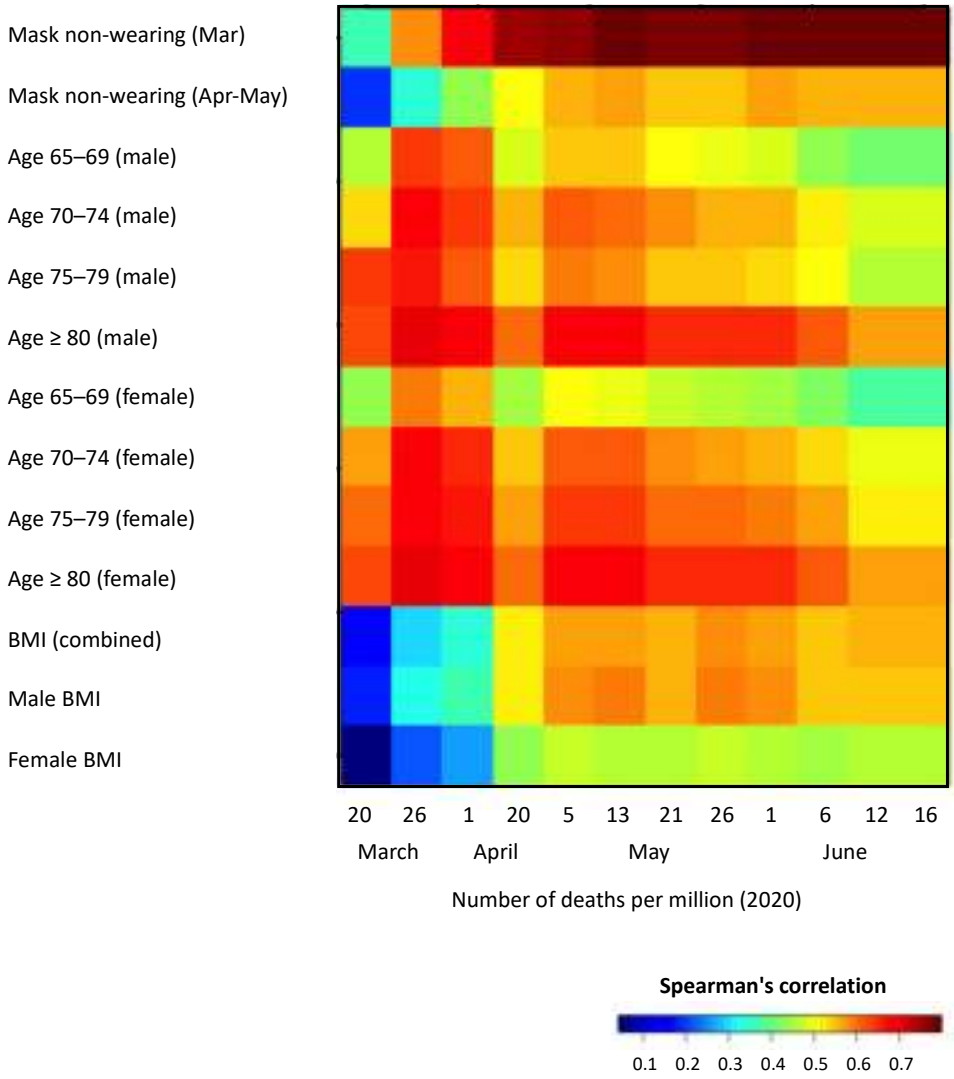

Fig. 1. Spearman's correlation (over time) among parameters related to COVID19 deaths, obesity, age, and mask non-wearing rate.

Time course profiles for Spearman's correlation coefficients of several highly correlated parameters demonstrated the unique feature of age ≥ 80 (male) among parameters used (Fig. 2). Spearman's correlation coefficients for this parameter remained almost constant throughout the study period,

medRxiv preprint doi: https://doi.org/10.1101/2020.06.22.20137745; this version posted June 23, 2020. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

whereas those for other three parameters showed time-dependent increase and reached the apparent plateau around day 50 (mid-May).

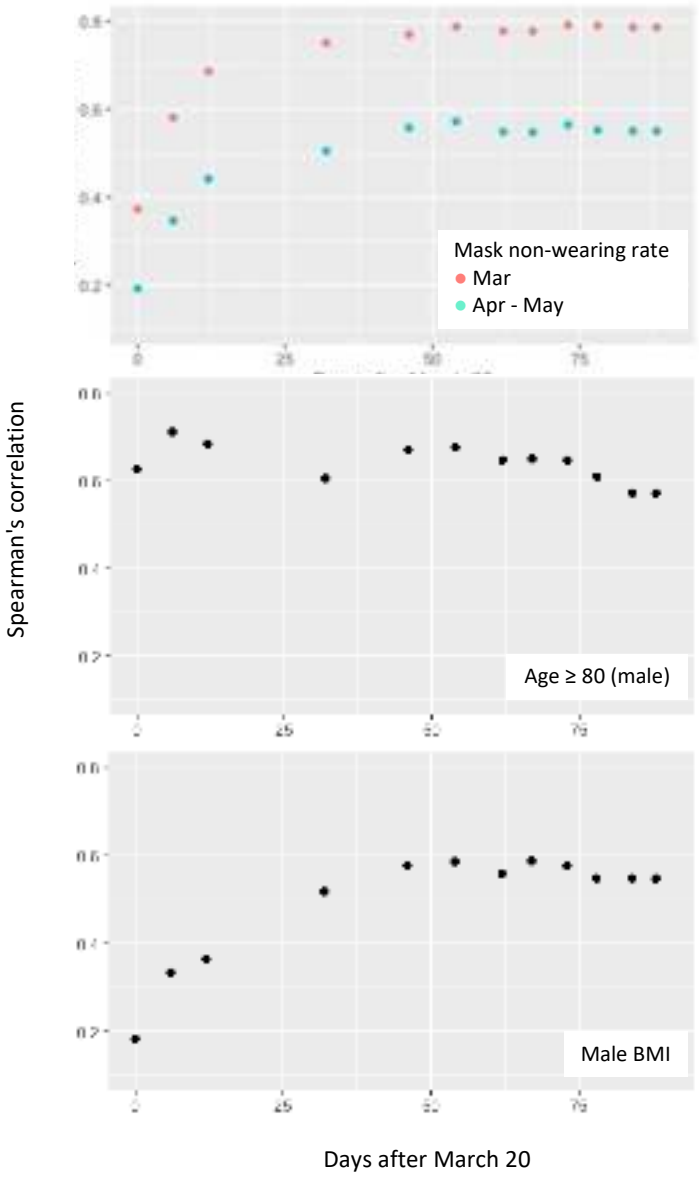

Fig. 2. Time-dependent changes in Spearman's correlations between the number of deaths per million on May 13 and mask non-wearing rates (mid-March and late April to early May), age ≥ 80, and male BMI.

Scatter plots

We subsequently made scatter plots showing the relationship between the number of deaths per million and predictors that showed high Spearman's correlation (Fig. 3). The number of deaths per million on May 13 was used because it showed the highest correlations with most important

medRxiv preprint doi: https://doi.org/10.1101/2020.06.22.20137745; this version posted June 23, 2020. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

predictors including the mask non-wearing rates (mid-March), age ≥ 80 (male), and male BMI. As expected, the number of deaths per million did not show a clear correlation with the mask non-wearing rate (late April to early May). The number of deaths per million showed exponential type increases in most plots, in particular with the mask non-wearing rate (mid-March).

We therefore applied the logarithmic transformation to the number of deaths per million. The transformed number of deaths per million on May 13 showed significant linear correlation with the mask non-wearing rate in mid-March (r = 0.865, P = 9.739e-08), mask non-wearing rate in late April to early May (r = 0.530, P = 0.009296), age ≥ 80 (male) (r = 0.658, P = 0.0008717), and BMI (male) (r = 0.682, P = 0.0004762). The relationship between the number of deaths per million (May 13) and age ≥ 80 (female) appeared to be similar in the scatter plot (data not shown), but their linear correlation did not reach the statistical significance with a lower Pearson correlation coefficient compared to that of age ≥ 80 of males (r = 0.416, P = 0.05381).

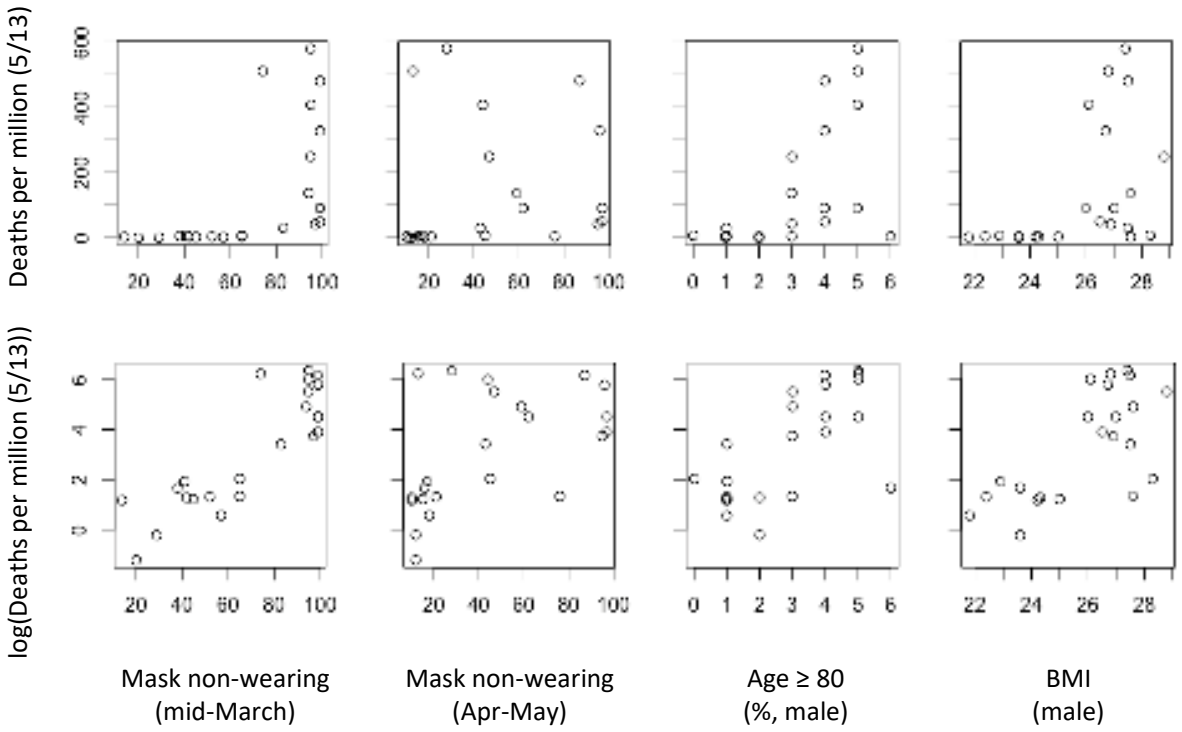

Fig. 3. Scatter plots showing the correlations among parameters related to COVID19 deaths, obesity, age, and mask non-wearing rate. The number of deaths per million on May 13 was used with (bottom panels) and without (top panels) logarithmic transformation.

Lasso regression

Next, we used the least absolute shrinkage and selection operator (lasso) regression to find the potential effects of these predictors on the log-transformed number of deaths per million. The lasso regression estimates the regression coefficients with the lasso penalty terms, retaining important

medRxiv preprint doi: https://doi.org/10.1101/2020.06.22.20137745; this version posted June 23, 2020. The copyright holder for this preprint

explanatory variables, while less important variables are removed from the regression (Tibshirani, 2011). When all parameters in Fig. 2 were included together with age ≥ 80 (female), the lasso regression selected BMI (male) (beta = 0.21610188), age ≥ 80 (male) (0.34906818), the mask non-wearing rate (mid-March) (0.06019861), and the mask non-wearing rate in late April to early May (-0.02008978) with an intercept of -6.65720405. Age ≥ 80 (female) was omitted from the regression. The observed number of deaths per million showed high correlation with the number predicted by the lasso regression model (Fig. 4; Pearson's coefficient = 0.918, P = 1.635e-09).

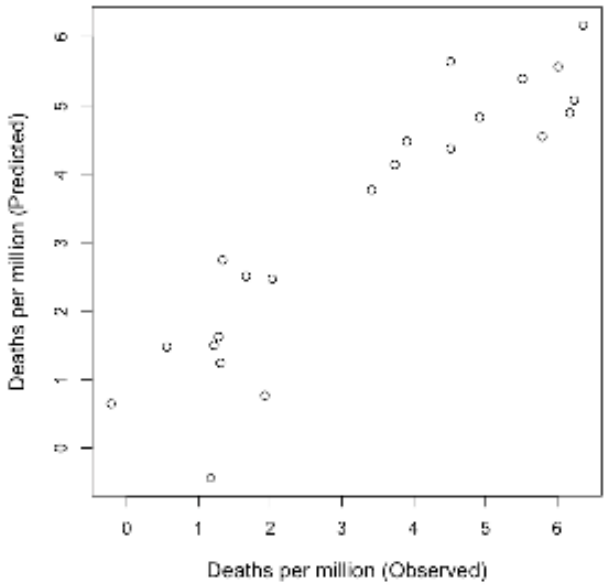

Fig. 4. Pearson's correlation between observed and predicted values of log-transformed number of deaths per million. The minimum lambda of 0.02511886 was used for the lasso regression. Pearson's coefficient = 0.918, P = 1.635e-09.

Multiple linear regression

We performed a hypothesis-driven linear regression using three or two of predictors selected by the lasso regression. Because the mask non-wearing rate is available only for 22 countries (Supplementary File 1), we first selected BMI (male), age ≥ 80 (male), and the mask non-wearing rate in mid-March for this regression (Table 1, model 1). This multiple regression model explained 76.0% variation of the number of deaths per million on May 13 (P = 2.075e-06), identifying the significant effects of mask non-wearing rate in mid-March and age ≥ 80 (male). BMI (male) also showed a trend for association, but the association was not statistically significant.

Other combinations of three predictors also resulted in significant associations between the number of deaths per million on May 13 and the selected predictors with ~0.7 adjusted R square values (Table 1). We found several important features in the multiple regressions. First, the effect of mask non-wearing rate in mid-March was significant in all regressions tested with low P values, and exclusion

medRxiv preprint doi: https://doi.org/10.1101/2020.06.22.20137745; this version posted June 23, 2020. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY 4.0 International license .

of this predictor markedly decreased the adjusted R square (model 2). Second, BMI (male) showed a relatively low association with the number of deaths on May 13, being significant only when the strongest predictor, mask non-wearing rate in mid-Match, was not included the regression (model 3). Third, the highest adjusted R square of 0.7934 was obtained when we include predictors age ≥ 80 (male) and mask non-wearing rates of mid-March and late April to early May (model 4). All regression coefficients were statistically significant in this model.

Regressions including two predictors also underscored the importance of the mask non-wearing rate in mid-March as the predictor for the number of deaths per million on May 13. Namely, the mask non-wearing rate in mid-March was always a significant predictor (models 5–7) with adjusted R square of up to ~0.75. While BMI (male) and age ≥ 80 (male) were also significantly associated with the number of deaths per million on May 13, exclusion of the mask non-wearing rate in mid-March dropped the adjusted R square to ~0.65.

Single regression

Because the mask non-wearing rate in mid-March showed the strong association with the number of deaths on May 13, we also built several single linear regression models for predicting the number of deaths from other dates using this predictor (Table 2). Overall, changes in adjusted R square showed the similar tendency with those of the Spearman's correlation coefficients (Fig. 1), in which the value gradually increased during March and April, reaching the plateau in mid-May. Overall, the mask non-wearing rate in mid-March explained up to 72% of variations of the number of deaths per million.

Prediction of mask non-wearing rates

Lastly, we examined the relationship between the mask non-wearing rate, age ≥ 80 (male), and male BMI (Fig. 5). The mask non-wearing rate in mid-March showed significant correlations with both age ≥ 80 (male) and male BMI. Multiple linear regressions found both age ≥ 80 (male) and male BMI as significant predictors of the mask non-wearing rate with regression coefficients of 5.224 (P = 0.042559) and 8.377 (P = 0.000682), respectively, with an interception of -160.020 (P = 0.006040). This multiple regression model explained 56.8% variation of the mask non-wearing rate in mid-March

medRxiv preprint doi: https://doi.org/10.1101/2020.06.22.20137745; this version posted June 23, 2020. The copyright holder for this preprint

(P = 0.0001325).

Compared to the mask non-wearing rate in mid-March, that in late April to early May showed a weak association with age ≥ 80 (male) and male BMI (Fig. 5). Accordingly, in the following multiple linear regression analysis, age ≥ 80 (male) and male BMI explained only 29.4% variation of the mask non-wearing rate although the regression was still statistically significant (P = 0.01419), The regression coefficients of men BMI and age ≥ 80 (male) were 8.422 and 3.270, respectively (P = 0.0141 and 0.3776, respectively).

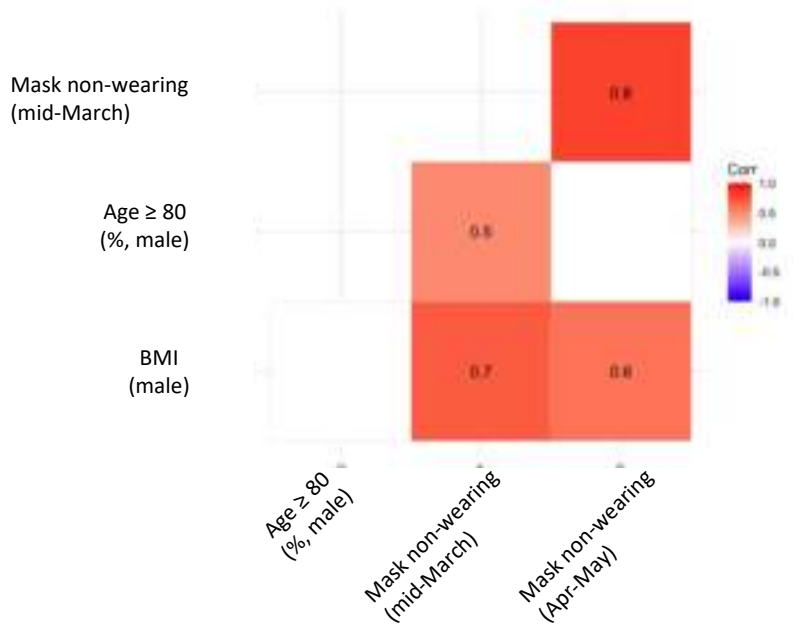

Fig. 5. Pearson's correlation matrix between mask non-wearing rate, age ≥ 80 (male), and mae BMI. Only significant correlations are shown (P < 0.05).

Discussion

The number of deaths per million on a certain date highly depends on when the epidemic began in the country, in particular in the early stages of the pandemic. In this study, we have tentatively determined March 20 as the start date of a global pandemic. It is likely that this assumption is a reasonable approximation for our hypothesis because all employed predictors (mask non-wearing rates, age and BMI) tended to show weak correlations with the number of deaths per million at the onset of the pandemic followed by marked increases as the progress of the pandemic. These features enabled us to select a specific date (May 13), at which most parameters showed the high correlations with the number of deaths per million, and to build regression models that well explain the variation of the response variable with limited number of predictors. On the other hand, it is noteworthy that the age-related predictors were highly correlated to the number of deaths per million from the very beginning

of the pandemic and then remained constant or gradually declined. Below we discuss the potential biomedical and socioeconomic mechanisms by which each predictor affects the number of deaths by COVID-19.

Obesity

We have proposed possible mechanisms by which obesity could be a risk factor for the severity of COVID-19 and H1N1 influenza infections (Miyazawa, 2020). Namely, respiratory failure is the most important pathology that contributes to the severity of both COVID-19 and H1N1 influenza infections. Since obese patients generally show a restrictive breathing pattern and reduced lung volumes, the obesity-hypoventilation syndrome can lead to respiratory failure in COVID-19 patients, being a risk factor especially for patients with severe symptoms. Also, obesity has been reported to be a risk factor for the development of acute respiratory distress syndrome (Zhi et al, 2016), which is a serious clinical manifestation of COVID-19 (Simonnet et al., 2020). According to Moriconi et al. (2020), in patients of COVID-19, inflammatory markers were higher in obese group than non-obese group at admission, and obese group showed a worse pulmonary clinical picture, with lower PaO2. Thus, obesity could be a risk factor for already hospitalized COVID-19 patients or even for those with serious symptoms.

These potential mechanisms may explain the reason why the association of BMI (male) and the number of deaths increased May to June 2020. Typical COVID-19 patients are hospitalized a few days to a week after infection and in some cases the symptom become severe a few weeks after hospitalization. If the obesity affects the last phase of the transition of the disease, there must be some delay in the increase in correlations between BMI and the number of deaths per million compared to the spread of COVID-19. However, we cannot rule out the possibility that obese people have high chance to be infected because obese adults are known to inhale air average 50% more per day than non-obese adults (Brochu, 2014), which may lead to increase the chance to inhale the virus.

Age

In contrast to BMI, age ≥ 80 (male) was correlated with the number of deaths from the onset of the global pandemic. This may reflect the common etiological feature that old people are more susceptible to infection and have higher risk of death after infection compared to young people because of the dysfunction of immunity.

The precise reason why older age contributes to the number of COVID-19-related deaths remains to be elucidated, while the immune dysfunction has been proposed as a potential mechanism (Mueller, McNamara, & Sinclair, 2020). Meanwhile, it is controversial whether the reduced immunity simply contributes to the higher mortality after infection. Excessive immunity could cause the cytokine storm and ARDS in COVID-19 in some cases (Ye, Wang, & Mao, 2020). Furthermore, two patients with X-

medRxiv preprint doi: https://doi.org/10.1101/2020.06.22.20137745; this version posted June 23, 2020. linked agammaglobulinemia have recovered from COVID-19, suggesting that B-cell response may not be necessary for the recover from this disease (Soresina et al., 2020). While other dysfunction of immunity, such as age-related T-cell dysfunction, may be involved in the severity of COVID-19 (Minato, Hattori, & Hamazaki, 2020), the mechanism should be carefully investigated.

Along with immune dysfunction, old individuals tend to provoke unwanted inflammation, which may contribute to the severity of COVID-19 (Mueller, McNamara, & Sinclair, 2020). This tendency can be seen in SARS-CoV-infected old nonhuman primate (Smits et al., 2010). Also, To et al. (2020) reported that older age is correlated with the higher salivary viral load, which is highest during the first week after symptom onset. Furthermore, as in the case of obese patients, decreased respiratory function of elderly could also be the reason. In elder individual, both forced expiratory volume in one second (FEV1) and forced vital capacity (FVC) decrease dramatically (Falaschetti et al., 2004), to almost half of their lifetime maximum values, especially in males (Leem et al., 2019).

Sex differences

We identified a clear sex-dependent difference in the Spearman's correlation coefficients between the number of deaths per million and obesity-related parameters. This is in line with the fact that males are more susceptible to severe outcomes from COVID-19 than females (Montopoli et al., 2020; Grandi , Facchinetti, & Bitzer, 2020). It has been proposed that estrogen may be protective against COVID-19 in females (Grandi , Facchinetti, & Bitzer, 2020), while androgens may worsen COVID-19 in males (Montopoli et al., 2020). It is also possible that smoking, which is more common in males globally, may play a role in worsening COVID-19 (Grandi , Facchinetti, & Bitzer, 2020). Also, females generally have more fear to COVID-19 and tend to take more preventive behaviors than males (Yıldırım, 2020)

Face mask

Face masks are considered to be effective in preventing transmission of COVID-19 to others, and also have a protective effect in preventing transmission from others. A recent simulation study showed that universal masking at 80% adoption suppresses COVID-19 deaths significantly more than maintaining a lockdown. Comparison between the validated modeling results and empirical data from Asian regions showed an almost perfect correlation between early universal masking and successful suppression of COVID-19 outbreaks (Kai et al., 2020). Also, Zhang et al. (2020) reported that face mask alone could have reduced the number of infections by over 78,000 in Italy from April 6 to May 9 and over 66,000 in New York City from April 17 to May 9, claiming that the failure in containing the propagation of COVID-19 pandemic worldwide is largely attributed to the unrecognized importance of airborne virus transmission.

Likewise, the mask non-wearing rate in mid-March was found to be the strongest predictor for the

medRxiv preprint doi: https://doi.org/10.1101/2020.06.22.20137745; this version posted June 23, 2020. The copyright holder for this preprint

number of deaths per million in this study, even the single regression by which explained more than 70% of the variation of the response variable.

There was a big difference in face mask wearing rates between Western countries and Asian countries (especially East Asian countries). The county's policy for wearing face mask alone cannot explain this big difference because, for example, face mask has never been mandated in Japan, despite its high face mask wearing rate. We speculate that the cultural may be the major reason for the difference. Many Japanese wear surgical masks on a daily basis not for shedding infections or pollens, but also for achieving anonymity just like westerners wearing sunglasses, which is referred to as "mask dependency" in excessive cases (Li, 2017). However, while people may hope to achieve anonymity, most of them want to avoid making others uncomfortable, and there is a regional difference in what people feel uncomfortable. Jack, Caldara, & Schyns (2012) mentioned that "whereas Western Caucasian internal representations predominantly featured the eyebrows and mouth, East Asian internal representations showed a preference for expressive information in the eye region" . This tendency may be the major reason why it is more considered rude wearing sunglasses among East Asia (Gesteland, 2020), whereas it is considered more suspicious to wear face masks in Western countries. Yamanaka (2020) wonders if Japan has an "X-factor" that led to the low rates of COVID-19 deaths. Although the present study is not intended to show the causal role of face mask wearing rate, future attempts for intervention may consider the face mask wearing rate as the major candidate for the "X-factor".

Additionally, most Japanese keep silent while using public transportation, because loud chatter in the public transportation is considered rude in Japan (Baseel, 2020). This may also be able to reduce the case of COVID-19 because more aerosols are exhaled from asymptomatic individuals during speaking than breathing (Buonanno, Stabile, & Morawska, 2020) and it is considered to contribute largely to spread of COVID-19 (Prather, Wang, & Schooley, 2020). Also aerosols' viral density should be different between speaking and breathing, because origin of the aerosols should be different, mainly from lung or mouth. Aerosols from mouth than lung may contain more virus in asymptomatic individuals. Long et. al (2020) noted that although virus shedding does not equate with viral infectivity, the asymptomatic group had a significantly longer duration of viral shedding than the symptomatic group.

Correlation between variables

There was a significant positive correlation between male BMI and mask non-wearing rate in mid-March. Although this does not simply indicate that obese people tend not to wear masks, it is possible to speculate that when people become more obese, they feel more uncomfortable to wear masks since obese adult inhale air average 50% more per day than non-obese adults (Brochu, 2014). Also, body temperature is positively associated with obesity (Bastardot, 2019), and face masks could rise body temperature (Yip, 2005; Hayashi 2004). Therefore, obese people may feel more heat and discomfort

(Li, 2005) when wearing face masks depending on the temperature and humidity. The small size of universal face masks may be a simple reason for the correlation.

There was a significant positive correlation between age ≥ 80 (male) and mask non-wearing rate in mid-March. Due to the lack of data on mask wearing rates by age, this cannot be fully discussed either. It has been reported that age was correlated with fear and were related to preventive behaviors (Yıldırım, 2020). Face mask wearing in public correlates with the proportion of people who are afraid of COVID-19, except for Scandinavian countries and United Kingdom (Smith, 2020). These facts are inconsistent with the correlation found in this study. Further data is required for detailed investigation.

Conclusion

The mask non-wearing rate in mid-March alone explained up to 72% of variations of the number of deaths per million. The fact that the face mask non-wearing rate in mid-March, the early phase of the pandemic, more strongly predicted the total number of deaths per population over the entire three-month course of the pandemic than the face mask non-wearing rate in late April to early May may suggest that face mask wearing from the early phase of the pandemic may be very important for suppressing COVID-19-related deaths, if mask wearing is assumed to be an independent risk factor.

In the lasso regression, four factors, BMI (male), age ≥ 80 (male), the mask non-wearing rate (mid-March), and the mask non-wearing rate in late April to early May were chosen, and the observed and predicted model of number of deaths per million showed high correlation (Pearson's coefficient = 0.918, P = 1.635e-09). Although this has not been proven at this time to be the cause of the differences in COVID-19 mortality by country, it may be a useful method for predicting COVID-19 mortality.

The death rate of the country in the early stages of a pandemic could be further predicted if factors such as the timing and number of infected people entering the country from abroad are taken into account.

Edited by Andrea Rinaldo, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland, and approved November 10, 2020 (received for review July 28, 2020)

We use the synthetic control method to analyze the effect of face masks on the spread of COVID-19 in Germany. Our identification approach exploits regional variation in the point in time when wearing of face masks became mandatory in public transport and shops. Depending on the region we consider, we find that face masks reduced the number of newly registered severe acute respiratory syndrome coronavirus 2 infections between 15% and 75% over a period of 20 days after their mandatory introduction. Assessing the credibility of the various estimates, we conclude that face masks reduce the daily growth rate of reported infections by around 47%.

COVID-19 | public health measures | face masks | synthetic control method

Many countries have experimented with several public health measures to mitigate the spread of COVID-19. One particular measure that has been introduced are face masks. It is of obvious interest to understand the contribution made by such a measure in reducing infections.

The effect of face masks on the spread of infections has been studied for a long time. The usefulness of facial protection for clinical personnel is beyond dispute, even though there are many questions left open (1). There is also evidence that face masks helped in mitigating the spread of earlier epidemics such as SARS 2003 (severe acute respiratory syndrome 2003) or influenza (see *SI Appendix*, section E for a brief literature survey). The impact of face masks worn in public on the spread of COVID-19 has yet to be systematically analyzed. This is the objective of this paper.

There is a general perception in Germany that the mandatory use of face masks in public reduces COVID-19 incidences considerably. This perception stems mainly from the city of Jena. After face masks became mandatory between 1 April and 10 April 2020 the number of new infections fell almost to zero. Jena is not the only region in Germany, however, that introduced face masks. Six further regions made masks compulsory before the introduction at the federal state level. Eventually, face masks became mandatory in all federal states between 20 April and 29 April 2020 (see *SI Appendix*, section A for background).

We quantify the effectiveness of face masks by employing the synthetic control method (SCM; refs. 2–5). Our identification approach exploits this regional variation in the point in time when face masks became mandatory. We use data for 401 regions in Germany (municipal districts) to estimate the effect of this particular policy intervention on the development of registered infections with COVID-19. We consider the timing of mandatory face covering as an exogenous event to the local population: Masks were imposed by local authorities and were not the outcome of some process in which the population was involved. We compare the COVID-19 development in various regions to their synthetic counterparts. The latter are constructed as weighted averages of control regions that are structurally similar to treated regions. Structural dimensions considered include prior COVID-19 cases, the demographic composition, and the local health care system.

A detailed analysis of the timing of all public health measures in the regions we study guarantees that we correctly attribute our findings to face masks (and not erroneously to other public health measures). We also employ a standard SIR (susceptible–infected–removed) model and undertake an analysis of the distribution of the lag between infection and reporting date. This allows us to provide a precise interpretation of our empirical effectiveness measure and to pin down the point in time when the effects of face masks should be visible in the data.

We find statistically significant and sizeable support for the general perception that the public wearing of face masks in Jena strongly reduced the number of incidences. We obtain a synthetic control group that closely follows the COVID-19 trend before the introduction of mandatory masks in Jena. The difference between Jena and this group becomes significant thereafter. Our findings indicate that the early introduction of face masks in Jena has resulted in a drop in newly registered COVID-19 cases of around 75% after 20 d. Put simply, if the control region observes 100 new infections over a period of 20 d, the mask region observes only 25 cases. This drop is greatest, by more than 90%, for the age group 60 y and above. Our results are robust to different sensitivity checks, among which are placebo-in-space and placebo-in-time analyses.

As a means to verify the generalizability of our findings for Jena, we move from a single- to a multiple-treatment approach and estimate average treatment effects of introducing face masks

Significance

Mitigating the spread of COVID-19 is the objective of most governments. It is of utmost importance to understand how effective various public health measures are. We study the effectiveness of face masks. We employ public regional data about reported severe acute respiratory syndrome coronavirus 2 infections for Germany. As face masks became mandatory at different points in time across German regions, we can compare the rise in infections in regions with masks and regions without masks. Weighing various estimates, we conclude that 20 d after becoming mandatory face masks have reduced the number of new infections by around 45%. As economic costs are close to zero compared to other public health measures, masks seem to be a cost-effective means to combat COVID-19.

First published December 3, 2020.

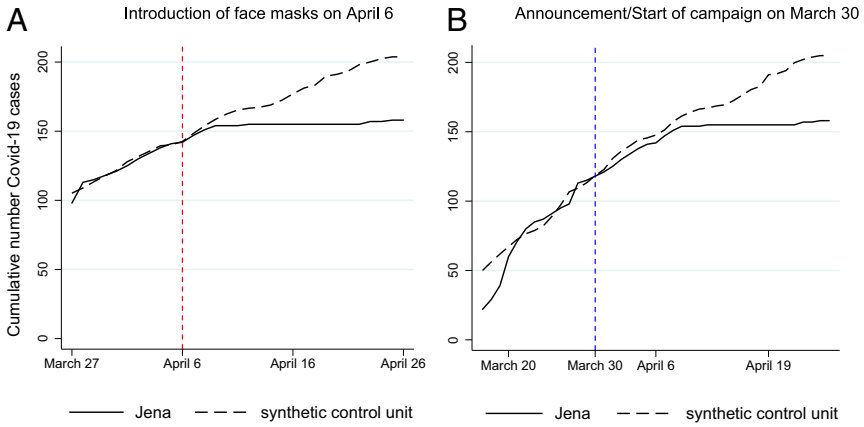

Fig. 1. Treatment effects of the mandatory introduction of face masks (6 April) and of its announcement (30 March) in Jena. The figure shows the development of the cumulative number of COVID-19 cases in Jena (treated region, black solid line) compared to a synthetic control group (gray dashed line) over time. (Details on the construction of the synthetic control group and SCM estimation are given in *Method and Data*.) Both panels distinguish between a pretreatment and treatment period. In *A*, the treatment period starts on 6 April when face masks became mandatory in public transport and shops. The start of the treatment period is indicated by the dashed vertical line (red). In *B*, the treatment period is set to begin on 30 March as starting date of the local campaign in Jena to wear face masks in public. The start of the treatment period is indicated by the dashed vertical line (blue). The panels show that the conclusion is independent of the starting dates: Face masks strongly reduced the number of COVID-19 cases in Jena.

on the spread of COVID-19 for all regions that introduced masks by 22 April (~8% of all German regions). Although the estimated average treatment effect is smaller compared to the one found for Jena, it is still statistically significant and sufficiently large to support our point that wearing face masks is an effective and cost-efficient measure for fighting COVID-19. When we summarize all of our findings in one single measure (*SI Appendix*, section D.2), we conclude that the daily growth rate of COVID-19 cases in the treatment group falls by around 47% due to mandatory mask-wearing relative to the synthetic control group.*

Our findings can be aligned with earlier evidence on face masks, public health measures, and the epidemic spread of COVID-19, although consolidated scientific knowledge is limited (*SI Appendix*, section E). While there is a growing consensus from clinical studies that face masks significantly reduce the transmission risk of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and COVID-19 (7, 10), nonclinical evidence on the effectiveness of face masks is still largely missing. Ref. 11 surveys evidence on the population impacts of a widespread community mask use and stresses that "no randomized control trials on the use of masks … has been published." The study which is "the most relevant paper" for ref. 11 is one that analyzed "exhaled breath and coughs of children and adults with acute respiratory illness" (ref. 12, p. 676), that is, used a clinical setting. Concerning the effect of masks on community transmissions, the survey needs to rely on pre–COVID-19 studies.

Ref. 13 is among the first to estimate the population impact of face masks on SARS-CoV-2 infections.† The authors track the development of COVID-19 in three pandemic epicenters, Wuhan, Italy, and New York City, between 23 January and 9 May 2020 and find sizable mitigating effects of face masks on epidemic spread. While their study offers important insights into the population effects of face masks, a methodical limitation is that estimates are only carried out in a "before–after" manner with no use of a strict control group approach. This may limit the causal interpretation of results. We therefore follow the spirit of ref. 4 and provide causal evidence identifying the population impact of mandatory face masks on the spread of COVID-19.

Results: The Effects of Face Masks on the Spread of COVID-19

All results are obtained by applying the synthetic control method. It is described briefly in *Method and Data* and in more detail in *SI Appendix*, section B.

Results for Jena. Face masks became mandatory in Jena in three steps between 1 and 10 April. The most important measure (in the sense of having the largest impact measured in terms of social contacts) requires face masks in public transports and shops and entered into force on 6 April (see *SI Appendix*, section A for detailed information). We therefore center our discussion on this date.

Fig. 1*A* shows the SCM results for the introduction of face masks in Jena on 6 April. The visual inspection of the development of cumulative COVID-19 cases shows that the trend development of the synthetic control group is very similar to Jena before the treatment, indicating a good fit.‡ The difference in the cumulated registered COVID-19 cases between Jena and its corresponding synthetic control group after the start of the treatment on 6 April can be interpreted as the treatment effect on the treated [see *SI Appendix*, section C.3 for (post)estimation details].

Fig. 1*A* clearly shows a gradually widening gap in the cumulative number of COVID-19 cases between Jena and its synthetic control group. The size of the effect 20 d after the start of the treatment (6 April) amounts to a decrease in the number of cumulative COVID-19 cases of 23%, which corresponds to a drop in newly registered cases of roughly 75%. Expressed differently, the daily growth rate of the number of infections decreases by 1.28 percentage points per day (see *SI Appendix*, section D.2 for computational details and an overview of all

*The main channel through which masks reduce transmission of SARS-CoV-2 is the limiting effect for the spread of exhaled air, as argued by ref. 6. Refs. 6 and 7 argue that aerosols (as opposed to larger droplets) are filtered only by high-quality masks. Droplets are also filtered by home-made masks. Earlier work includes ref. 8 that was recently extended by ref. 9. Ref. 9 finds that all face covers (without an outlet valve) "reduce the front flow through jet by more than 90%." As surgical and hand-made masks generally do not tightly fit, they generate backward and downward jets.

†Ref. 10 conducts a systematic review and meta-analysis. They do not report a study (see their table 1) that analyzes the entire population of a country.

‡As a measure for the quality of the fit between the treated region and its synthetic control group, the pretreatment root-mean-square prediction error (RMSPE) can be calculated and compared to a reference case. For Jena the pretreatment RMSPE is 3.145. This is considerably lower than an average RMSPE of 6.669 for all other 400 regions and their synthetic controls in the pretreatment period until 6 April. This points to the relatively good fit of the synthetic control group for Jena in this period.

measures). If we look at the estimated differences by age groups, *SI Appendix*, Fig. S7 indicates that the largest effects occur for individuals above 60 y of age. Here the reduction in cumulative cases even exceeds 50%, which corresponds to a drop in newly registered SARS-CoV-2 infections by more than 90%. The significant drop can be explained by the introduction of face masks in elderly and nursing homes, which had already started on 1 April. For the other two age groups the decrease in the number of cumulative cases lies between 10% and 20%.

If we consider a median time lag of 10.5 d from infection until registration (see *SI Appendix*, section A.3), the occurrence of a gradually widening gap between Jena and its synthetic control in the first week after the introduction of mandatory face masks seems fast. One might conjecture that an announcement effect played a role. As shown in *SI Appendix*, section C.6.1, online searches for (purchasing) face masks peaked on 22 April, when it was announced that face masks would become compulsory in all German federal states.[§] Another peak in online searches, almost as large (70% of the peak of 22 April), appeared on 31 March. This marks the date of the regulation making masks compulsory between 1 and 10 April in Jena. The regulation was accompanied by a campaign "*Jena zeigt Maske*," communicating the necessity to wear face masks in public, that started on 30 March.[#]

Fig. 1*B* plots the estimated effect size when we define the start of the treatment period by the start of the campaign on 30 March. The visual inspection of the difference between Jena and its synthetic control group points to the presence of a small anticipation effect. Yet, the gap to the synthetic control significantly widens only ∼10 to 12 d after the announcement and then grows considerably over time. As this temporal transmission channel appears plausible given a median time lag between infection and registration of almost equal length, we take this as first evidence for a face mask effect in the reduction of SARS-CoV-2 infections.

Robustness Checks. Obviously, the estimated difference in COVID-19 development in Jena vis-à-vis the synthetic Jena is only convincing if 1) the requirements of the SCM are fulfilled and 2) potentially concurrent policies other than masks can be ruled out. The role of the first set of robustness checks consists of understanding the sensitivity to the length of the preintervention period (*Cross-Validation Tests*) and to the composition of the control pool (*Changing the Donor Pool*).[‖] In a second step, we rule out unobserved macro effects shared by many regions (*Placebo-in-Space Tests*) and test for anticipation effects potentially caused by other public health measures (*Placebo-in-Time Tests*). The second step also comprises difference-in-difference estimation as a further test for latent concurrent policies that go beyond observable policies (displayed in *SI Appendix*, Fig. S2).

Cross-validation tests. We study the sensitivity of our estimates with respect to the length of the training and validation period before the start of the treatment. We accordingly alter the imposed lag structure for predictors that have a time dimension, that is, the number of cumulative and newly registered COVID-19 cases. The set of time-constant predictors is kept unchanged by this test. As shown in *SI Appendix*, section C.7, we do not find a systematic estimation bias of our baseline SCM specification compared to alternative ones with longer lag structures (up to 7 d) and accordingly shorter trainings periods. Given that regional COVID-19 cases developed very dynamically and nonlinearly in the pretreatment period, this is an important finding in terms of the robustness of our results.

We also test for the sensitivity of the estimated treatment effects to changes in the set of time-constant predictors. We do so by sequentially excluding individual variables from the set of predictors. As shown in *SI Appendix*, section C.7, the estimated trajectories for the respective synthetic control groups follow a very similar trend. All of them identify a reduction in the number of cumulative COVID-19 cases in Jena vis-à-vis the synthetic Jena that widens over time. We conclude from these results that using the full set of predictors is the most reasonable approach.

Changing the donor pool. This may be equally important as our baseline specification includes the region of Heinsberg in the donor pool used to construct the synthetic Jena (with a weight of 4.6%; compare *SI Appendix*, Table S5). As Heinsberg is one of the German regions that was significantly affected by the COVID-19 pandemic during the Carnival season, one may expect that this leads to an overestimation of the effects of face masks. Accordingly, *SI Appendix*, section C.8 presents estimates for alternative donor pools. Again, we do not find evidence for a significant bias in our baseline specification. By tendency, the treatment effect becomes larger, particularly if we compare Jena only to other regions in Thuringia (to rule out macroregional trends) and to a subsample of larger cities (*kreisfreie Städte*). The latter comparison reduces the degree of latent regional heterogeneity, for instance, with regard to social interactions. Both subsamples exclude Heinsberg. We also run SCM for subsamples excluding Thuringia (to rule out spatial spillover effects) and for East and West German regions only (again to test for specific macro regional trends). Generally, these sensitivity tests underline the robustness of the estimated treatment effect for Jena.

Placebo-in-space tests. These tests check whether other cities that did not introduce face masks on 6 April have nonetheless experienced a similar decline in the number of registered COVID-19 cases. If this had been the case, the treatment effect might have been driven by other latent factors rather than by face masks. Such latent factors may, for instance, be related to the macroregional dynamics of COVID-19 in Germany. Therefore, *SI Appendix*, section C.9 reports pseudo-treatment effects for similarly sized cities in the federal state of Thuringia assuming that they had introduced face masks on 6 April—although, in fact, they did not. As the figure illustrates, these cities show either a significantly higher or a similar development of registered COVID-19 cases compared to their synthetic controls. This result provides further empirical support for a relevant effect in the case of Jena.

As a more comprehensive test, we run placebo-in-space tests for all other regions that did not introduce face masks on 6 April or closely afterward. Again, we estimate the same model on each untreated region, assuming it was treated at the same time as Jena. The empirical results in Fig. 2 indicate that the reduction in the reported number of COVID-19 cases in Jena clearly exceeds the trend in most other regions—both for the overall sample in Fig. 2*A* and the subsample of large cities (*kreisfreie Städte*) in Fig. 2*B*.

One advantage of these tests is that they allow us to conduct inference on the significance of the estimated treatment effects for Jena. Accordingly, Fig. 2 *C* and *D* visualize the estimated treatment effects together with 90% confidence intervals. Intervals have been calculated on the basis of (one-sided) *P* values (pretreatment match quality adjusted) reported in Fig. 2 *E* and *F*.[**] The latter indicate the probability that the reduction in the number of COVID-19 cases was observed by chance given the distribution of pseudo-treatment effects in the other German regions (see ref. 18). In both panels, the reported confidence intervals and underlying *P* values indicate that the reduction in

[§]For a German-wide news report see, for example, ref. 14.

[#]See local newspaper reports, for instance ref. 15.

[‖]Further requirements, that are less central to our application, are listed in *Method and Data* and are discussed in *SI Appendix*, section B.

[**]We follow the method proposed in ref. 16 to calculate confidence intervals from P values. As pointed out in ref. 17, the interpretation of confidence intervals and P values is restricted to the question of whether or not the estimated effect of the actual treatment is large relative to the distribution of placebo effects.

STATISTICS

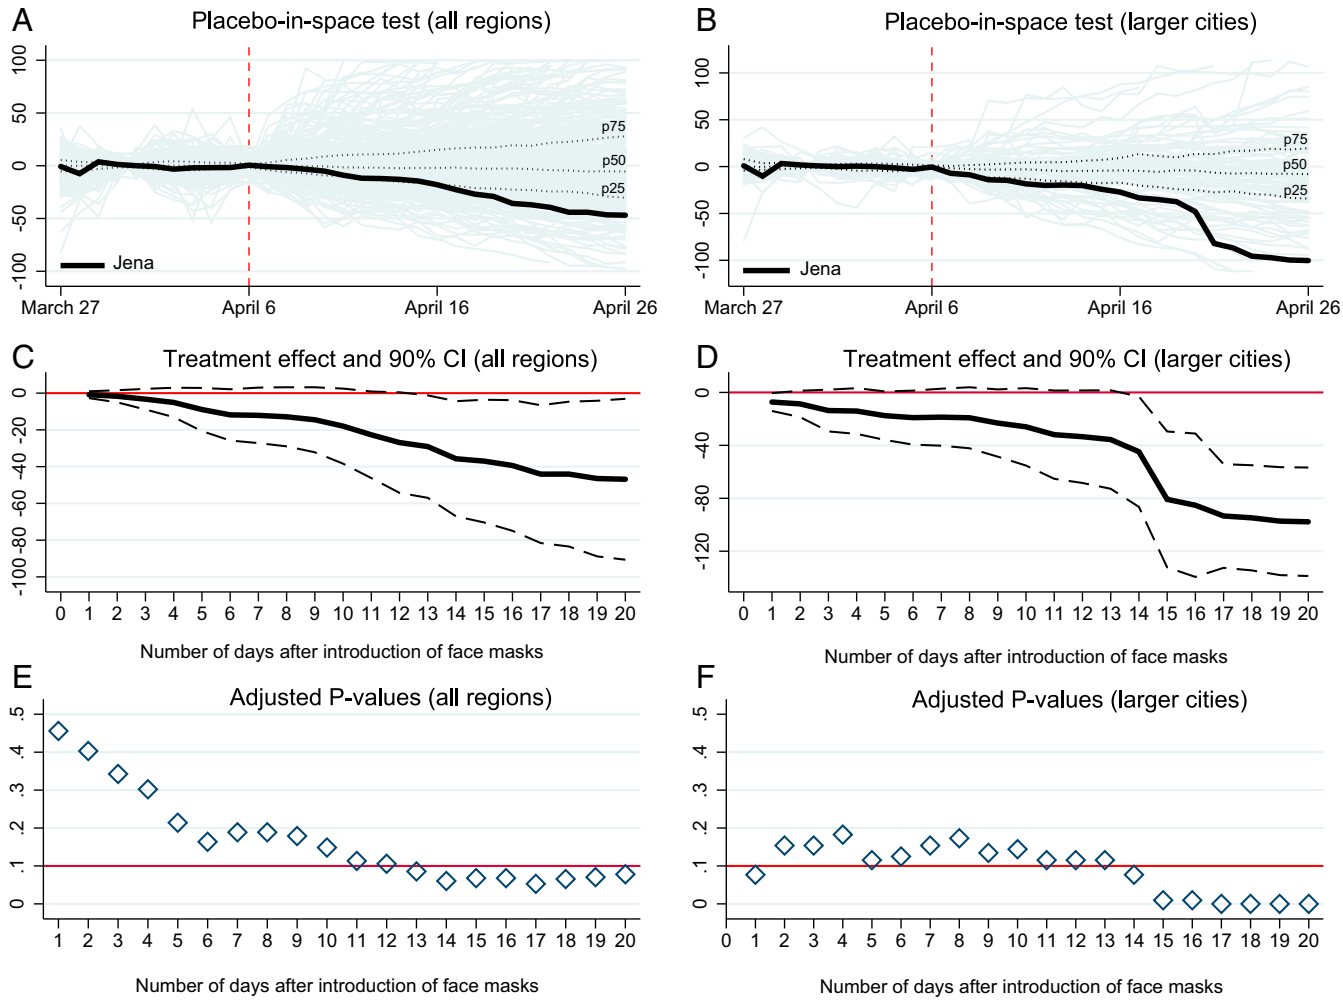

Fig. 2. Comprehensive placebo-in-space tests for the effect of face masks on COVID-19 cases. The figure compares the difference in the cumulative number of COVID-19 cases between Jena and its synthetic control group with the differences between all other regions in the donor pool and their respective controls over time. Differences have been calculated for the treatment period after 6 April when Jena de facto introduced mandatory face masks. For all other regions, the reported differences in the treatment period constitute pseudo-treatment effects since these regions had not introduced face masks back then. In *A*, the black solid line measures the treatment effect for Jena. The solid gray lines measure the pseudo-treatment effects for all other German regions in the donor pool (see *Method and Data* for details on the specification of the donor pool). Plots are shown for donor regions with an acceptable pretreatment root-mean-square prediction error (RMSPE), that is, less than 10 times the RMSPE of Jena; dotted lines indicate the median (p50), 25th percentile (p25), and 75th percentile (p75) of pseudo-treatment effects. In *B*, the donor pool is reduced to comprise only larger cities (*kreisfreie Städte*). *C* and *D* also plot the treatment effect for Jena and 90% confidence intervals (gray dashed lines) for the full sample of regions and the subsample of larger cities, respectively. Confidence intervals are constructed on the basis of pseudo *P* values as shown in *E* and *F* for the first 20 d after the introduction of face masks in Jena. These *P* values are adjusted for the pretreatment match quality (see *Method and Data* for details). The red horizontal line in *E* and *F* indicates a threshold *P* value of 0.1.

the number of COVID-19 cases was not a random event. In larger cities (Fig. 2*D*), the reduction due to the introduction of face masks is clearly visible 2 wk after the start of the treatment. Again, this timing is in line with our above argument that a sufficiently long incubation time and testing lags need to be considered in the evaluation of treatment effects.[††]

Placebo-in-time tests. As for the case of placebo-in-space tests, it is important for the validity of results that we do not observe significant treatment effects for Jena prior to the introduction of face masks on 6 April or its announcement on 30 March. To rule out such anticipation effects, we have systematically reviewed all general decrees published by the local administration in Jena. Of particular interest are those decrees that significantly differ with respect to their timing from those at the federal state level in Thuringia.

Looking at *SI Appendix*, Fig. S2, Jena and Thuringia passed at least 40 public health measures before the end of April 2020. Jena implemented 27 of these 40 either earlier than Thuringia or on its own. Examples of earlier implementation include the closing of bars, cafés, and restaurants or quarantine rules for travelers returning home. Relevant regions included foreign countries but also other German federal states, among which were Bavaria, Baden-Wurttemberg, and North-Rhine Westphalia. Measures

[††]We analyze a measure that is introduced for the first time in this region. One might conjecture that our estimation measures both the true effect of a face mask but also any other change in behavior (washing hands, limiting interactions, staying at home more, etc.) that was triggered by this policy. This change in behavior is known as the Hawthorn effect. Individuals in this pioneer region might take the crisis more seriously than in the other areas. Although German health authorities had been strongly recommending such behavioral changes in daily life since mid-March, we cannot fully rule out this mixing of effects. Mobility data for federal states in *SI Appendix*, section C.6.2 show that federal states moved in a relatively coordinated way in this respect. Unfortunately, mobility data for Jena are not easily available.

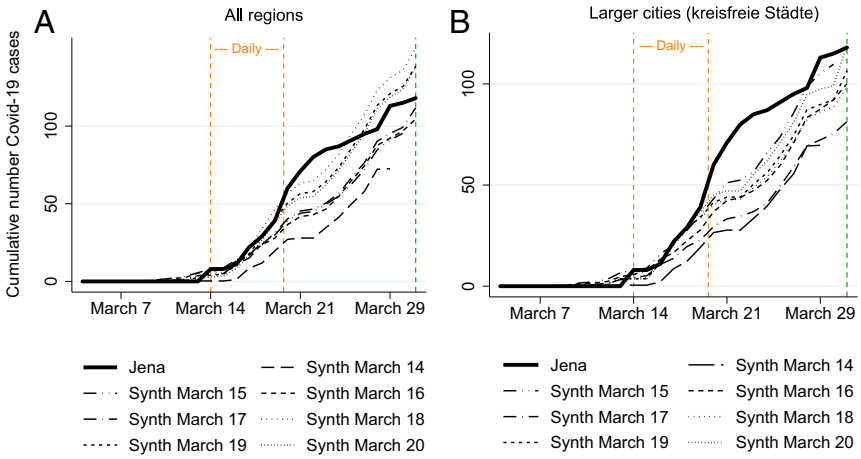

Fig. 3. Placebo-in-time tests for (pseudo) treatment effects in the period 14 to 20 March. The figure shows the empirical development of the cumulative number of COVID-19 cases in Jena (treated region, black solid line) and the estimated development in different synthetic control groups over time. The key difference between these synthetic control groups lies in the starting point of the (pseudo) treatment period. The starting point varies on a daily basis between 14 and 20 March. In *A*, the full sample of German regions is used as the donor pool for the construction of synthetic control groups (see *Method and Data* for details on the specification of the donor pool). Vertical dashed lines (orange) indicate the time corridor in which the respective (pseudo) treatment periods start. In *B*, the donor pool is reduced to comprise only larger cities (*kreisfreie Städte*). Again, vertical dashed lines (orange) indicate the time corridor in which the respective (pseudo) treatment periods start.

imposed by Jena only include the complete closing of hotels (in contrast to closing of hotels for tourism only in Thuringia) and a curfew (which lasted for only 2 wk, though).

As these major health decrees were accompanied by smaller ones on an almost daily basis until 20 March, we run a series of SCM estimations using each day between 14 and 20 March as a (pseudo) treatment period.[‡‡] The results for the full donor pool including all other German regions and the subsample of larger cities are shown in Fig. 3 *A* and *B*. Results are reported until 30 March when the mandatory introduction of face masks was announced.

To take an example, consider the graph with the long dashes in Fig. 3*A* denoted "Synth March 14." It shows the cumulative number of COVID-19 cases for a synthetic control group for Jena extracted from the full donor pool under the assumption that some treatment had started on 14 March. Similarly, "Synth March 15" (and so on) show the evolution of COVID-19 cases for a starting date of 15 March. Hence, each SCM estimation starts at a different point in time.

The visual inspection of the relative development of COVID-19 cases in Jena vis-à-vis its synthetic Jena does not indicate a clear treatment effect in terms of reducing COVID-19 cases prior to 1 April. The results are particularly clear-cut for the sample of larger cities in Fig. 3*B*, indicating that earlier public health measures alone did not significantly suppress the number of COVID-19 cases in Jena in the first 2 wk after their introduction.

Difference-in-difference tests. The reported trajectories of synthetic Jena in Fig. 3*A* leave us with some degree of ambiguity, though. To explicitly test for a potential trend reversal in the development of COVID-19 cases prior to the introduction of face masks, we further run an alternative robustness test on the basis of incremental difference-in-difference (DiD) estimation. The DiD estimator is particularly well-suited to estimate dynamic treatment effects in the context of limited information about the exact length of transmission lags before individual policy interventions show measurable effects (a detailed description is given in *SI Appendix*, section F). As the results clearly show, treatment effects from public health measures in Jena in terms of a reduction in COVID-19 cases only become statistically significant roughly 2 wk after the introduction of face masks on 6 April. If we resort to the estimated incubation and reporting lag as shown in *SI Appendix*, section A.3, this result supports our main SCM findings that the relative reduction in the cumulative number of COVID-19 cases is mainly attributable to the timing of introducing face masks. The incremental DiD results also support our main SCM findings in terms of the magnitude of the treatment effect.

Results for Other Regions. Jena may be a unique case. We therefore also study treatment effects for other individual regions that introduced face masks earlier than other regions. Further single-unit treatment analyses are shown in *SI Appendix*, section D.1. SCM estimation for multiple treated units can be undertaken as not only did some individual regions introduce face masks earlier than their federal states (see Fig. 5, below the time line) but also some federal states (Saxony and Saxony-Anhalt) before the remaining German federal states (*SI Appendix*, Fig. S1). To ensure a sufficiently long treatment period, we consider all regions as treated which introduced face masks on or before 22 April. We estimate average treatment effects in a multiple treatment SCM approach for 1) all of these regions and 2) a subset consisting of larger cities (*kreisfreie Städte*) only. In the former case we have a total of 32 treated units, and in the latter there are 8 treated units. The donor pool of control regions (all regions in Germany and only larger cities, respectively) is specified such that the minimum time lag in the introduction of face masks between treated and control regions ranges between 5 and 13 d.

The results, visible in Fig. 4, point to a significant face mask effect in the reduction of SARS-CoV-2 infections over a period of 20 d after the introduction. The temporal evolution of the average number of cumulative COVID-19 cases for treated regions and their corresponding synthetic control groups are shown in Fig. 4 *A* and *B*, respectively. The reported 90% confidence intervals in Fig. 4 *C* and *D* calculated on the basis of adjusted *P* values shown in Fig. 4 *E* and *F* indicate that the estimated treatment effects are not random for both samples. While treatment effects of face masks turn significant after roughly 1 wk for the overall sample, the emergence of a reduction in the subsample of larger cities is fast and points to early anticipation effects of face masks in urban areas, particularly during the period when local economies were gradually reopened after 20 April.

[‡‡]Alternatively, we have also tested for pseudo-treatment effects in Jena over a period of 20 d before the introduction of face masks. This period is equally split into a pre- and pseudo posttreatment period. As *SI Appendix*, Fig. S11*B* shows, there is no strong deviation from the path of the synthetic control group.

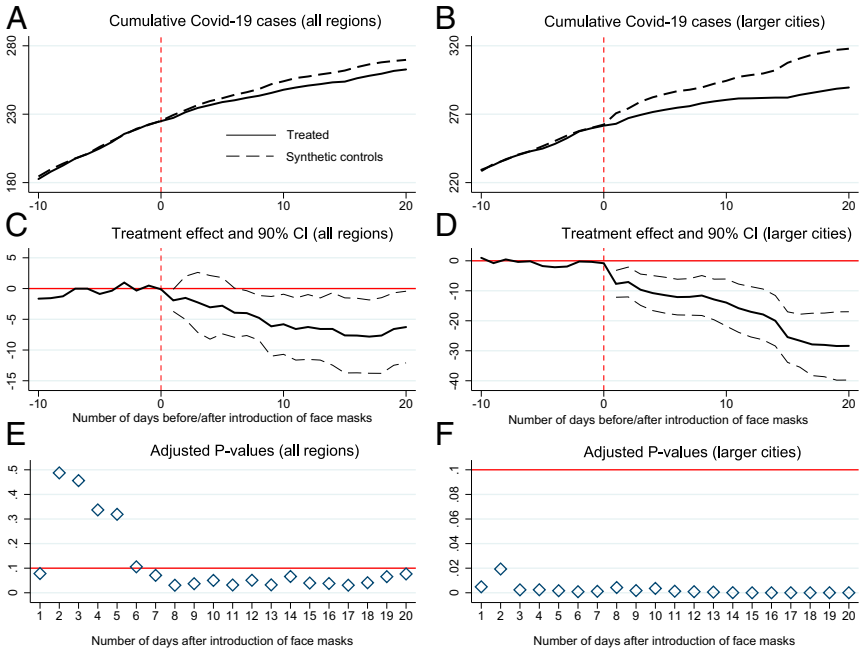

Fig. 4. Average treatment effects for the introduction of face masks with multiple treated units. The figure shows the average development of the cumulative number of COVID-19 cases for treated units (defined as all regions that introduced face masks on or before 22 April), for their synthetic control groups and estimated treatment effects. *A* plots the average number of cumulative COVID-19 cases in treated regions (black solid line) and synthetic controls (black dashed line) for the full sample of German regions in the donor pool (see *Method and Data* for details on the specification of the donor pool). The horizontal axis plots the number of days before and after the start of the treatment (mandatory introduction of face masks). The vertical dashed line (red color) indicates the start of the treatment period, which is allowed to vary by treated regions. In *B*, the number of treated and the donor pool for control regions is limited to larger cities (*kreisfreie Städte*). *C* and *D* plot the estimated average treatment effects, that is, average reduction in the cumulative number of COVID-19 cases (black solid lines) over time joint with 90% confidence intervals (gray dashed lines) for the two samples. Confidence intervals are constructed on the basis of pseudo *P* values as shown in *E* and *F* for the first 20 d after the start of the treatment. These (one-sided) *P* values are adjusted for the pretreatment match quality (see *Method and Data* for details). Inference has been conducted on the basis of a randomly drawn sample of 1 million placebo averages. The red horizontal line in *E* and *F* indicates a threshold *P* value of 0.1.

Importantly, however, the trend development for larger cities as shown in Fig. 4 not only indicates a drop in the number of newly registered COVID-19 cases around the immediate timing of the introduction of face masks but also points to the presence of dynamic treatment effects as the average gap between treated regions and their synthetic control groups widens over time. This hints at the role played by mandatory face masks in avoiding a new wave of new infections once the economy and labor market is reopened. As Fig. 4*B* highlights, such an avoidance effect may be particularly important in larger cities with higher population density and accordingly higher intensity of social interaction[§§]

Taken together, over a period of 20 d, we observe an average reduction of 28.4 cases between treated and control regions in the context of urban areas. Relative to the average number of cumulative COVID-19 cases on 11 May in control regions (317.9), this amounts to a reduction of 8.9% in the cumulative number of COVID-19 cases and a reduction of 51.2% in newly registered cases. The difference in the daily growth rate of the number of infections correspondingly amounts to 0.46 percentage points. For the full sample, this difference is estimated to be 0.13 percentage points (see *SI Appendix*, section D.2 for an overview of all measures and *Method and Data* for theoretical background). This smaller magnitude in the latter sample including all municipal districts has to be evaluated against the background of a considerable degree of structural heterogeneity, for instance, related to the composition of the local population but also the local COVID-19 spread. We argue that the latter should thus be interpreted as a lower bound for the true treatment effects.

[§§]This is perfectly in line with ref. 7 given the reduction in aerosols and droplets via using masks.

Discussion

We set out by analyzing the effect of face masks on the spread of COVID-19 for a comparative case study of the city of Jena. Our quasi-experimental control group approach using SCM shows that the introduction of face masks on 6 April reduced the number of newly registered COVID-19 cases over the next 20 d by 75% relative to the synthetic control group. Comparing the daily growth rate in the synthetic control group with the observed daily growth rate in Jena, the latter shrinks by around 70% due to the introduction of face masks. This is a sizeable effect. The introduction of mandatory face masks and the associated signal to the local population to take the risk of person-to-person transmissions seriously apparently helped considerably in reducing the spread of COVID-19. Looking at average treatment effects for all other regions puts this result in some perspective. The reduction in the daily growth rate of infections amounts to 14% only. By contrast, when we focus on larger cities, we find a reduction in the daily growth rate of infections by roughly 47%.

What would we reply if we were asked what the effect of introducing face masks would have been if they had been made mandatory all over Germany? The answer depends, first, on which of the percentage measures we found above is the most convincing and, second, on the point in time when face masks are made compulsory. The second aspect is definitely not only of academic interest but would play a major role in the case of a second wave.[##]

[##]We implicitly assume that compliance to rules in Germany is sufficiently homogenous. Some field observations in this respect would be very useful, especially across federal states in Germany and worldwide. Ref. 19 reports that compliance for distancing rules rises when masks are worn. As a first guess and assuming a compliance of 100% in our treated regions, one would expect that a reduction in compliance by x% of the population leads to a reduction of the effects of masks by x%.

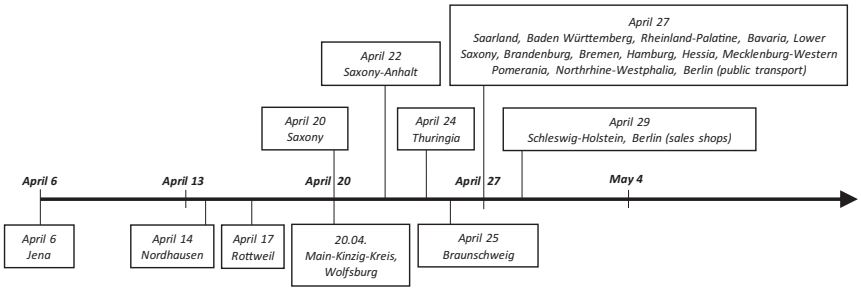

Fig. 5. The timing of mandatory face mask wearing in German federal states (*Top*) and individual regions (*Bottom*). The figure shows the regional variation in the introduction of face masks in public transport and shops over time. While text boxes above the timeline on the horizontal axis indicate the timing when the wearing of face masks became compulsory in the respective federal states (NUTS1 level), text boxes below the timeline identify individual NUTS3 regions that have anteceded the general introduction of face masks at the federal state level. The first NUTS3 region that introduced mandatory face masks in Germany was Jena on 6 April. By 29 April face masks had become mandatory in all German regions. (See *SI Appendix*, section A.1 for more background.)

We believe that the reduction in the daily growth rates of infections between 47% and 70% is our best estimate of the effects of face masks. Arguments in favor of the high 70% stress that Jena introduced face masks before any other region did so. It announced face masks as the first region in Germany while in our posttreatment period hardly any other public health measures were introduced or eased. Hence, it provides the most clear-cut quasi-experimental setting for studying its effects. Second, as described in *Method and Data*, Jena is a fairly representative region of Germany in terms of COVID-19 cases. Third, the smaller treatment effects observed in the multiple-treatment analysis may also result from the fact that—by the time that other regions followed the example of Jena—behavioral adjustments in Germany's population had already taken place. Wearing face masks gradually became more common and more and more people started to adopt their usage even when it was not yet required. The results for the subsample of larger cities are, however, quantitatively similar to Jena.

Arguments for the lower 47% state that the stronger impact of face masks on the infectious in Jena may thereby partly be driven by a Hawthorn effect. The population in this pioneer region might have reacted very strongly to the mandatory introduction of face masks by taking the other imposed public health measures and hygiene rules (washing hands, limiting interactions, staying at home more, etc.) more seriously.

Concerning the point in time (or better, the point in the epidemic cycle) when face masks become mandatory, all of our estimates might actually be modest. The daily growth rates in the number of infections when face masks were introduced in Jena was around 2 to 3%. These are low growth rates compared to the early days of the epidemic in Germany, where daily growth rates lay above 50% (20). One might therefore conjecture that the effects might have been even greater if masks had been introduced earlier.

This timing effect might also explain the difference between Jena estimates and lower estimates for other regions. By the time Jena introduced face masks on 6 April, the general trend in development of COVID-19 cases was still relatively dynamic across German regions. In mid-April, when other regions followed the example of Jena and introduced face masks before the general introduction at the federal state level, overall daily growth rates were already lower.

We simultaneously stress the need for further complementary analyses. First, Germany is only one specific country. Different regulations, norms (which relate to compliance), or climatic conditions might change the empirical picture for other countries. Second, we ignored the impact of the number of tests on reported infections. While we do not believe that this matters for Germany as rules for testing are homogenous across regions, this might play a bigger role for international comparisons. Third, we have ignored spatial dependencies in the epidemic diffusion of COVID-19. This might also matter. Fourth, there are various types of face masks. We cannot identify differential effects since mask regulations in German regions do not require a certain type. Finally, economic costs should be taken into account. When we compare masks with other common measures,*** the implied economic costs for community masks seem comparatively low. This applies to disposable masks and reusable nonmedical masks. Yet, the cost of information campaigns should be taken into account. While a detailed cost–benefit analysis is needed, we would expect that a comparison with other policy actions would speak in favor of face masks. [See *SI Appendix*, section E.3 for a brief introduction to the literature. We estimate that costs (of households only) for face masks amount to 1.4 to 2.5% of disposable income.]

Method and Data

Variation in Timing. Six regions in Germany (municipal districts, equivalent to the European Union nomenclature of territorial units for statistics, NUTS, level 3 categorization) made face masks mandatory before their respective federal states. They are displayed in Fig. 5. The figure also shows differences across federal states in the timing of introducing mandatory face masks.

Statistical Method. We estimate treatment effects from introducing face masks by means of the SCM for single and multiple treated units. (All analyses are undertaken in Stata. The corresponding files plus data are available in *SI Appendix*.) The SCM has become increasingly popular for policy evaluations that rely on comparative case studies. The intuition of SCM estimation can briefly be described as follows (see ref. 2–5 and *SI Appendix*, section B for more background).

First, the method can be applied to policy interventions (thereafter treatment) which only target a small number of treated units (in our case, one or a few regions). Treatment effects are identified by comparing the development of outcomes in treated and control regions during the treatment period. For causal inference, the proper selection and weighting of control regions is crucial to credibly estimate what outcome would have been observed in the treated region in the absence of the treatment. To establish this counterfactual, the SCM approach constructs a synthetic control group as weighted average of regions in the donor pool of controls. Weights for individual control regions vary between 0 and 1, sum up to 1 over all control regions, and are determined on the basis of a minimum distance approach. The latter involves a set of predictor variables chosen by the researcher as to closely match the outcome of the treated region prior to the treatment (predictors used here are listed in *SI Appendix*, Table S4 and selected weights for control regions are displayed in *SI Appendix*, Table S5).

Second, statistical significance of the estimated treatment effect is based on permutation. The SCM estimates a series of placebo treatment effects for all regions in the donor pool, that is, each region in the donor pool is treated

***Common measures can be grouped inter alia into closures (of, e.g., restaurants or hotels, educational institutions or clubs, and leisure facilities), contact bans (for individuals, faith groups, or visits to hospitals or retirement homes), and contact rules (social distancing or quarantines after traveling).

STATISTICS

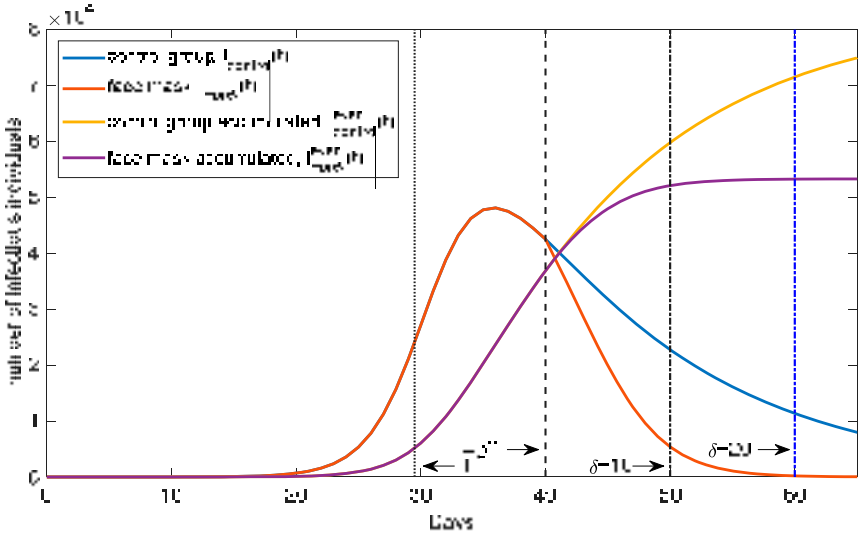

Fig. 6. Theoretical effects of face masks on the number of infectious individuals I(t) and on the accumulated number of infectious individuals I^{ever}(t). The horizontal axis plots time and the vertical axis the number of infectious individuals, both new cases (blue and red curves) and accumulated cases (yellow and purple curves). The curves show time paths following from a standard SIR model. We let an intervention take place on day $T = 29$. After a delay of D^m days, where D^m is the median of the delay between infection and reporting, the effect of the intervention is visible. Waiting 10 or 20 d then allows us to quantify the effect of the intervention.

as if it had been treated. The distribution of placebo effects is then compared with the treatment effect for the treated region. If the magnitude of the latter effect is large relative to the distribution of the placebo effects, the treatment effect is considered not to be observed by chance, that is, it is deemed to be significant.

Third, the effective use of SCM relies on contextual requirements: 1) A donor pool of controls is available, that is, not all regions receive the treatment during the period of the study; 2) predictor values of the treated region are not extreme relative to those of controls, that is, the treated region lies in the convex hull of control regions; 3) data are available for a sufficiently long time horizon before and after the start of the treatment; 4) spillover effects of the treatment on controls are absent; and 5) there are no early anticipation effects. Implications of these requirements for our analysis are discussed in *SI Appendix*, section B and we apply a series of robustness tests to check if the requirements hold in our data settings (reported in *Robustness Checks*).

Finally, as we also employ DiD estimation, we briefly touch upon the relationship between these two approaches. Similar to SCM, the DiD approach estimates treatment effects by contrasting changes in outcomes between a pretreatment and treatment period for treated and nontreated (control) regions. An attractive feature of the DiD approach is its flexibility in estimating dynamic treatment effects, that is, those that build up over time potentially determined by (unobserved) interventions starting at different time periods. (This is the reason why we employed DiD above.) By contrast, DiD has its limits when only one or a few treated regions are available as heteroscedastic errors might occur (see ref. 21). DiD estimation also relies strongly on the validity of the parallel trends assumption: It requires that treated and control regions would have followed parallel trajectories over time if treatment had not occurred. Given the highly dynamic development of regional COVID-19 cases and the likely presence of macroregional trends, the validity of the common trend assumption is questionable in our data settings. For SCM estimation, we do not need to impose this assumption as the presence of common trends between treated and control regions is in itself a favorable factor for finding an appropriate counterfactual trajectory (2, 3, 22).

Data. We use the official German statistics on reported COVID-19 cases from the Robert Koch Institute (23). We build a balanced panel for 401 NUTS level 3 regions and 105 d spanning the period from 28 January to 11 May 2020 (42,105 observations). We use the cumulative number of registered COVID-19 cases in each district and the number of cumulative COVID-19 cases per 100,000 inhabitants as main outcome variables. We estimate overall effects for these variables together with disaggregated effects by age groups (persons aged 15 to 34 y, 35 to 59 y, and 60+ y). We also employ regional data to inter alia identify control regions. *SI Appendix*, Table S4 shows summary statistics.

Face masks are clearly not the only public health measures to mitigate the spread of COVID-19. Identification of the face mask effect therefore needs to take the timing of other public health measures into account. To this end, we built a database for all public health measures in Jena and Thuringia and for face masks in all other federal states. See *SI Appendix*, sections A.1 and A.2 for details. The database indicates that our results indeed capture the effects of face masks and not of other public health measures.

Conceptional Background. To facilitate the interpretation of our findings, we employ a standard SIR model with three states: susceptible, infectious, and removed (see *SI Appendix*, section A.4 for more details.) Imagine we study a region where face masks are not mandatory. The time path $I(t)$ of infections individuals in this (synthetic) control group is displayed in Fig. 6 as $I_{control}$(t). The time path for I^{ever}(t) in the control group is denoted by $I^{ever}_{control}$(t). Now consider the introduction of mandatory face masks at T (set to 29.5 in Fig. 6).[†††] Mandatory masks reduce the infection rate (via a parameter r in the SIR model). Given a (median) delay of D^m between infection and reporting to authorities (estimated at 10.5 d in *SI Appendix*, section A.3), we model this delay by effectively reducing r at $T + D^m$. Hence, as of $T + D^m$, the number of infectious individuals falls faster, see "face masks I_{mask}(t)," and the number of individuals ever infected rises less quickly, as visible when looking at I^{ever}_{mask}(t). Note the qualitative similarity between the yellow and purple curve here and the corresponding curves in Figs. 1*A* and 4 *A* and *B*.

Now imagine we want to quantify the effect of face masks. The model suggests that the effect of face masks can be described by the reduction in the total number of individuals ever infected. As an example, consider time $T + D^m + \delta$, that is, δ days after face masks became effective. The difference between the control region and the face-mask region is given by $I^{ever}_{control}(T + D^m + \delta) - I^{ever}_{mask}(T + D^m + \delta)$. Hence, the introduction of face masks reduced the number of COVID-19 cases by

[†††]We chose $T = 29.5$ as this yields a date when masks show an effect in the data on $T + D^m = 40$ where the epidemic is already beyond its peak in our simple model. This is consistent with Jena, where the incidence had already been declining when face masks became mandatory. Numerical solutions are computed in MATLAB. The code is available in *SI Appendix*.

$$\textit{reduction over } \delta \textit{ days } = \frac{I^{ever}_{control}(T + D^m + \delta) \; - \; I^{ever}_{mask}(T + D^m + \delta)}{I^{ever}_{control}(T + D^m + \delta) \; - \; I^{ever}_{control}(T + D^m)} * 100\%. \quad [1]$$

This equation produces the numbers we report to quantify the effects of face masks. *SI Appendix*, section D.2 describes our measures based on daily growth rates.

Data Availability. Public health data have been deposited in FigShare (https://doi.org/10.6084/m9.figshare.13065920). All study data are included in the paper and *SI Appendix*.

ACKNOWLEDGMENTS. We are grateful for an almost uncountable number of worldwide comments on the earlier version of this paper, from colleagues from many disciplines, public administration, and the general public. They considerably helped in improving this analysis. We would especially like to thank Enikö Bán, Soeren Enkelmann, Jan Franke, Manfred Hempfling, Christof Kuhbandner, Falk Laser, and Philip Savage and two reviewers for their constructive comments. Carolin Kleyer and David Osten provided excellent research assistance. K.W. thanks IZA Institute of Labor Economics. This paper would have never taken this shape without a visiting research position at IZA.

ABSTRACT

Introduction: SARS-CoV-2 is the beta-coronavirus responsible for COVID-19. Facemask use has been qualitatively associated with reduced COVID-19 cases, but no study has quantitatively assessed the impact of government mask mandates (*MM*) on new COVID-19 cases across multiple US States.

Data and Methods: We utilized a non-parametric machine-learning algorithm to test the *a priori* hypothesis that *MM* were associated with reductions in new COVID-19 cases. Publicly available data were used to analyze new COVID-19 cases from 37 States and the District of Columbia (i.e., "38 States"). We conducted confirmatory All-States and State-Wise analyses, validity analyses [e.g., leave-one-out (LOO) and bootstrap resampling], and covariate analyses.

Results: No statistically significant difference in the daily number of new COVID-19 infections was discernable in the All-States analysis. In State-Wise LOO validity analysis, 11 States exhibited reductions in new COVID-19 and the reductions in four of these States (AK, MA, MN, VA) were significant in bootstrap resampling. Only the Social Capital Index predicted *MM* success (training $p<0.028$ and LOO $p<0.013$).

Conclusion: Results obtained when studying the impact of *MM* on COVID-19 cases varies as a function of the heterogeneity of the sample being considered, providing clear evidence of Simpson's Paradox and thus of confounded findings. As such, studies of *MM* effectiveness should be conducted on disaggregated data. Since transmissions occur at the individual rather than at the collective level, additional work is needed to identify optimal social, psychological, environmental, and educational factors which will reduce the spread of SARS-CoV-2 and facilitate *MM* effectiveness across diverse settings.

INTRODUCTION

The significance of respiratory droplets and airborne viral particles in the spread of SARS-CoV-2 and propagation of the COVID-19 pandemic gained early attention.[1] Asymptomatic carriage of SARS-CoV-2 is important to community spread because these individuals can transmit the virus in exhaled breath.[2, 3] Corollary research reported that face masks are protective[4-7] and may limit the severity of COVID-19 among individuals who become infected.[8] Indeed, the Centers for Disease Control and Prevention (CDCP) has advocated wearing a facemask when social isolation is impossible or impractical,[9] and recently reported that dining-out is among the riskiest known activities during the coronavirus pandemic—since face masks *are not used* when people are eating and drinking.[10] Other activities associated with an increased risk of SARS-CoV-2 transmission include singing[11] and aerosol generating procedures in the healthcare setting.[12] Small droplet formation, which can lead to aerosolization of the virus, is a major driver of infection risk,[13] thus wearing a facemask is expected to reduce inhalation of aerosolized virus.[4] Indeed, low rates of positive serology were observed (i.e., < 4% n=1/27) when healthcare workers followed aerosol minimizing procedures *and* used personal protective equipment to perform deep respiratory sampling in patients with COVID-19.[14] Thus, there is consensus in the scientific, clinical, and business communities that appropriate wearing of facemasks is a "best-practice" personal behavior, which can reduce the chances of being infected by, or of infecting others with, SARS-CoV-2 and other airborne disease-causing microbes.

Mathematical and time-series models of COVID-19 data collected in the US investigated salutary effects of masking on reducing the spread of the pandemic.[15, 16] These models suggest that a consistent application of best-practice public-health orders and citizen behaviors is needed to slow the spread of the pandemic.[17] A hybrid modeling approach used by the Institute for Health Metrics and Evaluation predicted that if 95% of people in the US wore masks outside their homes, the number of projected deaths from COVID-19 would drop by half within four months.[18] Thus, experts hypothesize that Mask Mandate

medRxiv preprint doi: https://doi.org/10.1101/2020.10.06.20208033; this version posted October 8, 2020. No reuse allowed without permission.

(*MM*) orders should result in reduced COVID-19 transmission and fatalities—assuming that the individuals in the community adhere to the *MM*.

Encouraged by research findings that wearing masks reduces the number of new COVID-19 cases, and motivated to intervene by increasing numbers of cases, Governors of 37 US States and the District of Columbia (hereafter called the "38 States") issued *MM* orders. However, the lack of clear, consistent Global, Federal, and State guidance on the use of face coverings (e.g., mandates *vs*. recommendations), and on who should be using masks (e.g., essential workers *vs*. private citizens), has initiated a nation-wide naturalistic experiment.[15] In the absence of clear guidance and direct leadership, variations in *MM* acceptance and enforcement have arisen within and between US States.[17, 19-22]

Promulgating and exacerbating confusion regarding the effectiveness of wearing face masks, adjudicating the effectiveness of *MM* orders has largely been left to *qualitative interpretations* and *visual/numerical inspections* of the epidemic curves depicting the number of new cases over time. Qualitative assessment cannot objectively test the *a priori* hypothesis that wearing a mask in public spaces reduces the incidence of COVID-19 cases. Accordingly, using publicly-available data, we employ non-parametric maximum-accuracy machine-learning to *quantitatively* test the confirmatory (*a priori*) hypothesis that imposing a *MM reduced* daily number of new COVID-19 cases in the month *after vs*. *before* the *MM*.

METHODS

Hypotheses

First, merging data from all 38 States in which the Governor issued a *MM*, we test the *a priori* hypothesis that "*All-States*" imposition of a *MM reduced* the daily number of new COVID-19 cases in the month *after vs*. in the month *before* the *MM*. States were included if State leadership (e.g., Governors) had mandated the use of facemasks by all public-facing employees.

Second, considering each State individually, we test the *a priori* hypothesis that "*State-Wise"* imposition of *MM reduced* the daily number of new COVID-19 cases in the month *after vs*. in the month *before* the *MM*.

Data

The daily number of new COVID-19 cases was obtained separately for each State in the month *before* the *MM* was made (maximum of 30 days), and in the month *after* the *MM* was made (maximum of 31 days). Case reports occurring before the *MM* were dummy-coded as class=0, and case reports occurring after the *MM* were coded as class=1. Data from The New York Times, based on reports from State and local health agencies, were initially downloaded from GitHub on August 8, 2020 (data re-confirmed on September 23, 2020)[23] and cross referenced against the COVID-19 State Policy Database (data through June 1, 2020) for dates that *MM* were issued in each State.[24]

Our decision to compare daily number of new cases in the month before *vs*. the month after the *MM* was based on methodological and statistical considerations. First, *MM* orders were made because the day-over-day increases in the number of new cases threatened the ability of available health care resources to meet patient and healthcare worker needs. Therefore, the month following the *MM* naturally offers great opportunity for increased mask wearing to meaningfully reduce the number of new cases. Second, some amount of time is required after the *MM* is made for citizens (who wish to comply) to obtain masks, learn

medRxiv preprint doi: https://doi.org/10.1101/2020.10.06.20208033; this version posted October 8, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

how and when to wear them, and how to care for them, and for new infections occurring in the two-week period prior to the *MM* to develop symptoms after the *MM* was made. Third, to maximize the available statistical power of our analyses for estimating short-term effects (see *Statistical Analysis*), we extracted the number of cases for up to 30 days before and up to 31 days after the *MM* was implemented (yielding a maximum of n=61 data points for each state).

Additional attributes, obtained for individual States, were used in an attempt to discriminate States for which a *MM* did *vs*. did not reduce the number of new COVID-19 cases. Numerical attributes included population estimates,[26] gross domestic product (State and per capita),[27] age (with arbitrary brackets of 0-18, 18-25, 26-34, 35-54, 55-64, and 65+),[28] pre-pandemic (January 2020) number of unemployed persons and rate,[29] homelessness,[30] shelter beds,[31] incarceration number and rate,[32] number of nursing home residents,[33] population density (people per square mile in 2015),[34] urban overcrowding (number of houses having >1 person per room),[35] severe urban overcrowding (number of houses having >1.5 people per room),[35] ethnicity (white, black, and Hispanic categories),[36] Social Capital Index (a measure of social cohesion, where higher positive numbers indicate greater societal cohesion),[37] and obesity.[38] Categorical attributes included if the State's Governor wore a mask in public after the *MM* was made (0=Did not wear mask, 1=wore mask) which was assessed using media reports and public database image searches, the Governor's political party (0=Republican, 1=Democrat),[39] and the Governor's gender (0=Female, 1=Male).[40]

Statistical Analysis

We used confirmatory *O*ptimal *D*iscriminant (or *D*ata) *A*nalysis (ODA) to ascertain the *predictive accuracy* attained by using maximum-accuracy models to evaluate the *hypothesized reduction in the number of new cases* occurring subsequent to the *MM*.[41-43] ODA is the moniker of the statistically-motivated non-parametric machine-learning algorithm which identifies the cut-point for an ordered *attribute* (i.e., "independent variable"), or the assignment rule for a categorical attribute, which yields the

133 *strongest achievable accuracy* in discriminating between two or more class categories (i.e., "dependent
134 variable") for a given sample and hypothesis.[41-43] In the present study all hypotheses were confirmatory.[42]
135 For both the All-States (38-State) and the State-Wise analysis, the *a priori* hypothesis was that the *MM*
136 (up to 31 days) reduced the number of new cases.[44, 45]

137 An ODA model is obtained by iterating through every possible different assignment rule that is consistent
138 with the *a priori* hypothesis, and identifying the model achieving the highest effect strength for sensitivity
139 (ESS) statistic.[41, 42] An index of classification accuracy adjusted to remove the effect of chance, ESS is a
140 function of the mean sensitivity of the model achieved across class categories, standardized such that 0
141 represents the discriminatory accuracy which is expected by chance, 100 represents errorless (perfect)
142 discrimination, and values of $-100 \leq ESS < 0$ represent accuracy which is worse than expected by chance.
143 For a two-category *class variable* such as studied herein (i.e., month before *MM*=class 0 *vs*. month after
144 *MM*=class 1),

145 Mean Classification Accuracy (%) = 100 x [(sensitivity for class 0 + sensitivity for class 1)/2], (1)
146 and
147 ESS = 100 x [(Mean Classification Accuracy–50)/50]. (2)

148 A nonparametric permutation test which requires no distributional assumptions is used to assess the
149 statistical significance (p value) of the achieved ESS.[41, 44, 45] Point estimates of p values for tests of
150 statistical hypotheses reported herein are indicated as being statistically significant ($p \leq 0.05$) at either the
151 *experimentwise* (confirmatory $p \leq p_{Bonferroni}$) or the *per-comparison* (confirmatory $p \leq 0.05$) criterion.[42]

152 Internal model validation was conducted using bootstrap resampling[46, 47] (n=25,000) of the State-Wise
153 models within the *ODA* package for R.[48] Specifically, resampling with 50% replacement was conducted
154 using the LOO (i.e., validity) ODA model confusion matrix for each State. Exact discrete 95% confidence
155 intervals (CI) for the given ODA model ("Model") and for randomly scrambled observations from the

model ("Chance") were obtained.[46] Graphical depictions of new cases organized across days, and histograms of bootstrapped 95% CIs, were created using *ggplot2* for R.[49]

Potential generalizability of the ODA model applied to classify an independent random sample is assessed using a one-sample "leave-one-out" (LOO) jackknife analysis.[42] The sample size offers greater than 90% power to identify an ODA model of moderate strength (i.e., 25≤ESS<50).[50]

Exploratory ODA analyses were conducted to model the association of inter-State differences 28 variables (e.g., age, wealth, population density) conceivably capable of discriminating States which did *vs*. did not exhibit the predicted decline in number of new cases in the month following a *MM* (see *Data Supplement*).[42]

Sensitivity analyses were conducted comparing the initial data (obtained August 8, 2020) to the data obtained September 23, 2020. The percentage difference between the two datasets were calculated for each value [i.e., 100 x ($data_{new}$-$data_{old}$) / $data_{old}$] to quantify differences between datasets. In sensitivity analyses, any differences between datasets were compared according to the ODA model cut-points obtained using the initial data to determine whether the model was invariant to new (updated) data.

RESULTS

All-States Analysis

The *mean* number of new COVID-19 cases before *vs*. after the *MM* for the sample of 38 States was 654 (N=1138, SD=1357) *vs*. 639 (N=1177, SD=975), respectively. In three instances, the daily report of new cases appeared to be outliers (GA 4/12/20, LA 5/29/20, and VA 5/6/20) and were coded as missing (i.e., coded as -999). Confirmatory ODA was used to test the *a priori* hypothesis that imposition of a *MM* reduced the *number* of new COVID-19 cases (the attribute) one-month *after vs*. one-month *before* the *MM* (the class variable). The confirmatory ODA model was: if >4 new cases-per-day then predict pre-*MM*; otherwise if ≤4 new cases-per-day, then predict post-*MM*. In training (using all observations from the sample) analysis, this model correctly classified 98.1% of the pre-*MM* cases, and 6.1% of the post-*MM* cases: ESS=4.1 (a weak effect), $p<0.13$.

Thus, when considering all 38 States having a *MM* as a single sample, there was no statistically significant difference in the daily number of new COVID-19 infections in the month before *vs*. the month after the *MM*.

State-Wise Analysis

As seen in Table 1, after the *MM* the *mean* number of new daily cases was numerically *lower* in 13 States (AK, GA, HI, LA, MA, MI, MN, NY, VA, VT, WA, WV, WY) post-*MM*, and numerically *higher* in the remaining 25 States. Table 2 gives the findings of ODA used to test the *a priori* hypothesis that State-Wise imposition of a *MM* (made by 38 different State Governors) *reduced the number of new COVID-19 cases* in the month *after vs*. in the month *before* the *MM*—with each State considered individually. In each State-Wise analysis, the class variable was a binary coded variable signifying the period before *vs*. after the *MM* occurred, and the attribute was the daily number of new cases. In Table 2, the States are ordered from strongest to weakest ESS of the confirmatory ODA model in training analysis.

193 Among all 38 States, training data for Minnesota (MN, the first State in Table 2) offer the greatest support
194 for the *a priori* hypothesis. The ODA model is: if >480 new cases-per-day, then predict pre-*MM*;
195 otherwise if ≤480 cases-per-day, then predict post-*MM*. This ODA model correctly classified 28 of 30
196 (93.3%) of the pre-*MM* days, and 27 of 31 (87.1%) of the post-*MM* days, thereby yielding a *strong*[42]
197 ESS=80.4, $p<0.0001$. However, this model showed modest instability in LOO jackknife analysis
198 (*relatively strong*[42] ESS=73.9, $p<0.0001$). In contrast, data for Alaska (AK, second row in Table 2) had
199 the second-strongest training effect (*strong* ESS=80.3, $p<0.0001$), which was stable in LOO analysis.
200 Among all 38 States, only AK returned a *strong* confirmation of the *a priori* hypothesis in training and
201 LOO analysis.

202 Of the total of 38 States included in this study, 11 (23.7%) achieved confirmatory $p<0.05$ at the
203 experimentwise criterion, and two (5.3%) achieved confirmatory $p<0.05$ at the per-comparison criterion[42]
204 (Table 2). Three States (MN, AK, HI) yielded a training model indicating a *strong* confirmation[42] (i.e.,
205 ESS≥75) of the *a priori* hypothesis. Five States (MA, VT, VA, MI, NY) yielded a training model
206 indicating a *relatively strong* confirmation[42] (i.e., 50≤ESS<75). And, three States (LA, WA, WY) yielded
207 a training model indicating a *moderate* confirmation[42] (i.e., 25≤ESS<50) of the *a priori* hypothesis.

208 Except for GA and WY, States having a numerically greater *mean* number of new daily cases pre- *vs.*
209 post-*MM* (Table 1) also had statistically-significant (at either the experimentwise or the per-comparison
210 criterion[42]) confirmatory (Table 2) and LOO (Table 3) ODA models supporting the *a priori* hypothesis.

211 For all 11 States in Table 2 having training $p<0.05$, Table 3 presents 95% exact discrete CIs obtained for
212 model and for chance.[46] For AK, VA, MA, and MN, the *lower bound* of the 95% exact discrete CI *for*
213 *model* is greater than the *upper bound* of the 95% exact discrete CI *for chance*—therefore the result is
214 statistically significant. For the remaining seven States, the upper bound for chance exceeded the lower
215 bound for the model, so the result was not statistically significant in bootstrap validity analysis.

medRxiv preprint doi: https://doi.org/10.1101/2020.10.06.20208033; this version posted October 8, 2020. For example, the daily number of new COVID-19 cases one-month pre- and one-month post-*MM* is illustrated in Figure 1.A for MN. Figure 1.B is a graphical summary of the model and chance bootstrap results: the blue histogram represents chance, the red histogram represents the model, the Y axis is frequency of the result in the Bootstrap analysis, and the X axis is training ESS. The dashed vertical lines inside the Figure represent the lower 95% CI for the model (red dashes), and the upper 95% CI for chance (blue dashes). When the blue dashes are on the same side as the blue histogram, and the red dashes are on the same side as the red histogram, the effect is statistically significant. Thus, evaluating MN in training analysis, the *a priori* hypothesis is accepted with experimentwise $p<0.05$.

In contrast, Figure 2.A presents the daily number of new COVID-19 cases one-month pre- and one-month post-*MM* for WA, and Figure 2.B is a graphical summary of the model and chance bootstrap results. Since the blue dashes are on the side of the red histogram, and the red dashes are on the side of the blue histogram, the hypothesized effect is not statistically significant for WA.

Modeling Success *vs*. Failure of a *MM* Order in Reducing the Number of New COVID-19 Cases

Finally, ODA was used to discriminate the four States (AK, MA, MN, VA) having a significantly lower number of new cases after the *MM vs*. the 34 States which did not support the *a priori* hypothesis. The only attribute which met the per-comparison criterion for statistical significance[42] was SCI, a measure of societal cohesion and the closeness of social ties.[51] The ODA model was: if SCI≤0.311, then predict the *MM did not reduce* the number of new cases of COVID-19; otherwise if SCI>0.311 then predict the *MM reduced* the number of new cases. In training ($p<0.028$) and LOO ($p<0.013$) analysis this model correctly classified all four States in which the *MM* reduced the number of new cases, and 25 of 35 (71.43%) States in which the *MM* failed to reduce the number of new cases. This level of classification accuracy corresponds to ESS=71.43, indicating a relatively strong effect.[42]

Sensitivity analyses

medRxiv preprint doi: https://doi.org/10.1101/2020.10.06.20208033; this version posted October 8, 2020. DISCUSSION

An *All-States* analysis was conducted using merged data for 38 US States. Results indicated *no statistically significant decrease* in the number of new daily COVID-19 cases in the month before *vs*. after the *MM* was made. In contradistinction, a *State-Wise* analysis identified *clear evidence of State-specific MM effectiveness in reducing the number of new cases within one month of enactment* for multiple States (Tables 2 and 3). Such clear inconsistency is attributable to improper analysis of merged samples creating an analytic anomaly called *Simpson's Paradox*—which may identify spurious relationships, may fail to identify actual relationships, and/or may over- or under-weight the strength of effects—in every area of quantitative empirical science.[42, 47] *Paradoxical confounding* exists when the finding obtained by statistical analysis conducted for a combined sample is different than the finding obtained by the same analysis conducted separately for the constituent samples.[52] In the setting of a public health emergency, such as the current pandemic, accurate knowledge of the effectiveness of public health interventions is essential so that public health authorities can communicate this to the public.

Combining disparate groups is the primary operating procedure in government, scientific, and media discussions about the number of new and cumulative daily, monthly, and total number of COVID-19 cases and fatalities. Examples of such combined groups include global (the maximum-possible combined group), regional (e.g., the northern hemisphere), continental (e.g., Europe, Africa), and country (e.g., China, US, India, Brazil, France, UK, Israel) daily and cumulative case counts.[53] However, disparities in regional increases in numbers of new cases prompted some analysts to issue a warning against focusing on National trends.[54] Findings presented herein—that four of 38 (10.5%) States reliably demonstrated the hypothesized reduction in number of new cases in the month after the *MM* was made—similarly suggest a warning against focusing on State trends. Cognizance of the need to combine groups in a manner that prevents invalid statistical conclusions begs the question of how small must a "catchment area" be to count new cases so as to prohibit paradoxical confounding. Unfortunately, it has been shown that Simpson's Paradox can even occur for single-subject, "N-of-1" designs.[55] Thus, while accurate case

medRxiv preprint doi: https://doi.org/10.1101/2020.10.06.20208033; this version posted October 8, 2020. counts and definitions are important for tracking the epidemiology of the pandemic, such measures do not necessarily reflect the "reality on the ground" in any specific community, nor can they reliably discern the individual effectiveness of public health interventions.

The current methodology of conducting after-the-fact pandemic accounting for convenient and familiar (statistically unmotivated) groups is obviously inadequate when it is considered from a problem-solving perspective that focuses on getting (and staying) ahead of the pandemic curve. Others have argued, early in the pandemic, that rapid and comprehensive contact tracing will empower understanding of the situations and the processes underlying new COVID-19 infections.[56] As is the case in fighting a wildfire, progress is made by going to the active location each day, extinguishing blazes, and reducing available fuel, rather than by assessing the number of acres which burned the day before. However, contact tracing is most effective when community spread is low, so multifaceted interventions are needed to control the spread of the pandemic and presently wearing a mask is the most efficacious known means of slowing the pandemic.[5, 6, 8, 15, 16]

Temporal counts of the number of new cases are an imprecise measure—including the month-over-month methodology used presently—for multiple reasons. Even with perfect *MM* compliance, there is an up to 14-day lag time between infection and presentation of symptoms, and potentially an even longer lag between infection and presentation at a healthcare facility. After a *MM* order is made, there are logistical problems in getting masks to people, and there is a learning curve for users—where, when and how to wear and care for masks. *MM* compliance is imperfect, and enforcement is difficult. Indeed, individual *MM* compliance is expected to be heterogeneous based on experimental evidence from behavioral psychology. Individuals are susceptible to cognitive biases and often use heuristics to address complex problems when uncertainty is high. Examples of such biases and heuristics related to *MM* use include availability bias (e.g., knowing someone who is sick *vs.* not), anchoring bias (e.g., fixation on initial recommendations to avoid mask use to preserve PPE), and substitution heuristics (e.g., physical

medRxiv preprint doi: https://doi.org/10.1101/2020.10.06.20208033; this version posted October 8, 2020. discomfort with wearing a mask is substituted for mask efficacy).[57] The impact of these and other biases and heuristics on mask effectiveness is currently understudied.

Because transmissions occur at the level of the individual, rather than at a State or National level, governments should emphasize best-practice personal behaviors, adequate contact tracing, and minimization of high-risk exposures. Indeed, we posit that the efficacy of mask wearing is not at question as this depends only on the use of the mask. Instead, the effectiveness of *MM* can be eroded by multiple factors including asymptomatic carriage, willful ignorance of *MM* and lack of knowledge of how and when to wear masks. Moreover, our State-Wise analysis supports the *a priori* hypothesis that *MM* do indeed have a significant salutary effect on the spread of the pandemic, but more work is needed to define the social, psychological, environmental, and educational facilitators that maximize *MM* effectiveness.

Experimentally speaking, the best test of public health intervention effectiveness (e.g., *MM*)—using a methodology called an "A (before intervention), B (after intervention)" design—would involve simultaneous uniform application, enforcement, and education around the intervention, coupled with exacting real-time contact-tracing. A science-based, consistent approach to disease management could reduce public misunderstanding in this realm, and diminish mistrust of the other public health interventions (e.g., vaccines currently under development).[58] Our analysis is limited because we were not able to utilize a rigorous AB analytic framework to test our *a priori* hypotheses. Rather, we took advantage of the naturalistic experiment created by the heterogeneous response to the pandemic across States to highlight the paradoxical results obtained when applying an All-States followed by a State-Wise analytic approach. Our analysis was limited to testing our *a priori* hypothesis and it is worth considering the time-dependent impact of *MM*. Additional work is needed to evaluate the impact of *MM* on the growth of the pandemic. Our analysis is conservative in that we focused only on reductions in new cases and may underestimate the true impact of *MM*. Future studies should evaluate the impact of MM on new deaths. Large-scale serological studies may provide more insights into the spread of SARS-CoV-2 *MM* in States with vs. those without early *MM*.

medRxiv preprint doi: https://doi.org/10.1101/2020.10.06.20208033; this version posted October 8, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

Finally, we found that SCI, a measure of social closeness and ties,[51] was a relatively strong predictor of *MM* effectiveness. This finding is notable in that SCI could be a facilitating factor that makes mandated public health interventions more efficient. For example, populations with higher levels of social cohesion are inherently more likely to work together when faced with a common problem based on a shared sense of identity and social bonds. However, this finding has limitations. States with higher SCI should not be interpreted as being inherently better at reducing new SARS-CoV-2 cases, but rather we believe this finding also supports a new corollary hypothesis that States with lower SCI may require different and multifaceted interventions to address the pandemic.

CONCLUSION

We identified paradoxical confounding whereby the effect of *MM* orders when analyzed using the pooled data from all 38 States available differed when compared to a State-Wise analysis. Overemphasis placed on National or State-level trends may obscure the true effectiveness of important public health interventions such as mask wearing, because transmission events are stochastic and occur at the level of individuals. Thus, greater emphasis on the impact of personal behaviors on *MM* effectiveness and thorough contact tracing are needed to combat the pandemic. While societal factors reflected by measures like the SCI may facilitate the efficiency of interventions like *MM* in select regions, more work is needed to define the optimal set of interventions that reduce SARS-CoV-2 transmission for socially diverse populations. Finally, optimal experimental designs, measurements, and analytic approaches are needed to provide the public with a clearer understanding of the evolution of the pandemic, and feedback on how current public health interventions are performing, in order to begin to restore broad-based trust in the scientific method.

CA	>2315 Cases	2/30 (6.7)	≤2315 Cases	21/31 (67.7)	0.99	-25.6	0.99	-32.2

Footnotes: a) Sensitivity gives the results for the predicted (numerator) and the actual (denominator) number of new cases after *MM*. b) Specificity gives the results for predicted (numerator) and actual (denominator) number of new cases before *MM*. c) ODA models explicitly maximize classification (i.e., predictive) accuracy adjusted for chance, which is assessed

medRxiv preprint doi: https://doi.org/10.1101/2020.10.06.20208033; this version posted October 8, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

by the effect strength for sensitivity (ESS) statistic: ESS=0 is the accuracy expected by chance; ESS<25 is a relatively weak effect; ESS<50 is a moderate effect; ESS<75 is a relatively strong effect; ESS<90 is a strong effect; and -100≤ESS<0 is accuracy which is worse than expected by chance. In this column, MN has a training model with an ESS that provides the strongest support for the *a priori* hypothesis and is statistically significant whereas CA has a training model that provides the least support for this hypothesis and is not significant. d) Classification performance in validity analysis was computed using a one-sample leave-one-out (LOO) jackknife validity assessment. In this column, AK has a validity model with an ESS that provides the strongest support for the *a priori* hypothesis and is statistically significant whereas ME has a validity model that provides the least support for this hypothesis and is not significant.

Table 3: LOO Confirmatory *p*, and Bootstrap 95% CI for LOO ESS, for 11 States Demonstrating Mask Mandate (*MM*) Effectiveness vis-à-vis Training $p<0.05$

State	$p <$	Chance 95% CI[a]	Model 95% CI[a]	95% CI overlap[b]
AK	0.0001	-36.1 – 35.9	64.6 – 100	No
VA	0.0001	-35.8 – 35.9	49.9 – 100	No
MA	0.0001	-35.0 – 34.8	41.7 – 92.9	No
MN	0.0001	-35.9 – 36.1	40.3 – 95.2	No
HI	0.0001	-36.1 – 35.9	34.9 – 91.7	Yes
VT	0.0001	-35.7 – 34.9	30.3 – 86.7	Yes
NY	0.0001	-36.1 – 35.8	25.5 – 86.1	Yes
LA	0.0037	-34.8 – 35.7	25.0 – 84.6	Yes
MI	0.0001	-35.8 – 36.1	11.1 – 76.6	Yes
WA	0.0028	-34.4 – 35.0	0.00 – 68.4	Yes
WY	0.04	-33.3 – 33.5	-10.1 – 58.3	Yes

Footnotes: a) Exact Discrete 95% Confidence Intervals (CIs) for Model and Chance ESS were estimated using bootstrap resampling of the ODA model confusion matrix from each respective State obtained in LOO analysis. b) For a given State, if the upper bound (UB) of the CI for chance falls *beneath* the lower bound (LB) of the CI for the model, this column indicates NO 95% CI overlap—so the confirmatory hypothesis is *accepted* (i.e., the *MM* reduced the number of new cases). And, for a given State, if the UB of the CI for chance falls *above* the LB of the CI for the model, this column indicates YES 95% CI overlap—so the confirmatory hypothesis is *rejected* (i.e., the *MM* did not reduce the number of new cases). In other words, if the exact discrete CIs for model and chance do not overlap, then the ODA model identified in LOO analysis is considered statistically robust and the findings are likely to be generalizable.

Summary. The role of complete lockdowns in reducing the reproduction ratios (R_t) of COVID-19 is now established. However, the persisting reality in many countries is no longer a complete lockdown, but restrictions of varying degrees using different choices of Non-pharmaceutical interaction (NPI) policies. A scientific basis for understanding the effectiveness of these graded NPI policies in reducing the R_t is urgently needed to address the concerns on personal liberties and economic activities. In this work, we develop a systematic relation between the degrees of NPIs implemented by the 26 cantons in Switzerland during March 9 – September 13 and their respective contributions to the R_t. Using a machine learning framework, we find that R_t which should ideally be lower than 1.0, has significant contributions in the post-lockdown scenario from the different activities - restaurants (0.0523 (CI. 0.0517-0.0528)), bars (0.030 (CI. 0.029-0.030)), and nightclubs (0.154 (CI. 0.154-0.156)). Activities which keep the land-borders open (0.177 (CI. 0.175-0.178)), and tourism related activities contributed comparably 0.177 (CI. 0.175-0.178). However, international flights with a quarantine did not add further to the R_t of the cantons. The requirement of masks in public transport and secondary schools contributed to an overall 0.025 (CI. 0.018-0.030) reduction in R_t, compared to the baseline usage even when there are no mandates. Although causal relations are not guaranteed by the model framework, it nevertheless provides a fine-grained justification for the relative merits of choice and the degree of the NPIs and a data-driven strategy for mitigating R_t.

1. Introduction.

COVID-19 has caused over a million deaths, and many millions of infections globally. Despite the intense global efforts, there is no scalable treatment or vaccine yet. This problem is compounded by the fact that the epidemiology of COVID-19 is very unique [2] and that it spreads efficiently, with an estimated 44% [3] to 69% [4] of the transmissions before the onset of symptoms. Non-pharmaceutical interventions (NPI) have been the only successful method of mitigating the spread of infections [5-7]. In addition to the initial recommendations on social-distancing and sanitizing, complete lockdowns and restricted opening of businesses had been implemented in various degrees. There have been several demonstrations of the effectiveness of the lockdowns in successfully reducing the reproduction ratio (R_t) and mitigating the spread of COVID-19 [8-11].

NPIs performing a balancing act. The goal of NPIs is to flatten the infection curve [12] until there is a change in the infection landscape due to a scalable vaccine, therapeutic intervention, or a mutation in the virus which reduces the case fatality rate. However, since NPIs affect both personal liberties and economic welfare, it is important to know the effectiveness of the different NPIs for evidence-based public health planning. The impact of the two extremes of the NPI spectrum [8-11], no restrictive measures and a complete lockdown are relatively easy to understand. However, many policies changes, such as the compulsory use of masks, different degrees of opening of the restaurants or bars have been applied simultaneously, and it has not been easy to quantify the effectiveness of the contributions from these different factors. To the best of our knowledge, there have not been any examples of deciphering the contributions of the policies to the R_t.

In this work, we apply a recently developed formalism [13] to decipher the role of the different NPI policies adopted by Switzerland. Until April, Switzerland had the highest per-capita COVID-19 infections globally, however Switzerland could open up most of its activities staring May. During May-July period, the number daily new infections was less than 100, and it was followed by increasing infections as well as tightening of regulations. The few cases together with an efficient infrastructure for contact tracing [14] helped isolate all potentially infected persons, and helped in mitigating the spread of infections. However, as the daily new cases crossed 1,000 the fears that the efficiency of the contact tracing are reaching the limits begins to resound. Further, another complicated aspect of the epidemiology of COVID-19 has been that the infections need not always be attributable to a symptomatic person. The ability to understand the overall impact of an NPI policy on the overall infections, which implicitly includes the secondary infections, asymptomatic transmissions is thus needed and is the focus of the present article.

2. Results.

2.1 Relating the policies to reproduction ratios

2.1.1 Determinants - NPI Policy data.

To perform a quantitative analysis, the different degrees of non-pharmaceutical intervention policies were curated and codified. Media reports published in english language were used for this curation and the policies were cross-checked with the official press releases of the Federal and Cantonal authorities. The following codes were employed:

medRxiv preprint doi: https://doi.org/10.1101/2020.10.11.20210641; this version posted October 14, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

- *BarbersSalonSpa*: Everything closed (0), Beauty salons, Barbers shops etc allowed to operate with the stipulated norms (1), Pre-lockdown level (2)
- *Bars*: Closed (0), Opened with limited capacity and restrictions on standing customers (1), Opened with full capacity while respecting social distancing (2), Pre-lockdown level (3)
- *Mask*: No mask requirement (0), Mask usage is mandatory in public transport (1), Mask usage is mandatory in shops (2)
- *Nightclubs and Discos*: Closed (0), Opened with contact tracing and checking the ID or with a limited audience of 50 to 100 (1), Opened with an audience of over 100 up to 300 (2), Pre-lockdown level (3)
- *Restaurants*: Closed (0), Takeaway only (1), restaurant occupancy limited to 50 (2), restaurant occupancy of 100 (3), Unrestricted but respecting social distancing (4), Pre-lockdown level (5)
- *Retail*: All non-essentials closed (0), Opening do-it stores (1), Opening all retail stores (2), Pre-lockdown level (3)
- *Schools*. Closed (0), Open with mask-requirements on pupils in all secondary-schools or when the distance between pupils is less than 2.25 meters (1), Open with no mask-requirements
- *Tourism potential.* The number of hotel rooms available in the cantons, invariable with time. This can be a surrogate for the general mobility and associated economic activity in the regions
- *Travel restrictions*: All travel from outside Switzerland is restricted (0), Travel by road to the cantons having a road-entry to Schengen countries is opened (1), In addition to the road travel from Schengen countries, International travel is permitted with a quarantine requirement upon arrival (2)

In this work we use the NPIs and R_t's with the resolution of a week [15]. Each NPI policy code was assumed to be the same for an entire week starting from Monday to Sunday. The data was applied over 26 weeks between March 9 to September 13. Several exceptional cases have not been included in the choice of the policy variables. Manufacturing was shutdown specifically in the early lockdown phase in Ticino (TI) canton. The states in USA had two major differences – "stay at home" versus "safe at home". The Swiss policies reflected more the latter, and unlike some states of USA or Italy had not restricted outdoor activities. Hence the permission for outdoor activities was not included in the analysis.

2.1.2 Consequences - Reproduction rates (R_t).

Time varying reproduction rate, R_t ($=\alpha_t/\gamma$) was estimated using the rates of transmission (α_t) and recovery from the infection (γ). The infected and recovered data was obtained from *https://www.corona-data.ch/*. We estimated the average recovery time in for Switzerland to be around 14 days, and $\gamma=1/14$. Using the number of active infections (I_{active}), and the number of daily new infections on a given day (dI/dt), the weekly averaged transmission rates were calculated as, $\alpha_t=\langle 1/I_{active} . (dI/dt)\rangle$.

2.1.3 Model - Interpretable Artificial Intelligence.

Our goal is to develop a model relating the controlling NPIs and the consequent reproduction ratios by a model, and to understand the relative contributions of the NPIs to the R_t. The NPIs of any week are assumed to affect the reproduction rate in the following week. To not restrict the model to linearity and maintain the generality, we used an artificial intelligence model. The data from 26 weeks and 26 cantons used, with 20% for testing and 80% for training. A 5-fold cross validation was used to further validate the results. The daily rates, their weekly averages α_t and how they change over the weeks is illustrated in Figure 2 and demonstrates a dynamic scenario.

The artificial intelligence (AI) model was developed using the *XGBoost* library in Python. 80% of the complete data set was used as the training set and 20% as the test set. The parameters for the AI model (*learning_rate*=0.08, *n_estimators*=525, *max_depth*=7, *min_child_weight*=5, *gamma*=0, *subsample*=0.85, *colsample_bytree*=0.75, *reg_alpha*=1) were obtained using *RandomizedSearchCV*. With these parameters, the predictions of the reproduction rates for the Cantons were good as shown in Table 1. Each model's

medRxiv preprint doi: https://doi.org/10.1101/2020.10.11.20210641; this version posted October 14, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

predictive ability is evaluated using a 5-fold cross-validation analysis and the best set of parameters is selected based on the average of mean squared error for the validation sets. The quality of prediction seemed to be robust against changes in the training set as shown by the 5-fold cross-validation analysis.

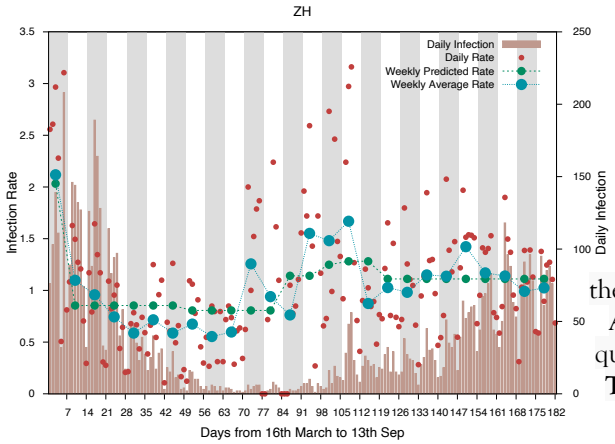

Figure 1. Comparing the observations and estimations from Zurich canton. The number of daily infection cases, the daily instantaneous R_t, and its weekly average are shown. Also shown is the R_t predicted using our AI model. The quality of predictions for the different cantons are shown in **Table 1**.

Table 1. Quality of predictions for the cantons. The co-efficient of determination R^2 is used as a metric to understand if the model results, including training and test, compare well with the R_t estimates. The results are good when the number of cases recorded were more than 1000. The uncertainties in both the estimation of R_t from the epidemiological data, and the predictions using a model are both expected when the number of infections are fewer.

2.2 Decoupling the contributions from the different NPIs.

2.2.1 Interpretable AI for relative contributions

We performed a retrospective analysis to understand the relation between the different non-pharmaceutical interventions policies imposed by each canton in every week between March 9 to September 13, which we codified as discussed above, and the reproduction ratios (R_t). To decouple the relative contributions from the individual NPIs to each of the weekly predictions, we post-processed the results of our AI model using an interpretable AI framework based on SHapley Adaptive exPlanation (SHAP) [16]. A Python implementation of SHAP (https://github.com/slundberg/shap) was used for our interpretable AI analyses. The SHAP analyses was repeated with a 5-Fold Cross-Validation and the variances were found to be minimal. The role of many NPIs with significant contributions to R_t are discussed below.

medRxiv preprint doi: https://doi.org/10.1101/2020.10.11.20210641; this version posted October 14, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY-NC-ND 4.0 International license .

2.2.2 Dine and drink.

The contributions to R_t from the different graded openings of the restaurants is shown in Figure 2A. The x-axis represents the different grades of opening of the restaurants: restaurants are closed (0), open with up to 50 clients (2), open with up to 100 clients (3), unrestricted clientele but following social distancing norms (4), pre-lockdown level (5). The restaurant-component to R_t from the predictions for the 26 cantons and 26 weeks (y-axis) is organized by the restaurant opening degree and displayed. The color of these points was used to represent the overall R_t in that canton in that week. The data shows a clear pattern of increasing contributions to the R_t from the increasing degrees of restaurant openings. Leaving the pre-lockdown conditions (code 5), which lacked sanitization, social-distancing measures, the maximum R_t one can expect because of opening restaurants at level 4 relative to a complete closure is 0.0523 (CI. 0.0517-0.0528). Similar analysis shows that different graded openings of the bars (Figure 2B) between a full opening of the bars (code 2) a complete closure (code 0) contribute 0.030 (CI. 0.029-0.030) to R_t. Nightclubs (Figure 2C) with more than 100 clients allowed (code 3) contributes 0.154 (CI. 0.154-0.156) to the R_t relative to their complete closure, and is the only case in all of our analysis where the R_t contribution is comparable to the contributions from the pre-lockdown period.

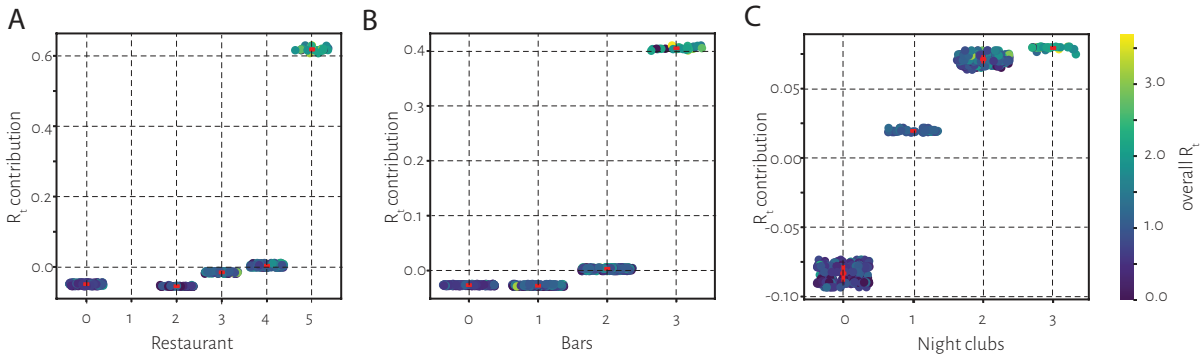

Figure 2. Impact of restrictive measures on dine and drink. The contributions to the R_t from the different restrictive policies for operating *A.* Restaurants *B.* Bars and *C.* Nightclubs are shown. Each point in the three graphs represents the contribution to the R_t from a specific week in one of the 26 cantons, and the colorbar represents the value of the R_t. In all three graphs, 0 on the x-axis represents the complete closure, and the highest value the pre-lockdown operational levels. The red lines indicate the confidence interval in each category.

2.2.3 Travel and tourism.

In March, Switzerland had closed entry access via road to Schengen countries as well as via air travel. Starting from mid-June, the road access to Schengen countries was opened (code 1 for cantons sharing borders with neighboring countries) and air-travel was permitted with a quarantine requirement upon arrival (code 2 for cantons with international airports). The contributions to R_t from this ease-of-access descriptor shown in Figure 3A, shows an additional R_t of 0.177 (CI. 0.175-0.178) due to opening of the land-borders. The international air-travel with a quarantine requirement did not contribute any further to the R_t. An additional factor that was included in the analysis was the tourism potential quantified by the number of hotel rooms in the canton, which of course remains constant during the 26 weeks of analysis. The variable contributed 0.179 (CI. 0.172-0.187) to the R_t. The tourism potential is neither the actual number of travels made in this year, nor an NPI policy, but a factor which remained a constant for each canton. However, given the magnitude of its contribution, it requires an interpretation, possibly of the surrogate it represents. Specifically, the cantons JU (code 102), AR (code 122) which have lower number of hotels are near the borders and have a high cross-border commuter traffic which is probably being captured in the analysis.

medRxiv preprint doi: https://doi.org/10.1101/2020.10.11.20210641; this version posted October 14, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY-NC-ND 4.0 International license .

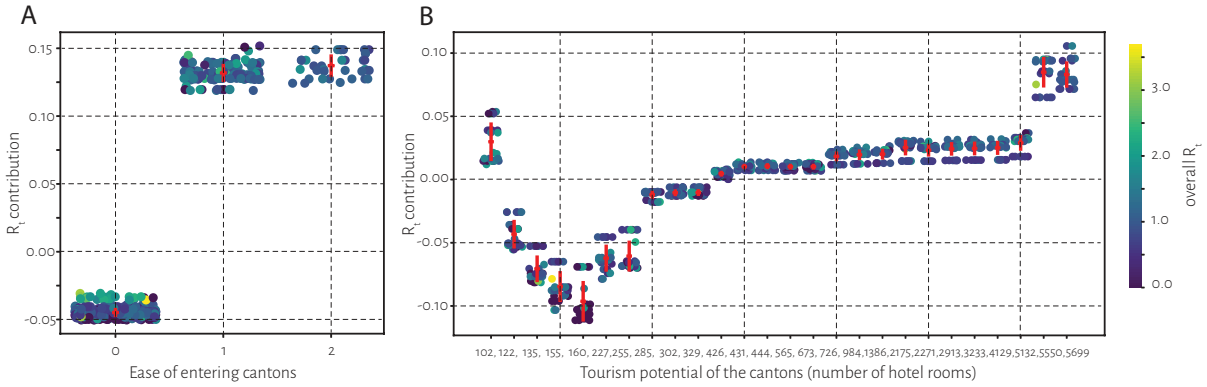

Figure 3. Impact of mobility. The contributions to R_t depending on *A.* the ease of entering the cantons by road or air travel where the codes 0 – no travel allowed, 1 – opening of Schengen borders, 2 – opening of international airports with quarantine on travelers were applied and *B.* Tourism potential, represented by the number of hotel rooms in the different cantons are indicated. The non-intuitive higher contributions to R_t in cantons with lower tourism potential, can be understood by the borders they share with other Schengen countries. At this moment, because of the lack of access to the actual travel data within Switzerland, it is not easy to infer whether this pattern is due to the commuters or domestic tourism.

2.2.4 Mask requirements.

Swiss Federal government made the use of masks in all public transport mandatory (code 1) since July 6. In subsequent weeks, many cantons made the use of a mask to enter the shops (code 2) compulsory. Compared to the no-mask requirement from the pre-lockdown period, a mandatory mask in public transport contributed to a reduction of 0.0139 (CI. 0.0132-0.0144) (Figure 4A). An additional requirement of using the masks in the shops when a requirement in public transport is already mandated (code 2) did not reduce R_t further. The use of mask in secondary schools was also made compulsory in some cantons (code 1), and its additional benefit relative to a scenario with schools not requiring masks (code 2) could be seen in Figure 4B. A reduction of R_t 0.011 (CI. 0.008-0.0127) was estimated because of the use of the masks in school. The combined effect of the use of mask in public transport and at schools is thus a reduction in R_t of 0.025 (CI. 0.018-0.030). It must be noted that the compliance in general may be different from the policy itself, where more people use the mask even if there is no recommendation. This will lead to underestimation of the beneficial effects of the use of the mask.

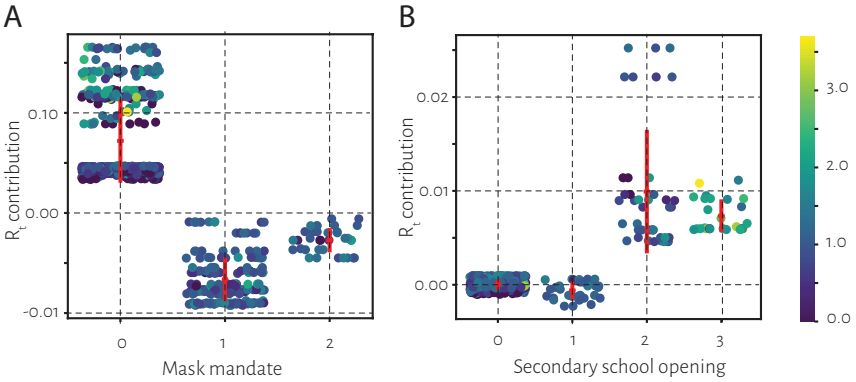

Figure 4. Impact of mask mandates. The mask imposition in *A.* public transport (code 1) and shops (code 2) and *B.* secondary schools (code1), and no-mask restrictions in schools (code 2) are compared. In both the settings the role of imposing a mask is clear.

3. Discussion

3.1 First estimates for the measure of effectiveness of individual NPIs.

Epidemiological scenario calculations forecast the number of infections and critical-care requirements for the various R_t's which are in-turn influenced by the NPIs. With an objective to understand how the different NPIs influence the reproduction ratios, the present work addresses the interesting and practically relevant zone between the extremes of a complete lockdown and no restrictions whose role on R_t is obvious. The present work attempts to decipher the contribution of each individual NPI

medRxiv preprint doi: https://doi.org/10.1101/2020.10.11.20210641; this version posted October 14, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY-NC-ND 4.0 International license .

implemented at a certain degree of restrictiveness. To the best of our knowledge there has been no precedence on the decomposition of the effectiveness of the different NPIs.

If we consider a mask mandate, there is no evidence for its effectiveness other than referring to the widespread use of masks in the Asian countries where the R_t's have been low. The efficacy of masks in reducing aerosol transmission under laboratory conditions [17] are cited as alternative evidences, although their relevance for real scenarios of mask usage in daily life and the impact on the transmission of the disease rather than aerosols is not clear. Our work which interprets what happened in real-life mask usage in public transport and in schools contributed to the reduction R_t is a better reflection of how the NPI policies affected COVID-19 transmission. These theoretical inferences for the individual NPI effectiveness are important as it is not easy to design randomized control trials which study each of the individual policies [18].

3.2 Overall effectiveness including all implicit transmissions.

Switzerland had employed a very efficient contact tracing system [14] which had identified several clusters of infections arising in different business interactions or in social contexts. However, the overall transmissions also include secondary transmissions or via asymptomatic persons, which may not be traced easily. Further, beyond a certain number of daily cases the infrastructure may not support efficient contact tracing. The method we propose here, while may appear redundant when the number of daily infections are few and contact tracing is efficient, will maintain its validity by identifying all potential downstream infections including those by asymptomatics. Although the method will not be helpful in identifying or isolating the infected, it can in principle quantify the impact of NPIs even when the contact-tracing is limited.

3.2 Non-causal impact of NPIs.

While we underscore the importance of decoupling the contributions using AI in this work, or alternatively by any other model, we also understand that these relations do not necessarily imply causality. The SHAP method identifies the best way of assigning the contributions to the different factors, in each individual prediction, but may not interpreted as causal. Despite this lacuna, the interpretable AI formulation of SHAP designed with the intent of creating "controllable knobs" which can be tuned to achieve the desirable result can be a helpful guide for the "evidence-based" or "data-driven" [19] NPI policies.

3.3 Bringing epidemiology and policy-making together using AI.

Our work integrates three different perspectives which attempt to understand the mitigation of COVID-19. Policy experts quantify the "stringency" of the Government policies to understand if the response is adequate [20], however, those studies typically do not quantify the consequences of the policies making a discussion on adequacy irrelevant. Epidemiological scenario studies discuss various scenarios of how the critical care requirements are for different possible the reproduction rates, and underscore the importance of maintaining lower reproduction rates without providing a prescription for how it can be achieved. Artificial intelligence has been used to make forecasts, such as predictions of the peaks. However, the predictions hold meaning for a shorter time until either the Government policy or behavioral patterns change. Thus, without addressing the root cause which is the relation between the NPIs and the reproduction ratios, the predictions lose relevance very quickly. In our work we attempt to bring together the policy principles, epidemiological interest in R_t, within the framework of AI to achieve this evidence for the effectiveness of the different NPI policies.

3.4 Learning from data and moving forward.

As the "new-normal" with COVID-19 appears to last long, it is important to understand the relative effectiveness of different NPIs for prioritizing them. For example, as per our analysis, and given the behavioral patterns until September, the effectiveness of keeping the borders closed is comparable to the

medRxiv preprint doi: https://doi.org/10.1101/2020.10.11.20210641; this version posted October 14, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY-NC-ND 4.0 International license .

effectiveness of restricting the nightclubs. However, their impacts on the overall society and economy may be completely different and can be weighed in other studies. The model is a first attempt at identifying the contributions of the different NPIs to the R_t. However, with time more data and considering newer scenarios such as seasonal changes, variable compliances to the NPIs, the model can be trained better. The model should be a living-model, which is regularly updated for reflecting the scenarios better.

4. Conclusions.

As the COVID-19 pandemic continues to persist for foreseeable future, drastic complete lockdowns may not be a sustainable option. The need for tailored and evidence-based non-pharmaceutical intervention policies which achieve an optimal balance between effectiveness in mitigation and inconvenience in other spheres requires an understanding of the effectiveness of individual policies. The model developed here for deciphering the individual contributions of the various simultaneously imposed non-pharmaceutical intervention policies to the time varying reproduction ratio is a first attempt for such understanding. While the model has to be constantly updated to stay relevant, it paves the possibility for an evidence-based or data-driven policy making where educated, scientifically justifiable and impactful choice of the non-pharmaceutical interventions can be made.

Author contributions. CKS, MRB performed the machine learning calculations; MRB, HJ, BS extracted the epidemiological data and performed analyses of rates; CKS, MRB, HJ, BS, MKP analyzed the results; MKP conceived the project, curated the data on government policies and wrote the paper;

Association of County-Wide Mask Ordinances with Reductions in Daily CoVID-19 Incident Case Growth in a Midwestern Region Over 12 Weeks

Enbal Shacham, PhD,[1] Stephen Scroggins, MSc, [1,3] Matthew Ellis, PhD(c), MPE; [1] Alexander Garza, MD, MPH[2]

[2]SSM Health, St. Louis, MO

[3]Sinquefield Center for Applied Economic Research, Saint Louis University

Abstract

Importance: This study assessed the longitudinal impact of new COVID-19 cases when a mask ordinance was implemented in 2 of a 5-county Midwestern U.S. metropolitan region over a 3-month period of time. Reduction in case growth was significant and reduced infection inequities by race and population density.

Objective: The objective of this study was to assess the impact that a mandatory mask wearing requirement had on the rate of COVID-19 infections by comparing counties with a mandatory policy with those neighboring counties without a mandatory masking policy.

Design: This was a quasi-experimental longitudinal study conducted over the period of June 12-September 25, 2020.

Setting: This study was a population-based study. Data were abstracted from local health department reports of COVID-19 cases.

Participants: Raw cases reported to the county health departments and abstracted for this study; census-level data were synthesized to address county-level population, income and race.

Intervention(s) (for clinical trials) or Exposure(s) (for observational studies): The essential features of this intervention was an instituted mask mandate that occurred in St. Louis City and St. Louis County over a 12 week period.

Main Outcome(s) and Measure(s): The primary study outcome measurement was daily COVID-19 infection growth rate. The mask mandate was hypothesized to lower daily infection growth rate.

Results: Over the 15-week period, the average daily percent growth of reported COVID-19 cases across all five counties was 1.81% (±1.62%). The average daily percent growth in incident COVID-19 cases was similar between M+ and M- counties in the 3 weeks prior to implementation of mandatory mask policies (0.90% [±0.68] vs. 1.27% [±1.23%], respectively, p=0.269). Crude modeling with a difference-in-difference indicator showed that after 3 weeks of mask mandate implementation, M+ counties had a daily percent COVID-19 growth rate that was 1.32 times lower, or a 32% decrease. At 12 weeks post-mask policy implementation, the average daily COVID-19 case growth among M- was 2.42% (±1.92), and was significantly higher than the average daily COVID case growth among M+ counties (1.36% (±0.96%)) (p<0.001). A significant negative association was identified among counties between percent

medRxiv preprint doi: https://doi.org/10.1101/2020.10.28.20221705; this version posted November 20, 2020. No reuse allowed without permission.

growth of COVID-19 cases and percent racial minorities per county ($p<0.001$), as well as population density ($p<0.001$).

Conclusions and Relevance: These data demonstrate that county-level mask mandates were associated with significantly lower incident COVID-19 case growth over time, compared to neighboring counties that did not implement a mask mandate. The results highlight the swiftness of how a mask ordinance can impact the trajectory of infection rate growth. Another notable finding was that following implementation of mask mandates, the disparity of infection rate by race and population density was no longer significant, suggesting that regional-level policies can not only slow the spread of COVID-19, but simultaneously create more equal environment.

Key Points

Question: How are local mask ordinances associated with growth of COVID-19 cases among adjacent counties?

Findings: Ecological longitudinal analysis reveals a significant slowing of daily COVID-19 case growth after mask ordinance implementation among counties.

Meaning: Local-level policy of mask ordinances are shown to be an effective COVID-19 mitigation strategy even within locations of diverse populations.

Introduction

COVID-19 has claimed over 210,000 lives in the U.S.[1] While urgent policies have been implemented to reduce COVID-19 infections throughout the pandemic, there has been significant variability across state and local governments. In particular, due to the difficulty in maintaining social distancing guidelines and in an attempt to allow the economy to recover by opening businesses, some elected officials have issued mask mandates for the public to reduce COVID-19 transmission. Research has demonstrated the effectiveness of masks in preventing the spread of infectious diseases through airborne droplets,[2] yet the majority of a community would need to be masked in order to reduce infection rates. Several governors have avoided state-level mandates by rationalizing that within-state variations of COVID-19 infection rates call for more localized public health policymaking than state-wide orders.[3]

While studies found mask policies to be effective in reducing infection growth rates early in the pandemic, there is an urgent need to know how the impact of such policy persists over time; in addition, the impact on unequal infection rates such as higher rates reported among African-American/Black and Hispanic/Latinx populations.[1] Mask wearing has transitioned to a politically nuanced behavior, and this has been particularly true in the region surrounding the Midwestern city of St. Louis, providing a natural experiment to understand the longitudinal impact of a variable mask mandate policies has on county-level changes in incident CoVID-19 rates over a 12-week period.

Methods

This ecological study evaluated the effects of a public mask mandate on the daily cumulative case growth of COVID-19 infections among five neighboring counties within the metropolitan statistical area of Saint Louis, Missouri: City of St. Louis, St. Louis County, Jefferson County, Saint Charles County, and Franklin County. The study period included a three-week period prior

medRxiv preprint doi: https://doi.org/10.1101/2020.10.28.20221705; this version posted November 20, 2020. No reuse allowed without permission.

to the implementation of a mandatory mask order in St. Louis City and County on July 3, 2020, and a 12-week post-implementation period, for a total of 15 weeks.

Outcome of Interest

The primary outcome of interest was the cumulative daily percent change of reported COVID-19 cases by county. Daily incident COVID-19 cases were sourced from publicly available data provided by the Missouri Department of Health and Senior Services.

Primary Predictor and Covariates

Presence of a mask ordinance was the primary predictor of interest. Among the five counties, two implemented a mask ordinance during the study period for individuals entering public indoor spaces; the City and County of Saint Louis[4] (M+), with three counties having no such mandate during the study period (M-).

As COVID-19 infections occur more often among areas with higher county-level population density per square mile, higher proportion of residents identifying as non-white, and lower median annual household income,[25,6] these variables were included from the 2018, 5-year American Community Survey to control for variations in COVID-19 case growth.

Statistical Analysis

Data were constructed with daily percent changes in COVID-19 cases as a function of time (daily) and location (county), with 530 unique observations from June 12, 2020 to September 25, 2020. The average percent change in cases per day was calculated across M+ and M- counties to understand the pattern of COVID-19 growth throughout the study period. Kendal's tau-b rank correlation test was employed to identify associations among county-level demographics and percent daily growth of COVID-19 cases.

medRxiv preprint doi: https://doi.org/10.1101/2020.10.28.20221705; this version posted November 20, 2020. A difference-in-difference (DID) framework was employed to evaluate the effect of mask ordinances on percent daily growth in COVID-19 prevalence. Specific to this study, a DID estimator (δ) was calculated using binary dummy variables for both treatment (M+ or M-) at time (prior to mask ordinance implementation and after implementation). The calculated DID estimator was then applied to a linear probability model to determine the effects of a mask ordinance on COVID-19 case growth. Four adjusted models were constructed, accounting for county-level characteristics, each at 3 week intervals past the implementation date.

Statistical analyses were completed using R 4.0 software with significance determined at $\alpha = 0.05$.

Results

Over the 15-week period, the average daily percent growth of reported COVID-19 cases across all five counties was 1.81%(±1.62%). A total of 44,294 cases were reported throughout this period among a total estimated population of just over 2,000,000 residents, which is approximately one-third of the population within the state of Missouri.

The average daily percent growth in incident COVID-19 cases was similar between M+ and M- counties in the 3 weeks prior to implementation of mandatory mask policies (0.90%[±0.68] vs. 1.27%[±1.23%], respectively, p=0.269) (Figure 1). Prior to the mandate implementation a there was no association between percent growth of COVID-19 cases and percent racial minorities, population density, nor median income per county.

At 12 weeks post-implementation, the average daily COVID-19 case growth among M- was 2.42%(±1.92), significantly higher than the average daily COVID case growth among M+ counties (1.36%[±0.96%], p<0.001).

In adjusted linear probability models (Table 1), the mask mandate was found to be significantly associated with slowing the reported growth of daily COVID-19 cases across the study period.

medRxiv preprint doi: https://doi.org/10.1101/2020.10.28.20221705; this version posted November 20, 2020. From 3 weeks pre-policy to 3 weeks post-policy, M+ counties had a daily average COVID-19 growth rate of 44% less than M- counties (1.08/2.44). At week 6, 9, and 12 assessments, modeling revealed a continuing significant reduction in COVID-19 cases in counties with mask mandates. From pre-policy to 12 weeks post-policy (Figure 2), M+ counties had a daily average COVID-19 growth rate of 40% less than of M- counties (0.47/1.16). Using the DID linear probability equation, a counterfactual line is estimated, indicating probable growth of counties with mask mandate had a mask mandate not been implemented. Within the adjusted models, accounting for the DID estimator, proportion non-white population and population density were negatively associated with increased daily growth rate, yet median income did not contribute significantly to any of the calculated models.

Discussion

This longitudinal study demonstrates that the implementation of county-level mask mandates lowered incident COVID-19 case growth over time, compared to neighboring counties with no such mask mandate. Importantly, the results highlight the swiftness of such impact, with significant effects seen at just 3 weeks post-implementation. As time progressed, this impact was slightly reduced, possibly due to the arbitrary political borders of counties and states, which do not necessarily constrain transmission as mobility across mask mandate and non-mandated regions occurs. Although broader state or national mandatory mask ordinances would likely have a significant reduction in COVID-19 infections, in their absence, support for governors and elected officials to minimize the interactions across these borders may be beneficial.

Furthermore, implementation of a mask mandate may have reduced the unequal burden on African American/Black and Hispanic/Latinx individuals, as well as areas with higher population density. COVID-19 has highlighted the impact and swiftness of racial and ethnic inequities through higher rates of COVID-19 morbidity and mortality among non-white communities. In particular, many individuals were unable to abide by stay-at-home orders that protected middle

and high-income communities as a result of “essential” employment in grocery stores, health care support positions, and public transportation. These jobs, often lacking PPE and paid sick leave, are more often filled by people of color, living in higher population density and lower socioeconomic areas.[7] The mask policy that was enacted in many communities may have provided a more equal approach to reducing COVID-19 infections, as it occurred in St. Louis, Missouri.

ABSTRACT

The paper evaluates the dynamic impact of various policies adopted by US states on the growth rates of confirmed Covid-19 cases and deaths as well as social distancing behavior measured by Google Mobility Reports, where we take into consideration people's voluntarily behavioral response to new information of transmission risks in a causal structural model framework. Our analysis finds that both policies and information on transmission risks are important determinants of Covid-19 cases and deaths and shows that a change in policies explains a large fraction of observed changes in social distancing behavior. Our main counterfactual experiments suggest that nationally mandating face masks for employees early in the pandemic could have reduced the weekly growth rate of cases and deaths by more than 10 percentage points in late April and could have led to as much as 19 to 47 percent less deaths nationally by the end of May, which roughly translates into 19 to 47 thousand saved lives. We also find that, without stay-at-home orders, cases would have been larger by 6 to 63 percent and without business closures, cases would have been larger by 17 to 78 percent. We find considerable uncertainty over the effects of school closures due to lack of cross-sectional variation; we could not robustly rule out either large or small effects. Overall, substantial declines in growth rates are attributable to private behavioral response, but policies played an important role as well. We also carry out sensitivity analyses to find neighborhoods of the models under which the results hold robustly: the results on mask policies appear to be much more robust than the results on business closures and stay-at-home orders. Finally, we stress that our study is observational and therefore should be interpreted with great caution. From a completely agnostic point of view, our findings uncover predictive effects (association) of observed policies and behavioral changes on future health outcomes, controlling for informational and other confounding variables.

1. Introduction

Accumulating evidence suggests that various policies in the US have reduced social interactions and slowed down the growth of Covid-19 infections.[1] An important outstanding issue, however, is how much of the observed slow down in the spread is attributable to the effect of policies as opposed to a voluntarily change in people's behavior out of fear of being infected. This question is critical for evaluating the effectiveness of restrictive policies in the US relative to an

alternative policy of just providing recommendations and information such as the one adopted by Sweden. More generally, understanding people's dynamic behavioral response to policies and information is indispensable for properly evaluating the effect of policies on the spread of Covid-19.

This paper quantitatively assesses the impact of various policies adopted by US states on the spread of Covid-19, such as non-essential business closure and mandatory face masks, paying particular attention to how people adjust their behavior in response to policies as well as new information on cases and deaths.

We present a conceptual framework that spells out the causal structure on how the Covid-19 spread is dynamically determined by policies and human behavior. Our approach explicitly recognizes that policies not only directly affect the spread of Covid-19 (e.g., mask requirement) but also indirectly affect its spread by changing people's behavior (e.g., stay-at-home order). It also recognizes that people react to new information on Covid-19 cases and deaths and voluntarily adjust their behavior (e.g., voluntary social distancing and hand washing) even without any policy in place. Our causal model provides a framework to quantitatively decompose the growth of Covid-19 cases and deaths into three components: (1) direct policy effect, (2) policy effect through behavior, and (3) direct behavior effect in response to new information.

Guided by the causal model, our empirical analysis examines how the weekly growth rates of confirmed Covid-19 cases and deaths are determined by (the lags of) policies and behavior using US state-level data. To examine how policies and information affect people's behavior, we also regress social distancing measures on policy and information variables. Our regression specification for case and death growths is explicitly guided by a SIR model although our causal approach does not hinge on the validity of a SIR model.

As policy variables, we consider mandatory face masks for employees in public businesses, stay-at-home orders (or shelter-in-place orders), closure of K-12 schools, closure of restaurants except take out, closure of movie theaters, and closure of non-essential businesses. Our behavior variables are four mobility measures that capture the intensity of visits to "transit", "grocery", "retail", and "workplaces" from Google Mobility Reports. We take the lagged growth rate of cases and deaths and the log of lagged cases and deaths at both the state-level and the national-level as our measures of information on infection risks that affects people's behavior. We also consider the growth rate of tests, month dummies, and state-level characteristics (e.g., population size and total area) as confounders that have to be controlled for in order to identify the causal relationship between policy/behavior and the growth rate of cases and deaths.

Our key findings from regression analysis are as follows. We find that both policies and information on past cases and deaths are important determinants of people's social distancing behavior, where policy effects explain more than 50% of the observed decline in the four behavior variables.[2] Our estimates suggest that there are both large policy effects and large behavioral effects on the growth of cases and deaths. Except for mandatory masks, the effect of policies on cases and deaths is indirectly materialized through their impact on behavior; the effect of mandatory mask policy is direct without affecting behavior.

Using the estimated model, we evaluate the dynamic impact of the following three counterfactual policies on Covid-19 cases and deaths: (1) mandating face masks, (2) allowing all businesses to open, and (3) not implementing a stay-at-home order. The counterfactual experiments show a large impact of those policies on the number of cases and deaths. They also highlight the importance of voluntary behavioral response to infection risks when evaluating the dynamic policy effects.

Our estimates imply that nationally implementing mandatory face masks for employees in public businesses on March 14th would have reduced the growth rate of cases and that of deaths by approximately 10 percentage points in late April. As shown in Fig. 1, this leads to reductions of 21% and 34% in cumulative reported cases and deaths, respectively, by the end of May with 90 percent confidence intervals of [9, 32]% and [19, 47]%, which roughly implies that 34 thousand lives could have been saved. This finding is significant: given this potentially large benefit of reducing the spread of Covid-19, mandating masks is an attractive policy instrument especially because it involves relatively little economic disruption. These estimates contribute to the ongoing efforts towards designing approaches to minimize risks from reopening (Stock, 2020b).

Fig. 2 illustrates how never closing any businesses (no movie theater closure, no non-essential business closure, and no closure of restaurants except take-out) could have affected cases and deaths. We estimate that business shutdowns have roughly the same impact on growth rates as mask mandates, albeit with more uncertainty. The point estimates indicate that keeping all businesses open could have increased cumulative cases and deaths by 40% at the end of May (with 90 percent confidence intervals of [17, 78]% for cases and [1, 97]% for deaths).

Fig. 3 shows that stay-at-home orders had effects of similar magnitude as business closures. No stay-at-home orders could have led to 37% more cases by the start of June with a 90 percent confidence interval given by 6% to 63%. The estimated effect of no stay-at-home orders on deaths is a slightly smaller with a 90 percent confidence interval of −7% to 50%.

We also conducted sensitivity analysis with respect to changes to our regression specification, sample selection, methodology, and assumptions about delays between policy changes and changes in recorded cases. In particular, we examined whether certain effect sizes can be ruled out by various more flexible models or by using alternative timing assumptions that define forward growth rates. The impact of mask mandates is more robustly and more precisely estimated than that of business closure policies or stay-at-home orders, and an undesirable effect of increasing the weekly

[2] The behavior accounts for the other half. This is in line with theoretical study by Gitmez et al. (2020) that investigates the role of private behavior and negative external effects for individual decisions over policy compliance as well as information acquisition during pandemics.

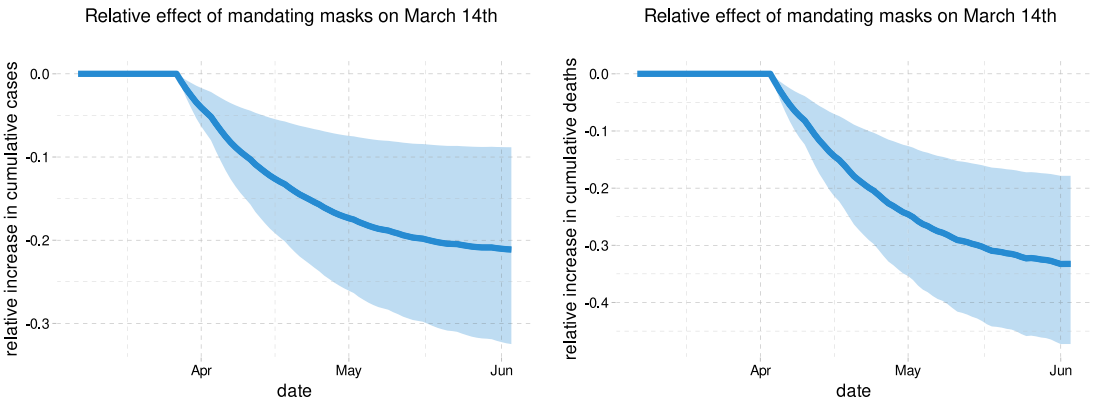

Fig. 1. Relative cumulative effect on confirmed cases and fatalities of nationally mandating masks for employees on March 14th in the US. This figure shows the estimated relative change in cumulative cases and deaths if all states had mandated masks on March 14th. The thick blue line is the estimated change in cumulative cases or deaths relative to the observed number of cases or deaths. The shaded region is a pointwise 90% confidence band.

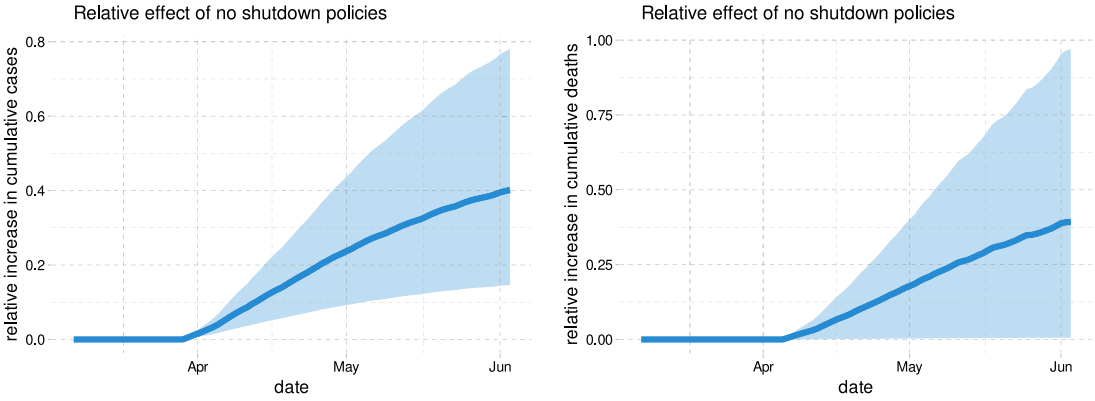

Fig. 2. Relative cumulative effect of no business closure policies on cases and fatalities in the US. This figure shows the estimated relative change in cases and deaths if no states had ever implemented any business closure policies. The thick blue line is the estimated change in cumulative cases or deaths relative to the observed number of cumulative cases or deaths. The shaded region is a pointwise 90% confidence band.

death growth by 5 percentage points is ruled out by all of the models we consider.[3] This is largely due to the greater variation in the timing of mask mandates across states. The findings of shelter-in-place and business closures policies are considerably less robust. For example, for stay-at-home mandates, models with alternative timing and richer specification for information set suggested smaller effects. Albeit after application of machine learning tools to reduce dimensionality, the range of effects $[0, 0.15]$ could not be ruled out. A similar wide range of effects could not be ruled out for business closures.

We also examine the impact of school closures. Unfortunately, there is very little variation across states in the timing of school closures. Across robustness specifications, we obtain point estimates of the effect of school closures as low as 0 and as high as -0.6. In particular, we find that the results are sensitive to whether the number of past national cases/deaths is included in a specification or not. This highlights the uncertainty regarding the impact of some policies versus private behavioral responses to information.

A growing number of other papers have examined the link between non-pharmaceutical interventions and Covid-19 cases.[4] Hsiang et al. (2020) estimate the effect of policies on the growth rate of cases using data from the United States, China, Iran, Italy, France, and South Korea. In the United States, they find that the combined effect of all policies they consider on the growth rate is -0.347 (0.061). Courtemanche et al. (2020) use US county level data to analyze the effect of interventions on case growth rates. They find that the combination of policies they study reduced growth rates by 9.1

[3] This null hypothesis can be generated by looking at the meta-evidence from RCTs on the efficacy of masks in preventing other respiratory cold-like deceases. Falsely rejecting this null is costly in terms of potential loss of life, and so it is a reasonable null choice for the mask policy from decision-theoretic point of view.

[4] We refer the reader to Avery et al. (2020) for a comprehensive review of a larger body of work researching Covid-19; here we focus on few quintessential comparisons on our work with other works that we are aware of.

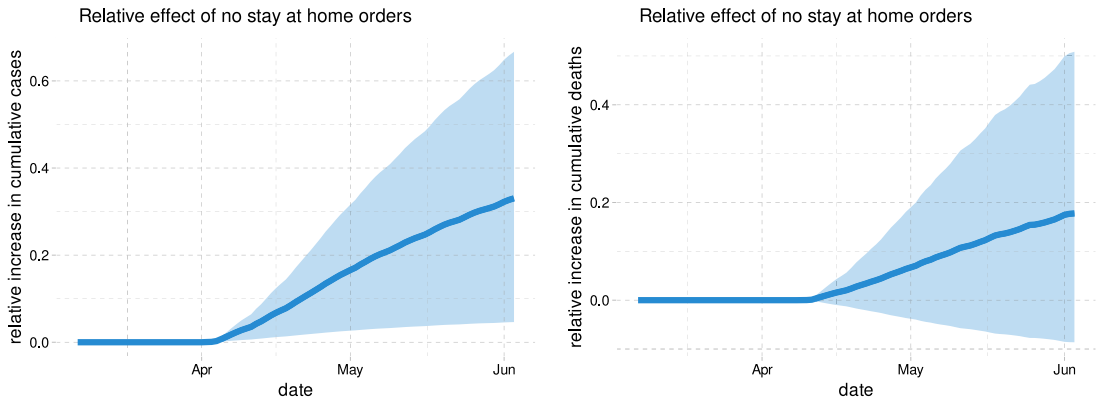

Fig. 3. Relative cumulative effect of not implementing stay-at-home order on cases and fatalities in the US. This figure shows the estimated relative change in cases and deaths if no states had ever issued stay at home orders. The thick blue line is the estimated change in cumulative cases or deaths relative to the observed number of cumulative cases or deaths. The shaded region is a point wise 90% confidence band.

percentage points 16–20 days after implementation, out of which 5.9 percentage points are attributable to shelter in place orders. Both Hsiang et al. (2020) and Courtemanche et al. (2020) adopt a reduced-form approach to estimate the total policy effect on case growth without using any social distancing behavior measures.[5]

Existing evidence for the impact of social distancing policies on behavior in the US is mixed. Abouk and Heydari (2020) employ a difference-in-differences methodology to find that statewide stay-at-home orders have strong causal impacts on reducing social interactions. In contrast, using data from Google Mobility Reports, Maloney and Taskin (2020) find that the increase in social distancing is largely voluntary and driven by information.[6] Another study by Gupta et al. (2020) also found little evidence that stay-at-home mandates induced distancing by using mobility measures from PlaceIQ and SafeGraph. Using data from SafeGraph, Andersen (2020) shows that there has been substantial voluntary social distancing but also provide evidence that mandatory measures such as stay-at-home orders have been effective at reducing the frequency of visits outside of one's home.

Pei et al. (2020) use county-level observations of reported infections and deaths in conjunction with mobility data from SafeGraph to conduct simulation of implementing all policies 1–2 weeks earlier and found that it would have resulted in reducing the number of cases and deaths by more than half. However, their study does not explicitly analyze how policies are related to the effective reproduction numbers.

Epidemiologists use model simulations to predict how cases and deaths evolve for the purpose of policy recommendation. As reviewed by Avery et al. (2020), there exists substantial uncertainty about the values of key epidemiological parameters (see also Atkeson, 2020a; Stock, 2020a). Simulations are often done under strong assumptions about the impact of social distancing policies without connecting to the relevant data (e.g., Ferguson et al., 2020). Furthermore, simulated models do not take into account that people may limit their contact with other people in response to higher transmission risks.[7] When such a voluntary behavioral response is ignored, simulations would necessarily exhibit exponential spread and over-predict cases and deaths. In contrast, as cases and deaths rise, a voluntary behavioral response may possibly reduce the effective reproduction number below 1, potentially preventing exponential spread. Our counterfactual experiments illustrate the importance of this voluntary behavioral change.

Whether wearing masks in public place should be mandatory or not has been one of the most contested policy issues with health authorities of different countries providing contradictory recommendations. Reviewing evidence, Greenhalgh et al. (2020) recognize that there is no randomized controlled trial evidence for the effectiveness of face masks, but they state "indirect evidence exists to support the argument for the public wearing masks in the Covid-19 pandemic".[8] Howard et al. (2020) also review available medical evidence and conclude that "mask wearing reduces the transmissibility per contact by reducing transmission of infected droplets in both laboratory and clinical contexts". The laboratory findings in Hou et al. (2020) suggest that the nasal cavity may be the initial site of infection followed by aspiration to the lung, supporting the argument "for the widespread use of masks to prevent aerosol, large droplet, and/or mechanical exposure

5 Using a synthetic control approach, Cho (2020) finds that the cases would have been lower by 75 percent had Sweden adopted stricter lockdown policies.

6 Specifically, they find that of the 60 percentage point drop in workplace intensity, 40 percentage points can be explained by changes in information as proxied by case numbers, while roughly 8 percentage points can be explained by policy changes.

7 See Atkeson (2020b) and Stock (2020a) for the implications of the SIR model for Covid-19 in the US. Fernández-Villaverde and Jones (2020) estimate a SIRD model in which time-varying reproduction numbers depend on the daily deaths to capture feedback from daily deaths to future behavior and infections.

8 The virus remains viable in the air for several hours, for which surgical masks may be effective. Also, a substantial fraction of individual who are infected become infectious before showing symptom onset.

to the nasal passages". He et al. (2020) examined temporal patterns of viral shedding in COVID-19 patients and found the highest viral load at the time of symptom onset; this suggests that a significant portion of transmission may have occurred before symptom onset and that universal face masks may be an effective control measure to reduce transmission.[9] Ollila et al. (2020) provide a meta-analysis of randomized controlled trials of non-surgical face masks in preventing viral respiratory infections in non-hospital and non-household settings, finding that face masks decreased infections across all five studies they reviewed.[10]

Given the lack of experimental evidence on the effect of masks in the context of COVID-19, conducting observational studies is useful and important. To the best of our knowledge, our paper is the first empirical study that shows the effectiveness of mask mandates on reducing the spread of Covid-19 by analyzing the US state-level data. This finding corroborates and is complementary to the medical observational evidence in Howard et al. (2020). Analyzing mitigation measures in New York, Wuhan, and Italy, Zhang et al. (2020b) conclude that mandatory face coverings substantially reduced infections. Abaluck et al. (2020) find that the growth rates of cases and of deaths in countries with pre-existing norms that sick people should wear masks are lower by 8 to 10% than those rates in countries with no pre-existing mask norms.[11] The Institute for Health Metrics and Evaluation at the University of Washington assesses that, if 95% of the people in the US were to start wearing masks from early August of 2020, 66,000 lives would be saved by December 2020 (IHME, 2020), which is largely consistent with our results. Our finding is also independently corroborated by a completely different causal methodology based on synthetic control using German data in Mitze et al. (2020).[12]

Our empirical results contribute to informing the economic-epidemiological models that combine economic models with variants of SIR models to evaluate the efficiency of various economic policies aimed at the gradual "reopening" of various sectors of economy.[13] For example, the estimated effects of masks, stay-home mandates, and various other policies on behavior, and of behavior on infection can serve as useful inputs and validation checks in the calibrated macro, sectoral, and micro models (see, e.g., Alvarez et al., 2020; Baqaee et al., 2020; Fernández-Villaverde and Jones, 2020; Acemoglu et al., 2020; Keppo et al., 2020; McAdams, 2020 and references therein). Furthermore, the causal framework developed in this paper could be applicable, with appropriate extensions, to the impact of policies on economic outcomes replacing health outcomes (see, e.g., Chetty et al., 2020; Coibion et al., 2020).

Finally, our causal model is framed using the language of structural equations models and causal diagrams of econometrics (Wright, 1928; Haavelmo, 1944; Tinbergen, 1940; Wold, 1954; Pearl, 1995) and genetics (Wright, 1923),[14] with natural unfolding potential/structural outcomes representation (Rubin, 1974; Tinbergen, 1930; Neyman, 1925; Imbens and Rubin, 2015). The work on causal graphs has been modernized and developed by Pearl (1995), Greenland et al. (1999), Pearl (2009), Pearl and Mackenzie (2018) and many others (e.g., Pearl and Mackenzie, 2018; White and Chalak, 2009; Robins et al., 2020; Peters et al., 2017; Bareinboim et al., 2020; Hernán and Robins, 2020), with applications in computer science, genetics, epidemiology, and econometrics (see, e.g., Heckman and Pinto, 2013; Hünermund and Bareinboim, 2019; White and Chalak, 2009 for applications in econometrics). The particular causal diagram we use has several "mediation" components, where variables affect outcomes directly and indirectly through other variables called mediators; these structures go back at least to Wright (1923, see Figure 6); see, e.g., Baron and Kenny (1986), Hines et al. (2020), Robins et al. (2020) for modern treatments.

2. The causal model for the effect of policies, behavior, and information on growth of infection

2.1. The causal model and its structural equation form

We introduce our approach through the Wright-style causal diagram shown in Fig. 4. The diagram describes how policies, behavior, and information interact together:

- The *forward* health outcome, $Y_{i,t+\ell}$, is determined last, after all other variables have been determined;
- The adopted policies, P_{it}, affect health outcome $Y_{i,t+\ell}$ either directly, or indirectly by altering human behavior B_{it};

9 Lee et al. (2020a) find evidence that viral loads in asymptomatic patients are similar to those in symptomatic patients. Aerosol transmission of viruses may occur through aerosols particles released during breathing and speaking by asymptomatic infected individuals; masks reduce such airborne transmission (Prather et al., 2020). Anfinrud et al. (2020) provide visual evidence of speech-generated droplet as well as the effectiveness of cloth masks to reduce the emission of droplets. Chu et al. (2020) conduct a meta-analysis of observational studies on transmission of the viruses that cause COVID-19 and related diseases and find the effectiveness of mask use for reducing transmission.

10 Whether wearing masks creates a false sense of security and leads to decrease in social distancing is also a hotly debated topic. A randomized field experiment in Berlin, Germany, conducted by Seres et al. (2020) finds that wearing masks actually increases social distancing, providing no evidence that mandatory masks leads to decrease in social distancing.

11 Miyazawa and Kaneko (2020) find that country's COVID-19 death rates are negatively associated with mask wearing rates.

12 Our study was first released in ArXiv on May 28, 2020 whereas Mitze et al. (2020) was released at SSRN on June 8, 2020.

13 Adda (2016) analyzes the effect of policies reducing interpersonal contacts such as school closures or the closure of public transportation networks on the spread of influenza, gastroenteritis, and chickenpox using high frequency data from France.

14 The father and son, P. Wright (economist) and S. Wright (geneticist) collaborated to develop structural equation models and causal path diagrams; P. Wright's key work represented supply–demand system as a directed acyclical graph and established its identification using exclusion restrictions on instrumental variables. We view our work as following this classical tradition.

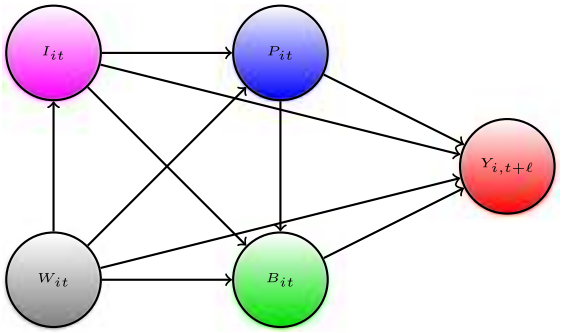

Fig. 4. S. & P. Wright type causal path diagram for our model.

- Information variables, I_{it}, such as lagged values of outcomes can affect human behavior and policies, as well as outcomes;
- The confounding factors W_{it}, which vary across states and time, affect all other variables.

The index i denotes observational unit, the state, and t and $t+\ell$ denotes the time, where ℓ is a positive integer that represents the time lag between infection and case confirmation or death.

Our main outcomes of interest are the growth rates in Covid-19 cases and deaths, behavioral variables include proportion of time spent in transit, shopping, and workplaces, policy variables include mask mandates, stay-at-home orders, and school and business closures, and the information variables include lagged values of outcome. We provide a detailed description of these variables and their timing in the next section.

The causal structure allows for the effect of the policy to be either direct or indirect — through behavior or through dynamics; all of these effects are not mutually exclusive. The structure also allows for changes in behavior to be brought by change in policies and information. These are all realistic properties that we expect from the contextual knowledge of the problem. Policies such as closures of schools, non-essential business, and restaurants alter and constrain behavior in strong ways. In contrast, policies such as mandating employees to wear masks can potentially affect the Covid-19 transmission directly. The information variables, such as recent growth in the number of cases, can cause people to spend more time at home, regardless of adopted state policies; these changes in behavior in turn affect the transmission of Covid-19. Importantly, policies can have the informational content as well, guiding behavior rather than constraining it.

The causal ordering induced by this directed acyclical graph is determined by the following timing sequence:

(1) information and confounders get determined at t,
(2) policies are set in place, given information and confounders at t;
(3) behavior is realized, given policies, information, and confounders at t;
(4) outcomes get realized at $t+\ell$ given policies, behavior, information, and confounders.

The model also allows for direct dynamic effects of information variables on the outcome through autoregressive structures that capture persistence in growth patterns. As highlighted below, realized outcomes may become new information for future periods, inducing dynamics over multiple periods.

Our quantitative model for causal structure in Fig. 4 is given by the following econometric structural (or potential) outcomes model:

$$\begin{aligned} Y_{i,t+\ell}(b,p,\iota) &:= \alpha' b + \pi' p + \mu' \iota + \delta_Y' W_{it} + \varepsilon_{it}^y, \\ B_{it}(p,\iota) &:= \beta' p + \gamma' \iota + \delta_B' W_{it} + \varepsilon_{it}^b, \end{aligned} \tag{SO}$$

which is a collection of functional relations with stochastic shocks, decomposed into observable part $\delta' W$ and unobservable part ε. The terms ε_{it}^y and ε_{it}^b are the centered stochastic shocks that obey the orthogonality restrictions posed below.

The policies can be modeled via a linear form as well,

$$P_{it}(\iota) := \eta' \iota + \delta_P' W_{it} + \varepsilon_{it}^p, \tag{P}$$

although linearity is not critical.[15]

[15] Under some additional independence conditions, this can be replaced by an arbitrary non-additive function $P_{it}(\iota) = p(\iota, W_{it}, \varepsilon_{it}^p)$, such that the unconfoundedness condition stated in the next footnote holds.

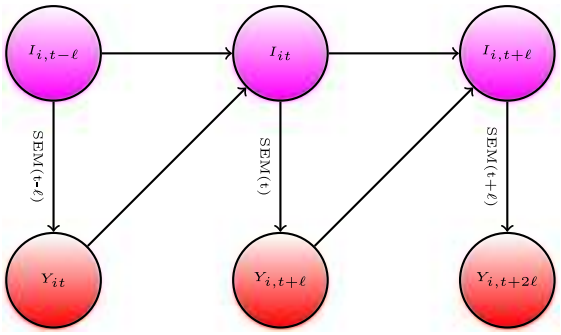

Fig. 5. Diagram for Information Dynamics in SEM.

The exogeneity restrictions on the stochastic shocks are as follows:

$$\begin{aligned} \varepsilon^{y}_{it} &\perp (\varepsilon^{b}_{it}, \varepsilon^{p}_{it}, W_{it}, I_{it}), \\ \varepsilon^{b}_{it} &\perp (\varepsilon^{p}_{it}, W_{it}, I_{it}), \\ \varepsilon^{p}_{it} &\perp (W_{it}, I_{it}), \end{aligned} \tag{E}$$

where we say that $V \perp U$ if $EVU = 0$.[16] This is a standard way of representing restrictions on errors in structural equation modeling in econometrics.[17]

The observed variables are generated by setting $\iota = I_{it}$ and propagating the system from the last equation to the first:

$$\begin{aligned} Y_{i,t+\ell} &:= Y_{i,t+\ell}(B_{it}, P_{it}, I_{it}), \\ B_{it} &:= B_{it}(P_{it}, I_{it}), \\ P_{it} &:= P_{it}(I_{it}). \end{aligned} \tag{O}$$

The specification of the model above grasps one-period responses. The dynamics over multiple periods will be induced by the evolution of information variables, which include time, lagged and integrated values of outcome[18]:

$$I_{it} := I_t(Y_{it}, I_{i,t-\ell}) := \left(g(t), Y_{it}, \sum_{m=0}^{\lfloor t/\ell \rfloor} Y_{i,t-\ell m}\right)' \tag{I}$$

for each $t \in \{0, 1, \ldots, T\}$, where g is deterministic function of time, e.g., month indicators, assuming that the log of new cases at time $t \leq 0$ is zero, for notational convenience.[19] In this structure, people respond to both global information, captured by a function of time such as month dummies, and local information sources, captured by the local growth rate and the total number of cases. The local information also captures the persistence of the growth rate process. We model the reaction of people's behavior via the term $\gamma' I_t$ in the behavior equation. The lagged values of behavior variable may be also included in the information set, but we postpone this discussion after the main empirical results are presented.

With any structure of this form, realized outcomes may become new information for future periods, inducing a dynamical system over multiple periods. We show the resulting dynamical system in a diagram of Fig. 5. Specification of this system is useful for studying delayed effects of policies and behaviors and in considering the counterfactual policy analysis.

Next we combine the above parts together with an appropriate initialization to give a formal definition of the model we use.

> Structural Equations Model (SEM). Let $i \in \{1, \ldots, N\}$ denote the observational unit, t be the time periods, and ℓ be the time delay. (1) For each i and $t \leq -\ell$, the confounder, information, behavior, and policy variables

[16] An alternative useful starting point is to impose the Rosenbaum–Rubin type unconfoundedness condition:

$$Y_{i,t+\ell}(\cdot,\cdot,\cdot) \perp\!\!\!\perp (P_{it}, B_{it}, I_{it}) \mid W_{it}, \;\; B_{it}(\cdot,\cdot) \perp\!\!\!\perp (P_{it}, I_{it}) \mid W_{it}, \;\; P_{it}(\cdot) \perp\!\!\!\perp I_{it} \mid W_{it},$$

which imply, with treating stochastic errors as independent additive components, the orthogonal conditions stated above. The same unconfoundedness restrictions can be formulated using formal causal DAGs, and also imply orthogonality restrictions stated above, once stochastic errors are modeled as independent additive components.

[17] The structural equations of this form are connected to triangular structural equation models, appearing in microeconometrics and macroeconometrics (SVARs), going back to the work of Strotz and Wold (1960).

[18] Our empirical analysis also considers a specification in which information variables include lagged national cases/deaths as well as lagged behavior variables.

[19] The general formula for $I_{i,t-1}$ is $S_{i,t,\ell} + \sum_{m=1}^{\lfloor t/\ell \rfloor} Y_{i,t-\ell m}$, where $S_{i,t,\ell}$ is the initial condition, the log of new cases at time $-t \mod \ell$.

$W_{it}, I_{it}, B_{it}, P_{it}$ are determined outside of the model, and the outcome variable $Y_{i,t+\ell}$ is determined by factors outside of the model for $t \leq 0$. (2) For each i and $t \geq -\ell$, confounders W_{it} are determined by factors outside of the model, and information variables I_{it} are determined by (I); policy variables P_{it} are determined by setting $\iota = I_{it}$ in (P) with a realized stochastic shock ε^p_{it} that obeys the exogeneity condition (E); behavior variables B_{it} are determined by setting $\iota = I_{it}$ and $p = P_{it}$ in (SO) with a shock ε^b_{it} that obeys (E); finally, the outcome $Y_{i,t+\ell}$ is realized by setting $\iota = I_{it}$, $p = P_{it}$, and $b = B_{it}$ in (SO) with a shock ε^y_{it} that obeys (E).

2.2. Main testable implication, identification, parameter estimation

The system above together with orthogonality restrictions (E) implies the following collection of projection equations for realized variables:

$$Y_{i,t+\ell} = \alpha' B_{it} + \pi' P_{it} + \mu' I_{it} + \delta_Y' W_{it} + \varepsilon^y_{it}, \qquad \varepsilon^y_{it} \perp B_{it}, P_{it}, I_{it}, W_{it} \qquad \text{(BPI}\to\text{Y)}$$

$$B_{it} = \beta' P_{it} + \gamma' I_{it} + \delta_B' W_{it} + \varepsilon^b_{it}, \qquad \varepsilon^b_{it} \perp P_{it}, I_{it}, W_{it} \qquad \text{(PI}\to\text{B)}$$

$$P_{it} = \eta' I_{it} + \delta_P' W_{it} + \varepsilon^p_{it}, \qquad \varepsilon^p_{it} \perp I_{it}, W_{it} \qquad \text{(I}\to\text{P)}$$

$$Y_{i,t+\ell} = (\alpha'\beta' + \pi')P_{it} + (\alpha'\gamma' + \mu')I_{it} + \bar{\delta}' W_{it} + \bar{\varepsilon}_{it}, \qquad \bar{\varepsilon}_{it} \perp P_{it}, I_{it}, W_{it}. \qquad \text{(PI}\to\text{Y)}$$

Therefore the projection equation:

$$Y_{i,t+\ell} = \mathsf{a}' P_{it} + \mathsf{b}' I_{it} + \tilde{\delta}' W_{it} + \bar{\varepsilon}_{it}, \quad \bar{\varepsilon}_{it} \perp P_{it}, I_{it}, W_{it}. \qquad \text{(Y}\sim\text{PI)}$$

should obey:

$$\mathsf{a}' = (\alpha'\beta' + \pi') \text{ and } \mathsf{b}' = (\alpha'\gamma' + \mu'). \qquad \text{(TR)}$$

Without any exclusion restrictions, this equality is just a decomposition of total effects into direct and indirect components and is not a testable restriction. However, in our case we rely on the SIR model with testing to motivate the presence of change in testing rate as a confounder in the outcome equations but not in the behavior equation (therefore, a component of δ_B and δ_P is set to 0), implying that (TR) does not necessarily hold and is testable. Furthermore, we estimate (PI→B) on the data set that has many more observations than the data set used to estimate the outcome equations, implying that (TR) is again testable. Later we shall also try to utilize the contextual knowledge that mask mandates only affect the outcome directly and not by changing mobility (i.e., $\beta = 0$ for mask policy), implying again that (TR) is testable. If not rejected by the data, (TR) can be used to sharpen the estimate of the causal effect of mask policies on the outcomes.

Validation of the model by (TR) allows us to check exclusion restrictions brought by contextual knowledge and check stability of the model by using different data subsets. However, passing the (TR) does not guarantee that the model is necessarily valid for recovering causal effects. The only fundamental way to truly validate a causal model for observational data is through a controlled experiment, which is impossible to carry out in our setting.

The parameters of the SEM are identified by the projection equation set above, provided the latter are identified by sufficient joint variation of these variables across states and time. We can develop this point formally as follows. Consider the previous system of equations, after partialling out the confounders:

$$\begin{aligned}
\tilde{Y}_{i,t+\ell} &= \alpha' \tilde{B}_{it} + \pi' \tilde{P}_{it} + \mu' \tilde{I}_{it} + \varepsilon^y_{it}, & \varepsilon^y_{it} &\perp \tilde{B}_{it}, \tilde{P}_{it}, \tilde{I}_{it}, \\
\tilde{B}_{it} &= \beta' \tilde{P}_{it} + \gamma' \tilde{I}_{it} + \varepsilon^b_{it}, & \varepsilon^b_{it} &\perp \tilde{P}_{it}, \tilde{I}_{it}, \\
\tilde{P}_{it} &= \eta' \tilde{I}_{it} + \varepsilon^p_{it}, & \varepsilon^p_{it} &\perp \tilde{I}_{it} \\
\tilde{Y}_{i,t+\ell} &= \mathsf{a}' \tilde{P}_{it} + \mathsf{b}' \tilde{I}_{it} + \bar{\varepsilon}^y_{it}, & \bar{\varepsilon}^y_{it} &\perp \tilde{P}_{it}, \tilde{I}_{it},
\end{aligned} \qquad (1)$$

where $\tilde{V}_{it} = V_{it} - W_{it}' \mathrm{E}[W_{it} W_{it}']^{-} \mathrm{E}[W_{it} V_{it}]$ denotes the residual after removing the orthogonal projection of V_{it} on W_{it}. The residualization is a linear operator, implying that (1) follows immediately from the above. The parameters of (1) are identified as projection coefficients in these equations, provided that residualized vectors appearing in each of the equations have non-singular variance, that is

$$\mathrm{Var}(\tilde{P}_{it}', \tilde{B}_{it}', \tilde{I}_{it}') > 0, \ \mathrm{Var}(\tilde{P}_{it}', \tilde{I}_{it}') > 0, \quad \text{and } \mathrm{Var}(\tilde{I}_{it}') > 0. \qquad (2)$$

Our main estimation method is the standard correlated random effects estimator, where the random effects are parameterized as functions of observable characteristic, W_{it}, which include both state-level and time random effects. The state-level random effects are modeled as a function of state level characteristics, and the time random effects are modeled by including month dummies and their interactions with state level characteristics (in the sensitivity analysis, we also add weekly dummies). The stochastic shocks $\{\varepsilon_{it}\}_{t=1}^T$ are treated as independent across states i and can be arbitrarily dependent across time t within a state.

Another modeling approach is the fixed effects panel data model, where W_{it} includes latent (unobserved) state level confonders W_i and time level effects W_t, which must be estimated from the data. This approach is much more demanding

of the data and relies on long time and cross-sectional histories to estimate W_i and W_t, resulting in amplification of uncertainty. In addition, when histories are relatively short, large biases emerge and they need to be removed using debiasing methods, see e.g., Chen et al. (2019) for overview. We present the results on debiased fixed effect estimation with weekly dummies as parts of our sensitivity analysis. Our sensitivity analysis also considers a debiased machine learning approach using Random Forest in which observed confounders enter the model nonlinearly.

With exclusion restrictions there are multiple approaches to estimation, for example, via generalized method of moments. We shall take a more pragmatic approach where we estimate the parameters of equations separately and then compute

$$\frac{1}{2}\hat{a}' + \frac{1}{2}(\hat{\alpha}'\hat{\beta}' + \hat{\pi}') \text{ and } \frac{1}{2}\hat{b}' + \frac{1}{2}(\hat{\alpha}'\hat{\gamma}' + \hat{\mu}'),$$

as the estimator of the total policy effect. Under standard regularity conditions, these estimators concentrate around their population analogues

$$\frac{1}{2}a' + \frac{1}{2}(\alpha'\beta' + \pi') \text{ and } \frac{1}{2}b' + \frac{1}{2}(\alpha'\gamma' + \mu'),$$

with approximate deviations controlled by the normal laws, with standard deviations that can be approximated by the bootstrap resampling of observational units i. Under correct specification the target quantities reduce to

$$\alpha'\beta' + \pi' \text{ and } \alpha'\gamma' + \mu',$$

respectively.[20]

2.3. Counterfactual policy analysis

We also consider simple counterfactual exercises, where we examine the effects of setting a sequence of counterfactual policies for each state:

$$\{P_{it}^\star\}_{t=1}^T, \quad i = 1, \ldots, N. \tag{CF-P}$$

We assume that the SEM remains invariant, except for the policy equation.[21] The assumption of invariance captures the idea that counterfactual policy interventions would not change the structural functions within the period of the study. The assumption is strong but is necessary to conduct counterfactual experiments, e.g. Sims (1972) and Strotz and Wold (1960). To make the assumption more plausible we limited our study to the early pandemic period.[22]

Given the policies, we generate the counterfactual outcomes, behavior, and information by propagating the dynamic equations:

$$\begin{aligned} Y_{i,t+\ell}^\star &:= Y_{i,t+\ell}(B_{it}^\star, P_{it}^\star, I_{it}^\star), \\ B_{it}^\star &:= B_{it}(P_{it}^\star, I_{it}^\star), \\ I_{it}^\star &:= I_t(Y_{it}^\star, I_{i,t-\ell}^\star), \end{aligned} \tag{CF-SEM}$$

with the same initialization as the factual system up to $t \leq 0$. In stating this counterfactual system of equations, we assume that structural outcome equations (SO) and information equations (I) remain invariant and so do the stochastic shocks, decomposed into observable and unobservable parts. Formally, we record this assumption and above discussion as follows.

> Counterfactual Structural Equations Model (CF-SEM). Let $i \in \{1, \ldots, N\}$ be the observational unit, t be time periods, and ℓ be the time delay. (1) For each i and $t \leq 0$, the confounder, information, behavior, policy, and outcome variables are determined as previously stated in SEM: $W_{it}^\star = W_{it}$, $I_{it}^\star = I_{it}$, $B_{it}^\star = B_{it}$, $P_{it}^\star = P_{it}$, $Y_{it}^\star = Y_{it}$. (2) For each i and $t \geq 0$, confounders $W_{it}^\star = W_{it}$ are determined as in SEM, and information variables $I_{it}^\star$ are determined by (I); policy variables $P_{it}^\star$ are set in (CF-P); behavior variables $B_{it}^\star$ are determined by setting $\iota = I_{it}^\star$ and $p = P_{it}^\star$ in (SO) with the same stochastic shock ε_{it}^b in (SO); the counterfactual outcome $Y_{i,t+\ell}^\star$ is realized by setting $\iota = I_{it}^\star$, $p = P_{it}^\star$, and $b = B_{it}^\star$ in (SO) with the same stochastic shock ε_{it}^y in (SO).

Figs. 6 and 7 present the causal path diagram for CF-SEM as well as the dynamics of counterfactual information in CF-SEM.

---

[20] This construction is not as efficient as generalized method of moments but has a nicer interpretation under possible misspecification of the model: we are combining predictions from two models, one motivated via the causal path, reflecting contextual knowledge, and another from a "reduced form" model not exploiting the path. The combined estimator can improve on precision of either estimator.

[21] It is possible to consider counterfactual exercises in which policy responds to information through the policy equation if we are interested in endogenous policy responses to information. Counterfactual experiments with endogenous government policy would be important, for example, to understand the issues related to the lagged response of government policies to higher infection rates due to incomplete information.

[22] Furthermore, we conducted several stability checks, for example, checking if the coefficients on mask policies remain stable (reported in the previous version) and also looking at more recent data during reopening, beyond early pandemic, to examine the stability of the model.

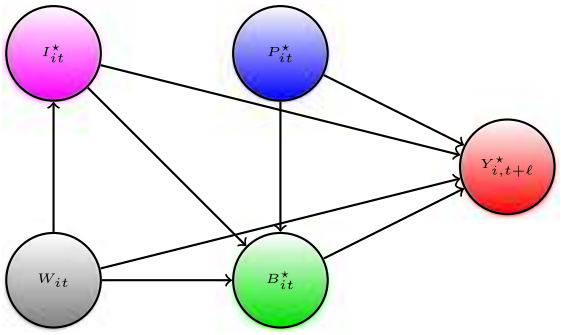

Fig. 6. Causal path diagram for CF-SEM.

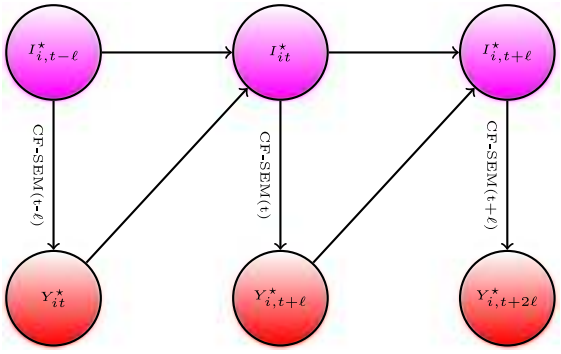

Fig. 7. A Diagram for Counterfactual Information Dynamics in CF-SEM.

The counterfactual outcome $Y^\star_{i,t+\ell}$ and factual outcome $Y_{i,t+\ell}$ are given by:

$$Y^\star_{i,t+\ell} = (\alpha'\beta' + \pi')P^\star_{it} + (\alpha'\gamma' + \mu')I^\star_{it} + \bar{\delta}'W_{it} + \bar{\varepsilon}^y_{it},$$

$$Y_{i,t+\ell} = (\alpha'\beta' + \pi')P_{it} + (\alpha'\gamma' + \mu')I_{it} + \bar{\delta}'W_{it} + \bar{\varepsilon}^y_{it}.$$

In generating these predictions, we explore the assumption of invariance stated above. We can write the counterfactual contrast into the sum of three components:

$$\underbrace{Y^\star_{i,t+\ell} - Y_{i,t+\ell}}_{\text{CF Change}} = \underbrace{\alpha'\beta'\left(P^\star_{it} - P_{it}\right)}_{\text{CF Policy Effect via Behavior}} + \underbrace{\pi'\left(P^\star_{it} - P_{it}\right)}_{\text{CF Direct Effect}}$$

$$+ \underbrace{\alpha'\gamma'\left(I^\star_{it} - I_{it}\right) + \mu'\left(I^\star_{it} - I_{it}\right)}_{\text{CF Dynamic Effect}}$$

$$=: \text{PEB}^\star_{it} + \text{PED}^\star_{it} + \text{DynE}^\star_{it}, \tag{3}$$

which describe the immediate indirect effect of the policy via behavior, the direct effect of the policy, and the dynamic effect of the policy. By recursive substitutions the dynamic effect can be further decomposed into a weighted sum of delayed policy effects via behavior and a weighted sum of delayed policy effects via direct impact.

All counterfactual quantities and contrasts can be computed from the expressions given above. For examples, given $\Delta C_{i0} > 0$, new confirmed cases are linked to growth rates via relation (taking t divisible by ℓ for simplicity):

$$\frac{\Delta C^\star_{it}}{\Delta C_{i0}} = \exp\left(\sum_{m=1}^{t/\ell} Y^\star_{i,m\ell}\right) \text{ and } \frac{\Delta C_{it}}{\Delta C_{i0}} = \exp\left(\sum_{m=1}^{t/\ell} Y_{i,m\ell}\right).$$

The cumulative cases can be constructed by summing over the new cases. Various contrasts are then calculated from these quantities. For example, the relative contrast of counterfactual new confirmed cases to the factual confirmed cases

is given by:

$$\frac{\Delta C_{it}^{\star}}{\Delta C_{it}} = \exp\left(\sum_{m=1}^{t/\ell}(Y_{i,m\ell}^{\star} - Y_{i,m\ell})\right).$$

We refer to the appendix for further details. Similar calculations apply for fatalities. Note that our analysis is conditional on the factual history and structural stochastic shocks.[23]

The estimated counterfactuals are smooth functionals of the underlying parameter estimates. Therefore, we construct the confidence intervals for counterfactual quantities and contrasts by bootstrapping the parameter estimates. We refer to the appendix for further details.

2.4. Outcome and key confounders via SIRD model

We next provide details of our key measurement equations, defining the outcomes and key confounders. We motivate the structural outcome equations via the fundamental epidemiological model for the spread of infectious decease called the Susceptible–Infected–Recovered–Dead (SIRD) model with testing.

Letting C_{it} denote the cumulative number of confirmed cases in state i at time t, our outcome

$$Y_{it} = \Delta \log(\Delta C_{it}) := \log(\Delta C_{it}) - \log(\Delta C_{i,t-7}) \tag{4}$$

approximates the weekly growth rate in new cases from $t-7$ to t. Here Δ denotes the differencing operator over 7 days from t to $t-7$, so that $\Delta C_{it} := C_{it} - C_{i,t-7}$ is the number of new confirmed cases in the past 7 days.

We chose this metric as this is the key metric for policy makers deciding when to relax Covid mitigation policies. The U.S. government's guidelines for state reopening recommend that states display a "downward trajectory of documented cases within a 14-day period" (The White House, 2020). A negative value of Y_{it} is an indication of meeting this criteria for reopening. By focusing on weekly cases rather than daily cases, we smooth idiosyncratic daily fluctuations as well as periodic fluctuations associated with days of the week.

Our measurement equation for estimating Eqs. (BPI→Y) and (PI→Y) will take the form:

$$\Delta \log(\Delta C_{it}) = X_{i,t-14}'\theta - \gamma + \delta_T \Delta \log(T_{it}) + \epsilon_{it}, \tag{M-C}$$

where i is state, t is day, C_{it} is cumulative confirmed cases, T_{it} is the number of tests over 7 days, Δ is a 7-days differencing operator, and ϵ_{it} is an unobserved error term. $X_{i,t-14}$ collects other behavioral, policy, and confounding variables, depending on whether we estimate (BPI→Y) or (PI→Y), where the lag of 14 days captures the time lag between infection and confirmed case (see Appendix A.6). Here

$$\Delta \log(T_{it}) := \log(T_{it}) - \log(T_{i,t-7})$$

is the key confounding variable, derived from considering the SIRD model below. We are treating the change in testing rate as exogenous.[24] We describe other confounders in the empirical section.

Our main measurement equation (M-C) is motivated by a variant of SIRD model, where we add confirmed cases and infection detection via testing. Let S, $\mathcal{I}$, R, and D denote the number of susceptible, infected, recovered, and deceased individuals in a given state. Each of these variables are a function of time. We model them as evolving as

$$\dot{S}(t) = -\frac{S(t)}{N}\beta(t)\mathcal{I}(t) \tag{5}$$

$$\dot{\mathcal{I}}(t) = \frac{S(t)}{N}\beta(t)\mathcal{I}(t) - \gamma\mathcal{I}(t) \tag{6}$$

$$\dot{R}(t) = (1-\kappa)\gamma\mathcal{I}(t) \tag{7}$$

$$\dot{D}(t) = \kappa\gamma\mathcal{I}(t) \tag{8}$$

where N is the population, $\beta(t)$ is the rate of infection spread, γ is the rate of recovery or death, and κ is the probability of death conditional on infection.

Confirmed cases, $C(t)$, evolve as

$$\dot{C}(t) = \tau(t)\mathcal{I}(t), \tag{9}$$

where $\tau(t)$ is the rate that infections are detected.

[23] For unconditional counterfactual, we need to make assumptions about the evolution of stochastic shocks appearing in Y_{it}. See, e.g., previous versions of our paper in ArXiv, where unconditional counterfactuals were calculated by assuming stochastic shocks are i.i.d. and resampling them from the empirical distribution. The differences between conditional and unconditional contrasts were small in our empirical analysis.

[24] To check sensitivity to this assumption we performed robustness checks, where we used the further lag of $\Delta \log(T_{it})$ as a proxy for exogenous change in the testing rate, and we also used that as an instrument for $\Delta \log(T_{it})$; this did not affect the results on policy effects, although the instrument was not sufficiently strong.

Our goal is to examine how the rate of infection $\beta(t)$ varies with observed policies and measures of social distancing behavior. A key challenge is that we only observed $C(t)$ and $D(t)$, but not $\mathcal{I}(t)$. The unobserved $\mathcal{I}(t)$ can be eliminated by differentiating (9) and using (6) as

$$\frac{\ddot{C}(t)}{\dot{C}(t)} = \frac{S(t)}{N}\beta(t) - \gamma + \frac{\dot{\tau}(t)}{\tau(t)}. \tag{10}$$

We consider a discrete-time analogue of Eq. (10) to motivate our empirical specification by relating the detection rate $\tau(t)$ to the number of tests T_{it} while specifying $\frac{S(t)}{N}\beta(t)$ as a linear function of variables $X_{i,t-14}$. This results in

$$\underbrace{\Delta \log(\Delta C_{it})}_{\frac{\ddot{C}(t)}{\dot{C}(t)}} = \underbrace{X'_{i,t-14}\theta + \epsilon_{it}}_{\frac{S(t)}{N}\beta(t)-\gamma} + \underbrace{\delta_T \Delta \log(T)_{it}}_{\frac{\dot{\tau}(t)}{\tau(t)}}$$

which is equation (M-C), where $X_{i,t-14}$ captures a vector of variables related to $\beta(t)$.

Structural Interpretation. Early in the pandemic, when the number of susceptibles is approximately the same as the entire population, i.e. $S_{it}/N_{it} \approx 1$, the component $X'_{i,t-14}\theta$ is the projection of infection rate $\beta_i(t)$ on $X_{i,t-14}$ (policy, behavioral, information, and confounders other than testing rate), provided the stochastic component ϵ_{it} is orthogonal to $X_{i,t-14}$ and the testing variables:

$$\beta_i(t)S_{it}/N_{it} - \gamma = X'_{i,t-14}\theta + \epsilon_{it}, \quad \epsilon_{it} \perp X_{i,t-14}.$$

The specification for growth rate in deaths as the outcome is motivated by SIRD as follows. By differentiating (8) and (9) with respect to t and using (10), we obtain

$$\frac{\ddot{D}(t)}{\dot{D}(t)} = \frac{\ddot{C}(t)}{\dot{C}(t)} - \frac{\dot{\tau}(t)}{\tau(t)} = \frac{S(t)}{N}\beta(t) - \gamma. \tag{11}$$

Our measurement equation for the growth rate of deaths is based on Eq. (11) but accounts for a 21 day lag between infection and death as

$$\Delta \log(\Delta D_{it}) = X'_{i,t-21}\theta + \epsilon_{it}, \tag{M-D}$$

where

$$\Delta \log(\Delta D_{it}) := \log(\Delta D_{it}) - \log(\Delta D_{i,t-7}) \tag{12}$$

approximates the weekly growth rate in deaths from $t-7$ to t in state i.

3. Empirical analysis

3.1. Data

All code is available at https://github.com/ubcecon/covid-impact. Our baseline measures for daily Covid-19 cases and deaths are from The New York Times (NYT). When there are missing values in NYT, we use reported cases and deaths from JHU CSSE, and then the Covid Tracking Project. The number of tests for each state is from Covid Tracking Project. As shown in the lower right panel of Fig. A.17 in the appendix, there was a rapid increase in testing in the second half of March and then the number of tests increased very slowly in each state in April.

We use the database on US state policies created by Raifman et al. (2020). In our analysis, we focus on 6 policies: stay-at-home, closed nonessential businesses, closed K-12 schools, closed restaurants except takeout, closed movie theaters, and face mask mandates for employees in public facing businesses. We believe that the first four of these policies are the most widespread and important. Closed movie theaters is included because it captures common bans on gatherings of more than a handful of people. We also include mandatory face mask use by employees because its effectiveness on slowing down Covid-19 spread is a controversial policy issue (Howard et al., 2020; Greenhalgh et al., 2020; Zhang et al., 2020b). Table 1 provides summary statistics, where N is the number of states that have ever implemented the policy. We also obtain information on state-level covariates mostly from Raifman et al. (2020), which include population size, total area, unemployment rate, poverty rate, a percentage of people who are subject to illness, and state governor's party affiliations. These confounders are motivated by Wheaton and Thompson (2020) who find that case growth is associated with residential density and per capita income.

We obtain social distancing behavior measures from "Google COVID-19 Community Mobility Reports" (Google LLC, 2020). The dataset provides six measures of "mobility trends" that report a percentage change in visits and length of stay at different places relative to a baseline computed by their median values of the same day of the week from January 3 to

Table 1
State policies.

	N	Min	Median	Max
Date closed K 12 schools	51	2020-03–13	2020-03–17	2020-04-03
Stay at home shelter in place	42	2020-03–19	2020-03–28	2020-04-07
Closed movie theaters	49	2020-03–16	2020-03–21	2020-04-06
Closed restaurants except take out	48	2020-03–15	2020-03–17	2020-04-03
Closed non essential businesses	43	2020-03–19	2020-03–25	2020-04-06
Mandate face mask use by employees	44	2020-04–03	2020-05–01	2020-08-03

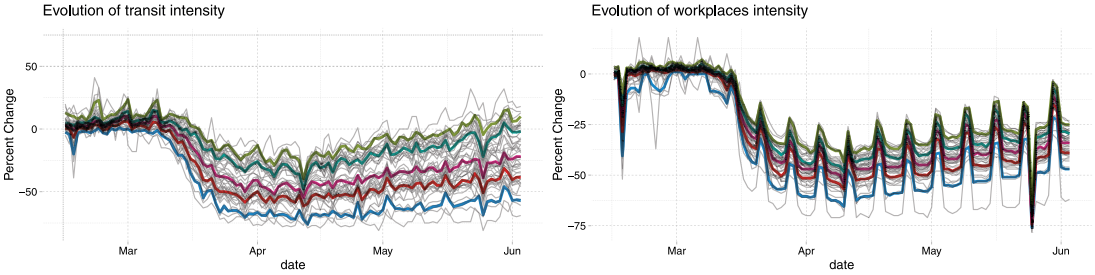

Fig. 8. The Evolution of Google Mobility Measures: Transit stations and Workplaces. This figure shows the evolution of "Transit stations" and "Workplaces" of Google Mobility Reports. Thin gray lines are the value in each state and date. Thicker colored lines are quantiles of the variables conditional on date. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

February 6, 2020. Our analysis focuses on the following four measures: "Grocery & pharmacy", "Transit stations", "Retail & recreation", and "Workplaces".[25]

Fig. 8 shows the evolution of "Transit stations" and "Workplaces", where thin lines are the value in each state and date while thicker colored lines are quantiles conditional on date. The figures illustrate a sharp decline in people's movements starting from mid-March as well as differences in their evolutions across states. They also reveal periodic fluctuations associated with days of the week, which motivates our use of weekly measures.

In our empirical analysis, we use weekly measures for cases, deaths, and tests by summing up their daily measures from day t to $t-6$. We focus on weekly cases and deaths because daily new cases and deaths are affected by the timing of reporting and testing and are quite volatile as shown in the upper right panel of Fig. A.17 in the appendix. Aggregating to weekly new cases/deaths/tests smooths out idiosyncratic daily noises as well as periodic fluctuations associated with days of the week. We also construct weekly policy and behavior variables by taking 7 day moving averages from day $t-14$ to $t-21$ for case growth, where the delay reflects the time lag between infection and case confirmation. The four weekly behavior variables are referred to "Transit Intensity", "Workplace Intensity", "Retail Intensity", and "Grocery Intensity". Consequently, our empirical analysis uses 7 day moving averages of all variables recorded at daily frequencies. Our sample period is from March 7, 2020 to June 3, 2020.

Table 2 reports that weekly policy and behavior variables are highly correlated with each other, except for the"masks for employees" policy. High correlations may cause multicolinearity problems and could limit our ability to separately identify the effect of each policy or behavior variable on case growth. For this reason, we define the "business closure policies" variable by the average of closed movie theaters, closed restaurants, and closed non-essential businesses variables and consider a specification that includes business closure policies in place of these three policy variables separately.

Fig. 9 shows the portion of states that have each policy in place at each date. For most policies, there is considerable variation across states in the time in which the policies are active. The one exception is K-12 school closures. About 80% of states closed schools within a day or two of March 15th, and all states closed schools by early April. This makes the effect of school closings difficult to separate from aggregate time series variation.

3.2. The effect of policies and information on behavior

We first examine how policies and information affect social distancing behaviors by estimating a version of (PI→B):

$$B_{it}^{j} = (\beta^{j})' P_{it} + (\gamma^{j})' I_{it} + (\delta_{B}^{j})' W_{it} + \varepsilon_{it}^{bj},$$

where B_{it}^{j} represents behavior variable j in state i at time t. P_{it} collects the Covid related policies in state i at t. Confounders, W_{it}, include state-level covariates, month indicators, and their interactions. I_{it} is a set of information variables that affect

[25] The other two measures are "Residential" and "Parks". We drop "Residential" because it is highly correlated with "Workplaces" and "Retail & recreation" at correlation coefficients of −0.98 and −0.97, respectively. We also drop "Parks" because it does not have clear implication on the spread of Covid-19.

Table 2
Correlations among policies and behavior.

	workplaces	retail	grocery	transit	masks for employees	closed K-12 schools	stay at home	closed movie theaters	closed restaurants	closed non-essent bus	business closure policies
workplaces	1.00										
retail	0.93	1.00									
grocery	0.75	0.83	1.00								
transit	0.89	0.92	0.83	1.00							
masks for employees	−0.32	−0.17	−0.15	−0.29	1.00						
closed K-12 schools	−0.91	−0.79	−0.55	−0.72	0.43	1.00					
stay at home	−0.69	−0.69	−0.70	−0.71	0.28	0.62	1.00				
closed movie theaters	−0.81	−0.76	−0.64	−0.71	0.34	0.82	0.72	1.00			
closed restaurants	−0.77	−0.82	−0.68	−0.76	0.21	0.74	0.72	0.82	1.00		
closed non-essent bus	−0.65	−0.68	−0.68	−0.64	0.08	0.56	0.76	0.68	0.71	1.00	
business closure policies	−0.84	−0.84	−0.75	−0.79	0.24	0.78	0.81	0.92	0.93	0.87	1.00

Each off-diagonal entry reports a correlation coefficient of a pair of policy and behavior variables. "business closure policies" is defined by the average of closured movie theaters, closured restaurants, and closured non-essential businesses.

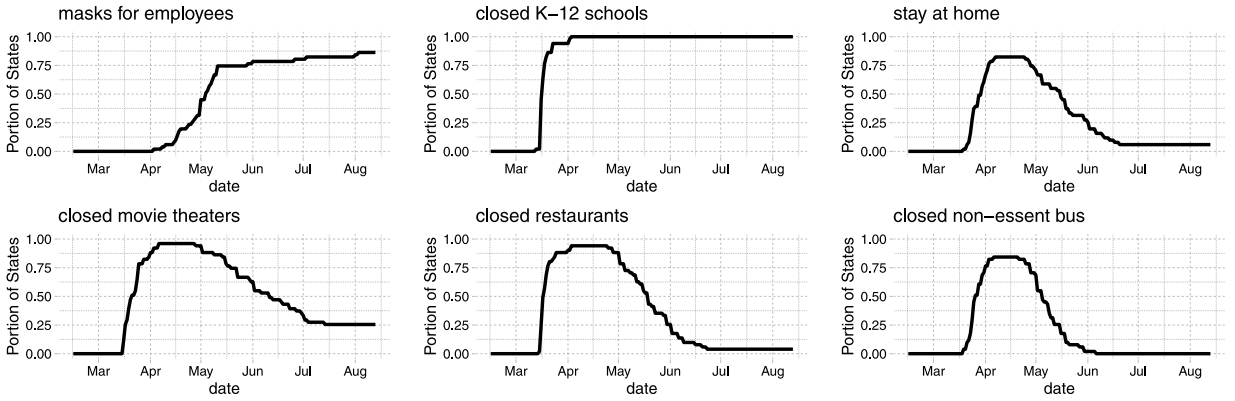

Fig. 9. Portion of states with each policy.

people's behaviors at t. As information, we include each state's growth of cases (in panel (a)) or deaths (in panel (b)), and log cases or deaths. Additionally, in columns (5)–(8) of Table 3, we include national growth and log of cases or deaths.

Table 3 reports the estimates with standard errors clustered at the state level. Across different specifications, our results imply that policies have large effects on behavior. Comparing columns (1)–(4) with columns (5)–(8), the magnitude of policy effects are sensitive to whether national cases or deaths are included as information. The coefficient on school closures is particularly sensitive to the inclusion of national information variables. As shown in Fig. 9, there is little variation across states in the timing of school closures. Consequently, it is difficult to separate the effect of school closures from a behavioral response to the national trend in cases and deaths.

The other policy coefficients are less sensitive to the inclusion of national case/death variables. After school closures, business closure policies have the next largest effect followed by stay-at-home orders. The effect of masks for employees is small.[26]

The row "$\sum_j \text{Policy}_j$" reports the sum of the estimated effect of all policies, which is substantial and can account for a large fraction of the observed declines in behavior variables. For example, in Fig. 8, transit intensity for a median state was approximately -50% at its lowest point in early April. The estimated policy coefficients in columns imply that imposing all policies would lead to roughly 75% (in column 4) or roughly 35% (in column 8) of the observed decline. The large impact of policies on transit intensity suggests that the policies may have reduced the Covid-19 infection by reducing people's use of public transportation.[27]

[26] Similar to our finding, Kovacs et al. (2020) find no evidence that introduction of compulsory face mask policies affect community mobility in Germany.

[27] Analyzing the New York City's subway ridership, Harris (2020) finds a strong link between public transit and spread of infection.

Table 3
The effect of policies and information on behavior (PI→B).

Dependent variables are "Transit Intensity," "Workplace Intensity," "Retail Intensity," and "Grocery Intensity" defined as 7 days moving averages of corresponding daily measures obtained from Google Mobility Reports. All specifications include state-level characteristics (population, area, unemployment rate, poverty rate, a percentage of people subject to illness, and governor's party) as well as their interactions with the log of days since Jan 15, 2020. The row "$\sum_j \text{Policy}_j$" reports the sum of four policy coefficients. Standard errors are clustered at the state level.

In Table 3(b), estimated coefficients of deaths and death growth are generally negative. This suggests that the higher number of deaths reduces social interactions measured by Google Mobility Reports perhaps because people are increasingly aware of prevalence of Covid-19 (Maloney and Taskin, 2020). The coefficients on log cases and case growth

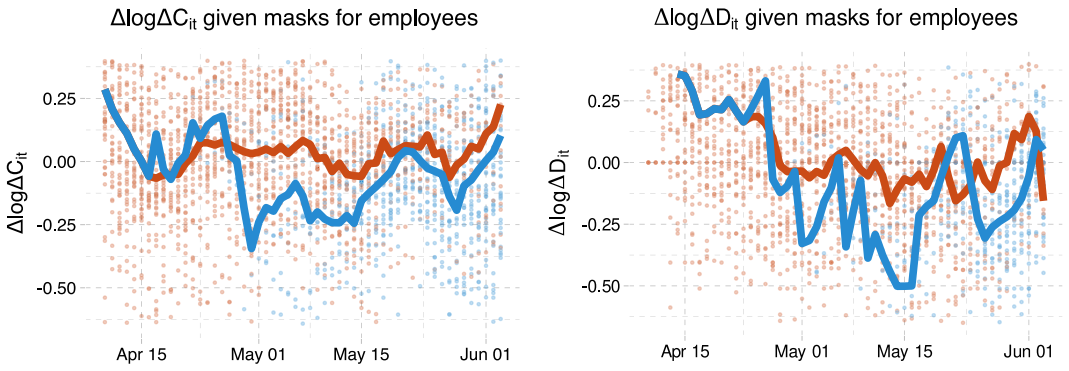

Fig. 10. Case and death growth conditional on mask mandates. In these figures, red points are the case or death growth rate in states without a mask mandate. Blue points are states with a mask mandate 14 (21 for deaths) days prior. The red line is the average across states without a mask mandate 14 (21 for deaths) days earlier. The blue line is the average across states with a mask mandate 14 (21 for deaths) earlier. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

in Table 3(a) are more mixed.[28] In columns (5)–(8) of both panels, we see that national case/death variables have large, negative coefficients. This suggests that behavior responded to national conditions although it is also likely that national case/death variables capture unobserved aggregate time effects beyond information which are not fully controlled by month dummies (e.g., latent policy variables and time-varying confounders that are common across states).

3.3. The direct effect of policies and behavior on case and death growth

We now analyze how behavior and policies together influence case and death growth rates. We begin with some simple graphical evidence of the effect of policies on case and death growth. Fig. 10 shows average case and death growth conditional on date and whether masks are mandatory for employees.[29] The left panel of the figure shows that states with a mask mandate consistently have 0–0.2 lower case growth than states without. The right panel also illustrates that states with a mask mandate tend to have lower average death growth than states without a mask mandate.

Similar plots are shown for other policies in Figs. A.20 and A.21 in the appendix. The figures for stay-at-home orders and closure of nonessential businesses are qualitatively similar to that for masks. States with these two policies appear to have about 0.1 percentage point lower case growth than states without. The effects of school closures, movie theater closures, and restaurant closures are not clearly visible in these figures. These figures are merely suggestive; the patterns observed in them may be driven by confounders.

We more formally analyze the effect of policies by estimating regressions. We first look at the direct effect of policies on case and death growth conditional on behavior by estimating equation (BPI→Y):

$$Y_{i,t+\ell} = \alpha' B_{it} + \pi' P_{it} + \mu' I_{it} + \delta_Y' W_{it} + \varepsilon_{it}^{y}, \tag{13}$$

where the outcome variable, $Y_{i,t+\ell}$, is either case growth or death growth.

For case growth as the outcome, we choose a lag length of $\ell = 14$ days for behavior, policy, and information variables to reflect the delay between infection and confirmation of case.[30] $B_{it} = (B_{it}^1, \ldots, B_{it}^4)'$ is a vector of four behavior variables in state i. P_{it} includes the Covid-related policies in state i that directly affect the spread of Covid-19 after controlling for behavior variables (e.g., masks for employees). We include information variables, I_{it}, that include the past cases and case growths because the past cases may be correlated with (latent) government policies or people's behaviors that are not fully captured by our observed policy and behavior variables. We also consider a specification that includes the past cases and case growth at the national level as additional information variables. W_{it} is a set of confounders that includes month dummies, state-level covariates, and the interaction terms between month dummies and state-level covariates.[31] For case growth, W_{it} also includes the test rate growth $\Delta \log(T)_{it}$ to capture the effect of changing test rates on confirmed cases. Eq. (13) corresponds to (M-C) derived from the SIR model.

[28] Rewrite a regression specification after omitting other variables as $B_{it} = \gamma_1 \Delta \log \Delta C_{it} + \gamma_2 \log \Delta C_{it} = (\gamma_1 + \gamma_2) \log \Delta C_{it} - \gamma_1 \log \Delta C_{i,t-7}$. In columns (1)–(4) of Table 3(a), the estimated values of both $(\gamma_1 + \gamma_2)$ and $-\gamma_1$ are negative except for grocery. This suggests that a higher *level* of confirmed cases reduces people's mobility in workplaces, retails, and transit. For grocery, the positive estimated coefficient of $(\gamma_1 + \gamma_2)$ may reflect stock-piling behavior in early pandemic periods.

[29] We take 14 and 21 day lags of mask policies for case and death growths, respectively, to identify the states with a mask mandate because policies affect cases and deaths with time lags. See our discussion in Appendix A.6.

[30] As we review in Appendix A.6, a lag length of 14 days between exposure and case reporting, as well as a lag length of 21 days between exposure and deaths, is broadly consistent with currently available evidence. Section 4 provides a sensitivity analysis under different timing assumptions.

[31] Month dummies also represent the latent information that is not fully captured by the past cases and growths.

Dependent variable is the weekly growth rate of confirmed cases (in the upper panel) or deaths (in the lower panel) as defined in Eq. (4). The covariates include lagged policy and behavior variables, which are constructed as 7 day moving averages between t to $t-7$ of corresponding daily measures. The row "$\sum_j \text{Policies}_j$" reports the sum of all policy coefficients. The row "$\sum_k w_k \text{Behavior}_k$" reports the sum of four coefficients of behavior variables weighted by the average of each behavioral variable from April 1st-10th. "business closure policies" is defined by the average of closured movie theaters, closured restaurants, and closured non-essential businesses. Standard errors are clustered at the state level.

For death growth as the outcome, we take a lag length of $\ell = 21$ days. The information variables I_{it} include past deaths and death growth rates; W_{it} is the same as that of the case growth equation except that the growth rate of test rates is excluded from W_{it} as implied by Eq. (M-D).

Table 4 shows the results of estimating (13) for case and death growth rates.

Column (1) represents our baseline specification while column (2) replaces business closure policies with closed movie theaters, closed restaurants, and closed non-essential businesses. Columns (3) and (4) include past cases/deaths and growth rates at national level as additional regressors.

The estimates indicate that mandatory face masks for employees reduce the growth rate of infections and deaths by 9–15 percent, while holding behavior constant. This suggests that requiring masks for employees in public-facing businesses may be an effective preventive measure.[32] The estimated effect of masks on death growth is larger than the effect on case growth, but this difference between the two estimated effects is not statistically significant.

Closing schools has a large and statistically significant coefficient in the death growth regressions. As discussed above, however, there is little cross-state variation in the timing of school closures, making estimates of its effect less reliable.

Neither the effect of stay-at-home orders nor that of business closure policies is estimated significantly different from zero, suggesting that these lockdown policies may have little direct effect on case or death growth when behavior is held constant.

The row "$\sum_k w_k \text{Behavior}_k$" reports the sum of estimated coefficients weighted by the average of the behavioral variables from April 1st-10th. The estimates of −0.80 and −0.84 for "$\sum_k w_k \text{Behavior}_k$" in column (1) imply that a reduction in mobility measures relative to the baseline in January and February have induced a decrease in case and death growth rates by 80 and 84 percent, respectively, suggesting an importance of social distancing for reducing the spread of Covid-19. When including national cases and deaths in information, as shown in columns (3) and (4), the estimated aggregate impact of behavior is substantially smaller but remains large and statistically significant.

A useful practical implication of these results is that Google Mobility Reports and similar data might be useful as a leading indicator of potential case or death growth. This should be done with caution, however, because other changes in the environment might alter the relationship between behavior and infections. Preventative measures, including mandatory face masks, and changes in habit that are not captured in our data might alter the future relationship between Google Mobility Reports and case/death growth.

[32] Note that we are *not* evaluating the effect of *universal* mask-wearing for the public but that of mask-wearing for employees. The effect of *universal* mask-wearing for the public could be larger if people comply with such a policy measure. Tian et al. (2020) considered a model in which mask wearing reduces the reproduction number by a factor $(1 - e \cdot pm)^2$, where e is the efficacy of trapping viral particles inside the mask and pm is the percentage of mask-wearing population. Given an estimate of $R_0 = 2.4$, Howard et al. (2020) argue that 50% mask usage and a 50% mask efficacy level would reduce the reproduction number from 2.4 to 1.35, an order of magnitude impact.

The negative coefficients of the log of past cases or deaths in Table 4 is consistent with a hypothesis that higher reported cases and deaths change people's behavior to reduce transmission risks. Such behavioral changes in response to

Table 5 (*continued*).

Dependent variable is the weekly growth rate of confirmed cases (in the upper panel) or deaths (in the lower panel) as defined in Eq. (4). The covariates include lagged policy variables, which are constructed as 7 day moving averages between t to $t-7$ of corresponding daily measures. The row "$\sum_j \text{Policies}_j$" reports the sum of all policy coefficients. "business closure policies" is defined by the average of closed movie theaters, closed restaurants, and closed non-essential businesses. Standard errors are clustered at the state level.

Direct effects capture the effect of policy on case growth holding behavior, information, and confounders constant. Direct effects are given by π in Eq. (BPI→Y). Indirect effects capture how policy changes behavior and behavior shift case growth. They are given by α from (BPI→Y) times β from (PI→B). The total effect is $\pi + \beta\alpha$. Column "PI→Y Coefficients" shows the coefficient estimates from (PI→Y). Columns "Difference" are the differences between the estimates from (PI→Y) and the combination of (BPI→Y) and (PI→B) while column "Average" are their averages. Standard errors are computed by bootstrap and clustered on state.

new information are partly captured by Google mobility measures, but the negative estimated coefficient of past cases or deaths imply that other latent behavioral changes that are not fully captured by Google mobility measures (e.g., frequent hand-washing, wearing masks, and keeping 6ft/2m distancing) are also important for reducing future cases and deaths.

If policies are enacted and behavior changes, then future cases/deaths and information will change, which will induce further behavior changes. However, since the model includes lags of cases/deaths as well as their growth rates, computing a long-run effect is not completely straightforward. We investigate dynamic effects that incorporate feedback through information in Section 5.

Direct effects capture the effect of policy on case growth holding behavior, information, and confounders constant. Direct effects are given by π in Eq. (BPI→Y). Indirect effects capture how policy changes behavior and behavior shift case growth. They are given by α from (BPI→Y) times β from (PI→B). The total effect is $\pi + \beta\alpha$. Column "PI→Y Coefficients" shows the coefficient estimates from (PI→Y). Columns "Difference" are the differences between the estimates from (PI→Y) and the combination of (BPI→Y) and (PI→B) while column "Average" are their averages. Standard errors are computed by bootstrap and clustered on state.

3.4. The total effect of policies on case growth

In this section, we focus our analysis on policy effects when we hold information constant. The estimated effect of policy on behavior in Table 3 and those of policies and behavior on case/death growth in Table 4 can be combined to calculate the total effect of policy as well as its decomposition into direct and indirect effects.

The first three columns of Table 6 show the direct (holding behavior constant) and indirect (through behavior changes) effects of policy under a specification that excludes national information variables. These are computed from the specification with national cases or deaths included as information (columns (1)–(4) of Table 3 and column (1) of Table 4). The estimates imply that all policies combined would reduce the growth rate of cases and deaths by 0.69 and 0.90, respectively, out of which more than one-half to two-third is attributable to the indirect effect through their impact on behavior. The estimate also indicates that the effect of mandatory masks for employees is mostly direct.

We can also examine the total effect of policies and information on case or death growth, by estimating (PI→Y). The coefficients on policy in this regression combine both the direct and indirect effects.

Table 5 shows the full set of coefficient estimates for (PI→Y). The results are broadly consistent with what we found above. As in Table 3, the effect of school closures is sensitive to the inclusion of national information variables. Also as above, mask mandates have a significant negative effect on growth rates.

Similarly to Table 6, the first three columns of Table 7 report the estimated direct and indirect effects of policy but impose that masks for employees only affect cases/deaths directly without affecting behavior and that business closure policies only affect cases/deaths indirectly through their effects on behavior.[33] The estimated total effect of masks for employees in the third column of Table 7 is higher than that of Table 6. Similarly, the total effect of business closure policies is estimated to be larger in Table 7 than in Table 6.

[33] These are computed from estimating the specification in columns (1)–(4) of Table 3 and column (1) of Table 4 but imposing that the coefficient of masks for employees is zero in (BPI→Y) and that the coefficient of business closure policies is zero in (PI→B).

Table 8

Direct effects capture the effect of policy on case growth holding behavior, information, and confounders constant. Direct effects are given by π in Eq. (BPI→Y). Indirect effects capture how policy changes behavior and behavior shift case growth. They are given by α from (BPI→Y) times β from (PI→B). The total effect is $\pi + \beta\alpha$. Column "PI→Y Coefficients" shows the coefficient estimates from (PI→Y). Columns "Difference" are the differences between the estimates from (PI→Y) and the combination of (BPI→Y) and (PI→B) while column "Average" are their averages. Standard errors are computed by bootstrap and clustered on state.

Column "Difference" in Tables 6 and 7 show the difference between the estimate of (PI→Y) in column "PI→Y Coefficient" and the implied estimate from (BPI→Y)-(PI→B) in column "Total". Differences are generally small except for the coefficient of closed K-12 schools and the sum of all policies in Table 6. The large differences in school closures may be due to the difficulty in identifying the effect of school closures given a lack of cross-sectional variation. Imposing the coefficients of masks for employees and business closure policies to be zero in (BPI→Y) and (PI→B), respectively, does not increase differences between "Total" and "PI→Y Coefficient" as reported in the last column of Table 7.

Tables 8 and 9 present the results for a specification that includes national information variables, where the estimates on masks for employees are similar to those in Tables 6 and 7. Column "Difference" of Table 9 indicates that the restrictions of zero coefficients for masks for employees in (BPI→Y) and for business closure policies in (PI→B) are not statistically rejected.

Column "Average" of Tables 6 and 8 reports the average of "Total" and "PI→Y Coefficient" columns. The average is an appealing and simple way to combine the two estimates of the total effect: one relying on the causal structure and another inferred from a direct estimation of equation (PI → Y). We shall be using the average estimate in generating the counterfactuals in the next section. Turning to the results, the estimates of Tables 6 and 8 imply that all policies combined would reduce $\Delta \log \Delta D$ by 0.93 and 0.39, respectively. For comparison, the median of $\Delta \log \Delta D_{it}$ reached its peak in mid-March of about 1.3 (see Fig. A.18 in the appendix). Since then it has declined to near 0. Therefore, −0.93 and −0.39 imply that policy changes can account for roughly one-third to two-third of the observed decrease in death growth. The remainder of the decline is likely due to changes in behavior from information.

Direct effects capture the effect of policy on case growth holding behavior, information, and confounders constant. Direct effects are given by π in Eq. (BPI→Y). Indirect effects capture how policy changes behavior and behavior shift case growth. They are given by α from (BPI→Y) times β from (PI→B). The total effect is $\pi + \beta\alpha$. Column "PI→Y Coefficients" shows the coefficient estimates from (PI→Y). Columns "Difference" are the differences between the estimates from (PI→Y) and the combination of (BPI→Y) and (PI→B) while column "Average" are their averages. Standard errors are computed by bootstrap and clustered on state.

4. Sensitivity analysis

4.1. Specifications, timings, and flexible controls via machine learning

In this section, we provide sensitivity analysis by estimating (PI→Y) with alternative specifications and methods. Fig. 11 shows the 90% confidence intervals of coefficients of (A) masks for employees, (B) closed K-12 school, (C) stay-at-home, and (D) the average variable of closed movie theaters, closed restaurants, and closed non-essential businesses for the following specifications and estimation methods:

(1) Baseline specification in columns (1) and (3) of Table 5.
(2) Exclude the state of New York from the sample because it may be viewed as an outlier in the early pandemic period.
(3) Add the percentage of people who wear masks to protect themselves in March and April as a confounder for unobserved personal risk-aversion and initial attitude toward mask wearing.[34]

[34] The survey is conducted online by YouGov and is based on the interviews of 89,347 US adults aged 18 and over between March 26–April 29, 2020. The survey question is "Which, if any, of the following measures have you taken in the past 2 weeks to protect yourself from the Coronavirus (COVID-19)?".

(4) Add the log of Trump's vote share in the 2016 presidential election as a confounder for unobserved private behavioral response.
(5) Add past behavior variables as information used to set policies. Under this specification, our causal interpretation is valid when policy variables are sufficiently random conditional on past behavior variables.
(6) Include all additional controls in (3)–(5) with the sample that excludes New York as in (2).
(7) Add weekly dummies to the baseline specification.
(8) Baseline specification estimated by instrumenting $\Delta \log T_{it}$ with one week lagged logarithm value of the number of tests per 1000 people.
(9) Estimated by Double Machine Learning (DML) (e.g., Chernozhukov et al., 2018) with Lasso to reduce dimensionality while including all additional controls in (3)–(5).
(10) Estimated by DML with Random Forest to reduce dimensionality and capture some nonlinearities while including all additional controls in (3)–(5).

In Fig. 11, "red", "green", "blue", and "purple" indicate the regression models for case growth without national information variables, case growth with national information variables, death growth without national information variables, and death growth with national information variables, respectively. The left panel of "(i) baseline timing" assume that the times from exposure to case confirmation and death reporting are 14 and 21 days, respectively, while they are 7 and 24 days, respectively, in the right panel of "(ii) alternative timing".[35]

Panel (A) of Fig. 11 illustrates that the estimated coefficients of mask mandates are negative and significant in most specifications, methods, and timing assumptions, confirming the importance of mask policy on reducing case and death growths.

In Panel (B) of Fig. 11, many estimates of closures of K-12 schools suggest that the effect of school closures is large. The visual evidence on growth rates for states with and without school closures in Fig. 12 also suggests that there may be a potentially large effect, though the history is very short. This evidence is consistent with the emerging evidence of prevalence of Covid-19 among children (Lee et al., 2020b; Szablewski et al., 2020). Davies et al. (2020) find that although children's transmission and susceptibility rates are half that of ages 20–30, children's contact rates are much higher. This type of evidence, as well as, evidence that children carry viral loads similar to older people (Jones et al., 2020), led Germany to make the early decision of closing schools.

Our estimates of school closures substantially vary across specifications, however. In particular, the estimated effects of school closures on case/death growth become notably smaller once national cases/deaths or weekly dummies are controlled for. In the US state-level data, there is little variation across states in the timing of school closures. Consequently, its estimate is particularly sensitive to an inclusion of some aggregate variables such as national cases or weekly dummies. Given this sensitivity, there still exists a lot of uncertainty as to the magnitude of the effect of school closures. Any analyses of re-opening plans need to be aware of this uncertainty. An important research question is how to resolve this uncertainty using additional data sources.

Panel (C) of Fig. 11 indicates that the estimated coefficients of stay-at-home orders are generally negative and often significant, providing evidence that stay-at-home orders reduce the spread of COVID-19, although the estimates are sometimes sensitive to timing assumptions. Panel (D) shows that the estimated coefficients of business closure policies substantially vary across specifications, providing a mixed evidence for the effect of closures of businesses on case/death growth.

4.2. Fixed effects specification

Table 10 presents the results of estimating (PI→Y) with state fixed effects and weekly dummies. Because fixed effects estimator could be substantially biased when the time dimension is relatively short, we report not only the standard fixed effects estimator in columns (1) and (3) but also the debiased fixed effects estimator (e.g., Chen et al., 2019) in columns (2) and (4), where the state-level clustered bootstrap standard errors are reported in all columns.

The estimated coefficients of masks for employees largely confirm our finding that mandatory mask policies reduce the case and death growths. The estimated coefficients of stay-at-home orders and business closures are negative in columns (1) and (2) but their magnitudes as well as statistical significance are somewhat sensitive to whether bias corrections are applied or not.

The results in Table 10 should be interpreted with caution. The fixed effects approach may not be preferred to random effects approach here because the former relies on long time and cross-sectional histories but, in our data, the effective time-dimension is short and the number of states is not large. Furthermore, the fixed effects approach could suffer more from measurement errors, which could be a concern for our behavior and policy variables.

[35] This alternative timing assumption is motivated by the lower bound estimate of median times from exposure to case confirmation or death reporting in Table 2 of https://www.cdc.gov/coronavirus/2019-ncov/hcp/planning-scenarios.html, which are based on data received by CDC through June 29, 2020. We thank C. Jessica E. Metcalf for recommending us to do a sensitivity analysis on the timing assumption while suggesting this reference to us.

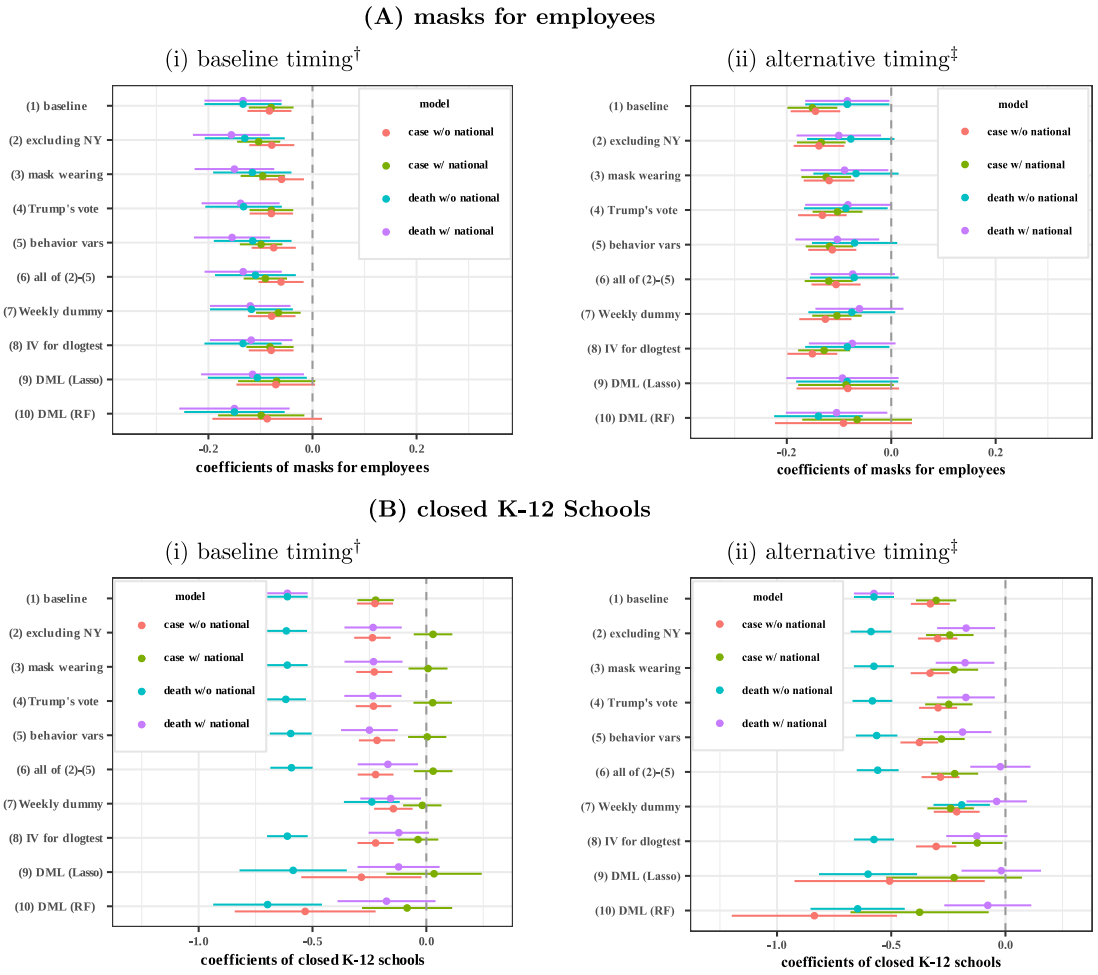

Fig. 11. Estimated Coefficients for Policy Variables: Sensitivity Analysis. †The times from exposure to case confirmation and death reporting are assumed to be 14 and 21 days, respectively. ‡The times from exposure to case confirmation and death reporting are assumed to be 7 and 24 days, respectively. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

5. Empirical evaluation of counterfactual policies

We now turn our focus to dynamic feedback effects. Policy and behavior changes that reduce case and death growth today can lead to a more optimistic, riskier behavior in the future, attenuating longer run effects. We perform the main counterfactual experiments using the average of two estimated coefficients as reported in column "Average" of Table 7 under a specification that excludes the number of past national cases and deaths from information variables and constrains masks to have only direct effects and business policies only indirect effects.[36] Details of the counterfactual computations are in Appendix B.4.

5.1. Business mask mandate

We first consider the impact of a nationwide mask mandate for employees beginning on March 14th. As discussed earlier, we find that mask mandates reduce case and death growth even when holding behavior constant. In other words, mask mandates may reduce infections with relatively little economic disruption. This makes mask mandates a particularly attractive policy instrument. In this section we examine what would have happened to the number of cases if all states had imposed a mask mandate on March 14th.[37]

[36] Results (not shown) using the unconstrained estimates in Table 6 are very similar.

[37] We feel this is a plausible counterfactual policy. Many states began implement business restrictions and school closures in mid March. In a paper made publicly available on April 1st, Abaluck et al. (2020) argued for mask usage based on comparisons between countries with and without pre-existing norms of widespread mask usage.

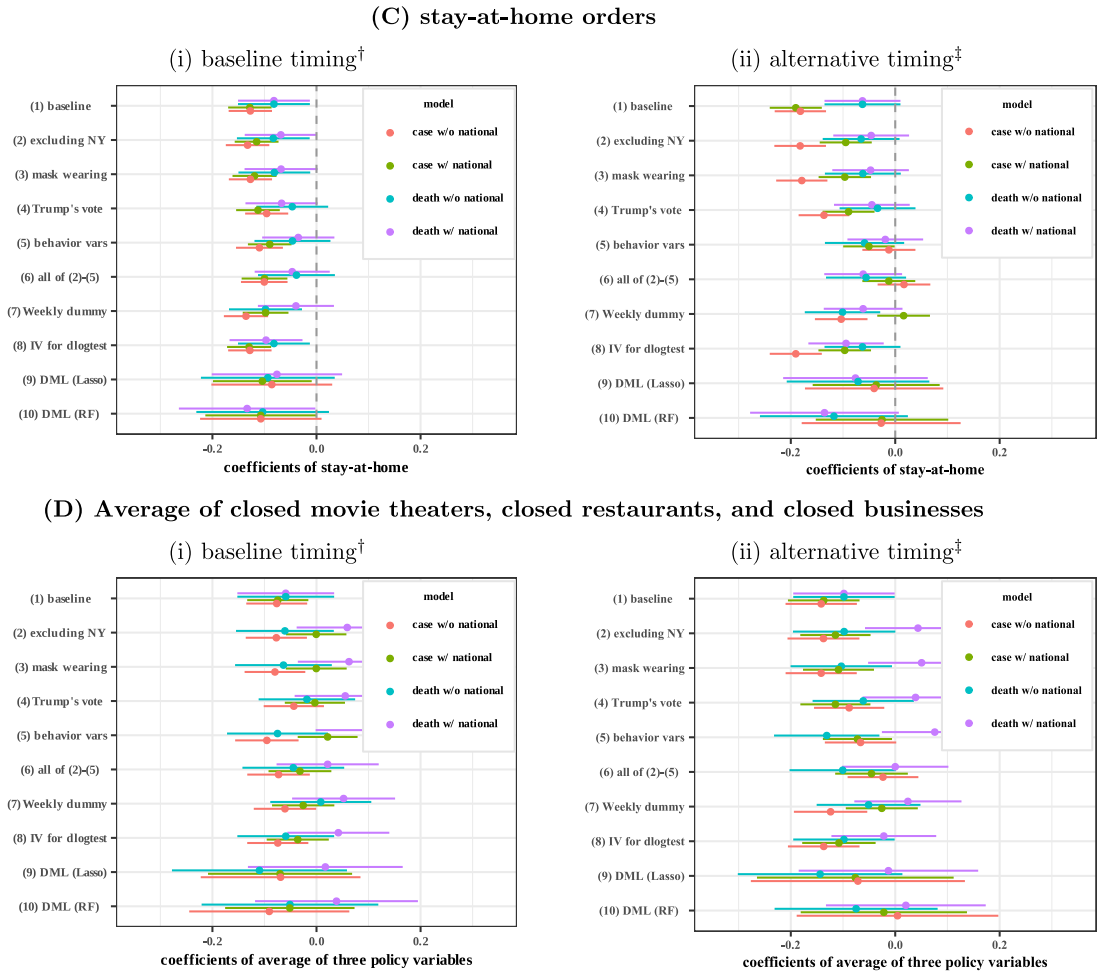

Fig. 11. (*continued*).

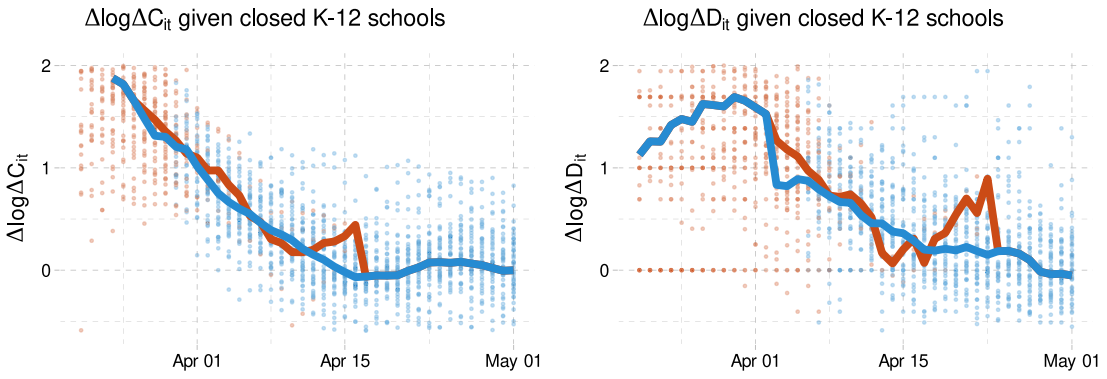

Fig. 12. Case and death growth conditional on school closures. In these figures, red points are the case or death growth rate in states without each policy 14 (or 21 for deaths) days earlier. Blue points are states with each policy 14 (or 21 for deaths) days earlier. The red line is the average across states without each policy. The blue line is the average across states with each policy. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

For illustrative purpose, we begin by focusing on Washington State. The left column of Fig. 13 shows the change in growth rate from mandating masks on March 14th. The shaded region is a 90% pointwise confidence interval. As shown, mandating masks on March 14th lowers the growth of cases or deaths 14 or 21 days later by 0.07 or 0.14. This effect then gradually declines due to information feedback. Mandatory masks reduce past cases or deaths, which leads to less

All specifications include weekly dummies and state fixed effects. Dependent variable is the weekly growth rate of confirmed cases (in the upper panel) or deaths (in the lower panel) as defined in Eq. (4). Columns (1) and (3) report the standard fixed effects estimator while Columns (2) and (4) report the fixed effects estimator with bias corrections. Standard errors are computed by multiplier bootstrap clustered at the state level.

cautious behavior, attenuating the impact of the policy. The reversal of the decrease in growth in late May is due to our comparison of a mask mandate on March 14th with Washington's actual mask mandate in early May. By late May, the counterfactual mask effect has decayed through information feedback, and we are comparing it to the undecayed impact of Washington's actual, later mask mandate.

The middle column of Fig. 13 shows how the changes in case and death growth translate into changes in daily cases and deaths. The estimates imply that mandating masks on March 14th would have led to about 70 fewer cases and 5 fewer deaths per day throughout April and May. Cumulatively, this implies 19% [9, 29]% fewer cases and 26% [14, 37]% fewer deaths in Washington by the start of June.

The results for other states are similar to those for Washington. Fig. 14 shows the national effect of mask mandate on March 14th. The top panel shows the effect on cases and the bottom panel shows the effect on deaths. The left column

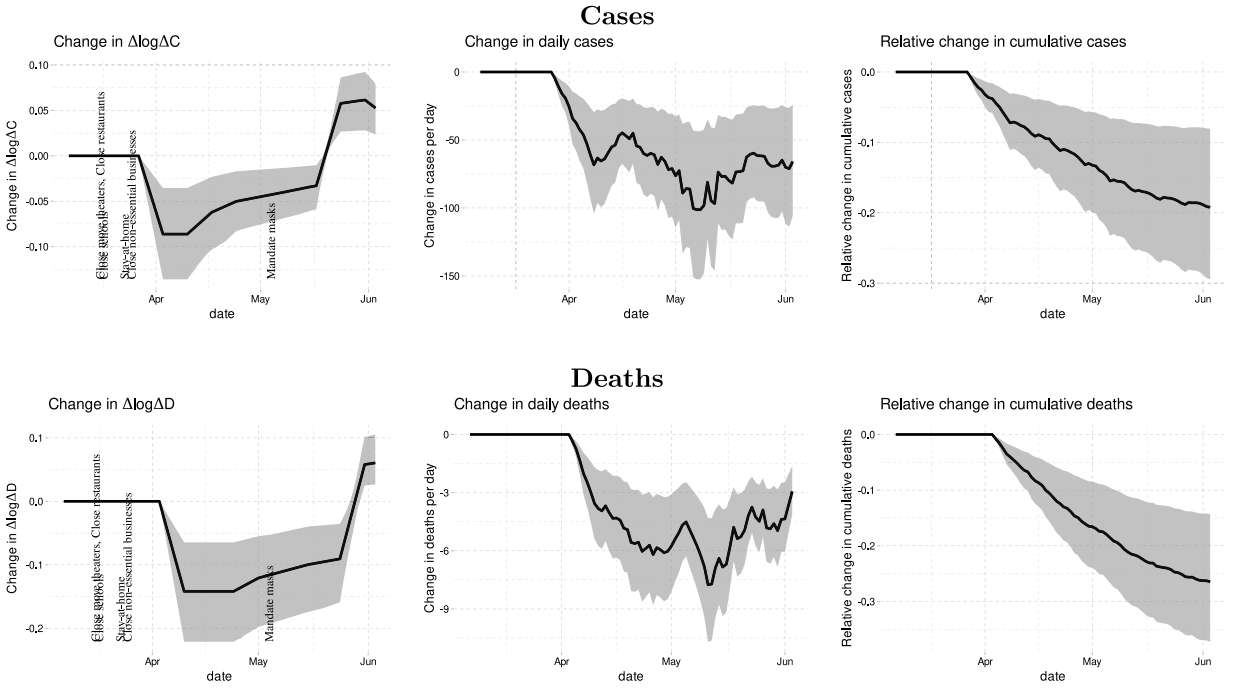

Fig. 13. Effect of mandating masks on March 14th in Washington State. The vertical text denotes the dates that Washington imposed each policy. To compute the estimated and counterfactual paths we use the average of two estimated coefficients as reported in column "Average" of Table 7. We set initial $\Delta \log \Delta C$ and $\log \Delta C$ to their values first observed in the state we are simulating. We hold all other regressors at their observed values. The shaded region is a point-wise 90% confidence interval. See Appendix B.4 for more details.

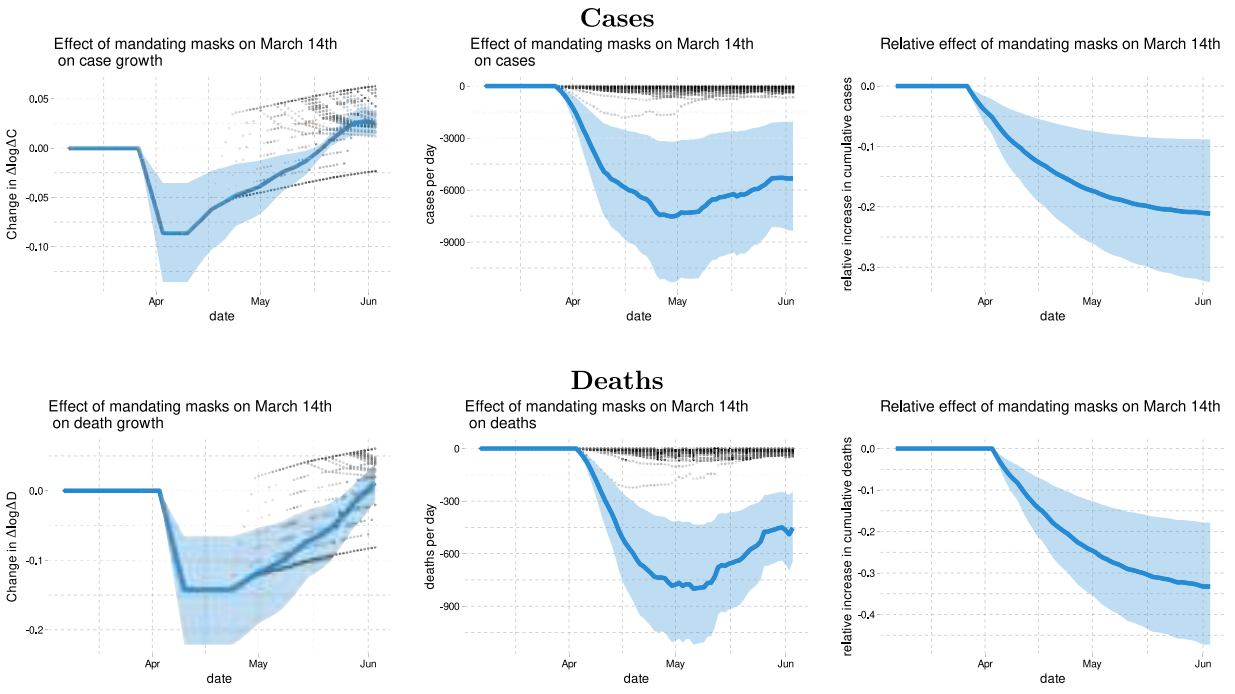

Fig. 14. Effect of nationally mandating masks for employees on March 14th in the US. In the left column, the dots are the average change in growth in each state. The blue line is the average across states of the change in growth. The shaded region is a point-wise 90% confidence interval for the national average change in growth. The middle column shows the total national change in daily cases and deaths. Black dots are the changes in each state. The right column shows the change in cumulative cases or deaths relative to the baseline of actual policies.

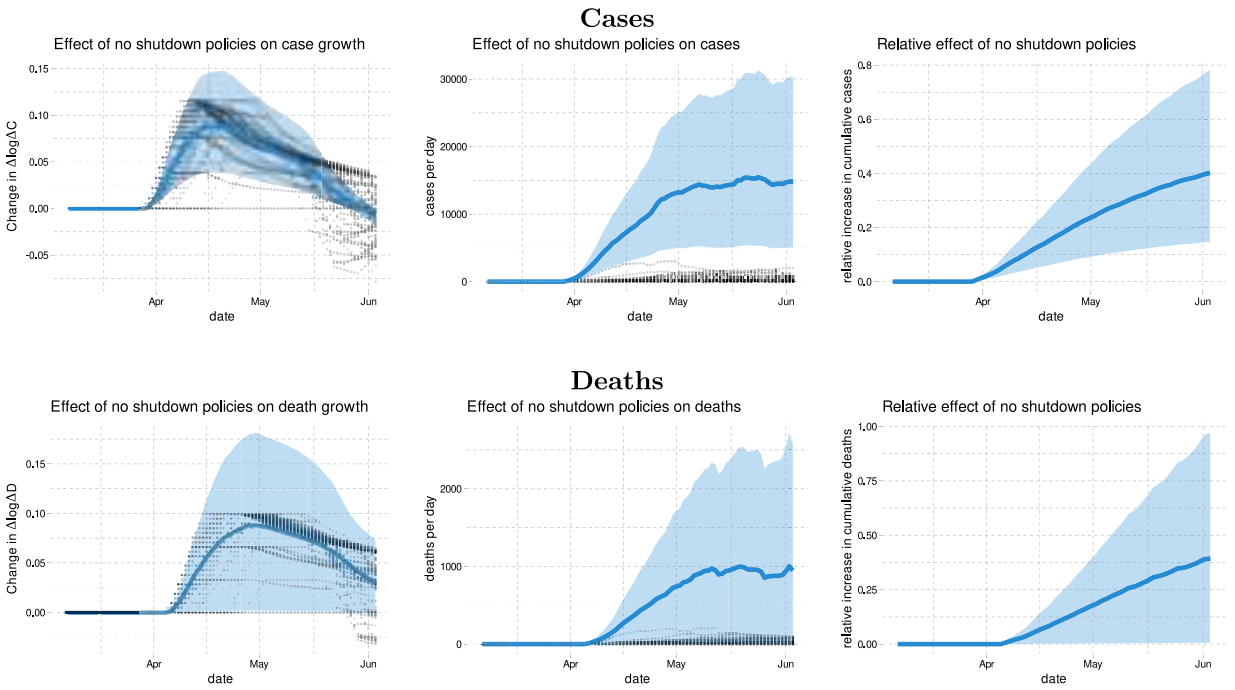

Fig. 15. Effect of having no business closure policies in the US. In the left column, the dots are the average change in growth in each state. The blue line is the average across states of the change in growth. The shaded region is a point-wise 90% confidence interval for the national average change in growth. The middle column shows the total national change in daily cases and deaths. Black dots are the changes in each state. The right column shows the change in cumulative cases or deaths relative to the baseline of actual policies.

shows the change in growth rates. Dots are the average change in growth rate in each state (i.e. the dots are identical to the solid line in the left panel of Fig. 13, except for each state instead of just Washington). The solid blue line is the national average change in growth rate. The shaded region is a 90% pointwise confidence band for the national average change in growth rate.

The middle column shows the changes in cases and deaths per day. Dots are the expected change in each state. The thick line is the national total change in daily cases or deaths. The shaded region is a pointwise 90% confidence band for the national total change. The estimates that a mask mandate in mid March would have decreased cases and deaths by about 6000 and 600 respectively throughout April and May.

The right column of Fig. 14 shows how these daily changes compare to the total cumulative cases and deaths. The right column shows the national relative change in cumulative cases or deaths. The point estimates indicate that mandating masks on March 14th could have led to 21% fewer cumulative cases and 34% fewer deaths by the end of May with their 90 percent intervals given by $[9, 32]$% and $[19, 47]$%, respectively. The result roughly translates into 19 to 47 thousand saved lives.

5.2. Business closure policies

Business closures are particularly controversial. We now examine a counterfactual where there are no business closure policies (no restaurant, movie theater, or non-essential business closure). Fig. 15 shows the national effect of never restricting businesses on cases and deaths. The point estimates imply that, without business closures, cases and deaths would be about 40% higher at the end of May. The confidence intervals are wide. A 90 percent confidence interval for the increase in cases at the end of May is $[17, 78]$%. The confidence interval for deaths is even wider, $[1, 97]$%.

5.3. Stay-at-home orders

We next examine a counterfactual where stay-at-home orders had been never issued. Fig. 16 shows the national effect of no stay-at-home orders. On average, without stay-at-home orders, case growth rate would have been nearly 0.075 higher in late April. This translates to 37% $[6, 63]$% more cases per week by the start of June. The estimated effect for deaths is a bit smaller, with no increase included in a 90 percent confidence interval, $[-7, 50]$%.

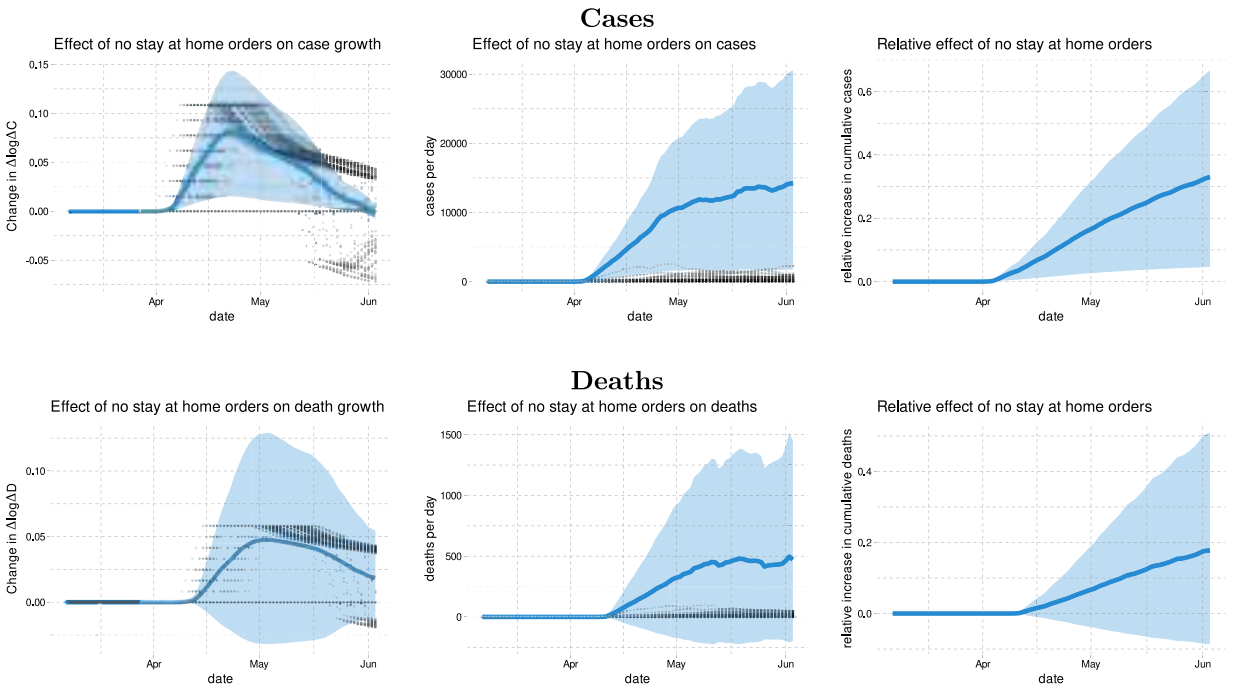

Fig. 16. Effect of having no stay-at-home orders in the US. In the left column, the dots are the average change in growth in each state. The blue line is the average across states of the change in growth. The shaded region is a point-wise 90% confidence interval for the national average change in growth. The middle column shows the total national change in daily cases and deaths. Black dots are the changes in each state. The right column shows the change in cumulative cases or deaths relative to the baseline of actual policies.

6. Conclusion

This paper assesses the effects of policies on the spread of Covid-19 in the US using state-level data on cases, tests, policies, and social distancing behavior measures from Google Mobility Reports. Our findings are summarized as follows.

First, our empirical analysis robustly indicates that mandating face masks has reduced the spread of Covid-19 without affecting people's social distancing behavior measured by Google Mobility Reports. Our counterfactual experiment suggests that if all states had adopted mandatory face mask policies on March 14th of 2020, then the cumulative number of deaths by the end of May would have been smaller by as much as 19 to 47%, which roughly translates into 19 to 47 thousand saved lives.

Second, our baseline counterfactual analysis suggests that keeping all businesses open would have led to 17 to 78% more cases while not implementing stay-at-home orders would have increased cases by 6 to 63% by the end of May although we should interpret these numbers with some caution given that the estimated effect of business closures and stay-at-home orders vary across specifications in our sensitivity analysis.

Third, we find considerable uncertainty over the impact of school closures on case or death growth because it is difficult to identify the effect of school closures from the US state-level data due to the lack of variation in the timing of school closures across states.

Fourth, our analysis shows that people voluntarily reduce their visits to workplace, retail stores, grocery stores, and people limit their use of public transit when they receive information on a higher number of new cases and deaths. This suggests that individuals make decisions to voluntarily limit their contact with others in response to greater transmission risks, leading to an important feedback mechanism that affects future cases and deaths. Model simulations that ignore this voluntary behavioral response to information on transmission risks would over-predict the future number of cases and deaths.

Beyond these findings, our paper presents a useful conceptual framework to investigate the relative roles of policies and information on determining the spread of Covid-19 through their impact on people's behavior. Our causal model allows us to explicitly define counterfactual scenarios to properly evaluate the effect of alternative policies on the spread of Covid-19. More broadly, our causal framework can be useful for quantitatively analyzing not only health outcomes but also various economic outcomes (Bartik et al., 2020; Chetty et al., 2020).

Acknowledgments

We are grateful to Daron Acemoglu, V.V. Chari, Raj Chetty, Christian Hansen, Glenn Ellison, Ivan Fernandez-Val, David Green, Ido Rosen, Konstantin Sonin, James Stock, Elie Tamer, and Ivan Werning for helpful comments. We also thank Chiyoung Ahn, Joshua Catalano, Jason Chau, Samuel Gyetvay, Sev Chenyu Hou, Jordan Hutchings, and Dongxiao Zhang for excellent research assistance. We are especially grateful to C. Jessica E. Metcalf and an anonymous referee for detailed and insightful comments, which considerably improved the paper. All mistakes are our own.

Appendix A. Data construction

A.1. Measuring ΔC and $\Delta \log \Delta C$

We have three data sets with information on daily cumulative confirmed cases in each state. As shown in Table A.11, these cumulative case numbers are very highly correlated. However, Table A.12 shows that the numbers are different more often than not.

The upper left panel of Fig. A.17 shows the evolution of new cases in the NYT data, where daily changes in cumulative cases exhibit some excessive volatility. This is likely due to delays and bunching in testing and reporting of results. Table A.13 shows the variance of log new cases in each data set, as well as their correlations. As shown, the correlations are approximately 0.9. The NYT new case numbers have the lowest variance.[38] In our subsequent results, we will primarily use the case numbers from The New York Times.

For most of our results, we focus on new cases in a week instead of in a day. We do this for two reasons as discussed in the main text. First, a decline in new cases over two weeks has become a key metric for decision makers. Secondly, aggregating to weekly new cases smooths out the noise associated with the timing of reporting and testing.

Table A.14 reports the correlation and variance of weekly log new cases across the three data sets. The upper right panel of Fig. A.17 shows the evolution of weekly new cases in each state over time from the NYT data. The upper panel of Fig. A.18 shows the evolution of the weekly growth rate of new cases in each state over time.

[38] This comparison is somewhat sensitive to how you handle negative and zero cases when taking logs. Here, we replaced log(0) with −1. In our main results, we work with weekly new cases, which are very rarely zero.

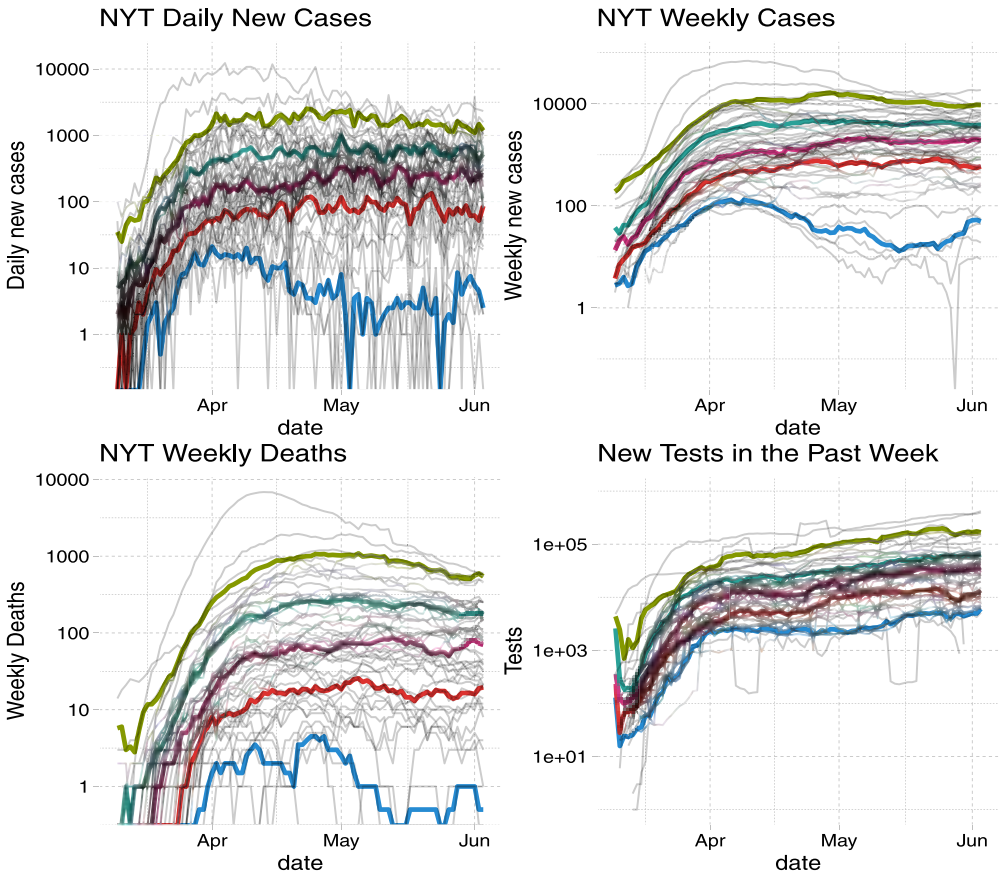

Fig. A.17. Daily Cases, Weekly Cases, Weekly Deaths from NYT Data, and Weekly Tests from JHU. Thin gray lines are the log of cases, death, and tests in each state and date. Thicker colored lines are their quantiles conditional on date. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Table A.15
Correlation and variance of weekly deaths.

	NYT	JHU	CTP
NYT	1.00	0.98	0.97
JHU	0.98	1.00	0.98
CTP	0.97	0.98	1.00
Variance	172292.15	174310.07	126952.94

A.2. Deaths

Table A.15 reports the correlation and variance of weekly deaths in the three data sets. The lower left panel of Fig. A.17 shows the evolution of weekly deaths in each state from the NYT data. As with cases, we use death data from The New York Times in our main results. The lower panel of Fig. A.18 shows the evolution of the weekly growth rate of new deaths in each state over time.

A.3. Tests

Our test data comes from The Covid Tracking Project. The lower right panel of Fig. A.17 shows the evolution of the weekly number of tests over time.

A.4. Social distancing measures

In measuring social distancing, we focus on Google Mobility Reports. This data has international coverage and is publicly available. Fig. A.19 shows the evolution of the four Google Mobility Reports variables that we use in our analysis.

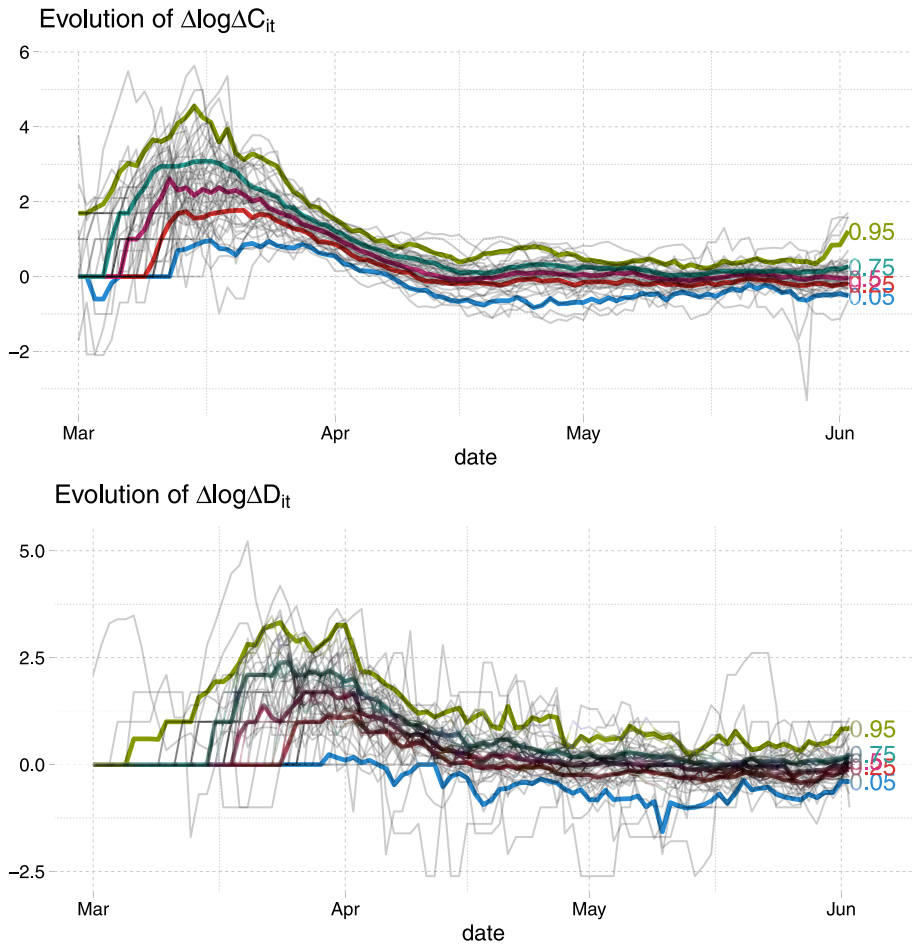

Fig. A.18. Case and death growth. Thin gray lines are case or death growth in each state and date. Thicker colored lines are quantiles of case or death growth conditional on date. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

A.5. Policy variables

We use the database on US state policies created by Raifman et al. (2020). As discussed in the main text, our analysis focuses on six policies. For stay-at-home orders, closed nonessential businesses, closed K-12 schools, closed restaurants except takeout, and closed movie theaters, we double-checked any state for which Raifman et al. (2020) does not record a date. We filled in a few missing dates. Our modified data is available here. Our modifications fill in 1 value for school closures, 2 for stay-at-home orders, 3 for movie theater closure, and 4 for non-essential business closures. Table A.16 displays all 25 dated policy variables in Raifman et al. (2020)'s database with our modifications described above.

Figs. A.20–A.21 show the average case and death growth conditional on date and whether each of six policies is implemented or not.

A.6. Timing

There is a delay between infection and when a person is tested and appears in our case data. MIDAS (2020) maintain a list of estimates of the duration of various stages of Covid-19 infections. The incubation period, the time from infection to symptom onset, is widely believed to be 5 days. For example, using data from Wuhan, Li et al. (2020) estimate a mean incubation period of 5.2 days. Siordia (2020) reviews the literature and concludes the mean incubation period is 3–9 days.

Estimates of the time between symptom onset and case reporting or death are less common. Using Italian data, Cereda et al. (2020) estimate an average of 7.3 days between symptom onset and reporting. Zhang et al. (2020a) find an average of 7.4 days using Chinese data from December to early February, but they find this period declined from 8.9 days in

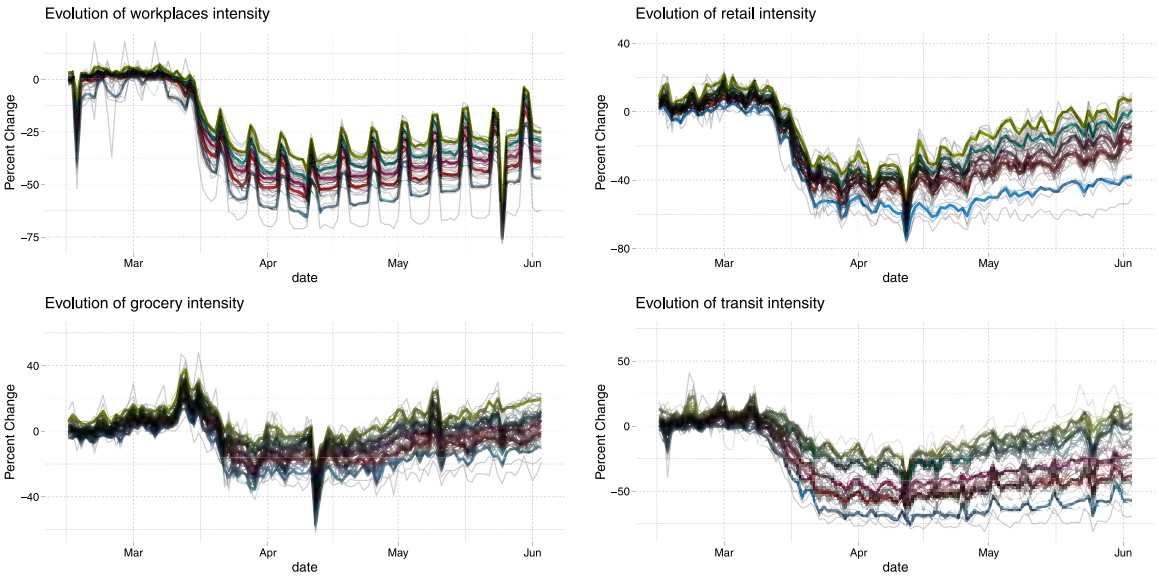

Fig. A.19. Evolution of Google Mobility Reports. This figure shows the evolution of Google Mobility Reports over time. Thin gray lines are the value of the variables in each state and date. Thicker colored lines are quantiles of the variables conditional on date. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Table A.16
State Policies.

	N	Min	Median	Max
State of emergency	51	2020-02-29	2020-03-11	2020-03-16
Date closed K 12 schools	51	2020-03-13	2020-03-17	2020-04-03

Mandate face mask use by employees in public facing businesses	44	2020-04-03	2020-05-01	2020-08-03
Stop Initiation of Evictions overall or due to COVID related issues	30	2020-03-16	2020-03-24	2020-05-30
Stop enforcement of evictions overall or due to COVID related issues	29	2020-03-15	2020-03-24	2020-06-08
Renter grace period or use of security deposit to pay rent	3	2020-04-10	2020-04-24	2020-05-20
Order freezing utility shut offs	34	2020-03-12	2020-03-19	2020-04-13
Froze mortgage payments	1	2020-03-21	2020-03-21	2020-03-21
Waived one week waiting period for unemployment insurance	36	2020-03-08	2020-03-18	2020-04-06

January to 5.4 days in the first week of February. Both of these papers on time from symptom onset to reporting have large confidence intervals covering approximately 1 to 20 days.

Studying publicly available data on infected persons diagnosed outside of Wuhan, Linton et al. (2020) estimate an average of 15 days from onset to death. Similarly, using publicly available reports of 140 confirmed Covid-19 cases in China, mostly outside Hubei Province, Sanche et al. (2020) estimate the time from onset to death to be 16.1 days.

Based on the above, we expect a delay of roughly two weeks between changes in behavior or policies, and changes in reported cases while a corresponding delay of roughly three weeks for deaths.

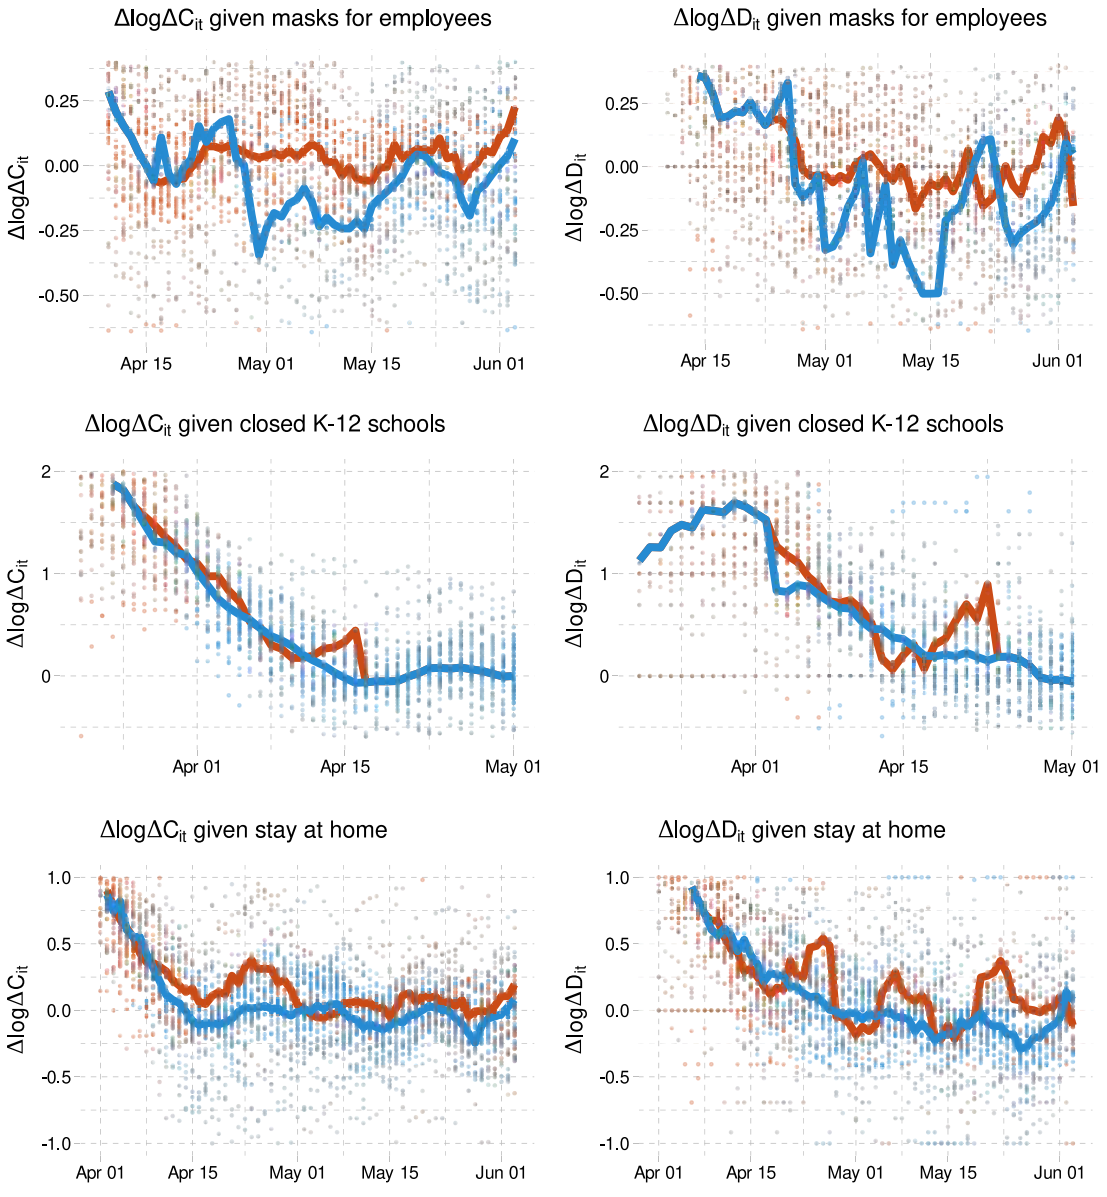

Fig. A.20. Case and death growth conditional on policies. In these figures, red points are the case or death growth rate in states without each policy 14 (or 21 for deaths) days earlier. Blue points are states with each policy 14 (or 21 for deaths) days earlier. The red line is the average across states without each policy. The blue line is the average across states with each policy. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Appendix B. Additional results

B.1. Direct and indirect policy effects with national case/death variables

Tables 8 and 9 present the estimates of direct and indirect effects of policies for the specification with past national case/death variables. The effects of school closures and the sum of policies are estimated substantially smaller in Table 8 when national case/death variables are included than in Table 6. This sensitivity reflects the difficulty in identifying the aggregate time effect—which is largely captured by national cases/deaths—given little cross-sectional variation in the timing of school closures across states. On the other hand, the estimated effects of policies other than school closures are similar between Tables 6 and 8; the effect of other policies are well-identified from cross-sectional variations.

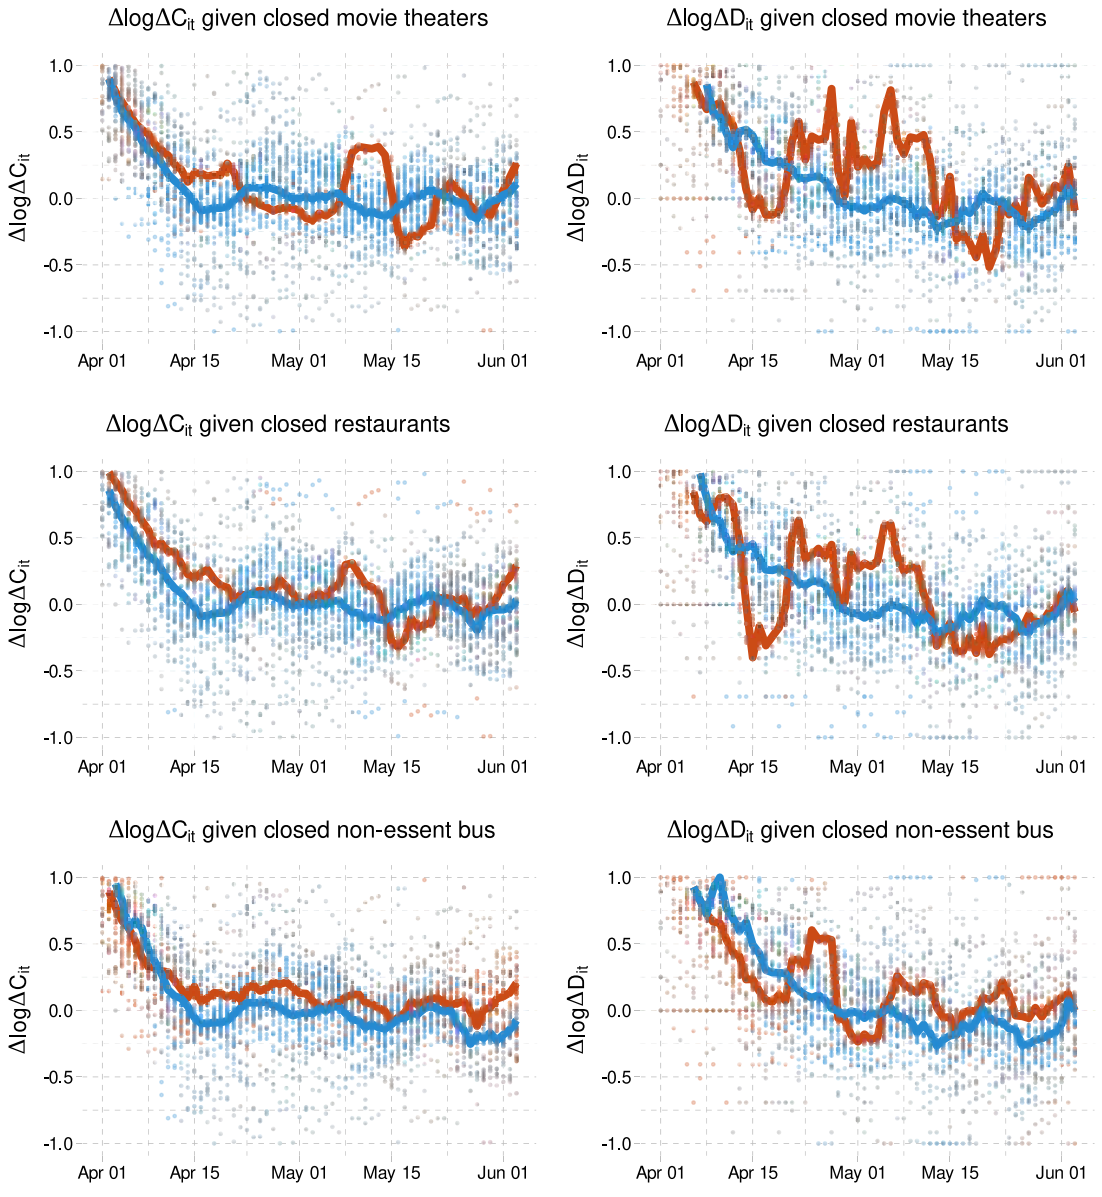

Fig. A.21. Case and death growth conditional on policies. In these figures, red points are the case or death growth rate in states without each policy 14 (or 21 for deaths) days earlier. Blue points are states with each policy 14 (or 21 for deaths) days earlier. The red line is the average across states without each policy. The blue line is the average across states with each policy. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

B.2. Double machine learning

To estimate the coefficient of the jth policy variable, P_{it}^j, using double machine learning (Chernozhukov et al., 2018), we consider a version of (PI→Y) as follows:

$$Y_{i,t+\ell} = P_{it}^j \theta_0 + \phi' X_{it} + g_0(W_{it}) + \xi_{it}, \qquad E[\xi_{it} | P_{it}^j, X_{it}, W_{it}] = 0,$$
$$P_{it}^j = \psi' X_{it} + m_0(W_{it}) + V_{it}, \qquad E[V_{it} | X_{it}, W_{it}] = 0,$$

where $X_{it} = ((P_{it}^{-j})', B_{it}', I_{it}')'$ collects policy variables except for the jth policy variables P_{it}^{-j}, behavior variables B_{it}, and information variables I_{it}. The confounding factors W_{it} affect the policy variable P_{it}^j via the function $m_0(W)$ and the outcome variable $Y_{i,t+\ell}$ via the function $g_0(W)$. We apply Lasso or Random Forests to estimate $g_0(W)$ for dimension reductions or for capturing non-linearity while the coefficients of X_{it} are estimated under linearity without imposing any dimension

reductions. We omit the details of estimation procedure here. Please see the discussion in Example 1.1 of Chernozhukov et al. (2018) for reference.

B.3. Debiased fixed effects estimator

We apply cross-over Jackknife bias correction as discussed in Chen et al. (2020) in detail. Here, we briefly describe our debiased fixed effects estimator.

Given our panel data with $N = 51$ states and $T = 75$ days for case growth equation (PI→Y), consider two subpanels as follows:

$$\mathbf{S}_1 = \{(i,t) : i \leq \lceil N/2 \rceil, t \leq \lceil T/2 \rceil\} \cup \{(i,t) : i \geq \lfloor N/2+1 \rfloor, t \geq \lfloor T/2+1 \rfloor\}$$

and

$$\mathbf{S}_2 = \{(i,t) : i \leq \lceil N/2 \rceil, t \geq \lfloor T/2+1 \rfloor\} \cup \{(i,t) : i \geq \lfloor N/2+1 \rfloor, t \leq \lceil T/2 \rceil\}$$

where $\lceil . \rceil$ and $\lfloor . \rfloor$ are the ceiling and floor functions. Each of these two subpanels includes observations for all cross-sectional units and time periods.

We form the debiased fixed effects estimator as

$$\widehat{\beta}_{BC} = 2\widehat{\beta} - \widetilde{\beta}_{\mathbf{S}_1 \cup \mathbf{S}_2},$$

where $\widehat{\beta}$ is the standard fixed effects estimator while $\widetilde{\beta}_{\mathbf{S}_1 \cup \mathbf{S}_2}$ denotes the fixed effects estimator using the data set $\mathbf{S}_1 \cup \mathbf{S}_2$ but treats the states in $\mathbf{S}_1$ differently from those in $\mathbf{S}_2$ to form the fixed effects estimator; namely, we include approximately twice more state fixed effects to compute $\widetilde{\beta}_{\mathbf{S}_1 \cup \mathbf{S}_2}$.[39] We obtain bootstrap standard errors by using multiplier bootstrap with state-level clustering.

B.4. Details for computing counterfactuals

We compute counterfactuals from the "total effect" version of the model, with behavior concentrated out.

$$Y_{i,t+\ell} = \mathsf{a}' P_{it} + \mathsf{b}' I_{it} + \tilde{\delta}' W_{it} + \bar{\varepsilon}_{it}$$

We consider a counterfactual change of P_{it} to $P^\star_{it}$, while W_{it} and $\bar{\varepsilon}_{it}$ are held constant. In response to the policy change, $Y_{i,t+\ell}$ and the part of I_{it} that contains Y_{it}, change to $Y^\star_{i,t+\ell}$ and $I^\star_{it}$. To be specific, let C_{it} denote cumulative cases in state i on day t. Our outcome is:

$$Y_{i,t+\ell} \equiv \log\left(C_{i,t+\ell} - C_{i,t+\ell-7}\right) - \log\left(C_{i,t+\ell-7} - C_{i,t+\ell-14}\right) \equiv \Delta \log \Delta C_{i,t+\ell}$$

where Δ is a 7 day difference operator. Writing the model in terms of $\Delta \log \Delta C$ we have:

$$\Delta \log \Delta C_{i,t+\ell} = \mathsf{a}' P_{it} + \mathsf{b}_D \Delta \log \Delta C_{i,t} + \mathsf{b}_L \log \Delta C_{i,t} + \tilde{\delta}' W_{it} + \bar{\varepsilon}_{it}$$

To simplify computation, we rewrite this model in terms of $\log \Delta C$:

$$\log \Delta C_{i,t+\ell} = \mathsf{a}' P_{it} + \log \Delta C_{i,t+\ell-7} + (\mathsf{b}_D + \mathsf{b}_L) \log \Delta C_{i,t} - \mathsf{b}_D \log \Delta C_{i,t-7} + \tilde{\delta}' W_{it} + \bar{\varepsilon}_{it}$$

This equation is used to iteratively compute $\log \Delta C^\star_{i,t+\ell}$ conditional on initial $\{\log \Delta C_{i,s}\}_{s=-\ell-7}^{0}$, and the entire sequence of $\{W_{i,t}, P^\star_{i,t}, \bar{\varepsilon}_{it}\}_{t=0}^{T}$.

Weekly cases instead of log weekly cases are given simply by

$$\Delta C^\star_{i,t+\ell} = \exp(\log \Delta C^\star_{i,t+\ell})$$

Cumulative cases can be recursively computed as:

$$C_{i,t} = C_{i,t-7} + \Delta C_{i,t} = C_{i,t-7} + \exp(\log \Delta C_{i,t})$$

given initial $\{C_{i,s}\}_{s=-7}^{0}$.

Note that $\log \Delta C^\star_{i,t+\ell}$ depends linearly on $\bar{\varepsilon}$, so the residuals (and our decision to condition on versus integrate them out) do not matter when considering linear constants of $\log \Delta C_{it}$ or $\Delta \log \Delta C_{it}$, or when considering relative contrasts of ΔC_{it}.

[39] Alternatively, we may form the cross-over jackknife corrected estimator as $\widehat{\beta}_{CBC} = 2\widehat{\beta} - (\widetilde{\beta}_{\mathbf{S}_1} + \widetilde{\beta}_{\mathbf{S}_2})/2$, where $\widetilde{\beta}_{\mathbf{S}_j}$ denotes the fixed effect estimator using the subpanel $\mathbf{S}_j$ for $j = 1, 2$. In our empirical analysis, these two cross-over jackknife bias corrected estimators give similar result.

Inference

Let $S(\theta, \boldsymbol{\varepsilon})$ denote some counterfactual quantity or contrast of interest, where $\theta = (\mathrm{a}, \mathrm{b}, \tilde{\delta})$ are the parameters, and $\boldsymbol{\varepsilon}$ is the vector of residuals. Examples of S that we compute include:

- Contrasts of growth rates: $S(\theta, \boldsymbol{\varepsilon}) = \Delta \log \Delta C_{it}^{\star} - \Delta \log \Delta C_{it}$
- Relative contrasts of weekly cases: $S(\theta, \boldsymbol{\varepsilon}) = \Delta C_{it}^{\star} / \Delta C_{it}$
- Relative contrasts of cumulative cases: $S(\theta, \boldsymbol{\varepsilon}) = \frac{C_{it}^{\star} - C_{it}}{C_{it}}$

The first two examples do not actually depend on $\boldsymbol{\varepsilon}$, but the third one does. Inference is by simulation. Let $\hat{\theta}$ denote our point estimates and $\hat{\boldsymbol{\varepsilon}}$ the associated residuals. We draw $\tilde{\theta}_j$ from the asymptotic distribution of $\hat{\theta}$. Let $\tilde{\varepsilon}_j$ denote the residuals associated with $\tilde{\theta}_j$. We then compute $\tilde{s}_j = S(\tilde{\theta}_j, \tilde{\varepsilon}_j)$ for $j = 1, \ldots, 200$ and plots the mean across j as a point estimate and quantiles across j for confidence intervals.

Face Masks and GDP

29 JUN 2020 TOPICS: COVID-19 | ECONOMIC OUTLOOKS

New US coronavirus cases have risen sharply in recent weeks, leading investors to worry that renewed lockdowns will again depress economic activity. But since the first infection wave in March and April, it has become clear that broad lockdowns are not the only way to lower virus transmission, and many governments have started to require the wearing of face masks in public settings. Should the United States follow suit with a national mandate? This is inherently a political decision, but we can

use our analytical tools to answer three questions that are relevant to it. First, how effective is a face mask mandate in increasing face mask usage? Second, does increased face mask usage lower virus transmission, and if so by how much? And third, how economically valuable is a face mask mandate in terms of reducing the need for broad lockdowns with their well-documented negative effects on GDP?

VIEW VIDEO: Jan Hatzius, head of Goldman Sachs Research and the firm's chief economist, explores the link between face masks and coronavirus outcomes, and the economic value of a national face mask mandate in reducing the need for broad lockdowns.

- The sharp increase in confirmed coronavirus cases in the US Sun Belt has led investors to worry about renewed broad lockdowns with large negative effects on GDP. But there are also other ways to reduce infections, including stringent bans on large gatherings and greater use of face masks.
- In particular, we argue that a national face mask mandate could partially substitute for renewed lockdowns. We start by showing that a national mandate would likely increase face mask usage

meaningfully, especially in states such as Florida and Texas where masks remain largely voluntary to date.

- We then investigate the link between face masks and coronavirus outcomes. Our analysis includes 1) a US regional panel in which we relate the growth rate of infections and fatalities to the introduction of state face mask mandates, 2) a large country-level cross section in which we relate cumulative infections and fatalities to the lag between the onset of spread and the introduction of a face mask mandate, and 3) a smaller country-level panel in which we relate the growth rate of infections and fatalities to lagged mask usage.
- We find that face masks are associated with significantly better coronavirus outcomes. Since this is true across all three of our models and the results are robust to the inclusion of a number of control variables, it seems to reflect a largely causal impact of masks rather than correlation with other factors (such as reduced mobility or avoidance of large gatherings). Our baseline estimate is that a national mandate could raise the percentage of people who wear masks by 15pp and cut the daily growth rate of confirmed cases by 1.0pp to 0.6%.
- Finally, we translate our results into GDP terms by asking how much our Effective Lockdown Index (ELI) would need to increase in order to cut infections by as much as a national mask mandate, and then converting the ELI impact into a GDP impact using the estimated cross-country relationship between the two. These calculations imply that a face mask mandate could potentially substitute for lockdowns that would otherwise subtract nearly 5% from GDP.

Face Masks and GDP [1]

New US coronavirus cases have risen sharply in recent weeks, with most of the deterioration concentrated in the "Sun Belt," including Florida, Texas, Arizona, and California. This has led investors to worry that renewed lockdowns will again depress economic activity. By our estimates, the increase in our Effective Lockdown Index (ELI)—a combination of official restrictions and actual social distancing data—subtracted 17% from US GDP between January and April, and other countries with even more aggressive restrictions saw even larger economic effects.

Since the first infection wave in March and April, however, it has become clear that broad lockdowns are not the only way to lower virus transmission significantly. For one thing, public health experts have long believed that bans on large gatherings can bring disproportionate benefits. This belief has only grown with a multitude of studies documenting the importance of "super spreader" events, such as those associated with the Shinjeonji Church in South Korea, the Austrian ski resort Ischgl, various European soccer matches, and the celebrations in New Orleans for Mardi Gras.

A more abrupt shift has occurred in the official view on face masks. As late as March 30, the World Health Organization advised that there was "no specific evidence to suggest that the wearing of masks by the mass population has any potential benefit."[2] Since

then, however, the public health community's thinking has changed dramatically and many governments have started to require the wearing of face masks.

Should the United States follow these countries and adopt a national face mask mandate? This is inherently a political decision, but we can use our analytical tools to answer three questions that are relevant to it. First, how effective is a face mask mandate in increasing face mask usage? Second, does increased face mask usage lower virus transmission, and if so by how much? And third, how economically valuable is a face mask mandate in terms of reducing the need for broad lockdowns with their well-documented negative effects on GDP?

Face Mask Mandates and Usage

At present, the United States is among the less restrictive countries with respect to face mask mandates. The federal government did issue a national "recommendation" to wear masks in public settings in April, and many state and local governments have taken more stringent measures. However, a recommendation is not a mandate and the governors of both Florida and Texas—the two most heavily affected large states—recently reiterated their opposition to a statewide mask mandate. By contrast, many European countries now have national mask mandates in place, as shown in Exhibit 1, and much of East Asia has strong social norms of mask wearing when sick and during pandemics.

Exhibit 1: The US Is Among the Less Restrictive Economies with Respect to Face Mask Mandates

Economy	Region	Mask Policy*	Policy Details*	Date Implemented*

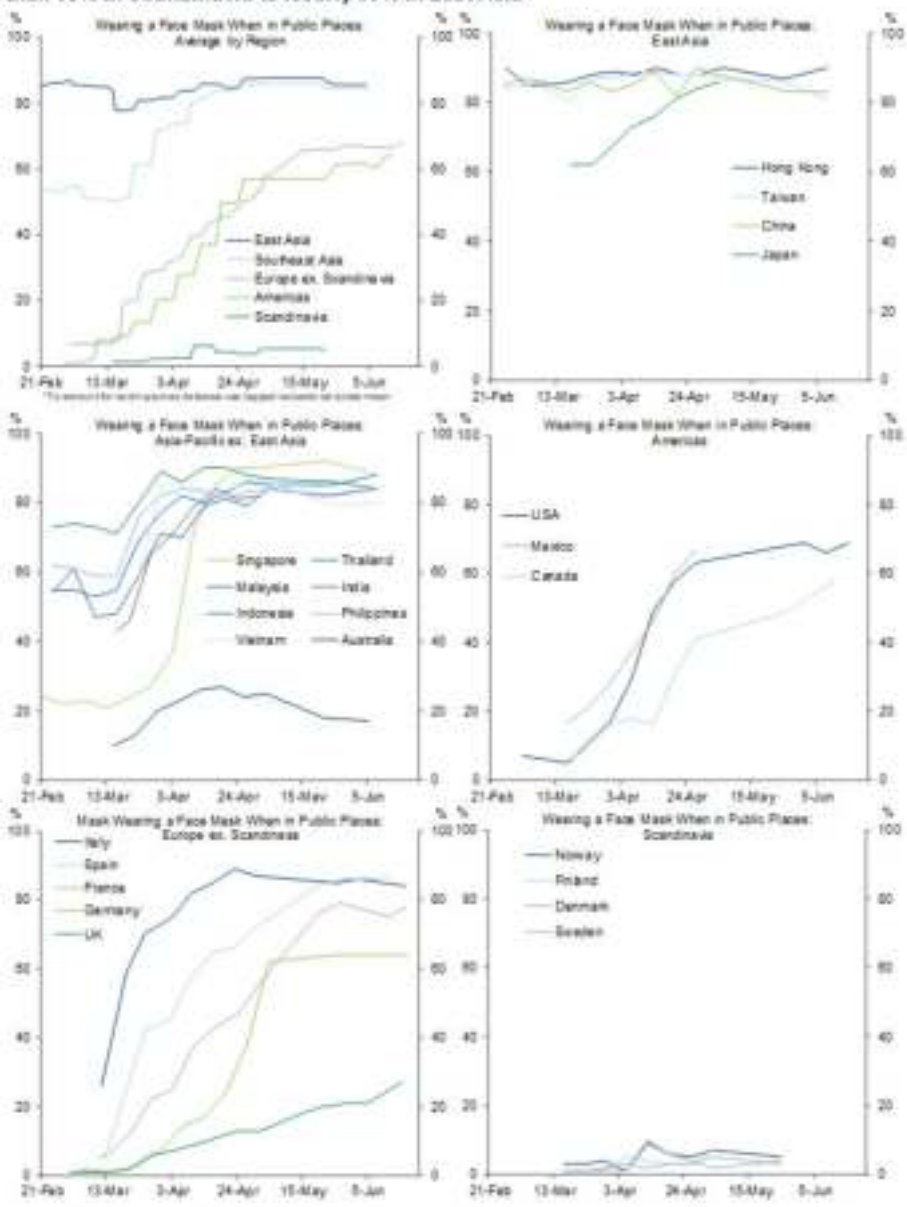
** Where social distancing is not possible.
*** List not exhaustive.

Source: masks4all.co, Leffler et al. 2020, Goldman Sachs Global Investment Research

What about actual mask usage? In this respect, the US scores somewhat better than one might expect, at least when looking at the national self-reported average. As shown in Exhibit 2, the share of respondents saying that they wear a face mask in public is nearly 90% in East Asia, 80% in Southern Europe, just below 70% in the US and Germany, 30% in the UK, and as low as 10% in Scandinavia. Most countries, including the US, have seen large increases in self-reported mask usage since the start of the pandemic.

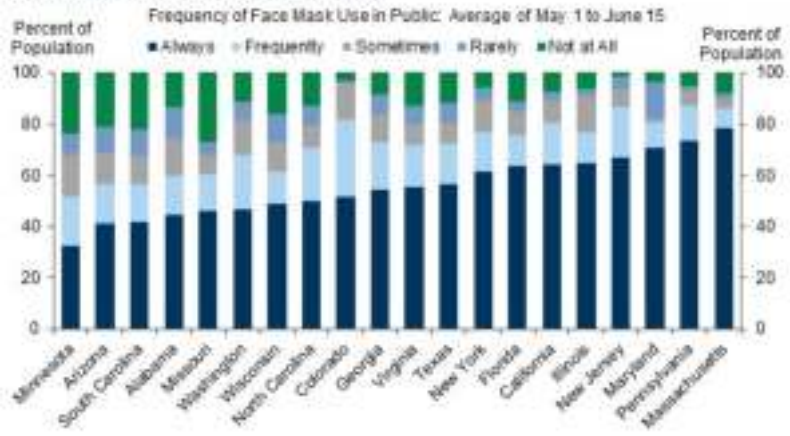
Exhibit 2: The Percentage of People Saying That They Wear a Face Mask in Public Ranges from Less than 10% in Scandinavia to Nearly 90% in East Asia



Source: YouGov, Goldman Sachs Global Investment Research

However, the national data don't tell the full story. As shown in Exhibit 3, face mask usage is highest in the Northeast, where the virus situation has improved dramatically in recent months, and generally lower in the South, where the numbers have deteriorated.[3] For example, only about 40% of respondents in Arizona say that they "always" wear face masks in public, compared with nearly 80% in Massachusetts.

Exhibit 3: The Share "Always" Wearing a Face Mask in Public Ranges from Around 40% in Minnesota and Arizona to 80% in Massachusetts



Source: YouGov, Goldman Sachs Global Investment Research

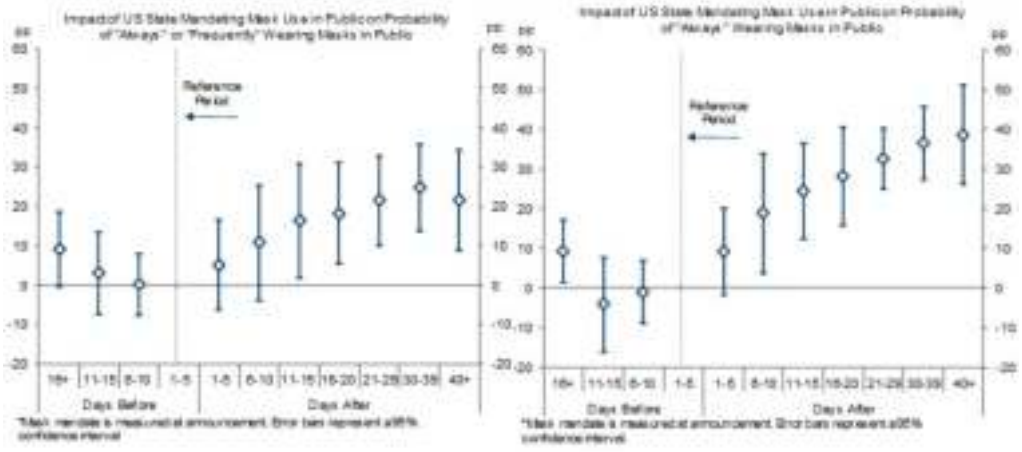
How effective would a national mask mandate be in pushing mask usage to Southern European or East Asian levels? To investigate this, we turn to a statistical event study that relates the adoption of mask mandates across US states to subsequent changes in self-reported mask usage.

We analyze the impact of face mask mandates issued by 20 US states plus DC between April 8 and June 24 in a state panel. We collect the announcement dates of mask mandates from a study in Health Affairs by Wei Lyu and George Wehby and construct statewide time series of face mask usage outside the home using YouGov Covid-19 Behaviour Tracker respondent-level data. We regress state-level mask usage on various event time dummies around the announcement and include state fixed effects and time fixed effects.[4]

Exhibit 4 shows our estimates of a large and highly significant impact of mandates on mask usage. We estimate that statewide mask mandates gradually raise the percentage of people who "always" or "frequently" wear masks by around 25pp in the 30+ days after

signing (left panel). The percent of respondents who "always" wear masks rises by nearly 40pp 30+ days after, reflecting some people switching from "frequently" and other categories to "always" (right panel).

Exhibit 4: Mask Mandates Raise the Percentage of People Who "Always" or "Frequently" Wear Masks by Around 25pp in the 30+ Days After Signing



Source: YouGov, Goldman Sachs Global Investment Research

Exhibit 4 suggests that a national mask mandate could increase US face mask usage by statistically significant and economically large amounts, especially in states such as Florida and Texas that currently don't have a comprehensive mandate and are seeing some of the worst outbreaks. Specifically, we estimate that a national mandate would increase the national average share of people who "always" or "frequently" wear masks by 15pp. This estimate is based on two assumptions. First, we assume that states that currently don't have a mandate—which account for 50% of the population—experience a 25pp rise in mask usage in line with the average response to statewide mandates. Second, we assume that states which already have a state mandate see a 5pp increase in mask usage because of increased focus on the issue.

Face Masks and Virus Outcomes

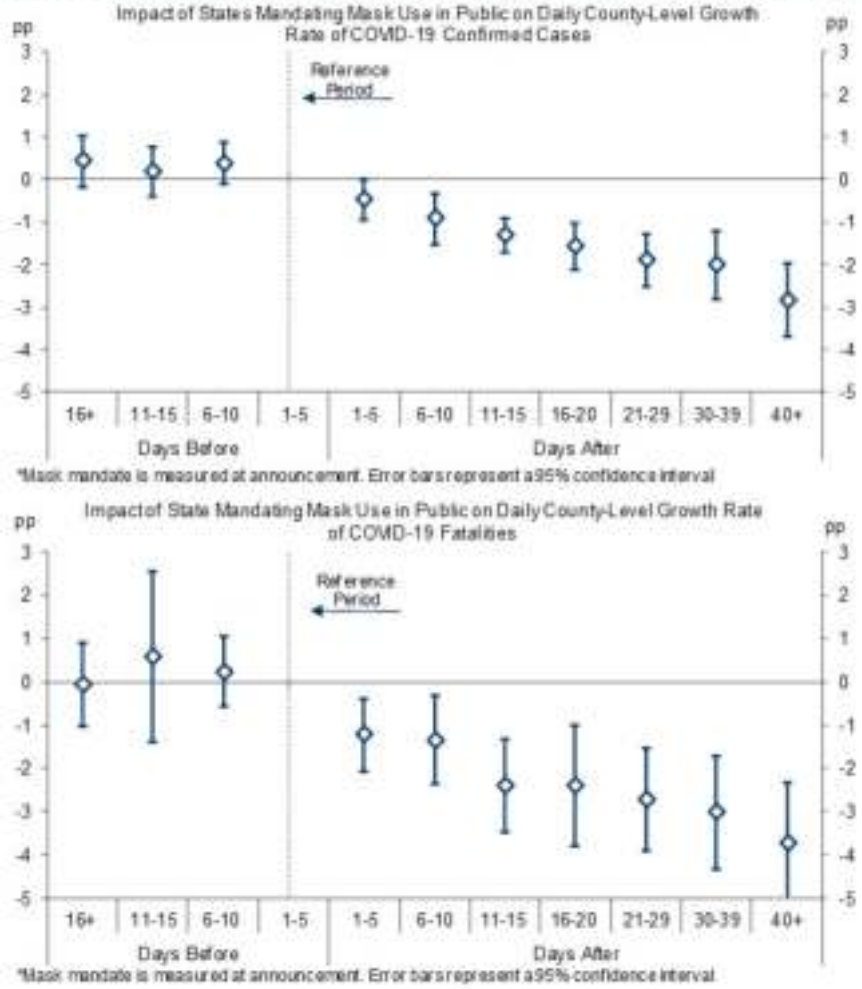
Approach 1: US County Panel

Does increased face mask usage lower virus transmission, and if so by how much? To investigate this, we turn to three statistical approaches relating face mask usage and mandates to virus spread and fatalities.

Our first approach extends our event study analysis of US state-level mandates to the impact on the growth rate of infections and fatalities. Specifically, we regress county-level growth rates of infections and fatalities on event time dummies around the announcement and control for state fixed effects, time fixed effects, and a rich set of county-level controls.[5]

As shown in Exhibit 5, we estimate that face mask mandates have large and highly statistically significant effects on health outcomes. Our estimates imply that mask mandates lower the infection growth rate by 1.3pp in the 11-15 days after announcement. Relative to the 5.4% average infection growth rate prior to announcement, the growth rate of infections is cut by 25%. We also estimate significant and somewhat larger declines in the growth rate of COVID-19 fatalities of 2.4pp in the 11-15 days after announcement and of 3.7pp in the 21-29 days after.

Exhibit 5: Mask Mandates Are Associated with Large Declines in COVID-19 Case and Fatality Growth



Source: YouGov, Goldman Sachs Global Investment Research

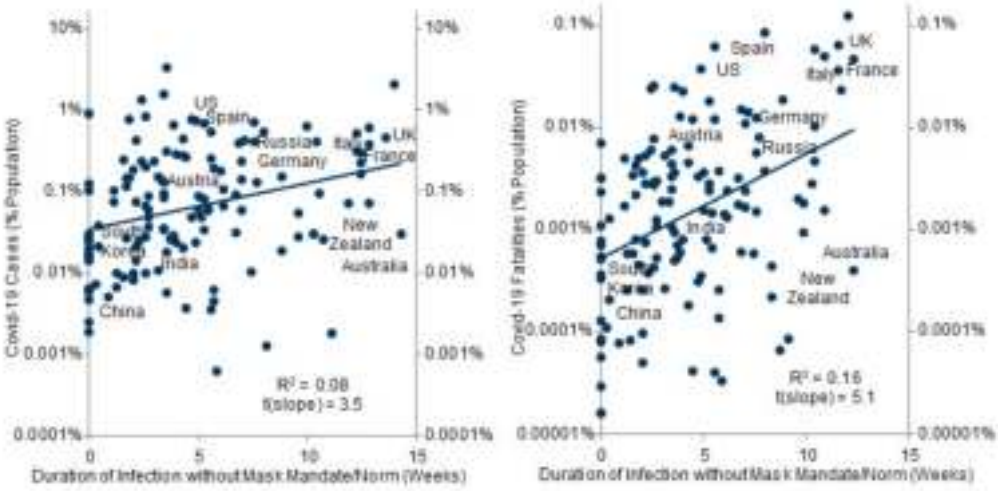
Approach 2: Large Country Cross-Section

Our second approach is a large country cross section in which we relate cumulative case counts and fatalities to the lag between the onset of spread and the introduction of a face mask mandate, building on a study by Christopher Leffler and co-authors.

Exhibit 6 presents the descriptive relationships graphically by plotting the length of the outbreak before masks were widely adopted against cumulative cases per capita (left panel) and cumulative fatalities per capita (right panel). We measure the start of the outbreak as the day of the first fatality. Both graphs show a positive and statistically significant slope,

indicating that countries which took longer to reach widespread mask usage (whether by policy or cultural norms) suffered more virus cases and fatalities. The better fit for fatalities than cases likely reflects the relatively better measurement of fatalities.

Exhibit 6: Countries Which Took Longer to Reach Widespread Mask Usage Experienced More COVID-19 Cases and Fatalities



Source: masks4all.co, Leffler et al. 2020, Goldman Sachs Global Investment Research

To formalize this finding, Exhibit 7 presents cross-sectional regression models of log cases and log fatalities for around 125 countries. In both regressions, we find statistically significant negative effects of masks on cumulative cases and fatalities after including controls such as the obesity rate, population density, age structure, and testing policy. Our numerical estimates are that cumulative cases grow 17.3% per week without a mask mandate but only 7.3% with a mask mandate, and that cumulative fatalities grow 29% per week without a mask mandate but only 16% with a mask mandate.

Exhibit 7: Mask Policies and Norms Have Lowered COVID-19 Case Counts and Fatalities

	Country Cross-Section: Impact of Mask Wearing on COVID-19*			
	Log COVID-19 Cumulative Cases per Capita		Log COVID-19 Fatalities per Capita

Source: World Bank, Blavatnik School of Government, Oxford, Leffler et al. 2020, MasksAll.co, Goldman Sachs Global Investment Research

Approach 3: Country Panel

Our third approach consists of a smaller country panel in which we relate the daily growth rate of infections and fatalities to lagged self-reported mask usage, plus a number of control variables. There are three main results, illustrated in Exhibit 8.

First, face masks have a large negative impact on infections and fatalities, controlling for population density and income inequality (columns 1 and 4). This negative and significant impact of face masks is robust to controlling for our Effective Lockdown Index (ELI), the share of the population that say they avoid crowded public places (columns 2 and 5), and country and time fixed effects (columns 3 and 6). Our estimates suggest that a 25pp increase in the self-reported mask usage, for instance as a result of a mask mandate, lowers the growth rate of cumulative cases by 1.9pp and the growth rate of cumulative fatalities by 0.8pp.[6]

Second, the share of respondents that avoid crowded public places also has a large and highly significant negative impact on infections and fatalities. This not

only suggests a significant role for “super spreader” events, but also strengthens our main results because it implies that the face mask result is not just driven by the correlation between face masks and other risky activities.

Third, the virus impact of mask usage is large, not just in absolute terms but also relative to the effect of economically costly shutdowns (as measured by our ELI). In fact, the coefficients on the percentage of self-reported mask usage are slightly bigger than those on the ELI, which is interesting as both variables are on a 0-100 scale.

Exhibit 8: Face Masks and Limiting Mass Gathering Lower COVID-19 Case and Fatality Growth

The Impact of a Mandate on Infections

Before we translate our statistical results into a baseline estimate of the impact of face mask mandates on virus outcomes, we need to address two potential concerns about our analysis up front.

The first concern is that the correlation between face masks and virus outcomes might reflect the effect of other unobserved forms of cautious behavior that are correlated with mask mandates or usage, instead of a truly causal effect of masks. But there are some reasons to believe that this type of bias in not a big issue for our analysis. Not only do we obtain remarkably similar estimates across our three approaches, but we also control for a number of other observable forms of cautious behavior. Specifically, our cross-country results on masks include our Effective Lockdown Index among the explanatory variables, and they are largely unchanged when we include the share of respondents who say they stay home from work, don't touch objects, improve personal hygiene, avoid contact with tourists, avoid raw meat, and don't send their children to school.[7]

The second potential concern is that our main results are based on confirmed infections, which can be distorted by a lack of testing. However, it is important to note that this would, if anything, lead to an understatement of the effect assuming that increases in testing are positively correlated with increases in mask usage. Moreover, we control for testing regime indicators in our cross-sectional regression, and we obtain generally similar estimates for fatalities—which are better measured—across all three of our approaches.

So what is a reasonable baseline estimate of the impact of a US national mask mandate on the growth rate of confirmed infections? To generate such an estimate, we

apply our country panel results separately to two groups of US states, namely ones with and without a state-level mask mandate in place.

States that currently don't have a state-level mandate account for 40% of US total confirmed cases, 45% of US GDP, half of the population, and two-thirds of new infections. This group has also experienced an average daily growth rate in confirmed infections of 2.9% in the past 7 days. Based on our analysis of state-level mandates, we estimate that a national mask mandate would raise mask usage by 25pp in these states. Our country panel shows that a 25pp increase in self-reported mask usage lowers the infection growth rate by 1.9pp (or just over 60%). The national mandate could therefore lower the daily growth rate in the group of states without a mandate from 2.9% to just over 1%.

States that currently do have a mandate have experienced a lower average daily growth rate in confirmed infections of 0.8% in the past 7 days. Combined with our assumption that a national mandate would lead to a smaller increase in mask usage of 5pp through extra awareness in this group of states, our country panel suggests a 0.4pp decline in the infection growth rate to 0.4-0.5%.

Combining the estimates for these two groups of states, we estimate that a national mandate could cut the national average growth rate of infections by nearly 1.0pp to 0.6-0.7%.

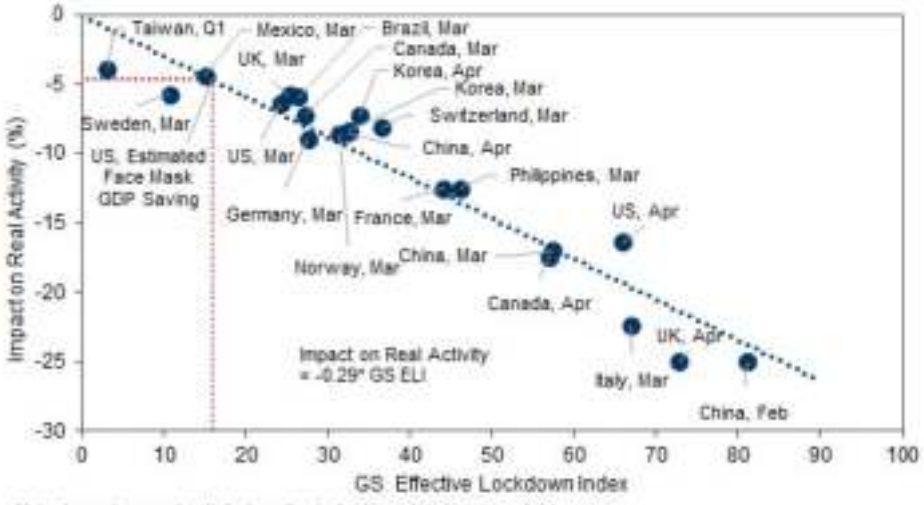
The Impact of a Mandate on GDP

If a face mask mandate meaningfully lowers coronavirus infections, it could be valuable not only from a public health perspective but also from an economic perspective because it could substitute for renewed lockdowns that would otherwise hit GDP.

How big is this potential effect? To generate an answer, we proceed in two steps. First, we use our cross-country panel analysis to ask how much our effective lockdown index (ELI) would need to increase in order to lower the daily case growth rate by 1.0pp, i.e. the estimated impact of a national face mask mandate. The answer is an increase in our ELI of 16pp.

Second, we ask how much a 16pp ELI increase would subtract from the level of GDP. As shown in Exhibit 9, the cross-country relationship implies that such an increase might reduce GDP by just under 5%.

Exhibit 9: A Close Relationship Between the ELI and GDP



Note: Impact on real activity is estimated where data is not available.

References to China are to Mainland China

Source: Goldman Sachs Global Investment Research

Thus, the upshot of our analysis is that a national face mask mandate could potentially substitute for renewed lockdowns that would otherwise subtract nearly 5% from GDP. It is important to recognize that this estimate is quite uncertain because it is based on a number of statistical relationships that are all measured with error. Despite the numerical uncertainty, however, our analysis suggests that the economic benefit from a face mask mandate and increased face mask usage could be sizable.

So will the US adopt a national face mask mandate? This is uncertain, partly because masks have become such a politically and culturally charged issue. However, even in the absence of a national mandate, state and local authorities might well broaden mandates in ways that ultimately mimic the impact of a national mandate. Either way, our analysis suggests that the economy could benefit significantly from such moves, especially when compared with the alternative of a return to broader lockdowns.

[1] We thank Sid Bhushan and Dan Milo for valuable help with this report.

[2] See Jaqueline Howard, "WHO stands by recommendation to not wear masks if you are not sick," CNN, March 30, 2020.

[3] As an aside, note that Minnesota has the lowest self-reported rate of mask usage among larger states in the US. This is interesting because the state is home to a

large population of Scandinavian-Americans and Scandinavia has some of the lowest rates of face mask usage in the world.

[4] Our mask usage regressions are weighted by state population, focus on states with more than 4 million people (given the small samples in the respondent-level data) and use robust standard errors at the state level. Our sample starts on April 2nd when respondent-level data become available. We also control for cumulative cases per million and cumulative deaths per million.

[5] The county-level controls are population density, median house value, median household income, homeownership, pollution, maximum summer temperature, and maximum winter temperature, educational attainment, mean Body Mass Index, and the share of population over 65. We use county population weights and cluster robust standard errors at the state level. Our sample covers 2,373 counties and extends from March 31 to June 24. See Lyu and Wehby (2020).

[6] Relative to the sample average growth rates of 3.8% and 2.8%, these estimates imply that a mask mandate raising mask usage by 25pp cuts the growth rates of infections and fatalities by nearly one half and one quarter respectively.

[7] The cross-country panel and cross-county panel results are also robust to controlling for the lagged levels of fatalities and infections per capita, which helps address the concern that the mask effects pick up the impact of other forms of unobserved cautious behavior in response to the size of the outbreak.

Summary

Background Whilst evidence of face masks' effectiveness in reducing COVID-19 cases is increasing, the impact of mandatory use across a large population has been difficult to assess. Introduction of mandatory mask use on July 22, 2020 during a resurgence of COVID-19 in Melbourne, Australia created a natural experiment to assess the impact of the policy on the epidemic growth rate as its introduction occurred in the absence of other changes to restrictions.

Methods Exponential epidemic growth or decay rates in daily COVID-19 diagnoses were estimated using a non-weighted linear regression of the natural logarithm of the daily cases against time, using a linear spline model with one knot (lspline package in R v 3.6.3). The model's two linear segments straddle the hinge day, determined from the model fit, on which the mask policy began to take effect. We used two forms of data to assess change in mask usage: population-based survey data and images of people wearing masks in public places obtained from a major media outlet. Potential confounding factors (including daily COVID-19 tests, number of COVID-19 cases among population subsets affected differentially by the mask policy – e.g. healthcare workers) were examined for their impact on the results.

Findings Introduction of a mandatory mask policy was associated with an estimated 23% reduction in the effective reproduction ratio, from 1.18 to 0.91. The hinge day in the linear spline model occurred eight days after the policy was introduced on July 23, 2020. Daily cases grew exponentially in the first log-linear segment (k = +0.042, s.e. = 0.007), and decayed exponentially in the second (k = -0.023, s.e. = 0.017). Analysis of images of people in public spaces showed mask usage rose from approximately 43% to 97%. Analysis of survey data found that on the third day before policy introduction, 44% of participants reported "often" or "always" wearing a mask; on the fourth day after, 100% reported "always" doing so. No potentially confounding factors were associated with the observed change in growth rates.

Interpretation. The mandatory mask use policy substantially increased public use of masks and was associated with a significant decline in COVID-19 transmission after introduction of the policy. The hinge date (where the shift in epidemic growth was observed) occurred eight days after policy introduction, consistent with the incubation time of COVID-19 and the time needed to test and report new cases. Although studies emphasise the importance of masks in a clinical setting, to our knowledge no previous peer reviewed publications measured the role of masks for controlling epidemics in the broader community.

Research in context

Evidence before this study

Multiple studies that show that face masks can reduce transmission of respiratory virus infections, with the use of facial coverings and masks to reduce transmission of COVID-19 being widely recommended and, in some cases, mandated. Most studies have occurred in laboratory or clinical settings; there is little evidence of masks' effectiveness in community settings.

Added value of this study

A policy of mandatory use of facial coverings and masks (hereafter, masks) was introduced in Melbourne, Australia during a period of exponentially increasing COVID-19 cases. The abrupt increase in mask use observed after policy introduction, coupled with strong surveillance of the population, allowed a unique assessment of the impact of a mandatory mask policy on COVID-19 cases. On day 8 following the introduction of the policy, there was a clear transition from an exponential increase to an exponential decrease in daily new cases that could not be explained by potential confounding factors. This study reinforces the strong correlation between the mandatory introduction of face masks and decreasing COVID-19 cases in a large metropolitan area.

Implications of all the available evidence

This new data, coupled with existing data on use of face masks, provides powerful evidence that introduction of the mandatory face mask policy was effective in reducing COVID-19 cases.

Background

Australia, like many countries, experienced an initial rise in SARS-CoV-2 (COVID-19) cases peaking on March 28, 2020, followed by a relatively sharp decline in April after federal and state governments introduced strict community controls, travel bans and quarantining of all travellers arriving in Australia.[1] Throughout late June and July, Victoria, Australia's second most populous state, experienced a resurgence of COVID-19, with 13,078 cases detected between 14th June and 10th August and new daily case numbers peaking at 686 on 5th August[2], with 95% in the state capital, Melbourne. By the end of September, daily numbers had declined to fewer than 20 and are continuing to decline.[2]

The resurgence of COVID-19 in Victoria led to multiple control measures being reintroduced in urban Melbourne, a city of 4.93 million people, in July 2020. These included Stage 3 restrictions (closure of pubs, bars, entertainment venues, places of worship, restricting restaurants and cafes to takeaway only, and limiting public gatherings to two people, plus requiring people in the restricted area to stay home, with only four reasons to leave home: shopping for essentials, caregiving, exercise, and work or study that cannot be done from home) in 10 postcodes with relatively high case numbers at 11:59pm on July 1, 2020. Stage 3 was expanded on 4th July to include two additional postcodes and complete quarantine/isolation of several high-rise public housing estates considered to be at high risk; residents were required to stay inside their homes under the 'detention' directives, unless granted permission to receive medical care. On 8th July, Stage 3 restrictions were extended to include all of metropolitan Melbourne and Mitchell Shire, and Victoria's borders with other states/jurisdictions were closed (Table 1). Previous work has shown that the introduction of Stage 3 restrictions slowed but did not reverse the exponential growth in daily cases[1]; the growth rate fell from 0.140 to 0.037 per day, which translates into a fall in the R_{eff} from 1.75 to 1.16. Despite the continued growth, this reduction was estimated to have averted 9,000–37,000 new infections throughout July, compared to a scenario of continued trend in growth.[1]

Mandatory use of masks or other face coverings including face shields, scarves and bandanas (hereafter, masks) in public settings was introduced in Victoria on 22nd July, while Stage 3 restrictions were in place. This was followed by an 8pm curfew and 5km movement restrictions introduced on 2nd August, and Stage 4 restrictions (closure of childcare and non-essential businesses, including retail, and schools delivering online learning only) on 5th August (Table 1).

[Table 1 about here[2]]

There is increasing evidence of the effectiveness of masks in reducing the transmission of SARS-CoV-2 and hence COVID-19; the World Health Organization (WHO), the United States' (US) Centre for

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3714648

Disease Control and Prevention (CDC), other public health organisations and governments recommend the use of masks in specific circumstances.[3-9] Simultaneously, some reports suggest mask use in public spaces has limited impact on COVID-19 transmission.[10] To date there have been few opportunities to examine the impact of a mandatory mask use policy at a population level. The timing of the introduction of a mandatory mask use policy created a natural experiment, allowing us to compare pre- and post-intervention epidemic growth and/or decay rates to estimate the population-level impact of the policy.

In this paper, we describe our examination of whether the mandatory mask use policy was associated with a statistically significant change in the COVID-19 epidemic growth rate in metropolitan Melbourne and the Mitchell Shire.

Methods:

Analysis of COVID-19 cases 10th July to 10th August inclusive.

Daily diagnosed COVID-19 case numbers in Victoria (excluding cases in returned international travellers in hotel quarantine) were derived from the cumulative cases reported in daily updates[2] from the Victorian Department of Health and Human Services (DHHS). Due to the generation interval for SARS-CoV-2 infection and delays in testing and reporting, there is an expected delay between the introduction of restrictions and observing them in diagnosis data. Previous work found that the introduction of Stage 3 took eight days to be observed in the diagnosis data.[1] Therefore, cases for the period 10th July to 10th August[2] were used for the analysis; the impact of Stage 3 would be already apparent, but the impact of curfew (2nd August) or Stage 4 restrictions (5th August) would not have commenced. The period prior to the mandatory introduction of masks on the 11.59pm on 22 July is referred to as the *pre-mask period* and the period from the 23rd July as the *post-mask period*.

The growth or decay of the daily number of new cases was approximated using an exponential model. This means that the logarithm of the daily cases should increase or decrease linearly with time, and analysis of residuals was used to test this assumption. The growth or decay rates of the epidemic were estimated using a non-weighted linear regression to fit the natural logarithm of the daily cases against time, using a linear spline model with one knot.[11] The knot allows for a possible deflection in the line of best fit during the period of observation, dividing the model into two linear segments that are connected at a hinge day. We tested the assumption of linearity of the two linear segments by assessing whether standardised residuals were normally distributed and independent of the time. To determine the optimal knot day, we performed sensitivity analysis to determine the

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3714648

knot/hinge day that returned the linear spline model with the maximal adjusted coefficient of determination R^2 (the best-fitting model).

This analysis estimated the growth constant (k) (i.e. the slope of the ln(daily cases) vs time regression) for each segment. We calculated the doubling/halving time of the epidemic as

$t_2 = \ln(2)/k$

We also calculated the daily multiplication rate of new cases as e^k and estimated the effective reproduction ratio (R_{eff}) as the relative change in new cases over one generation interval for SARS-CoV-2 infections, using the estimate of four days based on 468 pairs of infections in Wuhan.[12] Since the measured intervals in this estimate had an approximately normal distribution, we used the following simple estimate

$$R_{eff} = e^{k*4}$$

The Survey of COVID-19 Responses to Understand Behaviour (SCRUB) project - analysis of mask use

The Survey of COVID-19 Responses to Understand Behaviour (SCRUB) project includes measures of protective behaviour adherence among Australians during the COVID-19 pandemic; it commenced in March 2020.[13] The survey targets a representative (age, gender, metro/regional) sample of 1000 Victorian residents and 700 Australian residents outside Victoria in each round.

An item measuring self-reported mask use frequency was included from wave 6 onwards. Here we include data from round 6 (data collected 20–26 July 2020) for the question "*In the past 7 days, how frequently have you taken the following actions?"* and the specific item "*Wear a face mask whenever in public" (response scale: Never, Rarely, Sometimes, Often, Always).* For this analysis, we collapsed responses into *Never, Rarely, Sometimes* vs *Often, Always*. Respondent postcode and survey completion date were used to identify responses from people living within the areas subjected to the mandatory mask policy (Melbourne metropolitan region and Mitchell Shire), which we compared across the pre-mask and post-mark periods.

Photographic observation of mask use

To triangulate self-report data from the SCRUB study, we assessed changes in mask-wearing behaviours using images from the digital archive of *The Age* (https://www.theage.com.au/), one of the two major daily Victorian newspapers. Using consecutive sampling of photos taken in public spaces in metropolitan Melbourne between July 10 and August 2, 2020 (14 days before and 14 days after mandatory mask policy introduction), we estimated the proportion of people wearing masks in public (number of people wearing masks / number of people in the image) across three time periods: period 1, 10–19 July (the period preceding mandatory mask policy announcement); period

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3714648

2, 20–22 July (period between announcing and commencing mandatory mask wearing); and period 3, 23 July to 2 August (mandatory mask wearing period). We excluded people who were potentially exempt from mask wearing under the relevant directions, such as children and people drinking or eating while in public. The proportions of individuals wearing masks in each period were compared using cross-sectional chi-square tests.

Possible confounders

Data collected to explore potential confounding effects included 1) daily cases from regional Victoria, 2) daily cases in health care workers, 3) daily COVID-19 tests, 4) the proportion of diagnosed cases assigned to a known cluster within 24 hours of testing, and 5) mobility indices for Melbourne residents. Secondary regression analyses were run to assess changes in these measures over the time period of interest.

Daily cases in regional Victoria were derived from the cumulative cases reported in daily updates.[2] Daily cases in health care workers, which were classified as acquired in health care and aged care facilities, were obtained from the Victorian DHHS web site.[14] Daily COVID-19 tests and the proportion of diagnosed cases assigned to known clusters within 24 hours of testing were obtained from the Australian Broadcasting Corporation's coronavirus summary.[15]

Mask use in residents of regional Victoria (other than Mitchell Shire) and in health care workers in health care and aged care facilities may not have changed as a result of the mandatory mask use policy in Melbourne. To test for the impact of these potential confounders, as well as any impact of variations in testing rates, we undertook secondary regression analyses using dependent variables of log(total daily cases less regional cases), log(total daily cases less HCW cases) and log(ratio of total daily cases to number of daily tests).

Mobility indices for Melbourne were obtained from CityMapper.[16] The Citymapper Mobility Index is calculated by comparing trips planned in the Citymapper app to a recent typical usage period. Typical usage period is defined as four weeks between January 6 and February 2, 2020. A day is defined as midnight to midnight UTC, thus for certain cities may not correspond with calendar days.

Results:

Impact of masks on total cases

There were 11,714 cases reported between July10 and August 10 inclusive, with daily cases increasing from 143 cases on July 10 to a peak of 686 cases on August 5, before declining to 310 cases on August 10.

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3714648

The sensitivity analysis indicated that the best fit for the linear spline model included a hinge day on July 31, eight days after the introduction of mandatory mask usage (Table S1). Using this as the hinge day, the first log-transformed linear segment, representing the pre-mask period, demonstrated significant exponential growth in daily cases (k = +0.042, standard error [s.e.] = 0.007; p<.001). This growth equated to a projected doubling of cases every 16.5 days. The second log-transformed linear segment, representing the post-mask period, demonstrated exponential decay in daily cases (k = -0.023, s.e. = 0.017; p=0.190). This decay equated to a projected halving of cases every 30 days. The difference in exponential growth/decay rates between the pre- and post-masks periods was statistically significant (Δk=-0.065, s.e. = 0.022; p=0.006) (Figure 1; Table 2). Based on a four-day generation interval, these growth rates correspond to a 23% reduction in the R_{eff} from 1.18 in the pre-mask period to 0.91 in the post-mask period.

[Figure 1 about here]

On testing our model for goodness-of-fit, the distribution of residual values of the log transformed cases was indistinguishable from a normal distribution and showed no variation with day. Thus, the data was an excellent fit to an exponential increase in the Stage 3 period followed by an exponential decrease after masks became mandatory.

[Table 2 about here]

SCRUB Study – self reported mask use

Analysis of data from Wave 6 of the SCRUB study found 44% of participants interviewed in Melbourne and Mitchell Shire on the third day before the mask policy was introduced (July 20, 2020) reported they "often" or "always" wore a mask, and 100% of those interviewed on the fourth day afterwards (July 26) reported "always" wearing a mask. The survey found that 56% of participants reported "often" or "always" wearing a mask over 20–22 July, and 71% over 23–26 July (χ^2(1, N=808) = 8.73, p=0.002) (Figure 2). This change in mask usage was not observed in SCRUB data collected from participants from other Australian states.

[Figure 2 about here]

Photographic observation of mask use

We analysed 44 published photographic images taken between July 10 and August 2, 2020. They included a range of public locations, including streetscapes, markets, train stations and supermarkets, and included 304 unique individuals (after excluding those potentially exempt from

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3714648

mask use, as described in Methods). Nineteen photos taken in period 1 (prior to mandatory mask policy announcement) contained 101 unique individuals, of whom 43 (43%) were wearing masks. Seven photos taken in period 2 (following mandatory mask policy announcement but prior to policy introduction) contained 47 unique individuals, of whom 35 (74%) were wearing masks. Eighteen photos taken in period 3 (mandatory mask wearing period) contained 156 unique individuals, of whom 153 (98%) were wearing masks. The proportion of individuals wearing masks significantly increased from period 1 to period 2 ($\chi^2(1) = 13.09$, $p<0.001$) and again from period 2 to period 3 ($\chi^2(1) = 29.42$, $p<0.001$).

Investigation of confounding variables

The proportion of non-metropolitan daily cases remained low (approximately 5%) across the period of interest (July 10 – August 10, 2020) and paralleled total Victorian cases. Subtracting rural cases from the total cases made no significant difference to the calculated pre- and post-growth constants of the metropolitan cases (Table 3). There was a significant change in the rural growth rates coincidental with the introduction of masks in the metropolitan region.

[Table 3 about here]

The proportion of daily cases in health care workers classified as acquired in health care and aged care facilities increased steadily, but there was no significant change in the case growth rates across the pre- and post-mask periods (Table 3). Subtracting these cases from total cases again made little difference to the estimated pre- and post-mask growth rates (Table 3).

There was a significant decrease in the number of tests per day performed over the study period, with approximately 33% fewer tests on the last day, August 10, than the first, July 10 (linear regression: intercept 29,496; slope -310; p=0.026). In addition, the pre- and post-mask period growth constants for the exponential increase and decrease in positive test ratio were higher than the corresponding growth rates for cases. However, the difference in the growth rates for pre- and post-mask were similar for cases and for the positive test ratio (Table 3). The proportion of cases that were assigned to known clusters within 24 hours was approximately constant throughout the analysis period.

The mobility data showed no significant change: 14.0% mobility pre-mask and 13.1% post-mask (p=0.09) relative to mobility in February 2020, prior to the onset of the Australian COVID-19 epidemic (Figure 1).

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3714648

Discussion:

We assessed growth rates in daily COVID-19 diagnoses in Victoria, Australia before and after the introduction of a mandatory mask policy in Melbourne and Mitchell Shire (where 95% of Victoria's diagnosed cases occurred), and estimated a 23% reduction in R_{eff} from 1.18 in the pre-mask period to 0.91 in the post-mask period. The policy was associated in a change from an exponential increase in the epidemic with a doubling time of 16.5 days, to an exponential decrease with a halving time of 30 days.

Sensitivity analysis identified a hinge day that marked the transition in the growth curves, eight days after the introduction of the mandatory mask policy. This is consistent with the delay observed in an earlier study following the introduction of stringent physical distancing, the Stage 3 restrictions (Table 1).[1] This also fits the observed generation interval for COVID-19 infections[12] combined with the estimated delays in undertaking and reporting testing.

A unique feature of this study is that it observed a rapid and substantial increase in the use of masks within the population after July 23, 2020, as demonstrated in both self-report data and photographic data, that preceded a significant change in the growth rate of the epidemic. The rapid transition in the adoption of mask usage, based on photographic evidence, was striking: from 43% before the announcement of the upcoming mandatory mask policy, to an average of 74% in a three-day transition period between announcement and policy introduction, to near-complete compliance (98%) after policy implementation. The photographic data was complemented by self-report survey data that showed consistent rapid change, from just over 40% of participants reporting always or often wearing a mask on July 20, to 100% always wearing a mask on 26 July (Figure 2).

Our work has several limitations. We measured the overall impact of the introduction of mandatory mask use on daily cases. Care should be taken in ascribing causality; we did not assess the direct effectiveness of masks in preventing COVID-19 transmission. We cannot determine whether masks had a direct effect or whether near-universal adoption of masks reminded wearers to engage in other behaviours recommended to reduce COVID-19 transmission, including regular hand hygiene and physical distancing. Interestingly, introduction of masks in the metropolitan area coincided with a decrease in the growth rate in rural areas, where masks were not introduced, which is consistent with an indirect effect, a decrease in seeding of rural areas from the metropolitan area, or both. Participants in the Scrub Study were meant to report their mask use in the previous seven days, the rapid change in behaviour over 20–26 July suggests participants interpreted this question as referring to their mask use on the day they responded to the survey.

Other factors may have contributed to the decline in COVID-19 transmission at the time the mandatory mask policy was introduced. Melburnians may have reduced their overall movement in response to other official messages or how they interacted with each other, such as whether people physically distanced from each other. Examination of mobility data across the relevant time period suggests mobility was stable[16], although unpublished behavioural data collected through July suggests people were less likely to interact with other people as the month wore on, and when they did, kept physically distanced (*pers comm., J McCaw, Doherty Institute*). It is difficult to know whether this change in interaction and physical distancing would increase or decrease the effect we observed. The decrease in interactions/contact may also have affected case numbers but the decline in interactions was steady over time, so cannot account for the hinge effect we observed. Moreover, reduced interaction could mean that the mask policy was more effective than measured, because masks were still effective despite potentially fewer episodes of risky contact. Changes to the time needed for contact tracing may have influenced the result; if the time taken from identifying a case to contacting and isolating all their contacts fell substantially during the period in question, it may have created its own reduction in transmission. However unpublished data from the Victorian DHHS suggests the time taken to perform contact tracing was relatively stable across the period of interest (*pers comm., B Sutton, DHHS Victoria*).

To make the analysis as robust as possible, we did not exclude health care workers classified as having acquired COVID-19 in health care and aged care facilities from the analysis, despite increasing numbers of cases in this group over the study period, reflecting the high occupational risk of infection in these settings. However, subtracting cases of health care workers from the Melbourne totals made little difference to the overall growth constants. Health care workers were wearing extensive personal protective equipment (PPE), including masks, in their work environment before mandatory mask policy implementation, and there is no reason to believe that mask usage changed in the health care setting during the study period; this supports the case that the changes observed in the general population are due to increased mask wearing.

We did not have access to daily case numbers for residents of aged care facilities over the whole of the analysis period, but the available data suggests that the cases in this group were growing rapidly during this time. Again, staff in aged care facilities were using PPE, including masks, extensively prior to masks becoming mandatory in the general community. This would suggest that the introduction of the mandatory mask policy would have less of an impact in this setting, given masks were already in use, hence leading to an underestimate of the overall impact of masks. Availability of more detailed case numbers over the whole Stage 3 and Stage 3+ masks period would allow this possibility to be tested rigorously. In addition, our analysis did not take account of transmission of COVID-19 in

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3714648

settings where mask use was not required, such as households or some workplaces. Given very high transmission within households[17], again, this would lead to an underestimation of the impact of the widespread use of masks.

Whilst acknowledging these limitations, we believe our results make an important contribution to the current literature on the population impact of masks in reducing COVID-19 transmission, as well as public dialogue concerning the appropriateness of mandatory mask policies. Despite WHO, CDC and others recommending the use of masks in specific settings[3,18-20] there is minimal data from community settings supporting mask use. An observational study in Beijing directly assessed the impact of mask use on SARS-CoV-2 transmission, measuring the reduction of secondary transmission in households due to face mask use. Masks were found to be 79% effective in preventing transmission if used by all household members prior to symptoms occurring.[21,22] A non-peer-reviewed report on the impact of mask mandates and other non-pharmaceutical interventions on COVID-19 cases found the introduction of a mask mandate in Ontario was associated with an average reduction of 25–31% in the weekly number of newly diagnosed COVID-19 cases.[7]

A German study used a synthetic control method to build a counterfactual to analyse the effect of face masks on the spread of COVID-19.[8] The authors compared the city of Jena and six regions in Germany that adopted a face mask policy in early to mid-April 2020, before their respective state mandates. The authors found that masks reduced the cumulative number of registered COVID-19 cases per region by between 2.3% and 13% over the 10 days after they became mandatory. They concluded that face masks reduced the average daily growth rate of reported infections by around 40%. A recent US report focusing on Arizona suggests the number of COVID-19 cases stabilised after the sustained implementation and enforcement of state-wide and local mitigation measures. There was an initial decrease in cases approximately two weeks after the implementation and enforcement of mask mandates and enhanced sanitation practices, followed by a further decrease in cases after the imposition of state-wide restrictions and the closure of certain services and businesses, but the effect of masks alone in this study is more difficult to separate compared to our study.[5]

A systematic review and meta-analysis examined how physical distancing, face masks and eye protection affect the spread of COVID-19, SARS, and MERS in both community and healthcare settings.[4] This work included 172 observational studies across 16 countries but did not identify any published randomised controlled trials on the effectiveness of masks. The review found that mask use (including respirator use) could result in an 85% risk protection overall, with surgical masks and well-designed cloth masks giving 67% protection. However, it should be noted that many of these studies were in health care settings; only three were from other settings and all three assessed SARS

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3714648

infection. Also, only six studies included data on COVID-19. These differences may account for the lower impact of mask wearing observed in our study.

Variation in the type and quality of masks may affect their overall effectiveness. A 12-16-layered cloth mask can protect as well as a surgical mask, but a single layered cloth mask may offer little or no protection.[4] Moreover, more recent work suggests the poor performance of some cloth masks was due to inadequate washing (masks washed daily in 60°C water and soap were protective).[23] The rapid imposition of the mask mandate in Melbourne and Mitchell Shire may have forced many people to resort to low-quality face coverings, such as scarves or bandanas, thereby reducing the effectiveness of the policy across the population.

Mask use in the community can protect by preventing outward transmission from infected people (source control) or protecting well people.[24] Normal breathing and speaking generate substantial aerosols[25], and masks can block coronaviruses being exhaled in tidal breathing.[26] The high rate of asymptomatic transmission of SARS-CoV-2 is an important rationale for community masking.[27] In the US, universal masking in a hairdressing salon prevented transmission from two infected stylists to their clients[28], providing some additional evidence for community mask use. Further, the use of masks may reduce the exposure dose of SARS-CoV-2 and result in less severe infection.[4]

Our results suggest the policy of mandatory face masks use was effective in reducing COVID-19 transmission in a community setting with restrictions already in place, accelerating the reduction of SARS-CoV-2 transmission. For the reasons outlined previously, we have probably underestimated the impact of masks in the community more broadly. Our work also indicates a high level of compliance with the Victorian Government's policy, and the rapid increase in mask use following a mandate. Face masks, whilst somewhat inconvenient for the individual user, are less likely to have unintended negative impacts on the broader community than policies restricting movement, social engagement and the operations of business, schools and childcare. During the pandemic, until an effective vaccine is widely available, the risk of recurrent local epidemics is real[29], and all available non-pharmaceutical interventions need to be used to mitigate that risk.

This is the first-time a mandatory mask policy has been shown to have an impact in a 'real-world' community setting in Australia, and is one of few examples anywhere in the world that has been able to capture the impact of such a policy. In the absence of randomised controlled trial data on the efficacy of masks to prevent COVID-19 transmission in community settings, outcomes of natural experiments such as that which occurred in Victoria are important to help guide public health policy.[30] Our work supports the use of face masks, and they should be considered in other settings in Australia and globally to reduce community transmission of SARS-CoV-2.

ABSTRACT

An ecologic study focuses on the comparison of groups, rather than individuals; thus, individual-level data are missing on the joint distribution of variables within groups. Variables in an ecologic analysis may be aggregate measures, environmental measures, or global measures. The purpose of an ecologic analysis may be to make biologic inferences about effects on individual risks or to make ecologic inferences about effects on group rates. Ecologic study designs may be classified on two dimensions: (*a*) whether the primary group is measured (exploratory vs analytic study); and (*b*) whether subjects are grouped by place (multiple-group study), by time (time-trend study), or by place and time (mixed study). Despite several practical advantages of ecologic studies, there are many methodologic problems that severely limit causal inference, including ecologic and cross-level bias, problems of confounder control, within-group misclassification, lack of adequate data, temporal ambiguity, collinearity, and migration across groups.

INTRODUCTION

An ecologic or aggregate study focuses on the comparison of groups, rather than individuals. The underlying reason for this focus is that individual-level data are missing on the joint distribution of at least two and perhaps all

0163-7525/95/0501-0061$05.00

variables within each group; in this sense, an ecologic study is an incomplete design (35). Ecologic studies have been conducted by social scientists for more than a century (14a) and have been used extensively by epidemiologists in many research areas. Nevertheless, the distinction between individual-level and group-level (ecologic) studies and the inferential implications are far more complicated and subtle than they first appear. Before 1980, ecologic studies were usually presented in the first part of epidemiology textbooks as simple descriptive analyses in which disease rates are stratified by place and/or time to generate or test hypotheses; little attention was given to statistical methods or inference (e.g. 41). The purpose of this review is to provide a methodologic overview of ecologic studies that emphasizes study design and causal inference. Although ecologic studies are easily and inexpensively conducted, the results are often difficult to interpret.

CONCEPTS AND RATIONALE

Before discussing the design and interpretation of ecologic studies, we must first define the concepts of ecologic measurement, analysis, and inference.

Levels of Measurement

The sources of data used in epidemiologic studies typically involve direct observations of individuals (e.g. age and sex), sometimes subindividual parts (e.g. intraocular pressure of each eye), and occasionally groups or regions (e.g. air pollution and social disorganization). These direct observations are then organized to measure specific variables in the study population: Individual-level variables are properties of individuals, and ecologic variables are properties of groups. To be more specific, ecologic measures may be classified into three types:

1. *Aggregate measures* are summaries (e.g. means or proportions) of observations derived from individuals in each group (e.g. the proportion of smokers or median family income).
2. *Environmental measures* are physical characteristics of the place in which members of each group live or work (e.g. air-pollution level or hours of sunlight). Note that each environmental measure has an analogue at the individual level, and these individual exposures, or doses, usually vary among members of each group, though they may remain unmeasured.
3. *Global measures* are attributes of groups or places for which there is no distinct analogue at the individual level, unlike aggregate and environmental measures (e.g. population density, level of social disorganization, or the existence of a specific law).

Annu. Rev. Public Health 1995.16:61-81. Downloaded from www.annualreviews.org
Access provided by McMaster University on 05/30/21. For personal use only.

Levels of Analysis

The unit of analysis is the common level for which the data on all variables are reduced and analyzed. In an *individual-level analysis*, a value for each variable is assigned to every subject in the study. It is possible, even common in environmental epidemiology, for one or more variables to be ecologic measures. For example, the average pollution level of each county might be assigned to every resident of that county.

In a *completely ecologic analysis*, all variables (exposure, disease, and covariates) are ecologic measures, so the unit of analysis is the group (e.g. region, worksite, school, demographic stratum, or time interval). Thus, within each group, we do not know the joint distribution of any combination of variables at the individual level (e.g. the frequencies of exposed cases, unexposed cases, exposed noncases, and unexposed noncases); all we know is the marginal distribution of each variable (e.g. the proportion exposed and the disease rate—the T frequencies in Figure 1).

In a *partially ecologic analysis* of three or more variables, we have additional information on certain joint distributions (the M and/or N frequencies in Figure 1 and/or rarely the L frequencies); but we still do not know the full joint distribution of all variables within each group (i.e. the ? cells in Figure 1 are missing). For example, in an ecologic study of cancer incidence by county, the joint distribution of age (a covariate) and disease status within each county (the M frequencies in Figure 1) might be obtained from the census and a population tumor registry.

Multilevel analysis is a special type of modeling technique that combines analyses conducted at two or more levels (6, 71, 72). For example, an individual-level analysis might be conducted in each group, followed by an ecologic analysis of all groups using the results from the individual-level analyses. This approach is described in a later section.

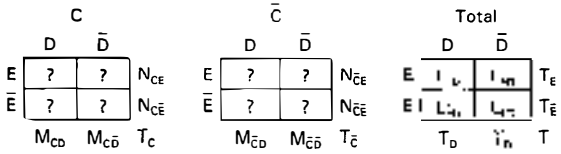

Figure 1 Joint distribution of exposure status (E vs $\bar{E}$), disease status (D vs $\bar{D}$), and covariate status (C vs $\bar{C}$) in each group of a simple ecologic analysis: T frequencies are the only data available in a completely ecologic analysis of all three variables; M frequencies require additional data on the joint distribution of C and D within each group; N frequencies require additional data on the joint distribution of E and C within each group; L frequencies require additional data on the joint distribution of E and D within each group (rarely available); and ? cells are missing in an ecologic analysis.

Levels of Inference

The underlying goal of a given epidemiologic study or analysis may be to make *biologic* (or *biobehavioral*) *inferences* about effects on individual *risks* or to make *ecologic inferences* about effects on group *rates* (45). The target level of causal inference, however, does not always match the level of analysis. For example, the purpose of an ecologic analysis may be to make a biologic inference about the effect of a specific exposure on disease risk. As we see later in this review, such *cross-level inferences* are particularly vulnerable to bias.

If the objective of a study is to estimate the *biologic effect* of wearing a motorcycle helmet on the risk of motorcycle-related mortality among motorcycle riders, the target level of causal inference is biologic. On the other hand, if the objective is to estimate the *ecologic effect* of helmet-use laws on the motorcycle-related mortality rate of riders in different states, the target level of causal inference is ecologic. Note that the magnitude of this ecologic effect depends not only on the biologic effect of helmet use but also on the degree and pattern of compliance with the law in each state. Furthermore, the validity of the ecologic-effect estimate depends on our ability to control for differences among states in the joint distribution of confounders, including individual-level variables such as age and amount of motorcycle riding.

We might also be interested in estimating the *contextual effect* of an ecologic exposure on individual risk, which is also a form of biologic inference (5, 64). If the ecologic exposure is an aggregate measure, we would generally want to separate its effect from the effect of its individual-level analogue. For example, we might estimate the contextual effect of living in a poor area on the risk of disease, controlling for individual poverty level (33). Similarly, in evaluating motorcycle-helmet laws in the U.S., we might want to estimate the contextual effect of living in a state that mandates helmet use on the risk of motorcycle-related mortality in riders, controlling for individual helmet use. Contextual effects are also relevant in infectious-disease epidemiology, where the risk of disease depends on the prevalence of the disease in others with whom the individual has contact (37, 65).

Rationale for Ecologic Studies

There are several reasons for the widespread use of ecologic studies in epidemiology, despite frequent cautions about their methodologic limitations:

1. *Low cost and convenience* Ecologic studies are inexpensive and take little time because various secondary data sources, each involving different information needed for the analysis, can easily be linked at the aggregate level. For example, data obtained from population registries, vital records,

Annu. Rev. Public Health 1995.16:61-81. Downloaded from www.annualreviews.org
Access provided by McMaster University on 05/30/21. For personal use only.

large surveys, and the census are often linked at the state, county, or census-tract level.

2. *Measurement limitations of individual-level studies* In environmental epidemiology and other research areas, we often cannot accurately measure relevant exposures or doses at the individual level for large numbers of subjects—at least not with available time and resources. Thus, the only practical way to measure the exposure may be ecologically (45, 46). This advantage is especially true when investigating apparent clusters of disease in small areas (66). Sometimes individual-level exposures, such as dietary factors, cannot be measured accurately because of substantial within-person variability; yet ecologic measures might accurately reflect group averages (31).
3. *Design limitations of individual-level studies* Individual-level studies may not be practical for estimating exposure effects if the exposure varies little within the study area. However, ecologic studies covering a much wider area might be able to achieve substantial variation in mean exposure across groups (e.g. 50).
4. *Interest in ecologic effects* As noted above, the stated purpose of a study may be to assess an ecologic effect, i.e. the target level of inference may be ecologic rather than biologic. Ecologic effects are particularly relevant when evaluating the impacts of population interventions such as new programs, policies, or legislation.
5. *Simplicity of analysis and presentation* In large, complex studies conducted at the individual level, it may be conceptually and statistically simpler to perform ecologic analyses and to present ecologic results than to do individual-level analyses. For example, data from large, periodic surveys, such as the National Health Interview Survey, are often analyzed ecologically by treating some combination of year, region, and demographic group as the unit of analysis.

STUDY DESIGNS

In an ecologic study design, the planned unit of analysis is the group. Ecologic designs may be classified on two dimensions: the method of exposure measurement and the method of grouping (35, 45). Regarding the first dimension, an ecologic design is called *exploratory* if the primary exposure of potential interest is not measured, and *analytic* if the primary exposure variable is measured and included in the analysis. In practice, this dimension is a continuum, since most ecologic studies are not conducted to test a single hypothesis. Regarding the second dimension, the groups of an ecologic study may be identified by place (multiple-group design), by time (time-trend design), or by a combination of place and time (mixed design).

Multiple-Group Study

EXPLORATORY In this type of exploratory study, we compare the rate of disease among many regions during the same period. The purpose is to search for spatial patterns that might suggest an environmental etiology or more specific etiologic hypotheses. For example, the National Cancer Institute (NCI) mapped the age-adjusted cancer mortality rates in the U.S. by county for the period 1950–69 (42). For oral cancers, they found a striking difference in geographic patterns by sex: Among men, the mortality rates were greatest in the urban Northeast, but among women, the rates were greatest in the Southeast. These findings led to the hypothesis that snuff dipping, which is common among rural southern women, is a risk factor for oral cancers (2). The results of a subsequent case-control study supported this hypothesis (70).

Exploratory ecologic studies may also involve the comparison of rates between migrants and their offspring and residents of their countries of emigration and immigration (31, 41). If the rates differ appreciably between the countries of emigration and immigration, migrant studies often yield results suggesting the influence of certain types of risk factors for the disease under study. For example, if US immigrants from Japan have rates of a disease similar to US whites but much lower than Japanese residents, the difference may be due to environmental or behavioral risk factors operating during adulthood. However, the interpretation of results from these studies is often limited by differences between countries in the classification and detection of disease or cause of death.

In mapping studies, such as the NCI investigation, a simple comparison of rates across regions is often complicated by two statistical problems. First, regions with smaller numbers of observed cases show greater variability in the estimated rate; thus the most extreme rates tend to be observed for those regions with the fewest cases. Second, nearby regions tend to have more similar rates than do distant regions (i.e. autocorrelation) because unmeasured risk factors tend to cluster in space. Statistical methods for dealing with both problems have been developed by fitting the data to an autoregressive spatial model and using empirical Bayes techniques to estimate the smoothed rate for each region (9, 44, 47). The degree of spatial autocorrelation or clustering can be measured to reflect environmental effects on the rate of disease (68, 69). The empirical Bayes approach can also be applied to data from analytic multiple-group studies (described below) by including covariates in the model (e.g. 8, 12).

ANALYTIC In this type of study, we assess the ecologic association between the average exposure level or prevalence and the rate of disease among many groups. This is the most common ecologic design; typically, the unit of analysis is a geopolitical region. For example, Hatch & Susser (29) examined the

Annu. Rev. Public Health 1995.16:61-81. Downloaded from www.annualreviews.org
Access provided by McMaster University on 05/30/21. For personal use only.

association between background gamma radiation and the incidence of childhood cancers between 1975 and 1985 in the region surrounding a nuclear power plant. Average radiation levels for each of 69 tracts in the region were estimated from a 1976 aerial survey. The authors found positive associations between radiation level and the incidence of leukemia (an expected finding) as well as solid tumors (an unexpected finding).

Data analysis in this type of multiple-group study usually involves fitting the data to a mathematical model. For example, Prentice & Sheppard (51) proposed a linear relative rate model using iteratively reweighted least-squares procedures to estimate the model parameters. Prentice & Thomas (52) also considered an exponential relative rate model, which, they argue, may be more parsimonious than the linear-form model for specifying covariates. These methods can be applied to data aggregated by place and/or time (to be discussed below). Use of ecologic modeling to estimate exposure effects is described in the next section.

Time-Trend Study

EXPLORATORY An exploratory time-trend or time-series study involves a comparison of the disease rates over time in one geographically defined population. In addition to providing graphical displays of temporal trends, time-series data can also be used to forecast future rates and trends. This latter application, which is more common in the social sciences than in epidemiology, usually involves fitting the outcome data to autoregressive integrated moving average (ARIMA) models (30, 48). The method of ARIMA modeling can also be extended to evaluate the impact of a population intervention (43), to estimate associations betweens two or more time-series variables (7, 48), and to estimate associations in a mixed ecologic design (60; see below).

A special type of exploratory time-trend analysis often used by epidemiologists is age-period-cohort (or cohort) analysis. Through graphical displays or formal modeling techniques, the objective of this approach is to estimate the separate effects of three time-dependent variables on the rate of disease: age, period (calendar time), and birth cohort (year of birth) (32, 35). Because of the linear dependency of these three variables, there is an inherent statistical limitation (identification problem) with the interpretation of age-period-cohort results. The problem is that each data set has alternative explanations with respect to the combination of age, period, and cohort effects; there is no unique set of effect parameters when all three variables are considered simultaneously. The only way to decide which interpretation should be accepted is to consider the findings in light of prior knowledge and, possibly, to constrain the model by ignoring one effect.

Lee et al (40) conducted an age-period-cohort analysis of melanoma mortality among white males in the U.S. between 1951 and 1975. They concluded

that the apparent increase in the melanoma mortality rate was due primarily to a cohort effect. That is, persons born in more recent years experienced throughout their lives a higher rate than did persons born earlier. In a subsequent paper, Lee (39) speculated that this cohort effect might reflect increases in sunlight exposure or sunburning during youth.

ANALYTIC In this type of time-trend study, we assess the ecologic association between change in average exposure level or prevalence and change in disease rate in one geographically defined population. As with exploratory designs, this type of assessment can be done by simple graphical displays or by time-series regression modeling (e.g. 48). With either approach, however, the interpretation of findings is often complicated by two problems. First, changes in disease classification and diagnostic criteria can produce very misleading results. Second, the latency of the disease with respect to the primary exposure may be long, variable across cases, or simply unknown. Thus, employing an arbitrary lag between observations—or an empirically defined lag that maximizes the estimated association between the two trends—can also produce misleading results (28).

Darby & Doll (13) examined the associations between average annual absorbed dose of radiation fallout from weapons testing and the incidence rate of childhood leukemia in three European countries between 1945 and 1985. Although the leukemia rate varied over time in each country, they found no convincing evidence that these changes were attributable to changes in fallout radiation.

Mixed Study

EXPLORATORY The mixed ecologic design combines the basic features of the multiple-group study and the time-trend study. Time-series (ARIMA) modeling or age-period-cohort analysis can be used to describe or predict trends in the disease rate for multiple populations. For example, to test Lee's (39) hypothesis that changes in sunlight exposure during youth can explain the observed increase in melanoma mortality in the U.S., we might conduct an age-period-cohort analysis, stratifying on region according to approximate sunlight exposure (without measuring the exposure). Assuming the amount of sunlight in the regions has not changed differentially over the study period, we might expect the cohort effect described above to be stronger for sunnier regions.

ANALYTIC In this type of mixed ecologic design, we assess the association between change in average exposure level or prevalence and change in disease rate among many groups. Thus the interpretation of estimated effects is en-

Annu. Rev. Public Health 1995.16:61-81. Downloaded from www.annualreviews.org
Access provided by McMaster University on 05/30/21. For personal use only.

hanced because two types of comparisons are made simultaneously: change over time within groups and differences among groups. For example, Crawford et al (11) evaluated the hypothesis that hard drinking water (i.e. water with a high concentration of calcium and magnesium) is a protective risk factor for cardiovascular disease (CVD) mortality. They compared the absolute change in CVD mortality rate between 1948 and 1964 in 83 British towns, by water-hardness change, age, and sex. In all sex-age groups, especially for men, the authors found an inverse association between water-hardness change and CVD mortality. In middle-aged men, for example, the increase in CVD mortality was less in towns that made their water harder than in towns that made their water softer.

EFFECT ESTIMATION

A major quantitative objective of most epidemiologic studies is to estimate the effect of one or more exposures on disease occurrence in a well-defined population at risk. A measure of effect in this context is not just any measure of association, such as a correlation coefficient; rather, it reflects a particular causal parameter, i.e. a counterfactual contrast in disease occurrence (21, 24, 27, 46, 58). In studies conducted at the individual level, effects are usually estimated by comparing the rate or risk of disease, in the form of a ratio or difference, for exposed and unexposed populations. In multiple-group ecologic studies, however, we cannot estimate effects directly in this way because of the missing information on the joint distribution within groups. Instead, we regress the group-specific disease rates (Y) on the group-specific exposure prevalences (X). For example, fitting the data to a linear model produces the following prediction equation: $\hat{Y} = B_0 + B_1X$, where B_0 and B_1 are the estimated intercept and slope, using ordinary least-squares methods. The estimated biologic effect of the exposure (at the individual level) can be derived from the regression results (1, 19). The predicted disease rate ($\hat{Y}$) in a group that is entirely exposed is $B_0 + B_1(1) = B_0 + B_1$, and the predicted rate in a group that is entirely unexposed is $B_0 + B_1(0) = B_0$. Therefore, the estimated rate difference is B_1 and the estimated rate ratio is $1 + B_1/B_0$. Note that this ecologic method of effect estimation requires rate predictions be extrapolated to both extreme values of the exposure variable (i.e. $X = 0$ and 1), which are likely to lie well beyond the observed range of the data. It is not surprising, therefore, that different model forms (e.g. log-linear vs linear) can lead to very different estimates of effect (22). Fitting a linear model, in fact, may lead to negative, and thus meaningless, estimates of the rate ratio.

As an illustration of rate-ratio estimation in an ecologic study, consider Durkheim's (16) examination of religion and suicide in four groups of Prussian provinces between 1883 and 1890 (see Figure 2). The groups were formed by

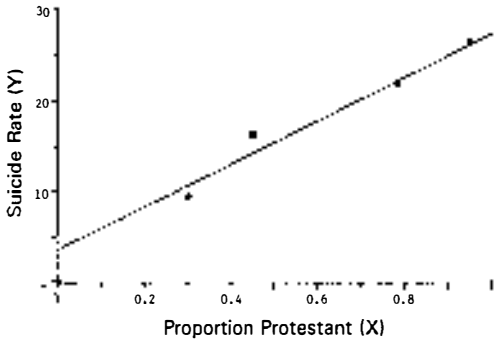

Figure 2 Suicide rate (Y, per 10^5/year) by proportion Protestant (X) for four groups of Prussian provinces, 1883–90. The four observed points (X, Y) are (0.30, 9.56), (0.45, 16.36), (0.785, 22.00), and (0.95, 26.46); the fitted line is based on unweighted least-squares regression [Source: Adapted from Durkheim (16)].

Annu. Rev. Public Health 1995.16:61-81. Downloaded from www.annualreviews.org
Access provided by McMaster University on 05/30/21. For personal use only.

ranking 13 provinces according to the proportion (X) of the population that was Protestant. Using ordinary least-squares linear regression, we estimate the suicide rate ($\hat{Y}$, per 10^5/year) in each group to be $3.66 + 24.0(X)$. Therefore, the estimated rate ratio, comparing Protestants with other religions, is $1 + (24.0/3.66) = 7.6$. Note in Figure 2 that the fit of the linear model is excellent ($R^2 = 0.97$).

There are two methods used to control for confounders in multiple-group ecologic analyses. The first is to treat ecologic measures of the confounders as covariates ($\mathbf{Z}$) in the model, e.g. percent male and percent white in each group. If the individual-level effects of the exposure and covariates are additive (i.e. if the disease rates follow a linear model), then the ecologic regression of Y on X and $\mathbf{Z}$ will also be linear with the same coefficients (22, 38). That is, the estimated coefficient for the exposure variable can be interpreted as the rate difference adjusted for other covariates, analogously to the crude estimate discussed above.

The second method used to control for confounders in ecologic analyses is rate standardization for these confounders (57), followed by regression of the standardized rates as the outcome variable. Note that this method requires additional data on the joint distribution of the covariate and disease within each group (i.e. the M frequencies in Figure 1). Nevertheless, it cannot be expected to reduce bias unless all predictors in the model (X and $\mathbf{Z}$) are mutually standardized for the same confounders (22, 25, 56). Standardization of the exposure prevalences, for example, requires data on the joint distribution of the covariate and exposure within groups (i.e. the N frequencies in Figure 1); however, this information is not often available in ecologic studies.

As in individual-level analyses, product terms (e.g. XZ) are often used in ecologic analyses to model interaction effects, i.e. to assess effect modification. In ecologic analyses, however, the product of X and Z (both group averages) is not, in general, equal to the average product of the exposure (x) and covariate (z) at the individual level within groups. Assuming a linear model, XZ will be equal to the mean xz in each group only if x and z are uncorrelated within groups (22). Thus, as pointed out in the next section, interaction (nonadditive) effects at the individual level complicate the interpretation of ecologic results.

Annu. Rev. Public Health 1995.16:61-81. Downloaded from www.annualreviews.org
Access provided by McMaster University on 05/30/21. For personal use only.

METHODOLOGIC PROBLEMS

Despite the many practical advantages of ecologic studies mentioned previously, there are several methodologic problems that may severely limit causal inference, especially biologic inference.

Ecologic Bias

The major limitation of ecologic analysis for making causal inferences is ecologic bias, which is the failure of expected ecologic effect estimates to reflect the biologic effect at the individual level (18, 19, 25, 45, 54). In addition to the usual sources of bias that threaten individual-level analyses (35, 57), the underlying problem of ecologic analyses for estimating biologic effects is heterogeneity of exposure level and/or covariate levels within groups; as noted earlier, this heterogeneity is not fully captured with ecologic data because of missing information on joint distributions (see Figure 1). Robinson (55) was the first to describe mathematically how ecologic associations could differ from the corresponding associations at the individual level within groups of the same population. He expressed this relationship in terms of correlation coefficients; this relationship was later extended by Duncan et al (15) to regression coefficients in a linear model. The phenomenon became widely known as the *ecologic(al) fallacy* (61), and the magnitude of the ecologic bias may be severe in practice (10, 17, 54, 62, 63).

As an illustration of ecologic bias, consider again Durkheim's data on religion and suicide (Figure 2). The estimated rate ratio of 7.6 in the ecologic analysis may not mean that the suicide rate was nearly eight times greater in Protestants than in non-Protestants. Rather, since none of the regions were entirely Protestant or non-Protestant, it may have been non-Protestants (primarily Catholics) who were committing suicide in predominantly Protestant provinces. It is certainly plausible that members of a religious minority might have been more likely to take their own lives than were members of the majority. The implication of this alternative explanation is that living in a predominantly Protestant area has a contextual effect on suicide risk among

non-Protestants, i.e. there is an interaction effect at the individual level between religion and religious composition of one's area of residence.

Interestingly, Durkheim (16) compared the suicide rates (at the individual level) for Protestants, Catholics, and Jews living in Prussia. From his data, we find that the rate was about twice as high in Protestants as in other religious groups. Thus, there appears to be substantial ecologic bias (i.e. comparing rate-ratio estimates of about 2 vs 8). Durkheim, however, failed to notice this quantitative difference because he did not actually estimate the magnitude of the effect in either analysis.

Greenland & Morgenstern (25) showed that ecologic bias can arise from three sources when using simple linear regression to estimate the crude exposure effect: The first may operate in any type of study; the latter two are unique to ecologic studies (i.e. *cross-level bias*), but are defined in terms of individual-level associations.

1. *Within-group bias* The exposure effect within groups may be biased by confounding, selection methods, or misclassification (35, 57). Thus, for example, if there is positive net bias in every group, we would expect the ecologic estimate to be biased as well.
2. *Confounding by group* Ecologic bias may result if the background rate of disease in the unexposed population varies across groups, specifically if there is a nonzero ecologic (linear) correlation between mean exposure level and the background rate.
3. *Effect modification by group* Ecologic bias may also result if the rate difference for the exposure effect at the individual level varies across groups.

Confounding and effect modification by group (the sources of cross-level bias) can arise in three ways: (*a*) Extraneous risk factors (confounders or modifiers) are differentially distributed across groups; (*b*) the ecologic exposure variable has an effect on risk separate from the effect of its corresponding individual-level analogue, e.g. living in a predominantly Protestant area vs being Protestant (in the suicide example); or (*c*) disease risk depends on the prevalence of that disease in other members of the group, which is true of many infectious diseases (37).

Unfortunately, those conditions that produce ecologic bias cannot be observed in ecologic data. Furthermore, the fit of the ecologic regression model, in general, gives no indication of the presence, direction, or magnitude of ecologic bias. Thus, a model with excellent fit may yield substantial bias (e.g. Figure 2), and one model with a better fit than another model may yield more bias.

A potential strategy for reducing ecologic bias is to use smaller units in an ecologic study (e.g. counties instead of states) in order to make the groups

Annu. Rev. Public Health 1995.16:61-81. Downloaded from www.annualreviews.org
Access provided by McMaster University on 05/30/21. For personal use only.

more homogeneous with respect to the exposure. On the other hand, this strategy might not be feasible because of the lack of available data aggregated at the same level, and it might lead to two other problems: greater migration between groups (see below) and less precise estimation of disease rates (45, 67).

Problems of Confounder Control

As already indicated, covariates are included in ecologic analyses to control for confounding, but the conditions for a covariate being a confounder are different at the ecologic and individual levels (25, 26). At the individual level, a risk factor must be associated with the exposure to be a confounder. In a multiple-group ecologic study, in contrast, a risk factor may produce ecologic bias (i.e. it may be an ecologic confounder) even if it is unassociated with the exposure in every group, especially if the risk factor is ecologically associated with the exposure across groups (22, 25). Conversely, a risk factor that is a confounder within groups may not produce ecologic bias if it is ecologically unassociated with the exposure across groups.

Control for confounders is more problematic in ecologic analyses than in individual-level analyses (22, 25, 26). Even when all variables are accurately measured for all groups, adjustment for extraneous risk factors may not reduce the ecologic bias produced by these risk factors. In fact, it is possible for such ecologic adjustment to increase bias. It follows from the principles presented in the previous section (25) that there will be no ecologic bias in a multiple-linear-regression analysis if the following conditions are met:

1. There is no residual within-group bias in exposure effect in any group because of confounding by unmeasured risk factors, selection methods, or misclassification.
2. There is no ecologic correlation between the mean value of each predictor and the background rate of disease in the joint reference (unexposed) level of all predictors.
3. The rate difference for each predictor is uniform across levels of the other predictors within groups (i.e. the effects are additive), and each rate difference is uniform across groups (i.e. group does not modify the effect of each predictor at the individual level).

These conditions are sufficient, but not necessary, for the ecologic estimate to be unbiased, i.e. there might be little or no bias even if none of these conditions are met. On the other hand, minor deviations from these conditions can produce substantial ecologic bias (22). Since the sufficient conditions for no ecologic bias cannot be checked with ecologic data alone, the unpredictable and potentially severe nature of such bias makes biologic inference from ecologic analyses particularly problematic. Prentice & Sheppard (51) have

suggested that ecologic data be supplemented with individual-level data from each group (or a representative sample) to enhance biologic inference.

Lack of additivity at the individual level (see #3 above) is common in epidemiology, but unmeasured modifiers do not bias results at the individual level if they are unrelated to the exposure (21). Furthermore, interactions may be handled readily at the individual level by including product terms as predictors in the model (e.g. xz). In ecologic analyses, however, lack of additivity within groups is a source of ecologic bias, and this bias cannot be eliminated or reduced by the inclusion of product terms (e.g. XZ) unless the effects are exactly multiplicative and the two variables are uncorrelated within groups (53).

Another source of ecologic bias is misspecification of confounders (26). Although this problem can also arise in individual-level analyses, it is more difficult to avoid in ecologic analyses because the relevant confounder may be the distribution of covariate histories for all individuals within each group. In ecologic studies, therefore, adjustment for covariates derived from available data (e.g. proportion of current smokers) may be inadequate to control confounding. It is preferable, whenever possible, to control for more than a single summary measure of the covariate distribution (e.g. the proportions of the group in each of several smoking categories). In addition, since it is usually necessary to control for several confounders (among which the effects may not be linear and additive), the best approach for reducing ecologic bias is to include covariates for categories of their joint distribution within regions. For example, to control ecologically for race and sex, the investigator might adjust for the proportions of white women, nonwhite men, and nonwhite women (treating white men as the referent), rather than the conventional approach of adjusting for the proportions of men (or women) and whites (or nonwhites).

Within-Group Misclassification

The principles of misclassification bias with which epidemiologists are familiar when interpreting the results of analyses conducted at the individual level do not apply to ecologic analyses. At the individual level, for example, nondifferential misclassification of exposure nearly always leads to bias toward the null. In multiple-group ecologic studies, however, this principle does not hold when the exposure variable is an aggregate measure. Brenner et al (4) have shown that nondifferential misclassification of a binary exposure within groups usually leads to bias away from the null and that the bias may be severe. Greenland & Brenner (23) have provided a simple method to correct for nondifferential misclassification of exposure or disease in ecologic analyses, based on estimates of sensitivity and specificity.

In studies conducted at the individual level, misclassification of a covariate, if nondifferential with respect to both exposure and disease, will usually reduce

Annu. Rev. Public Health 1995.16:61-81. Downloaded from www.annualreviews.org
Access provided by McMaster University on 05/30/21. For personal use only.

our ability to control for that confounder (20, 59). That is, adjustment will not completely eliminate the bias due to the confounder. In ecologic studies, however, nondifferential misclassification of a binary confounder within groups does not affect our ability to control for that confounder, provided there is no cross-level bias (3).

If all but one variable (e.g. the exposure or a covariate) in a given analysis is measured at the individual level, this partially ecologic analysis may also be regarded as nonecologic with the ecologic variable misclassified. Thus, the resulting bias may be understood in terms of misclassification bias operating at the individual level.

Other Problems

LACK OF ADEQUATE DATA Certain types of data, such as medical histories, may not be available in aggregate form; or available data may be too crude, incomplete, or unreliable, such as sales data for measuring behaviors (45, 67). In addition, secondary sources of data from different administrative areas or from different periods may not be comparable. For example, disease rates may vary across countries because of differences in disease classification or case detection. Furthermore, since many ecologic analyses are based on mortality rather than incidence data, causal inference is further limited (35).

TEMPORAL AMBIGUITY In a well-designed cohort study of disease incidence, we can usually be confident that disease occurrence did not precede the exposure. In ecologic studies, however, use of incidence data provides no such assurance against this temporal ambiguity (45). The problem is most troublesome when the disease can influence exposure status in individuals or when the disease rate can influence the mean exposure in groups (through the impact of population interventions designed to change exposure levels in areas with high disease rates).

The problem of temporal ambiguity in ecologic studies (especially time-trend studies) is further complicated by an unknown or variable latent period between exposure and disease occurrence (28, 67). The investigator can only attempt to deal with this problem in the analysis by examining associations for which there is a specified lag between observations of average exposure and disease rate. Unfortunately, there may be little prior information about latency on which to base the lag, or appropriate data may not be available to accommodate the desired lag.

COLLINEARITY Another problem with ecologic analyses is that certain predictors, such as sociodemographic and environmental factors, tend to be more highly correlated with each other than they are at the individual level (10, 62).

The implication of such collinearities is that it is very difficult to separate the effects of these variables statistically; analyses yield model coefficients with very large variances, so effect estimates may be severely distorted. In general, collinearity is most problematic in multiple-group ecologic analyses involving a small number of large, heterogeneous regions (15, 64).

MIGRATION ACROSS GROUPS Migration of individuals into or out of the source population can produce selection bias in a study conducted at the individual level because migrants and nonmigrants may differ on both exposure prevalence and disease risk. Although it is clear that migration can also cause ecologic bias (36, 49), little is known about the magnitude of this bias or how it can be reduced in ecologic studies (46).

CONTEXTUAL AND MULTILEVEL ANALYSES

Knowing the severe methodologic limitations of ecologic analysis for making biologic inferences, many epidemiologists who report ecologic results argue that there can be no cross-level bias because their primary objective is to estimate an ecologic effect. For example, we might want to estimate the ecologic effect (effectiveness) of state laws requiring smoke detectors by comparing the fire-related mortality rate in those states with the law vs other states without the law (45). Although this is a reasonable objective, the interpretation of observed ecologic effects is complicated by two issues:

First, biologic inference may be implicit to the objectives of an ecologic study unless the underlying biologic and contextual effects are already known from previous research. Can smoke detectors placed appropriately in homes reduce the risk of fire-related mortality in those homes by providing an early warning of smoke? Does living in an area where most homes are properly equipped with smoke detectors reduce the risk of fire-related mortality in homes with and without smoke detectors? The first question refers to a possible biologic (biobehavioral) effect; the second question refers to a possible contextual effect. Even if these effects exist, the ecologic effect of smoke-detector laws also depends on other factors, e.g. the level of enforcement, the quality of smoke-detector design and construction, the cost and availability of smoke detectors, and their proper placement, installation, operation, and maintenance. In an ecologic study without additional information, the ecologic effect is completely confounded with biologic and contextual effects.

The second complicating issue in interpreting observed ecologic effects is the need to control for confounders measured at the individual level. Even if the exposure is a global measure, such as a law, groups are seldom completely homogeneous or comparable with respect to confounders. To make a valid comparison between states with and without smoke-detector laws, for example,

Annu. Rev. Public Health 1995.16:61-81. Downloaded from www.annualreviews.org
Access provided by McMaster University on 05/30/21. For personal use only.

we would need to control for differences among states in the joint distribution of extraneous risk factors, such as socioeconomic status of residents, firefighter availability and access, building design, and construction (see also *Problems of Confounder Control*).

Perhaps the best solution to these problems is to incorporate both individual-level and ecologic measures in the same analysis. This approach might include different measures of the same factor; e.g. each subject would be characterized by his/her own exposure level as well as the average exposure level for all members of the group to which s/he belongs (aggregate measure). Not only would this approach help to clarify the sources and magnitude of ecologic and cross-level bias, but it would also allow us to separate biologic, contextual, and ecologic effects. It is especially appropriate in social epidemiology, infectious-disease epidemiology, and the evaluation of population interventions.

Annu. Rev. Public Health 1995.16:61-81. Downloaded from www.annualreviews.org
Access provided by McMaster University on 05/30/21. For personal use only.

There are two statistical methods for including both individual-level and ecologic measures in the same analysis. The first method, often called *contextual analysis* in the social sciences, is a simple extension of conventional modeling such as multiple linear regression or logistic regression (5, 34). The model, which is fit to the data at the individual level, includes both individual-level and ecologic predictors. For example, suppose we wanted to estimate the effect of "herd immunity" on the risk of an infectious disease. The risk (y) of disease might be modeled as a function of the following linear component: $b_0 + b_1x + b_2\bar{x} + b_3x\bar{x}$, where x is the individual's immunity status and $\bar{x}$ is the prevalence of immunity in the group to which that individual belongs (65). Therefore, b_2 represents the contextual effect of herd immunity, and b_3 represents the interaction effect, which allows the herd-immunity effect to depend on the individual's immune status. The interaction term is needed in this application, since we would expect no herd-immunity effect among immune individuals. Note, however, that the interpretation of the interaction effect depends on the form of the model (35, 57).

An important limitation of contextual analysis is that observations for individuals within groups are not likely to be independent, which is a basic assumption of conventional modeling. If there are contextual effects, then the outcomes for individuals in the same group are more likely to resemble each other than are the outcomes for individuals in different groups. To handle this problem of within-group clustering, we treat the sampling of individuals from groups as random effects; this approach is called *multilevel modeling, hierarchical regression,* or *random-effects modeling* (6, 71, 72).

Multilevel modeling is a powerful technique with many applications; it can be used to estimate contextual and ecologic effects and to derive improved (empirical Bayes) estimates of biologic effects. At the first level of analysis, we might predict individual risk or health status within each group as a function

of several individual-level variables. At the second (ecologic) level, we predict the estimated regression parameters (e.g. the intercept and slopes) from the first level as a function of several ecologic variables. For example, Humphreys & Carr-Hill (33) used multilevel modeling to estimate the contextual effect of living in a poor area on several health outcomes, controlling for the individual's income and other covariates. In a conventional ecologic analysis, the effects of living in a poor area and income would be confounded, and ecologic estimates of effect would be susceptible to cross-level bias.

CONCLUSIONS

Several practical advantages make ecologic studies especially appealing for undertaking various types of epidemiologic research. Despite these advantages, however, ecologic analysis poses major problems of interpretation when making ecologic inferences and especially when making biologic inferences (due to ecologic bias, etc). From a methodologic perspective, it is best to have individual-level data on as many relevant nonglobal measures as possible. Just because the exposure variable is measured ecologically, for example, does not mean that other variables should be as well.

Even when the stated purpose of the study is to estimate an ecologic effect, biologic inference is usually implicit in epidemiology. Thus, to address the underlying research questions, we typically would want to estimate and/or control for biologic and contextual effects, preferably using multilevel analysis. In contemporary epidemiology, the "ecologic fallacy" reflects the failure of the investigator to recognize the need for biologic inference and thus for individual-level data.

THE ECOLOGICAL FALLACY

STEVEN PIANTADOSI,[1,2] DAVID P. BYAR,[1] AND SYLVAN B. GREEN[1]

The purpose of this paper is to emphasize for epidemiologists the possibility of serious errors resulting from inferences based on ecological analyses. Variables that describe groups of individuals, rather than the individuals themselves, are termed "ecological" and are often used when the analysis of individuals' data is not possible (1). Ecological analyses may be preferred when 1) variables are more conveniently defined or measured on groups because the analysis on individuals would require excessive time or extensive data gathering; 2) ecological analyses permit study of a wider range of values for the independent variable, as in international studies of diet; 3) the precision of aggregate measures like alcohol consumption is likely to be higher for groups than for individuals; and 4) population responses such as smoking quit rates may be of primary interest. Frequently, more than one reason applies. For example, some of the evidence favoring environmental and dietary causes of cancer comes from the comparison of incidence or mortality rates with average levels of risk factors measured on culturally or geographically defined groups of individuals. The first three reasons are relevant to this type of study.

We assume in this paper that measurements on individuals are not available, as in the diet and cancer example, since when this information is known, it might be used in place of, or to correct for biases in, the ecological analysis. Serious errors can result when an investigator makes the seemingly natural assumption that the inferences from an ecological analysis must pertain either to the individuals within the groups or to individuals across groups. A frequently cited early example of an ecological inference was Durkheim's study of the correlation between suicide rates and religious denominations in Prussia (2) in which the suicide rate was observed to be correlated with the number of Protestants. However, it could as well have been the Catholics who were committing suicide in largely Protestant provinces. The potential falsity of ecological inferences, at least in the case of simple correlations, was pointed out by Robinson (3), who gave it the name "ecological fallacy" and provided the mathematical relation, without proof, between the ecological correlation and the individual correlation across all groups. Duncan et al. (4) have extended the equations to include simple linear regression coefficients. The dangers of inferences about individuals from ecological studies have been emphasized by some investigators (5–7), while others (8–11) have sought to minimize the concern over the possible biases in ecological analyses, proposing alternatives or delineating circumstances in which ecological inferences are justified (e.g., certain linear regression models when data on individuals are available). Firebaugh (11) gives a particularly thorough discussion and list of references related to this aspect of the problem.

Although there has been a persistent interest in the problems associated with ecological analyses in the social science literature, the impression seems to remain, even among seasoned epidemiologists, that ecological analyses may not have large biases,

at least in certain cases. Such impressions result, in part, from the nonintuitive sound of serious disparity between group level and individual level statistics. Our goal is to provide convincing evidence, intuitively, mathematically, and empirically, of the possibility of important bias in ecological analyses and to clarify some recent work on this topic. We present a hypothetical example of the ecological fallacy and a simple derivation of the relation between the individual correlation and the ecological correlation. We extend this derivation to outline the relation between the individual regression slope and the ecological regression slope. In addition, theoretical observations are supported by an ecological analysis of correlations and regression coefficients for a set of real data, using variables often encountered in epidemiologic practice.

Hypothetical example

The ecological fallacy is illustrated in a simple case by considering the hypothetical data in table 1. Although these data are contrived, they are useful since the relevant correlations are evident by inspection or simple calculation. Here, N individuals are classified into r groups of equal size $n_i = k$. A variable, X, is assigned to each individual and has the values of the consecutive integers from $k(i-1)+1$ to ki in the ith group. Within each group, the values of a second variable, Y, are chosen to be the descending consecutive integers from ki to $k(i-1)+1$ in the ith group (i.e., the reverse order of the X's). These data have the following characteristics. The overall means of X and Y, $\bar{X}$ and $\bar{Y}$, are equal, as are the within-group means, $\bar{X}_i$ and $\bar{Y}_i$. Similarly, the overall variances are equal, as are the within-group variances. The within-group correlation coefficient, ρ_i, equals -1 for all i, but since the group means for X and Y are identical, the between-group or ecological correlation, ρ_e, equals 1. It is easily shown (see Appendix 1), however, that for these data, the overall correlation between X and Y, ignoring groups, is

$$\rho = \frac{N^2 + 1 - 2k^2}{N^2 - 1}.$$

Thus, $\rho = \rho_i$ only when $k = N$ (i.e., a single group), and $\rho = \rho_e$ when $k = 1$ or as $N \to \infty$ and $k \ll \infty$. In instances like this, however, in which there is an appreciable group effect (i.e., the expected value of Y given X, $E(Y \mid X)$, is not the same in all groups), the correlation of interest is neither ρ nor ρ_e but the average within-group correlation, ρ_a, (defined later), which in the present example equals -1 since all ρ_i are the same. For this example, the value of ρ always exceeds 0.5, 0.92, and 0.98, respectively, for two, five, and 10 groups, whatever the number of subjects in each group. Furthermore, since the overall and within-group variances for X and Y are equal, the linear model

$$Y = \alpha + \beta X$$

and its ecological counterpart

$$\bar{Y}_i = \alpha_e + \beta_e \bar{X}_i$$

would give estimates $\hat{\beta} = \rho$ and $\hat{\beta}_e = \rho_e$. This simple example demonstrates maximal disparity between the ecological correlation or the ecological regression slope, and the corresponding overall or within-group estimates.

Derivation of general relations

To understand the source of the ecological fallacy in the general case, consider N individuals classified into r groups of size n_i, where $i = 1, 2, \ldots, r$, and a single covariate, X, linearly related to a response Y for each individual. The relation between ecological analyses and other analyses based on individuals can be seen by appropriate partitions of the total sums of squares and cross-products. Define

$$X_{\cdot\cdot} = \sum_{i=1}^{r} \sum_{j=1}^{n_i} X_{ij} = N\bar{X}_{\cdot},$$

and an analogous definition for Y. For notational convenience, sums of squares and cross-products are denoted by T (total), W (within groups), or E (ecological or between groups), with subscripts indicating the variables involved. Thus, in the usual analysis of covariance (12) (table 2), T_{xx} is the total sum of squares of X, W_{xy} is the within-groups sum of cross-products of X and Y, and E_{yy} is the between-groups sum of squares of Y. The total sum of cross-products about the mean across all individuals may be partitioned into within-group and between-group components as follows:

$$T_{xy} = \sum_{i=1}^{r} \sum_{j=1}^{n_i} (X_{ij} - \bar{X}_{\cdot})(Y_{ij} - \bar{Y}_{\cdot}) = W_{xy} + E_{xy},$$

where

$$W_{xy} = \sum_{i=1}^{r} \sum_{j=1}^{n_i} (X_{ij} - \bar{X}_{i})(Y_{ij} - \bar{Y}_{i}),$$

and

$$E_{xy} = \sum_{i=1}^{r} n_i(\bar{X}_{i} - \bar{X}_{\cdot})(\bar{Y}_{i} - \bar{Y}_{\cdot}).$$

The corresponding formulas for the sum of squares of X (or Y) are obtained by replacing Y with X (or X with Y) in these equations. The between-group or ecological sums of squares and cross-products are weighted by the number of individuals in each group. The correlation coefficient between X and Y, ignoring groups, is

$$\rho = \frac{T_{xy}}{\{T_{xx}T_{yy}\}^{1/2}} = \frac{E_{xy}}{\{T_{xx}T_{yy}\}^{1/2}} + \frac{W_{xy}}{\{T_{xx}T_{yy}\}^{1/2}}. \quad (1)$$

Rewriting equation 1 as

$$\rho = \frac{\{E_{xx}E_{yy}\}^{1/2}}{\{T_{xx}T_{yy}\}^{1/2}} \cdot \frac{E_{xy}}{\{E_{xx}E_{yy}\}^{1/2}} + \frac{\{W_{xx}W_{yy}\}^{1/2}}{\{T_{xx}T_{yy}\}^{1/2}} \cdot \frac{W_{xy}}{\{W_{xx}W_{yy}\}^{1/2}}, \quad (2)$$

we may now define the *ecological correlation*

$$\rho_e = \frac{E_{xy}}{\{E_{xx}E_{yy}\}^{1/2}},$$

and the *average within-group correlation*

$$\rho_w = \frac{W_{xy}}{\{W_{xx}W_{yy}\}^{1/2}};$$

so that

$$\rho = \left\{\frac{E_{xx}E_{yy}}{T_{xx}T_{yy}}\right\}^{1/2} \rho_e + \left\{\frac{W_{xx}W_{yy}}{T_{xx}T_{yy}}\right\}^{1/2} \rho_w. \quad (3)$$

Note that ρ_w is not influenced by group effects. Some additional definitions will show that this last result is equivalent to that given originally by Robinson (3). Details are given in Appendix 2.

In an analogous fashion, we may define

TABLE 2

A general analysis of covariance

Source	df	Sum of squares and products

the regression coefficients

$$\beta = \frac{T_{xy}}{T_{xx}},$$

$$\beta_e = \frac{E_{xy}}{E_{xx}},$$

and

$$\beta_w = \frac{W_{xy}}{W_{xx}},$$

and show that

$$\beta = \frac{E_{xx}}{T_{xx}}\beta_e + \frac{W_{xx}}{T_{xx}}\beta_w, \qquad (4)$$

where β, β_e, and β_w are the overall regression slope, *ecological regression* slope, and the *average within-group regression* slope, respectively. This can be written

$$\beta_e = \frac{T_{xx}}{E_{xx}}\beta - \left\{\frac{T_{xx}}{E_{xx}} - 1\right\}\beta_w$$

$$= \beta_w + \frac{T_{xx}}{E_{xx}}(\beta - \beta_w), \qquad (5)$$

with the first equality being the relation given by Duncan et al. (4).

Analysis of General Relations

In the absence of group effects, the regression coefficient of interest is β_e, whereas when group effects are present, β_w is a more appropriate description of the data. In fact, when group effects are absent, $\beta = \beta_w$, so that β_w is always the regression coefficient of interest. The ecological fallacy consists of incorrectly assuming that, when group effects are present, $\beta_e = \beta_w$.

We can see immediately from equation 4 that the coefficients of β_e and β_w sum to 1, so that β is always a weighted average of the ecological and within-group regression slopes. The consequence of this is that β either lies between β_e and β_w (although the order of β_e and β_w cannot be predicted) or, when there are no group effects, $\beta = \beta_e = \beta_w$. More generally, however, there are group effects so that β and β_w are unequal, and thus β_e and β_w are also unequal. For regression coefficients, the notion of separating "cross-level" bias into aggregation bias (the difference between β and β_e) and specification bias (the difference between β and β_w) (1) is not meaningful since both biases either occur together or not at all, as implied by Firebaugh (11). In fact, it may easily be shown that

$$\beta_e - \beta = \frac{W_{xx}}{E_{xx}}(\beta - \beta_w),$$

further emphasizing that aggregation bias and specification bias do not occur separately.

The results for correlation coefficients are similar. The multipliers of ρ_t and ρ_w in equation 3 do not, however, sum to 1, so that ρ is not always constrained as β was. For correlations, the ecological fallacy consists of incorrectly assuming that ρ_e estimates either ρ or ρ_w.

The point has been correctly made (1, 10, 11) that ecological correlations are likely to be poorer estimates of their individual counterparts than ecological regression slopes. This is because correlations depend on the relative dispersions of X and Y and thus are determined by the design of the experiment. Note that

$$\rho_w = \beta_w\left\{\frac{W_{xx}}{W_{yy}}\right\}^{1/2} \text{ and } \rho_e = \beta_e\left\{\frac{E_{xx}}{E_{yy}}\right\}^{1/2}.$$

Selecting groups specifically because they differ in $\bar{X}_i$ will tend to increase the variance of $\bar{X}_i$ compared with the variance of $\bar{Y}_i$, and therefore increase the ecological correlation. In the absence of group effects in regression ($\beta = \beta_e = \beta_w$), the correlations can nevertheless differ, and the relation of ρ_e and ρ_w will depend on how the groups are chosen. Although demonstrating that $\rho_e \neq 0$ can be useful, its actual value seems quite arbitrary. If the goal is to make statements about Y on the basis of X, then in this situation, β_e is a more useful quantity than ρ_e.

It has been stated by some writers (see for example Stavraky (13) and Kleinbaum et al. (14)) that ecological associations are frequently an overestimate of the magni

Downloaded from aje.oxfordjournals.org at University of California, Los Angeles on August 3, 2011

tude of the underlying individual effects. While this is always possible, we can find no justification for assuming that it is more likely than the alternative. As noted above, in the absence of group effects, the selection of groups will affect ρ_w (and may well tend to increase correlations). When group effects do, however, exist (which is quite likely in epidemiologic studies), the bias can be in either direction.

The concept of group effects in regression can be expressed in other ways. As stated above, by group effects we mean that $E(Y \mid X)$ is not the same in all groups or, equivalently, that $\beta \neq \beta_a \neq \beta_w$ (i.e., there is cross-level bias). Thus, group membership is related to some confounding factor(s) which affects the observed relation between X and Y. Firebaugh (11) addresses this situation by considering a regression of the form $Y = \alpha + \beta X + \gamma \bar{X}_i$; the presence of group effects implies that $\gamma \neq 0$. Without data on individuals, this situation cannot be detected, yet it is quite likely to exist in epidemiologic studies. Of course, if an investigator is aware of potential confounding variables measured on the groups, these can be included in the ecological regression to decrease the bias (10). The issue to consider is how likely are the groups to differ by other (unmeasured) variables.

A confounder can exist on two levels. A variable could be confounding only on the group level, and thus affect both β (the overall slope for X) and β_e (the ecological slope for X), but not β_w. For example, the variable could be a characteristic of the whole group rather than the individual (e.g., geographic latitude) or the variable could be independent of X within groups, but correlated with X across groups. If such a variable were known, it could be properly incorporated in an ecological regression. The problem is that variables such as this could well exist but not be identified. If individual level data on X and Y were available, individual level regression adjusted for group effect would permit unbiased estimation of the desired effect of X on Y.

Alternatively, a variable could be confounding on both the individual and group levels (e.g., age confounding the effect of diet). In this situation, information on the confounder would have to be incorporated into the regression whether at the individual level or the ecological level.

In theory, there is a third alternative in which a variable is confounding on the individual level but is not confounding in linear regression at the group level (because the variable is uncorrelated with group membership). For example, in an investigation of the relation of diet to the risk of colon cancer, sex is a possible confounding factor, but it is conceivable that all groups have essentially the same sex ratio. In this situation, ecological regression might be preferable to unadjusted individual level regression.

EMPIRICAL STUDY OF ECOLOGICAL CORRELATIONS

We now consider an ecological analysis of data from the Second National Health and Nutrition Examination Survey (NHANES II) in which we can compare individual level and grouped estimates. This study, conducted by the National Center for Health Statistics between 1976 and 1980, was intended to assess the health and nutritional status of the general civilian noninstitutionalized population of the United States (15). Initially, a nationwide probability sample of approximately 28,000 persons was taken with oversampling in those groups thought to be at high risk of malnutrition (low income, preschool children, and the elderly). A 24-hour dietary recall questionnaire was given to a subset of 13,820 adults. From these records, we selected 11 variables for analysis describing or derived from health history, food frequency, and anthropometry (16). Measurements were on continuous scales for dietary measures, height, weight, age, and body mass index (weight in kilograms divided by the square of height in meters), ordered categories for income and education, and binary categories for sex and race (table 3). These variables were selected not because

of pathologic behavior but, because they represent the type of measurements likely to appear in ecological analyses conducted by epidemiologists. Three levels of aggregation were studied. Because individuals were originally selected for the NHANES II study through one of 64 primary sampling units consisting of counties or county aggregates, the primary sampling unit made a convenient grouping variable and was the lowest level of aggregation used. Individuals also represented 34 different states which were used as a second level of aggregation. Finally, states were classified into one of six regions (northeast, north central, etc.) for the highest level of aggregation. Primary sampling units contained an average of 216 people with extremes of 130 and 343. Aggregation into states resulted in an average group size of 4,086 with extremes of 132 and 1,250. The six region sizes were 3,078, 2,869, 3,395, 2,333, 763, and 1,382 (mean = 2,303).

Table 4 shows a partition of sums of squares and cross-products for the variables income and education (highest grade attained). The between-group sums of squares are weighted by the number of individuals in each area. These quantities are presented here because of their relevance to the derivation of equations 3 and 4 and could be used to calculate the necessary statistics. In practice, however, it is easier to calculate the ecological correlation coefficients and regression parameters directly from suitable statistical software packages without using the intermediate sums of squares. The quantity ρ_e is a weighted correlation of $\bar{X}_i$ and $\bar{Y}_i$ with weights equal to the number of individuals in each group. Similarly, β_e can be calculated as the weighted regression of $\bar{Y}_i$ on $\bar{X}_i$ with weights equal to the number of individuals in each group. The quantity ρ_w may be conveniently calculated from the within-group sums of squares. These same quantities may be used to calculate β_w. Alternatively, β_w can be calculated as the weighted average of within-group regression slopes; the weights for β_w are the within-group sums of squares about the mean for the independent variable X. Alternatively, in a linear analysis of covariance model that fits a separate intercept for each group, the common slope is β_w.

The behavior of ecological correlations in the NHANES II data can be seen by examining the results in table 5. Significance levels for these estimated correlation coef-

ficients were calculated by comparing $(N - 2)^{1/2}\,\hat{\rho}/(1 - \hat{\rho}^2)^{1/2}$ with the t distribution with $N - 2$ df (17), where N is the number of observations on which the correlation is based. It is apparent that correlations among group averages not only inadequately estimate both the correlation among individuals and the average within-group correlation but also show no discernible qualitative consistency to this effect. The ecological correlations may under- or overestimate the correlation among individuals, with equally unpredictable significance levels. The average within-area correlations in table 5 are, however, essentially identical to the overall correlation that ignores groups, indicating that for these data, most of the total variation is due to within-group variation.

Of the 13 variable pairs examined in table 5, four show increasing positive or negative correlation as the level of aggregation increases, three show the reverse pattern, and six are mixed. The levels of statistical significance for testing the hypothesis that the correlation is zero (not shown) may either increase or decrease with higher aggregation. It is not surprising that aggregation fails to preserve the statistical significance of some overall correlations (e.g., race-income) because of reduced degrees of freedom at higher levels of aggregation, but it is worrisome that nonsignificant individual level statistics can produce significant ecological estimates (e.g., height-body mass index).

The behavior of ecological regression coefficients in the NHANES II data can be seen by examining table 6. Approximate 95 per cent confidence limits were calculated as $\pm\, t_{0.975}\,(N - 2\ \text{df})$ times the estimated standard error of each regression coefficient. These confidence bounds are useful for testing the hypothesis that a coefficient differs from zero, but they are not as useful for testing the equality of coefficients across levels of grouping because the covariance of two coefficients is not zero. Here again, there appears to be no constant pattern to the relation among the β's, except that β lies between β_c and β_w as required by expression 4. The order of β_c and β_w is, however, not consistent: The ecological regression coefficients may fluctuate (weight-body mass index), increase (income-education), or decrease (protein-fat) with respect to the overall regression. As for the correlation coefficients, nonsignificant individual level effects may produce significant ecological regressions (height-body mass index) and, conversely, significant individual level effects may produce nonsignificant ecological regressions (race-income). This correspondence between the regression and correlation occurs because the significance of the coefficients is assessed using equivalent tests. We note the relative consistency of the dietary ecological regressions in table 6, except at the regional level for two of them, but can offer no theoretical explanation for the observed behavior. For most variables in table 6, β_w

is close to β, indicating that most of T_{xx} is due to W_{xx}. Even when β_w is close to β, the ratio T_{xx}/E_{xx} can be large, making β_x and β_w different (equation 5).

Examination of the confidence bounds reveals that, in some cases such as height-weight and income-education, the values of β_x are not consistent with the values of β_w. In other words, the disparity between the ecological and individual regression estimates is not due solely to the larger variability of the former but is due, presumably, to a confounding factor. For the protein-fat pair, the ecological regression on regions not only is inconsistent with the individual coefficient but also has the wrong algebraic sign. We note the particularly wide confidence limits for ecological regression coefficients when the independent variable is the binary variable sex. This occurs because the sex ratio differs little across groups, suggesting that in such a situation ecological regression is particularly unwise.

Finally, the results for regressions reversing the role of the dependent and independent variables may be deduced from tables 5 and 6 since the correlation coefficient is the geometric mean of the regression coefficient for Y on X and that for X on Y. The significance levels for the two regressions are the same.

Discussion

This paper shows that the relation between β_x and the individual level measurements is not qualitatively constant but depends on the effects of grouping. The case $\beta = \beta_x = \beta_w$ could arise only when the grouping has no effect on the regression. The emphasis here is, however, on observational studies in which individual level data are unavailable, and hence the assumption of no group effects cannot be verified.

In the case of linearly related variables, the ecological fallacy can be understood as the incorrect equating of between-group ratios of the sums of squares and cross-products with the relations between the totals (or within groups). When data are

available on individuals and the groups to which they were assigned, the ecological analysis is seen to be a part of the usual analysis of covariance. Ecological analyses are, however, incomplete analyses of covariance since, if the information on individuals were available, it could be used to avoid these problems, although covariance adjustment on unplanned experimental data has its own difficulties (18). We believe that the investigator is never justified in interpreting the results of ecological analyses in terms of the individuals who give rise to the data. This may seem to many readers to be an overstatement; however, our theoretical and empirical analyses offer no consistent guidelines for the interpretation of ecological correlations or regressions when data on individuals are unavailable.

We note that the literature on ecological analysis, as well as our derivation above, generally neglects the possibility of interactions. If, after adjustment for confounding, the regression coefficient for X is found to differ significantly according to some other variable, that variable and X are said to have an interaction (on the scale of measurement being used). In such a situation, one may well be interested in more than the overall slope (whether individual level or ecological) or the average within-group slope. For example, if the effect of X on Y were significantly different for males compared with females, then in addition to the coefficient for X, the interaction term would also be important. This could only be determined if sex were included in the regression. While in theory this could be done for both individual level and ecological regression, in the latter situation the groups would have to have different sex ratios as well as different values of X in order to fit the full regression.

Ecological analyses become flawed in exactly the same circumstances that individual level analyses do, i.e., in the presence of confounding. The consequences of confounding bias in the ecological analysis are more severe, however. With respect to inferences about individuals, the proper role of ecological analyses is to generate new hypotheses which must then be tested using more appropriate experimental or observational methods. To interpret ecological analyses sensibly, the investigator should use outside information to judge the likelihood of serious errors. Additionally, inferences should be confined to the level of observation (or experimentation). These conclusions apply both to simple correlation coefficients and to linear regression slopes. While we are unaware of theory for nonlinear response models, it seems likely that similar problems might arise, and the same caution should be used.

Appendix 1

Theorem: For the data in table 1,

$$\rho = \frac{N^2 + 1 - 2k^2}{N^2 - 1}. \tag{A.1}$$

Proof: By definition, the overall correlation coefficient is

$$\rho = \frac{\sum\sum X_i Y_i - N\bar{X}\bar{Y}}{[(\sum\sum X_i^2 - N\bar{X}^2)(\sum\sum Y_i^2 - N\bar{Y}^2)]^{1/2}}.$$

Since $\sum\sum X_i^2 = \sum\sum Y_i^2$ and $\bar{X} = \bar{Y}$,

$$\rho = \frac{\sum\sum X_i Y_i - N\bar{X}^2}{\sum\sum X_i^2 - N\bar{X}^2}. \tag{A.2}$$

We begin by calculating

$$\sum\sum X_i Y_i = \sum_{i=1}^{N/k}\sum_{j=1}^{k}(ik - (i-1)k + j)(ik + 1 - j).$$

Expanding the product and using the relations

$$\sum_{i=1}^{n} i = \frac{n(n+1)}{2}$$

and

$$\sum_{i=1}^{n} i^2 = \frac{n(n+1)(2n+1)}{6},$$

yields

$$\sum\sum X_i Y_i = \frac{2N^3 + 3N^2 - k^2 N + 2N}{6}. \tag{A.3}$$

Similarly,

$$N\bar{X}^2 = \frac{N^3 - 2N^2 + N}{4}. \tag{A.4}$$

and

$$\sum\sum X_i^2 = \frac{2N^3 + 3N^2 + N}{6}. \tag{A.5}$$

Substituting expressions A.3–A.5 into A.2 yields equation A.1.

Appendix 2

To show that equation 3 is Robinson's result (3), define

$$a_W = \frac{E_W}{T_W}.$$

and

$$a_* = \frac{E_*}{T_*}.$$

Downloaded from aje.oxfordjournals.org at University of California, Los Angeles on August 3, 2011

These quantities, termed the correlation ratios, measure the degree of clustering in X and Y among areas (3, p. 356). We can write equation 3 in terms of η_x^2 and η_y^2 by noting

$$(1 - \eta_y^2) = \frac{T_{yy} - B_{yy}}{T_{yy}} = \frac{W_{yy}}{T_{yy}},$$

and

$$(1 - \eta_x^2) = \frac{W_{xx}}{T_{xx}}.$$

Therefore, equation 3 becomes

$$\rho = \eta_x \eta_y \rho_b + (1 - \eta_x^2)^{1/2} (1 - \eta_y^2)^{1/2} \rho_w. \tag{B.1}$$

Solving equation B.1 for ρ_b yields

$$\rho_b = (1/\eta_x \eta_y)\, \rho - \left[\frac{(1 - \eta_x^2)^{1/2} (1 - \eta_y^2)^{1/2}}{\eta_x \eta_y}\right] \rho_w, \tag{B.2}$$

which is the relation given by Robinson (3) without proof.

Robust parameter extraction for decision support using multimodal intensive care data

By G. D. Clifford[1,*], W. J. Long[2], G. B. Moody[1] and P. Szolovits[2]

Digital information flow within the intensive care unit (ICU) continues to grow, with advances in technology and computational biology. Recent developments in the integration and archiving of these data have resulted in new opportunities for data analysis and clinical feedback. New problems associated with ICU databases have also arisen. ICU data are high-dimensional, often sparse, asynchronous and irregularly sampled, as well as being non-stationary, noisy and subject to frequent exogenous perturbations by clinical staff. Relationships between different physiological parameters are usually nonlinear (except within restricted ranges), and the equipment used to measure the observables is often inherently error-prone and biased. The prior probabilities associated with an individual's genetics, pre-existing conditions, lifestyle and ongoing medical treatment all affect prediction and classification accuracy. In this paper, we describe some of the key problems and associated methods that hold promise for robust parameter extraction and data fusion for use in clinical decision support in the ICU.

Keywords: clinical errors; data fusion; decision support; intensive care unit; noise; signal quality

1. Introduction

Intensive care provides one of the most challenging locales for both clinicians and engineers who try to support clinical activities. Intensive care unit (ICU) patients are often the sickest, frequently having several pathophysiological problems that must be managed simultaneously to avoid death or severe morbidity. Both physiological state and external interventions change frequently, demanding rapid analysis and quick, high-stakes decisions.

Advances in the development of technology, computational signal processing and biological modelling have led to a growing interest in the archiving and use of extensive hospital–medical databases. Although current clinical practice is centred on human expert assessment of the correlations between parameter values and symptoms, there is a growing awareness within medical communities that the enormous quantity and variety of data available cannot be effectively assimilated and processed without automated or semi-automated assistance.

Automated systems have been in place in the ICU and the operating theatre (OR) for several decades, including automated arrhythmia analysis of the bedside electrocardiogram (ECG) and low (or high) oxygen saturation warnings from the photoplethysmograph (PPG). However, each device acts in an isolated fashion with no reference to related signals or an individual's prior medical information, such as genetics or medical history. Some patient-specific data are used in an ad hoc manner, such as body weight (for the adjustment of drug rates), allergies (to restrict medications) and age (for arrhythmia alarm thresholds). However, automated use of such information is rare.

In this paper, we outline a long-term approach to develop systematic bases for extracting information in order to provide assistance to clinicians faced with the enormous challenges of providing high-quality ICU care. We are currently collecting large datasets of actual patient experiences in the ICU, developing methods to analyse and abstract those data, retrieval systems to allow selection of events of interest, creating models that relate such data to patients' clinical conditions and pathophysiological status, and building both physiological and statistical models to enable sophisticated decision support systems that base alarms on an integrated view of the patient and that can assess or even suggest alternative courses of action. Although we frame these ideas within a wider context, here, we focus principally on the problems we have encountered and the solutions we have developed for collecting ICU patient data and extracting information that is useful for decision support.

We have instituted a large-scale systematic collection of data about ICU patients (Saeed *et al.* 2002) to provide a baseline understanding of what currently happens in the ICU and to allow us to learn to model patients' conditions and their responses to various interventions. These data derive from a heterogeneous set of sources, including bedside monitoring equipment; clinical observations by doctors and nurses; laboratory measurements; records of both continuous and discrete drug administration; reports from physical examinations, referring physicians, radiologists, pathologists and other specialists; and records of past conditions, treatments and outcomes, as normally recorded in discharge summaries. Each of these sources of data carries its own set of technical problems, ranging from mundane issues of data standardization to difficulties in assessing the quality of recorded data and dealing with missing data. To date, we have collected data on approximately 30 000 patients from four different ICUs at a large tertiary-care teaching hospital. Approximately 10 per cent of those records include high-frequency physiological signals recorded from the bedside monitors, including multichannel ECG, invasive arterial blood pressure (ABP) and PPG. Associated derived parameters, such as heart rate, systolic/diastolic blood pressure and oxygen saturation, are also available.

In the following sections, we describe issues we have encountered in

(i) the collection, measurement, transmission, transcription and storage of these data,
(ii) abstraction and robust parameter extraction from often noisy and incomplete data, and
(iii) extraction of clinically relevant concepts from unstructured text, which is the form in which many notes and reports are stored.

2. Errors in collection, measurement, transmission, transcription and storage of data

The first problem faced in gathering ICU data is the necessity of collecting the data from a variety of sources: instruments that acquire and digitize continuous signals; devices such as respirators and intravenous drug delivery systems that must be interrogated to record their settings; laboratory results that may have been automatically or manually transcribed into clinical information systems; and medical histories, admitting notes, progress notes, problem lists and discharge summaries that must be obtained from online or paper medical records. These diverse data streams must be synchronized in order to make sense of their inter-relationships. Even establishing basic causal relationships among data elements (did the patient's symptoms prompt a change in medication, or did the medication change cause the symptoms?) can be problematic when time is recorded by independent and unsynchronized clocks. At an even more basic level, it is necessary to match each recorded data stream with the correct patient among all those currently in the hospital, a problem that should be trivially easy to solve but is often complicated by instruments with poorly designed set-up procedures that are not always completed in the context of urgent care, human transcription errors (Hug & Clifford 2007; Vawdrey *et al.* 2007) and policies intended to protect patient privacy. The use of proprietary formats and protocols for medical data storage and communications is slowly giving way to open formats (e.g. EDF, WFDB, XML; Clifford *et al.* 2008) and protocols (such as HL7 and the IEEE medical information bus standard P1073; Alsafadi *et al.* 1994), which will reduce transcription errors. However, the processes of capturing and digesting these data into a consistent format remain complex.

Having solved all of these problems by whatever means necessary, it may be possible to assemble an electronic medical record containing most of the information upon which medical decisions are founded. Just as traditional medical records may contain errors from a variety of sources, so may their electronic equivalents. Measurement errors may stem from incorrect calibration, improperly located or malfunctioning transducers, artefact, environmental noise, or from errors in transmission, transcription, storage or retrieval (Clifford & Oefinger 2006). Some of these errors can be minimized by use of good biomedical, computer and human engineering practices, for example by stabilizing sensors to limit motion-related artefact; minimizing the area of low-voltage sensing circuits and using shielded cables to avoid signal contamination by induced currents; using error detecting and correcting codes when transmitting and storing packets of digital data; employing data communication protocols that incorporate handshaking, retransmission and redundancy to avoid data loss; redesigning workflow to capture data automatically, to avoid manual transcription of data where possible, and to verify data that must be transcribed at the time of transcription; and regular reviews of data collection practices to identify and address deficiencies.

Conscientious use of best practices can reduce but not eliminate measurement errors. The effects of those errors that remain upon subsequent analysis of the record can be minimized by searching for logical inconsistencies (such as when the systolic blood pressure is lower than the mean or diastolic blood pressure), or by

comparing multiple redundant measures of the same physiological parameters. For example, heart rate may be derived from the ECG, an invasive ABP line and the PPG. These issues are explored further in §3*d*, after discussing problems and solutions related to noise reduction, signal quality, artefacts and missing data.

3. Abstraction and robust parameter extraction

In order to provide information for medical experts (or automated decision support systems) to make choices concerning patient care, the wealth of available data must be reduced to a set of distinct concepts and features. Although many parameters are derived from patient data 'on the fly' and recorded for later review, trust metrics or signal quality measures associated with these parameters are rarely stored. Therefore, it is difficult to ascertain the credibility of a given parameter unless the original data from which the parameter was derived are available, either to visually verify the data or in order to derive independent quality metrics.

Noise reduction algorithms often introduce misleading distortions in medical time-series data and, therefore, they should be applied only when the data are determined to be too noisy for a feature extraction algorithm to be applied accurately. However, it is often necessary to extract features and compare them with a population norm, or a patient's history, in order to determine whether significant amounts of noise are present. A method for simultaneously (or recursively) extracting features and estimating noise levels is, therefore, appropriate.

In this section, we describe a generic approach to noise reduction and signal quality analysis, together with a data fusion framework that provides for a robust estimate of extracted physiological parameters that evolve over time.

(*a*) *Noise reduction*

After appropriate formatting, storage and initial coding of data, perhaps the most important stage in data processing is the application of signal processing algorithms to deal with the noisy and transient nature of physiological signals. Even when the data are continuously available and the sampling rate is high enough, data can still be masked by periods of intense noise due to movement artefact. Strategies for detecting and (where possible) removing noise in physiological data depend on the nature of both the noise and the data source and typically include infinite impulse response filters, finite impulse response filters, principal component analysis (PCA; Moody & Mark 1989), independent component analysis (ICA; McSharry & Clifford 2004; He *et al.* 2006) and wavelets (Addison 2005). Much of the data recorded in the ICU are nonlinear or non-stationary, however, and the mixing between the noise and the signal is also non-stationary. Therefore, techniques such as ICA cannot work reliably unless calculated over small, quasi-stationary segments of data and frequently updated. Furthermore, the noise and the signal are not independent, such as when heart rate increases due to activity are associated with increasing frequency of artefact (Clifford *et al.* 2002) and methods to separate them, which assume independence (such as PCA and ICA), only work when the coupling between the signal and the noise is weak. It should be noted that PCA-based techniques have proved

extremely effective for filtering on a beat-by-beat basis, particularly in applications such as QT analysis (Okin *et al.* 2002), ST analysis (Moody & Jager 2003; Jager *et al.* 2004), QRS subtraction and QRS classification (Moody & Mark 1989).

Takla *et al.* (2006) provided a thorough review of the types of contamination of signals in the OR and methods that have been proposed to deal with the noise. Although much of this information is pertinent to monitoring in general, the ICU is more problematic than the OR, since the latter is more highly controlled, with a higher staff-to-patient ratio. ICU data are often only available on an infrequent basis (relative to the underlying dynamics), and removal of noise becomes problematic. The best method to deal with noise is often simply the use of a median filter to reject outliers (Mäkivirta *et al.* 1991). For example, heart rate and blood pressure averages recorded by nursing staff every hour sometimes exhibit artefacts that are significantly different from the underlying waveform data (Hug & Clifford 2007). Although a median filter is able to reduce the average magnitude of the error in this scenario, this is only because patients tend to be stable and exhibit the same physiological parameter values from hour to hour. However, there is no guarantee that the *outlier* is not a real event. In fact, it is the rare outliers that are often of interest in biomedical time-series data, since they indicate that the aim of managed stability for a patient may be unsuccessful and that changes in treatment are required.

To allow for the non-stationary nature of ICU data, an adaptive filter is often more appropriate, where the transfer function changes in response to each new data sample or feature (Takla *et al.* 2006). Adaptive filters are generally either ad hoc (Martinez *et al.* 1997; Husoy *et al.* 2002) or model-based (Clifford *et al.* 2005; Clifford 2006; Sameni *et al.* 2007). Although model-based filters provide a much more effective suppression of noise, they tend to be more computationally intensive, and their effectiveness is dependent on the accuracy and applicability of the model employed. In Sameni *et al.* (2007), the authors recently proposed an adaptation of a model-based filtering approach to the ECG, which is particularly suitable to a real-time implementation. By using an unscented Kalman filter, a nonlinear version of the Kalman filter (KF), they leveraged the beat-to-beat dynamics (and similarities) to allow a computationally efficient Bayesian approach to ECG model parameter estimation. Although Sameni *et al.* demonstrated that the technique outperforms the best of previously described ECG filters on normal sinus rhythm ECGs, performance on arrhythmic data is unclear. In all likelihood, unless a pre-classification algorithm is employed, the model will have to be refitted to the data for moderate changes in morphology, and classified as abnormal or artefactual. It is also worth noting that, since the model is based upon a superposition of Gaussians, it is easily adapted to filtering and classification of other cardiovascular signals such as the blood pressure (Clifford & McSharry 2004; Clifford *et al.* 2005).

(*b*) *Artefacts and missing data*

Most filtering techniques are also sensitive to artefacts and missing data. In particular, even when signals have been sampled above the Nyquist limit, intervals of missing data may be frequent, due to disconnections, sensor errors, equipment

changes, intrusive diagnostics and request-based data (such as blood tests). Sometimes noise and artefact can be so high that it is best just to discard the section of data, effectively making an evenly sampled signal irregularly sampled.

Often the sampling frequency is inherently uneven, particularly in the case of diagnostic data, which are ordered when an event or combination of observations indicate that a particular test is required. Missing data and irregular sampling are highly related concepts, although the former implies that useful data may exist between each sample point and may carry further information about the state of the patient (such as a significant change in a given variable). Some form of interpolation may, therefore, be useful in estimating the unobserved information. However, it may not be appropriate to guess the values of missing or hidden data, since any slight error might lead to an erroneous decision; there are cases when an estimate is useful. Furthermore, reporting the bounds of error in an estimate allows a clinician to make safe harbour decisions.

For single-parameter time series, little more than a sample-and-hold approach (with a time-out) is generally used to fill in the missing data. This is generally a good approach for frequently sampled data from ICU patients who are usually managed for stability, and thus exhibit infrequent large changes in the value of a physiological parameter. However, the situations that are often more interesting and informative are the infrequent changes and resampling schemes are often used (such as sample-and-hold, linear or cubic spline interpolation). However, these approaches introduce spurious low- and high-frequency noise and can be extremely sensitive to the number of missing data points or to the irregularity of the missing data (Clifford *et al.* 2005).

Other more complex methods for filling in missing data involve using the statistical and/or dynamic nature of the data (rather than just neighbouring gradients) to form estimates of the intervening sample values such as min–max interpolation (Fessler & Sutton 2003), autoregressive modelling (Rajan *et al.* 1997; Cassidy & Penny 2002) and KF methods (Chin 2001; Yarita *et al.* 2007). Sometimes, however, it is more appropriate to use methods specifically designed to be used with missing data (or irregularly sampled signals). For spectral estimation, the Lomb–Scargle periodogram (LSP; Lomb 1976; Scargle 1982) is a particularly robust method for extracting frequency estimates of unevenly sampled data, and has been shown to be particularly suited to spectral quantification of heart rate variability (Moody 1993; Laguna *et al.* 1998). The LSP does not require the interpolation of any data, as it performs a least-squares fit of sinusoids at each frequency to form an estimate of the power spectral density. The LSP has been shown to be relatively insensitive to the density of missing data and removed artefact with relatively insignificant changes for up to 20 per cent missing data (Clifford *et al.* 2005).

When multiple sources of related information are available, it is possible to exploit the covariance of the data, such as when using PCA or imputation. However, such techniques again assume stationarity of the dynamics of the data (unless incremental updates are calculated on a frequent basis), and they require that the missing data be missing at random or that an accurate model of how the missing data are distributed be known. Furthermore, these techniques are sensitive to outliers and non-removed errors. Since no accurate model exists of how missing or noisy data are distributed, the interpolation of missing ICU data is extremely difficult (Abdala & Saeed 2004). (In general, data are missing because

they are perceived to be irrelevant for the current clinical problems, or because exogenous interventions or endogenous activity has rendered the data useless. Neither of these circumstances is random, or amenable to simple models.)

It should be noted that the frequency at which a parameter needs to be sampled depends on both the parameter type and the question we are asking about the patient. For example, although blood pressure can exhibit large changes over a period of a few seconds (e.g. during a head-up tilt), if we are looking for evidence of haemorrhage, we may not need to sample more frequently than once every 5 or 10 min to capture the dynamics of the situation. The required sampling frequency is also related to the intrinsic dynamics of the parameter, so that heart rhythm, which can change over a few beats, is sampled rapidly (at 100 Hz or more), whereas blood creatinine (abnormal levels of which indicate renal insufficiency) may change only over hours. Consequently, creatinine values are sampled much less frequently and can be reliably interpolated over several minutes, whereas heart rate estimates cannot. The effective Nyquist frequency for a particular parameter also depends on an individual's physiology and medical condition, and so it is difficult to be sure whether parameters are being undersampled. However, clinical teams tend to sample parameters more frequently when they believe a patient may be unstable with a rapidly changing (usually degenerating) physiological condition. Therefore, the clinical team often notices signs or symptoms indicative of rapid changes and adjusts the sampling rate so that loss of important information does not occur.

(*c*) *Signal quality analysis*

Since robust methods for dealing with missing data are not always available, it is sometimes more appropriate to define a signal quality measure for a given data stream, and simply ignore the segments of data that have a signal quality below a given value. However, metrics for signal quality are both signal and application specific. For example, noise above 20 Hz, which does not distort ABP estimates, can disturb ECG peak detection algorithms and cause heart rate variability algorithms to report incorrect values, while leaving heart rate estimation algorithms unaffected. Low-frequency noise (below 1 Hz), which only disturbs subtle features in the ECG such as the QT interval or ST segment, can cause significant errors in the estimate of the blood pressure. A general treatment of signal quality measures is therefore not possible. However, signal quality indices (SQIs) can generally be constructed by thresholding on known physiological limits such as the maximum field strength for the ECG, the maximum rate of change of the blood pressure or the distribution of energy in the frequency domain. However, it is the relationship between physiological parameters that provides the greatest opportunity to construct SQIs. For example, if heart beats are detected in several ECG and/or pulsatile waveforms within an expected period of time, all signals can be considered to be of reasonable quality.

SQIs are generally calculated by bedside monitoring equipment but are rarely used by clinical teams or automated alert systems, since there is often an assumption that the monitor will provide either no information or a *best guess* of a parameter in the absence of good quality data. However, as we have already discussed, it is very difficult to make an accurate or useful guess of a missing parameter in non-stationary data, such as that found in the ICU, and

a sample-and-hold approach is often used. Although this can be useful to a human attempting to observe the current state of the patient, this is an inappropriate solution for passing data to an automated or semi-automated algorithm.

With current trends towards semi-automated analysis, it is important that SQIs are available for each datum and, if possible, be calibrated to provide a known error for a given value of the SQI. In this way, another algorithm can make informed choices concerning the validity of the datum for a given application, and derived estimates can be provided with accurate error bounds. In Li *et al.* (2008), we calibrated a set of ECG signal quality metrics (based upon statistical, temporal, spectral and cross-spectral features of the ECG), so that a given value of an SQI metric was equated to known error in heart rate. A similar approach was also taken to ABP, and hence error bounds in derived estimates that rely on heart rate and blood pressure (such as the cardiac output) can easily be estimated from the standard compound error formula. Generally, data in the ICU are processed in isolation from other parameters and signal quality labels are therefore rarely constructed with reference to other signals. In our approach to SQI derivation, we have concentrated on the relationships between signals, such as the transit time between the ECG and the ABP (Zong *et al.* 2004) and the inter-ECG lead relationships (Li *et al.* 2008). By comparing related signals and thresholding these relationships on known physiological limits, it is possible to determine whether the data are logically consistent. Since it is rare that a sequence of extracted features will randomly manifest in a physiologically plausible manner, internal consistency between signals can indicate high signal quality on the contributing leads.

Frequently measured parameters (such as heart rate and blood pressure) are amenable to SQI analysis because there is usually an underlying rapidly sampled waveform from which the metrics can be derived. When the sampling rate of the data available drops to around 1 Hz or below, signal quality measures become problematic, since it is almost impossible to differentiate between a real physiological change and an artefact.

Errors in less frequently sampled clinical data (such as blood tests) are more difficult to determine for two reasons. First, the sampling rate is low compared with how rapidly a variable can change. (It should also be noted that there is often a considerable delay between the biological samples being sent for testing and the received results, and so an accurate knowledge of the time of the original sampling must be known.) Second, the relationship of a blood test to other signals is extremely complex, and testing the 'truth' of a measurement would require an extremely complex and accurate model of an individual's physiology. The general approach is that a clinician makes a hypothesis concerning the outcome of the test, based upon current monitored data and a medical history. If the prediction turns out to be accurate, then the belief in the result is high. Otherwise, a test may be reordered, particularly if subsequent data indicate that the test results are contradictory. This type of modelling is extremely complex and the reader is referred to Long (2001) for more details.

(*d*) *Robust data fusion*

Exploitation of the covariance structure of the data is one method of data fusion, since a non-diagonal covariance matrix implies redundancy in the individual data streams. However, weighting different data streams can be

difficult when the measurement units are different and the distributions of the data are different (and non-Gaussian). For instance, what blood pressure change (measured in mm Hg) is equivalent to a 5 per cent drop in oxygen saturation? Townsend and Tarassenko (Nairac *et al.* 1997; Tarassenko *et al.* 2001, 2002*b*) approached this problem by using a large ICU database to renormalize five clinical parameters (heart rate, blood pressure, respiration rate, oxygen saturation and temperature) to zero-mean unit variance. Large statistical deviations in this five-dimensional space equate to abnormality that has been shown to be predictive of future interventions (Tarassenko *et al.* 2006).

When the data to be fused pertain to the same parameter, the data fusion is technically more straightforward, although it requires a method for arbitrating between conflicting estimates. In a recent work, we have extended the work of Tarassenko and Townsend (Tarassenko *et al.* 2002*a*, 2003) to fuse multiple observations of different physiological signals (such as heart rate and blood pressure) from multiple sources, recorded at arbitrary times, within a KF framework (Li *et al.* 2008).

The KF is an optimal state estimation method for a stochastic signal that estimates the state of a discrete-time controlled process, x, with observable measurement data z. The KF uses the *a posteriori* state estimate $\hat{x}_k^-$, a state transition matrix $\boldsymbol{H}$ and the *Kalman gain* $\boldsymbol{K}_k$ to recursively predict the *a priori* kth state estimate, such that

$$\hat{x}_k = \hat{x}_k^- + \boldsymbol{K}_k(z_k - \boldsymbol{H}\hat{x}_k^-). \tag{3.1}$$

The Kalman gain is given by $\boldsymbol{K}_k = \boldsymbol{P}_k^- \boldsymbol{H}^{\mathrm{T}}(\boldsymbol{H}\boldsymbol{P}_k^- \boldsymbol{H}^{\mathrm{T}} + \boldsymbol{R})^{-1}$, where $\boldsymbol{P}_k^-$ is the error covariance of the *a priori* estimate and $\boldsymbol{R}$ is the state noise covariance. The above estimate minimizes the measurement innovation η (or residual, sometimes denoted r) given by $\eta_k = z_k - \boldsymbol{H}\hat{x}_k^-$ (the error between the prediction and the observation).

Note that $\boldsymbol{K}$ is inversely proportional to $\boldsymbol{R}$, the measurement noise covariance, and represents how rapidly the KF will adapt to new observations. In a recent paper (Li *et al.* 2008), we have proposed a modification to $\boldsymbol{R}$ by a multiplicative factor, such that $\boldsymbol{R} \rightarrow \gamma \boldsymbol{R}$, where

$$\gamma = \mathrm{e}^{(s^{-1}-1)}, \tag{3.2}$$

and s is a signal quality threshold raging between 0 (poor signal) and 1 (excellent signal quality) inclusively. This modification has the effect of forcing a KF tracking algorithm to trust any given observation when the SQI, s, is high (since as $s \rightarrow 1$, $\gamma \rightarrow 1$). When the SQI, s, is low, γ tends to infinity and the resultant large increase in $\boldsymbol{R}$ results in a low Kalman gain. Therefore, the KF no longer trusts the current observation to make a prediction, and relies on previous observations instead. This approach turns out to provide a low error, unbiased estimator for cardiovascular time series of heart rate and blood pressure, even in extremely high noise scenarios since noisy segments of data are automatically rejected.

This KF approach also provides a robust framework for fusing multiple observations of the same parameter from different sensors. Tarassenko and Townsend (Tarassenko *et al.* 2002*a*, 2003) proposed weighting each observation, x_k, of a physiological parameter by the inverse of the normalized innovation, η, for each channel. In the two-channel scenario ($k=1, 2$), the weighted estimate of

a parameter becomes

$$x = \left(\frac{\eta_2^2}{\eta_1^2 + \eta_2^2}\right) x_1 + \left(\frac{\eta_1^2}{\eta_1^2 + \eta_2^2}\right) x_2. \tag{3.3}$$

In their application, x was separately given as a scalar heart rate or respiration rate. Furthermore, $\boldsymbol{H}$ was assumed to be unity and so the current state is approximately the same as the last state ($x_k \approx x_{k-1}$). For beat-to-beat or breath-to-breath updates, this can be considered approximately true.

Although equation (3.3) weights observations with low innovations more heavily, the higher innovation can sometimes be associated with the more accurate estimate. Therefore, we added a scaling function to the innovation, such that $\eta^2 \rightarrow \eta^2 s^{-2}$, for each channel and low-quality estimates are 'unweighted'. For N-channels, this becomes

$$x = \sum_{k=1}^{N} \left(\frac{\prod_{i=1, i\neq k}^{N} \left(\frac{\eta_i}{\lambda_i s_i}\right)^2}{\sum_{i=1}^{N} \left(\prod_{j=1, j\neq i}^{N} \left(\frac{\eta_j}{\lambda_i s_j}\right)^2 \right) x_k} \right) \quad (k = 1, 2, \ldots, N), \tag{3.4}$$

where the $0 \leq \lambda \leq 1$ are *trust* factors for each of the channels of data. This formulation is particularly useful for the ICU data where multiple estimates of the same physiological parameter can be derived. For example, one might use the PPG, or pulmonary arterial pressure, as well as the ABP and ECG to determine physiological parameters such as HR, ABP or cardiac output.

The trust factor λ can be useful when two measurements of the same variable come from devices that are known to have independent and different error profiles, such as the invasive and non-invasive cuff measurement of blood pressure. In this case, the λ for the invasive arterial line could be set to 0.9 (to reflect a 10% error) and the λ for the sphygmomanometer cuff measurement could be set to 0.8 (to reflect an inherent 20% error in the reading).

This approach can also be thought of as a robust weighted interpolation scheme, with a sampling frequency of the combined set of observations. That is, the KF is updated at every observation, and every channel of data provides an estimate of the physiological parameter at a different time point. Therefore, the resultant time series has a sample point at each observation that is fit to a weighted sum of previous and current measurements.

The signal quality-modified KF approach described above involves a scalar observation model with the simplest dynamical approach (assuming that the next observation will be approx. equal to the last observation). Extensions that employ models of the dynamic evolution of the cardiovascular system, or vector KF formulations that employ models of how each signal is related to each of the other recorded signals, are likely to improve this method of tracking and noise rejection approach.

For example, Pueyo *et al.* (2008) used a KF to fuse information from the QT and RR intervals to dynamically characterize beat-to-beat adaptation of the repolarization period to changes in heart rate. Our group has also made significant progress in building both statistical (Roberts *et al.* 2006) and explicit cardiovascular models (Parlikar *et al.* 2006, 2007) for the ICU data. In particular,

cycle-averaged models of blood pressure changes have proved accurate for modelling changes in the blood pressure and estimating cardiac output (Parlikar *et al.* 2007).

However, considerable barriers remain, including modelling non-stationarities in the parameters and dealing with the underlying noise. Without good methods for rejecting (or unweighting) noise, no system of modelling, data fusion or missing information estimation is likely to work reliably. Signal quality measures should therefore be evaluated on large databases, and then calculated and stored for all possible signals in the ICU.

(*e*) *False alarms in the ICU*

One example of where we have applied the concepts of signal quality and data fusion is in the arena of false alarm (FA) suppression in the ICU. FAs in the ICU can lead to a disruption of care, impacting both the patient and the clinical staff. The resultant excessive noise pollution, desensitization to warnings and slowing of response times (Chambrin 2001) can lead to missed alarms, decreased quality of care (Donchin & Jacob 2002; Imhoff & Kuhls 2006), sleep problems (Meyer *et al.* 1994; Parthasarathy & Tobin 2004), stress for both patients and staff (Baker 1992; Novaes *et al.* 1997), depressed immune systems and longer patient stays (Hagerman *et al.* 2005).

Tsien & Fackler (1997) conducted a prospective, observational study in a multidisciplinary ICU to record the occurrence rate, cause and appropriateness of all alarms from tracked monitors. After 298 monitored hours, 86 per cent of a total of 2942 alarms were found to be false-positive alarms, while an additional 6 per cent were classified as clinically irrelevant true alarms (TAs). Only 8 per cent of all alarms tracked during the study period were determined to be TAs with a clinical significance associated with them.

Recently, Zhang *et al.* (2007) designed a system to simultaneously collect physiological data and clinical annotations at the ICU bedside, and to develop alarm algorithms in real time based on patient-specific data collected while using the system. After deployment of a prototype in a paediatric ICU equipped with a newer generation bedside monitoring system, a dataset of 196 hours of vital sign measurements at 1 Hz together with associated alarms was collected. Approximately 89 per cent of the recorded alarms were found to be clinically relevant true positives, 6 per cent were true positives without clinical relevance and 5 per cent were false positives (Zhang *et al.* 2007). Real-time machine learning showed improved performance over time and generated alarm algorithms that outperformed the previous generation of bedside monitors and came close in performance to the latest generation of bedside monitor alarm algorithms (Zhang 2007). Interestingly, this work shows that an algorithm trained only on data from a specific patient can approach the level of performance of commercial algorithms that are trained on much larger datasets (Zhang & Szolovits 2008).

Our recent analysis concerned the suppression of false life-threatening arrhythmia alarms issued by the bedside ECG monitor. Using two independent reviewers, we annotated 5386 alarms from a total of 447 adult patient records spanning 41 301 hours of simultaneously acquired ECG and ABP. A third reviewer then checked each alarm to adjudicate discrepancies and check the

overall quality of the alarms. The critical arrhythmia alarm types were selected to be (i) asystole, (ii) extreme bradycardia, (iii) extreme tachycardia, (iv) ventricular tachycardia (VTach), and (v) ventricular fibrillation. Annotation revealed the FA rates of these five alarm types to be 90.7, 29.3, 23.1, 46.6 and 79.6 per cent, respectively, with an average FA rate of 42.7 per cent. An algorithm to suppress these FAs was then developed, which used a signal quality measure, s_N, derived from the ABP waveform to decide on the truth of the ECG arrhythmia alarm. (In this application, s_N was actually a signal 'normality' index (Sun *et al.* 2006). Signal normality equates to a high signal quality and no features indicative of a non-sinus rhythm.) At each ECG alarm point, a reference was made back to a 20 s synchronous segment of the ABP waveform, and if s_N was higher than a given threshold, the blood pressure was considered to be commensurate with a sinus rhythm, and the ECG alarm was suppressed if the ABP-derived heart rate was too slow (or fast). The threshold, s_N, was expected to differ for each alarm type since abnormalities in the ECG will differ depending on rhythm and heart rate. Therefore, the annotated alarms were divided into two sets: a training set and a testing set. Each s_N was then optimized (together with other alarm-specific thresholds, such as the number of beats from which to calculate the heart rate), to determine the highest FA reduction rate, with the lowest TA suppression rate.

This approach provided an overall FA reduction rate for the five alarm categories above of (i) 93.5 per cent, (ii) 81.0 per cent, (iii) 63.7 per cent, (iv) 33.0 per cent, and (v) 58.2 per cent, with an overall suppression rate of 59.7 per cent. This equates to an equivalent FA rate of (i) 5.5 per cent, (ii) 5.5 per cent, (iii) 8.4 per cent, (iv) 30.8 per cent, and (v) 33.1 per cent, with an overall FA rate of 17.2 per cent. However, it should be noted that invasive arterial lines are not available for all patients in the ICU (only approx. two-thirds of the population), and so to provide this level of FA suppression for all life-threatening alarms would require an extension of the algorithm to use the oxygen saturation waveform. TA suppression rates were all zero except for VTach, indicating that VTach does not always manifest as an abnormal ABP waveform, and referencing back to the ECG is required. A full description of the method and results can be found in Clifford *et al.* (2006) and Aboukhalil *et al.* (2008).

Significant work still remains in the arena of FA reduction, particularly with respect to lower priority alarms, which, although less important, still add significantly to the problem of FA pollution in the ICU. In fact, non-critical alarms constitute over 90 per cent of the alarms in the ICU. Furthermore, these alarms are not split into groups relating to clinically insignificant, clinically relevant and immediately actionable. The data and annotated alarms, a subset of the MIMIC II database, have therefore been made publicly available via PhysioNet (Goldberger *et al.* 2000; LCP 2008) in the hope that public collaboration will rapidly improve this situation.

4. Coding of clinically relevant events and concepts

Once parameters have been robustly extracted, they must be provided with a useful label. In the case of standard cardiovascular parameters, the label is self-evident (heart rate, blood pressure, cardiac output, etc.). However, combinations

of parameters can provide a richer picture of the state or class of a patient. For example, a series of desaturations during the night followed by cessations in breathing are indicative of apnoea. The prior probability of placing the patient into a given class can be extremely important and a rich database of ICU data also provides the opportunity to extract information for such prior probabilities from alternative sources.

(*a*) *Medical lexicons for annotating ICU data*

The objective (or semi-objective) classification of ICU data requires a standardized lexicon or system of labelling. Although such systems exist for some signals (such as the ECG), many labels rely on subjective observations with high interobserver variability. Furthermore, for many medical diagnoses, there are no agreed definitions, and the divisions between categories are fuzzy. For example, more than 30 different definitions of acute renal failure have been used in the literature (Bellomo *et al.* 2004). However, with multiple experts and a well-defined set of criteria, the labelling of a given event or condition reaches agreement levels of 95 per cent (Douglass *et al.* 2004; Neamatullah *et al.* 2008). Labelling of ICU data can occur manually, automatically or in a semi-automated fashion, but in each case, a standard lexicon is required. There are several standard lexicons for labelling ICU data, depending on the category of data. These include Logical Observation Identifiers, Names and Codes (LOINC; for laboratory and other diagnostic results), the Systematized Nomenclature of Medicine–Clinical Terms (SNOMED-CT; for diseases, findings, procedures, micro-organisms, pharmaceuticals, etc.), Medical Subject Headings (the National Library of Medicine's controlled vocabulary thesaurus of naming descriptors organized in a hierarchical structure) and the International Classification of Diseases (Chen *et al.* 2007).

The Unified Medical Language System (UMLS) acts as an umbrella lexicon for many of these subsystems (although with some enhanced features; Zhang *et al.* 2005). The UMLS is very large and complex, however; it poses significant comprehension problems for users and database maintenance personnel (Gu *et al.* 2000). Furthermore, the UMLS contains omissions of concepts, errors of semantic type classification and concept ambiguities. In particular, there is no one-to-one mapping between sub-lexicons and often multiple UMLS terms are required to describe a particular event or procedure.

We have therefore developed open-source Java software for using a subset of the UMLS to construct descriptors of events in the ICU data (Shu *et al.* 2004). The UMLS descriptors associated with a given event generally consist of an event code (such as 'C0340535, acute massive pulmonary embolism') or a *state* code (such as 'C0018802, congestive heart failure'). The codes are often associated with a qualifier (such as 'C0184511, improved', 'C0205360, stable' or 'C0332271, worsening'). Although many of these codes are predefined in drop-down lists to enable rapid and accurate coding, some events necessarily require a new code. In this case, a free text string can be entered by the clinician to see a range of possible codes to select from. We found that spell checking, general abbreviation dictionaries and personalized abbreviation dictionaries were necessary to enable clinicians to find relevant codes in a timely manner.

(b) *Extracting clinical data from text*

Much of the data about patients that are not directly measured by computerized instruments is available only in the form of unstructured natural language statements by clinicians. These data can be typed directly by a clinician or transcribed from dictation or handwritten notes. Unfortunately, manual data entry practices and conversion of data into electronic medical records are prone to error. One study (Dean *et al.* 1995) showed that the most common types of data errors in 1995 were omitted and incorrect doses (in UK hospitals) and incorrect and unordered doses (in US hospitals). More recently, Lisby *et al.* (2005) showed that errors in medication ordering and transcription can be frequent and lead to potentially adverse events. However, the most common types of error throughout the medication process were found to be lack of convenient input modalities (forms or entry terminals), unordered drugs, omission of drugs/dosage levels and lack of identity control.

However, inaccurate transcription and data entry is not confined to medications. Recently, we compared manual acceptance of measurements of heart rate and blood pressure from bedside monitors, with measurements gated by robust automatic measures of signal quality (Hug & Clifford 2007). Results showed that the clinically verified BP values exhibit a small but significant bias towards overestimation. In particular, we demonstrated that hypotensive events are often missed by the action of human recording. Other studies (Nelson *et al.* 2005; Vawdrey *et al.* 2007) have also demonstrated the inherent errors in human recording of physiological signals.

Regardless of the method of transcription, the notes must be interpreted by fairly sophisticated algorithms in order to turn them into a structured form that is suitable for searching, modelling and further analysis. We have found that the notes taken by clinicians during the delivery of care are often most difficult to analyse, even when they are typed rather than handwritten. Perhaps owing to the pressing need for speed, these are often poorly organized, full of non-standard abbreviations and typographic errors, and thus pose the greatest challenges to automated processing. By contrast, more formal notes such as discharge summaries, which summarize a patient's hospital stay, are often more carefully written, consciously trying to inform readers other than the writer, and are thus easier to analyse.

We have developed a computer program to extract diseases and procedures attributed to patients in discharge summaries as an aid to semi-automated annotation of our large case collection. The program maps phrases from the text to the approximately 6 million terms that represent approximately 1.5 million concepts listed in the UMLS, and then maps these to the approximately 1 million listed SNOMED-CT concepts. (In practice, of course, very few of these actually appear in clinical texts.) As reported in Long (2007), this program was able to find 93 per cent of the 1326 clinically significant concepts that had been identified in 96 discharge summaries through a manual review by one to three clinicians. However, the program achieves this high level of recall by allowing many irrelevant and misclassified concepts (almost three times as many as the relevant concepts that it finds). Because the purpose of this program was to help annotators find all the relevant concepts, and it is much easier in annotation to reject an unneeded concept than to code a concept de novo, this bias is

acceptable for our application. Nevertheless, we would prefer to have an automated annotation tool that finds almost all the needed concepts but few spurious ones.

If we could build a program that 'understands' natural language, then it would be relatively easy to pick out the concepts we want to recognize. However, the problem of understanding text is thought to be *artificial intelligence complete*—it would require a program with true human-level intelligence. Of course, we are not anywhere near that in our technical abilities. Therefore, researchers have taken a range of approaches to the extraction problem. At one extreme are systems that use the best available computational linguistics methods to assign likely parts of speech and semantic categories to individual words, to parse the linguistic structure of the phrases, clauses, sentences and paragraphs that express information, and thus to do a deep analysis of the text. Our program takes a more minimalist approach, dividing the text using punctuation, conjunctions, numbers and a few verbs into phrases. Within these, it looks for the maximum length sub-phrase that matches a UMLS concept, without regard to the surrounding text. We have demonstrated that this approach works well when sensitivity is the overriding concern. It needs further enhancement when elimination of irrelevant concepts is important (e.g. when a disease name is mentioned in a note, but is not associated with the patient).

5. Summary

Over the last 5 years, we have encountered significant barriers to the analysis of data in the ICU. These include inaccuracies in time stamps, the sparseness or incompleteness of information (such as when databases are not fully integrated, or events are not recorded), non-specific labelling (such as when free text is used instead of a standard medical lexicon), contradictory information (such as when two monitors disagree about a measurement) and simply incorrect information (such as FAs). To some extent, we have addressed many of these issues using data fusion techniques, model construction and automated coding. However, the issues described in this paper still present significant barriers to the use of ICU data for decision support, particularly with respect to the sparseness of the data and the non-specific labelling of clinical information in free text. Despite this, current trends in hospital information systems provide for an optimistic horizon, as increasing volumes of more frequent data are being captured automatically from monitors (together with event codes and signal quality indicators). Hospital information systems are also moving towards using universal lexicons. Furthermore, current trends towards open data storage formats and interchange protocols mean that open source tools we have developed are likely to be generally useful on a wide variety of data.

Special Article

The Quality of Modern Cross-Sectional Ecologic Studies: A Bibliometric Review

Brenden Dufault* and Neil Klar

* Correspondence to Brenden Dufault, Department of Community Health Sciences, Faculty of Medicine, University of Manitoba, S113 Medical Services Building, 750 Bannatyne Avenue, Winnipeg, Manitoba, Canada R3E 0W3 (e-mail: bdufault@uwo.ca).

Initially submitted November 08, 2010; accepted for publication June 20, 2011.

The ecologic study design is routinely used by epidemiologists in spite of its limitations. It is presently unknown how well the challenges of the design are dealt with in epidemiologic research. The purpose of this bibliometric review was to critically evaluate the characteristics, statistical methods, and reporting of results of modern cross-sectional ecologic papers. A search through 6 major epidemiology journals identified all cross-sectional ecologic studies published since January 1, 2000. A total of 125 articles met the inclusion requirements and were assessed via common evaluative criteria. It was found that a considerable number of cross-sectional ecologic studies use unreliable methods or contain statistical oversights; most investigators who adjusted their outcomes for age or sex did so improperly (64%), statistical validity was a potential issue for 20% of regression models, and simple linear regression was the most common analytic approach (31%). Many authors omitted important information when discussing the ecologic nature of their study (31%), the choice of study design (58%), and the susceptibility of their research to the ecological fallacy (49%). These results suggest that there is a need for an international set of guidelines that standardizes reporting on ecologic studies. Additionally, greater attention should be given to the relevant biostatistical literature.

cross-sectional studies; ecological models; epidemiologic methods; research design; review

The ecologic study design is one of the oldest in epidemiology. Its susceptibility to bias has been well known since Robinson (1) popularized the concept of the ''ecological fallacy'' in 1950, although the potential incongruence between group and individual associations was studied by Thorndike (2) as far back as 1939. Since then, there has been significant progress in discovering the many avenues by which ecologic bias may manifest. It is now well documented that the relations between individual- and group-level inferences are often complex, and sometimes even counterintuitive. In spite of this wealth of knowledge, the ecologic design and its fallacy often remain misunderstood (3).

Limitations of the ecologic design have not prevented its use. This is especially true in community health research, where investigators are often interested in both individual-level and ecologic associations with the study outcome. The appeal of ecologic studies reflects interest in collecting information beyond the level of individuals by incorporating aggregate variables as well as those without individual-level analogs. Additionally, ecologic studies do not require information on individuals within groups, making such studies easier to conduct and less expensive. In recent articles, authors have defended the ecologic design and nonindividualistic perspectives in general (4–6), arguing that ecologic analyses need not always be relegated to the role of a poor approximation of other designs, since legitimate insights may exist at the group level. Shifts in the conception of causality and the means by which it exerts itself have also helped in asserting the value of ecologic studies. For these reasons and others, ecologic studies continue to be performed in epidemiology.

Given that ecologic analyses are often misunderstood yet continue to be used, it is important to assess the quality of the literature. Insofar as we are aware, there have been no reviews of ecologic studies. Our objective in this bibliometric review was to address this need by evaluating how well modern ecologic studies are designed, analyzed, and reported in epidemiology. Emphasis was placed on statistical methods and the clarity of reporting. All articles were collected from 6 major epidemiology journals, with attention restricted to cross-sectional etiologic studies. A total of 125 articles published between the years 2000 and 2009 met the inclusion

Downloaded from https://academic.oup.com/aje/article/174/10/1101/105347 by guest on 30 May 2021

requirements and were analyzed according to common evaluative criteria.

MATERIALS AND METHODS

Journal selection

Articles published in 6 high-impact epidemiology journals were selected to collectively represent the discipline. The following journals were chosen: the *American Journal of Epidemiology*, the *Annals of Epidemiology*, *Epidemiology*, the *International Journal of Epidemiology*, the *Journal of Clinical Epidemiology*, and the *Journal of Epidemiology and Community Health*. Although many epidemiologic articles are published outside of pure epidemiology journals, it was nevertheless felt that these 6 would provide a useful core sample for the purposes of the review. Articles published between 2000 and 2009 were included, reflecting our interest in recent applications of ecologic studies.

Search method

Articles were found by reading through each issue of the selected journals for the time period January 1, 2000, through December 31, 2009. An alternative approach would have been to conduct computer searches of databases such as MEDLINE with the use of strategic keywords or Medical Subject Headings. While this may be an adequate means of obtaining data on many types of studies, the ecologic design is so varied in its applications that some researchers may use it unknowingly or without including the kinds of keywords that would be found by search engines or database categorization. Thus, a manual search was performed.

Inclusion and exclusion criteria

The focus of this review was on etiologic cross-sectional studies. Therefore, each study had to employ a cross-sectional design. Ecologic studies using temporal, spatiotemporal, or case-control designs were excluded from the review. For example, Loomis et al. (7) analyzed workplaces to determine risk characteristics for homicide. Workplaces were selected on the basis of whether or not a homicide had taken place there, which made the study design case-control, not cross-sectional.

Additionally, investigators in each study needed to present original research of an etiologic nature. Consequently, spatial descriptive studies or articles that discussed ecologic methodology were excluded. An article did not need to be entirely ecologic to be included in the review, as long as the study's ecologic aspects met the inclusion criteria. Thus, articles with multilevel or individual-level components in addition to ecologic analyses were included as well.

Evaluation criteria

Each article was evaluated according to 3 broad themes: study design, statistical methodology and practices, and quality of reporting.

Study design and focus. We attempted to obtain an impression of the scope of each study, its nontechnical methods, and its focus. Aspects of study design which were analyzed included sample size, given by the number of ecologic units; the level of aggregation at which the units existed, grouped from smallest to largest as census tracts or neighborhoods, municipalities, municipal areas or counties, states or provinces, and nations; whether the inferences were made at the group level or the individual level; and whether the ecologic units were explicitly chosen to suit the hypothesis or were seemingly motivated by convenience or necessity. This last criterion was deemed relevant because many ecologic analyses may be limited by the availability of preexisting aggregate data.

We also recorded the primary outcome for each study according to a set of broad classifications. Whenever possible, outcomes were given one of the following categorizations, which were motivated by the literature itself: cancer, cardiovascular disease, respiratory disease, chronic disease, infectious disease, mortality, suicide or self-harm, and criminal activity. Often, a given study had more than one outcome and thus more than one classification. In this case, all outcomes were recorded.

Statistical methodology. Four aspects of statistical methodology were evaluated: analytic methods, the number of ecologic units relative to the number of regression coefficients modeled, whether any consideration was given to spatial dependence, and methods used to account for confounders. Whenever possible, analytic methods used were grouped by topic. The notation of statistical methodology was intended to provide a measure of the analytical sophistication, diversity, and propriety of current ecologic studies. It was especially important to note the prevalence of simple methods such as ordinary least squares regression and Pearson correlation, since these have well-known limitations in ecologic settings (8, 9).

The statistical validity of each regression model was also observed. Simulation studies have indicated that the validity of statistical inferences is probably compromised when the ratio of covariates to observations or events exceeds a certain threshold (10). The most common recommendation is to have a minimum of 10 observations per covariate, though this may be too conservative for some models (11). Therefore, for each regression analysis, we recorded whether there were fewer than 10 ecologic units per covariate, 10–20 units per covariate, or more than 20 units per covariate. This criterion was developed in the context of individual-level analyses for independent outcomes. It probably only holds approximately for ecologic studies, as event rates and cluster size are likely to play a role in the validity of statistical inferences.

Spatial autocorrelation is a potential concern for many ecologic studies, since units are often aggregated over spatial regions such as contiguous census tracts. The concern is that the omission of spatial effects may cause a loss of information that could otherwise improve parameter estimation, as indicated by recent simulation studies (12, 13). Indeed, explicitly modeling spatial variability may help account for bias when the spatial variation of the covariate is similar to that of disease risk and location itself acts as a confounder (14). However, it is sometimes difficult to know which approaches are based on reasonable assumptions for a given situation, since assumptions are often untestable (15). Nonetheless, we recorded the number of studies accounting for spatial effects

Downloaded from https://academic.oup.com/aje/article/174/10/1101/105347 by guest on 30 May 2021

to report the habits of researchers and the sophistication of the literature.

The final methodological criterion investigated the use of covariate adjustment. Although more complex, confounding may still occur at the ecologic level, and under certain conditions it can be accounted for by the inclusion of covariates. Similarly, we sought to determine whether the covariates were themselves properly adjusted when regressed upon adjusted outcomes; Rosenbaum and Rubin (16) point out that aggregate studies commonly regress age- or sex-standardized outcomes on unstandardized predictors, which may lead to bias. They recommend that regression analyses with group-level data incorporate either adjusted covariates or crude covariates along with moments of the population distribution for the confounder (such as mean age). We report how often this is done in practice.

Quality of reporting. The complexities of the ecologic design are such that in every ecologic study, investigators should justify their choice of study design and present their results in a transparent fashion. Each article should be written so that even readers unfamiliar with the ecological fallacy are mindful of its potential. To this end, we searched each paper to see whether the authors mentioned one of the keywords ''ecologic,'' ''ecological,'' or ''aggregate'' in their article, excluding references. This was intended to estimate the proportion of authors who clearly informed the reader of the study design. We also looked to see whether the authors explicitly justified an ecologic analysis. A justification allows readers to be informed of the rationale for the choice of design and to decide for themselves whether an ecologic analysis was truly warranted. It was not deemed essential for the justification to mention any of the above keywords as long as the authors presented a clear explanation.

We also recorded whether the authors sufficiently cautioned readers, in interpreting their results, against making heedless individual-level inferences, preferably with the use of terms such as ''ecological fallacy'' or ''cross-level bias.'' The statement did not need to be elaborate. It merely needed to point out that the results were not necessarily applicable to different levels of aggregation.

None of the above criteria for reporting are present in the STROBE guidelines for the reporting of observational studies in epidemiology (17), which presently omit ecologic studies.

RESULTS

Our search yielded a total of 125 cross-sectional ecologic papers. Table 1 shows their distribution by journal and year of publication. From Table 1, it can be seen that the number of published cross-sectional studies has remained relatively stable over the past decade.

Study design and focus

The most common area of focus was cancer, which comprised 16% of all primary outcomes. Other research areas such as mortality, chronic disease, and cardiovascular disease followed behind, representing 14%, 13%, and 10% of total analyses, respectively. Infectious and respiratory diseases

Table 1. Numbers of Cross-Sectional Ecologic Studies Included in a Bibliometric Review, by Journal and Period, 2000–2010

comprised 9% and 8% of all outcomes, respectively; suicide and self-harm accounted for another 7%; and criminal activity such as homicide accounted for 6% (Table 2). Twenty-six analyses did not fall into one of the above broad subclassifications, with outcomes ranging from pollution exposure to regional disparity.

It appears that much cross-sectional research potentially has its data dictated by either the convenience or the necessity of using preexisting information. We suspect that this is the case after observing that only in 22 studies (18%) did authors implicitly or explicitly justify their choice of ecologic units. In a few cases, the units of aggregation were constructed specifically for the study.

Potentially, investigators in many other studies simply used what was available. With regard to level of aggregation, many studies utilized small areas. Ecologic units aggregated approximately at the level of census tracts were by far the most numerous, being the observational units for 48 studies (38%). Large international studies were the second most prevalent, being the focus of 25 studies (20%). All other levels of aggregation were present as follows: towns and cities, 9%; counties (which include not only cities but their contiguous areas as well), 18%; and states or provinces, 12%. Four studies could not have their ecologic units classified as above, either because the units were disparate areas specifically constructed for the study or because they were nonspatial.

Many investigators intended their inferences to be applied at the individual level. Of the 125 articles in the review, 43 (34%) clearly had conclusions or hypotheses concerned with individual-level risks and outcomes. In 34 studies, authors unambiguously tailored their discussions to group-level inferences (27%). However, this should be taken lightly, since a lack of clarity on the part of 48 studies (38%) prevented us from confidently determining their intended levels of inference. The vast majority of outcomes were aggregate in nature (97%), meaning they had individual-level analogs which could apply to units within groups. Nonaggregate outcomes included measures such as regional socioeconomic inequality and governmental health-care expenditures.

Sample sizes ranged from very small to extremely large. The minimum sample size was 8 ecologic units, and the maximum was approximately 200,000. The median sample size was 70. Fifty-four percent of studies relied on fewer than 100 observations.

Quality of statistical methods and practices

The literature is highly diverse in its methodological complexity. Nevertheless, there were notable preferences. The most common approach was to use either ordinary least squares regression or Poisson regression, methods that were employed in 47 and 20 analyses, respectively (Table 3). Weighted linear regression was the third most common approach, being used in 18 analyses. Nonparametric approaches and simple Pearson or Spearman correlations each accounted for 12 analyses. The more complex approaches of Bayesian analytic methods, logistic regression, and negative binomial regression appeared in 12, 7, and 7 articles, respectively. An additional 18 analyses did not fall into any of these categories, employing disparate techniques such as sophisticated geospatial methods, spatial autoregressive models, and simple calculations of standardized mortality ratios. Note that these counts do not refer to the number of studies but rather to the number of analyses, since investigators may have used more than 1 method. In terms of covariate adjustment, 92 studies obtained adjusted results, either by stratifying the analyses or using additional covariates in the models. Unfortunately, in 23 of 36 papers, the investigators failed to adjust covariates for age or sex when the outcomes had been standardized for these potential confounders. Thus, it would appear that in over half of all studies using standardized outcomes, investigators were at risk of publishing biased inferences.

Downloaded from https://academic.oup.com/aje/article/174/10/1101/105347 by guest on 30 May 2021

There was mixed performance with regard to the statistical validity of regression models. Although we were unable to determine the ratio of ecologic units to predictor variables for 5 studies, we found that of the 109 studies with regression models, 27 had fewer than 10 units per covariate. Forty-eight analyses had 10–20 units per covariate, and 43 regression analyses had more than 20.

One-fifth of all studies included some investigation of spatial effects. Techniques such as spatially autocorrelated regression models and spatial scan statistics appeared to be the most common. Some of these techniques merely detect and describe spatial clustering, while others seek to incorporate spatial data into effect measure estimation.

Quality of reporting

Of the papers reviewed, authors in 86 (69%) clearly specified their study design by mentioning ''ecologic,'' ''ecological,'' or ''aggregate'' at some point in the main body of their work in a clear and relevant fashion (Table 4). Only 52 studies (42%) adequately and explicitly justified an ecologic analysis, while the other articles did not provide any rationale whatsoever as to why the design was either necessary or desirable. Perhaps most significantly, we discovered that in the majority of the reviewed studies, investigators did not sufficiently inform the reader about the possibility of cross-level bias; in 55 articles (44%), authors tempered their results in some fashion, whereas in 61 (49%) they did not. For 9 articles this criterion did not apply, either because the ecologic investigations appeared alongside multilevel analyses or because the predictors were entirely group-level in nature, thereby precluding individual-level interpretations.

DISCUSSION

Ecologic research in epidemiology is extremely diverse in its applications and sophistication. However, it appears that a combination of methodological limitations, apparent dependence on preexisting data, and insufficient reporting has compromised the quality and clarity of some articles.

Broadly speaking, the distribution of the reviewed studies could best be described as bimodal. Many investigators performed elementary analyses coupled with unclear, insufficient reporting. At the same time, a significant number of studies employed analyses appropriately suited to the study design and presented the results in a model fashion. In between these extremes, many studies were adequate with respect to 1 or 2 of the 3 fundamentals, only to perform unsatisfactorily in another.

In terms of statistical methodology, researchers must better heed many of the important technical results published in the biostatistical and epidemiologic literature. More attention needs to be paid to proper covariate adjustment and the validity of regression models. It is also apparent that linear regression and simple correlation coefficients have become the default techniques for many ecologic studies. Given their documented susceptibility to ecologic bias, this may indicate that some technical details of group-level analysis remain unknown or misunderstood. While the validity of these approaches must be decided on a case-by-case basis, the fact that over half of analyses rely on them suggests that ecologic researchers depend too often on techniques of uncertain reliability.

The area of greatest concern in this review was the quality of reporting. The results showed a lack of important information when it came to stating the origins of the data, the intended level of inference, the nature of the study design, and the study's limitations. The sensitive and diverse nature of ecologic analyses makes it essential that readers from all backgrounds be sufficiently informed. Too often, authors seemingly assumed that their choice of study design was self-evident, did not require justification, and provided unambiguous results.

For the selection of ecologic groups, the ideal is that in every study investigators choose their units according to the specific causal constructs of their research. However, as Morgenstern (18) stated, ecologic studies are often made possible by preexisting data. Since few investigators made their selection criteria known, there is often reason to wonder how or why the data were chosen. The high prevalence of studies conducted at the census tract and national levels may be a result of the fact that easily available information tends to exist at these scales of aggregation. In future papers, researchers should state why their particular units and levels of aggregation were suitable for the hypothesis at hand.

In accordance with recommendations made by von Elm et al. (17), we submit that there is presently a need for a set of guidelines to standardize the reporting of results from ecologic studies. Many of the concerns we identified could be attenuated or prevented altogether if such a document were published. Providing a set of guidelines that not only lists detailed criteria but also explains their importance and the potential consequences of their neglect may emphasize their relevance to the research community. From the results of this review, it is clear that the cross-sectional ecologic design continues to be an important approach relied upon by epidemiologists and public health researchers, and therefore it would be worthwhile to augment the STROBE document (17) with recommendations for the reporting of ecologic findings.

In Appendix Table 1, we list 9 items that could serve as a useful beginning for updating the STROBE document. For ease of reference, the table has the same headings, titles, and numberings as the STROBE document itself (17). Ideally, future discussions on this topic by others in the epidemiology community would provide further critiques of and refinements to this list.

Difficulties in correctly designing, analyzing, and reporting results are not unique to ecologic studies. Analogous methodological errors have been reported for both observational studies (19) and randomized trials (20). There may be some reason for optimism, since Hopewell et al. (20) did find some improvement in the reporting of randomized trials following release of the CONSORT statement (21). This provides further motivation for developing reporting guidelines for ecologic studies.

Appendix Table 1. Suggested Additions to the STROBE Document for Ecologic Reporting[a]

STROBE Section	Recommendation Addition(s)
Title and abstract	Indicate the study's design with a commonly used term in the title or abstract.
	Ecologic study—Use one of the following terms in your description: "ecological," "ecologic," or "aggregate."
Introduction	
Objectives	State specific objectives, including any prespecified hypotheses.
	Ecologic study—Specify the level(s) of inference to which your investigation is intended to apply.
Methods	
Study design	Present key elements of the study design early on in the paper.
	Ecologic study—Provide a rationale or justification for the design, taking your study objectives into account.
Participants	Ecologic study—Give the eligibility criteria for the ecologic units, as well as their sources and any sampling methods used. Provide a rationale for their selection. If the units were aggregated for the study, explain how this was done and the criteria by which they were constructed.
Discussion	
Limitations	Discuss limitations of the study, taking into account sources of potential bias or imprecision.
	Ecologic study—Provide a discussion that either informs the reader of the potential for cross-level bias or explains why it is not a possibility for your results and inferences.

Abbreviation: STROBE, Strengthening the Reporting of Observational Studies in Epidemiology.

ABSTRACT

Introduction Transmission of COVID-19 within families and close contacts accounts for the majority of epidemic growth. Community mask wearing, hand washing and social distancing are thought to be effective but there is little evidence to inform or support community members on COVID-19 risk reduction within families.

Methods A retrospective cohort study of 335 people in 124 families and with at least one laboratory confirmed COVID-19 case was conducted from 28 February to 27 March 2020, in Beijing, China. The outcome of interest was secondary transmission of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) within the family. Characteristics and practices of primary cases, of well family contacts and household hygiene practices were analysed as predictors of secondary transmission.

Results The secondary attack rate in families was 23.0% (77/335). Face mask use by the primary case and family contacts before the primary case developed symptoms was 79% effective in reducing transmission (OR=0.21, 95% CI 0.06 to 0.79). Daily use of chlorine or ethanol based disinfectant in households was 77% effective (OR=0.23, 95% CI 0.07 to 0.84). Wearing a mask after illness onset of the primary case was not significantly protective. The risk of household transmission was 18 times higher with frequent daily close contact with the primary case (OR=18.26, 95% CI 3.93 to 84.79), and four times higher if the primary case had diarrhoea (OR=4.10, 95% CI 1.08 to 15.60). Household crowding was not significant.

Conclusion The study confirms the highest risk of transmission prior to symptom onset, and provides the first evidence of the effectiveness of mask use, disinfection and social distancing in preventing COVID-19. We also found evidence of faecal transmission. This can inform guidelines for community prevention in settings of intense COVID-19 epidemics.

Summary box

What is already known?

- Mitigation of the COVID-19 pandemic depends solely on non-pharmaceutical interventions until drugs or vaccines are available. Transmission of COVID-19 within families and close contacts accounts for the majority of epidemic growth. Community mask wearing, hand washing and social distancing are thought to be effective but the evidence is not clear.

What are the new findings?

- The overall secondary attack rate in households was 23.0%. Face masks were 79% effective and disinfection was 77% effective in preventing transmission, while close frequent contact in the household increased the risk of transmission 18 times, and diarrhoea in the index patient increased the risk by four times. The results demonstrate the importance of the pre-symptomatic infectiousness of COVID-19 patients and shows that wearing masks after illness onset does not protect.

What do the new findings imply?

- The findings inform universal face mask use and social distancing, not just in public spaces, but inside the household with members at risk of getting infected. This further supports universal face mask use, and also provides guidance on risk reduction for families living with someone in quarantine or isolation, and families of health workers, who may face ongoing risk.

INTRODUCTION

In the absence of a vaccine for COVID-19, non-pharmaceutical interventions (NPIs) are the only available disease control measures. We have shown that population level NPIs, including travel bans and the national emergency response, were effective in flattening

BMJ Glob Health: first published as 10.1136/bmjgh-2020-002794 on 28 May 2020. Downloaded from http://gh.bmj.com/ on January 23, 2021 by guest. Protected by copyright.

the COVID-19 epidemic curve in China.[1] However, the effect of other NPIs, such as mask use and hygiene practices, have not been well studied in the COVID-19 pandemic.

In the USA, the use of face masks in the community has been recommended.[2] It is thought that universal face mask use (UFMU) may reduce outward transmission from asymptomatically infected people and protect well people from becoming infected. However, the World Health Organization and Public Health England recommend against UFMU on the grounds that there is little evidence from randomised controlled trials to support this. Some experts suggest that in a pandemic, the precautionary principle should be used and UFMU encouraged as it is unlikely to cause harm and may result in public health gain.[3 4] In countries where personal protective equipment is scarce, people are making their own masks.

In China, over 70% of human-to-human transmission of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) occurred in families.[5 6] However, data to inform COVID-19 risk reduction in households are unavailable. Given epidemic growth is dominated by household transmission,[5 6] studying the use of NPIs, such as face masks, social distancing and disinfection in the household setting, may inform community epidemic control and prevent transmission of COVID-19 in households.

METHODS

Study population and design

We conducted a retrospective cohort study involving families of laboratory confirmed COVID-19 cases in Beijing, China. We defined family members as those who had lived with primary cases in a house for 4 days before and for more than 24 hours after the primary cases developed illness related to COVID-19. As of 21 February 2020, all laboratory confirmed COVID-19 cases reported in Beijing were enrolled in our study and followed-up. The outcome of interest was secondary transmission in the household. Families with secondary transmission were defined as those where some or all of the family members become infected within one incubation period (2 weeks) of symptom onset of the primary case.

To analyse the predictors of household transmission, we compared families with and without secondary transmission for various measured risk factors, preventive interventions and exposures.

Definition of confirmed case

According to national prevention and control guideline (fifth edition),[7] confirmed cases were those who met the clinical, epidemiological and laboratory testing criteria for COVID-19 simultaneously.

1. Clinical criteria included: (a) fever and/or one or more respiratory symptoms; (b) radiological evidence of pneumonia; (c) white blood cell count normal or decreased, and lymphocyte count decreased at the early stage of illness.
2. Epidemiological criteria included: (a) visits to/living in Wuhan or cities around Wuhan or other communities which had already reported COVID-19 cases in the 14 days prior to the onset of symptoms; (b) having contact with a person known to have infection with SARS-CoV-2 in the 14 days prior to onset of symptoms; (c) having contact with a person who had fever or respiratory symptoms and came from Wuhan or adjacent cities or other communities which had already reported COVID-19 cases in the 14 days prior to onset of symptoms; (d) being one of the cluster cases.

Suspected cases met one of the epidemiological criteria and any two of the clinical criteria, or met all of the clinical criteria. Confirmed cases were those suspected cases who met one of the following criteria: (a) respiratory or blood specimen tested positive for SARS-CoV-2 by real time reverse transcriptase-polymerase chain reaction; (b) virus in respiratory or blood specimen was highly homologous with known SARS-CoV-2 through gene sequencing.

Data collection

A three part structured questionnaire was developed. The first part included demographic and clinical information of the primary case. The second part was mainly focused on the primary case's knowledge about and attitudes toward COVID-19, and their self-reported practices (mask wearing, social distancing, living arrangements) and activities in the home. The third part was about self-reported behaviours of all family members, as well as the family's accommodation and household hygiene practices from 4 days before the illness onset to the day the primary case was isolated, including room ventilation, room cleaning and disinfection. Close contact was defined as being within 1 m or 3 feet of the primary case, such as eating around a table or sitting together watching TV. The frequency of contact, disinfection and ventilation was measured.

After diagnosis, the primary case was hospitalised as per standard practice in Beijing. Eligible primary cases and their family members were interviewed between 28 February and 8 March. Data on the primary case were extracted from epidemiological investigating reports from Beijing Centre for Disease Prevention and Control and supplemented by interview.

The clinical severity of the COVID-19 case was categorised as mild, severe or critical. Mild disease included non-pneumonia and mild pneumonia cases. Severe disease was characterised by dyspnoea, respiratory frequency ≥30/min, blood oxygen saturation ≤93%, PaO2/FiO2 ratio <300 and/or lung infiltrates >50% within 24–48 hours. Critical cases were those who exhibited respiratory failure, septic shock and/or multiple organ dysfunction/failure.[8]

BMJ Glob Health: first published as 10.1136/bmjgh-2020-002794 on 28 May 2020. Downloaded from http://gh.bmj.com/ on January 23, 2021 by guest. Protected by copyright.

Statistical analysis

Risk factors for secondary transmission were analysed by characteristics of the primary case, characteristics of well family members and household hygiene practices. Categorical variables are presented as counts and percentages, and continuous variables as medians (IQR). The χ^2 test and Fisher exact test were applied to compare difference between groups when necessary. A composite COVID-19 knowledge score and hand hygiene score were created with multiple sub-questions. A multivariable logistic regression model was used to identify risk factors associated with SARS-CoV-2 household transmission. Univariable analysis was first performed with all measures and only those variables significant at $p<0.1$ could be selected in the following multivariable logistic regression analysis. Backward elimination was performed to establish a final model retaining those with $p<0.05$ in the model. Statistical analyses were performed using SAS software (V.9.4).

Ethics statement

As our study was embedded within the COVID-19 prevention and control practice within public health units, and the telephone interview was a supplementary survey of the epidemiological field investigation, ethics approval was not required. We obtained subjects' verbal informed consent before the start of the interviews.

Patient and public involvement

No patients or the public were involved in the study design, setting the research questions, interpretation or writing up of results, or reporting of the research.

RESULTS

As of 21 February 2020, 399 confirmed COVID-19 cases in 181 families were reported in Beijing. Four family clusters were excluded because we were unable to determine whether there was secondary transmission or co-exposure, leaving 177 families. After reviewing information in the epidemiological investigation reports and survey calls, 40 families were excluded as they did not meet the study inclusion criteria. A further 13 families declined to be interviewed and were also excluded, leaving 124 families for study (figure 1).

Over the 2 weeks of follow-up from onset of the primary case, secondary transmission occurred in 41/124 families (77 secondary cases), and 83/124 families had no secondary transmission. The overall secondary attack rate in families was 23.0% (77/335). In the secondary transmission group, 41 primary cases caused 77 secondary cases, with a median secondary case number in families of 2 (IQR 1–2). In the secondary transmission group, the secondary attack rate in children <18 years of age was 36.1% (13/36), compared with 69.6% (64/92) in adults, and the difference between these two age groups was significant (χ^2=12.08, $p<0.001$). The median age of the 13 secondary child cases was 3 years (IQR 2–6), 12/13 were

*Primary case ever had the symptom of cough when living with others at home.
†Primary case ever had the symptom of diarrhoea (change of character of stool) when living with others at home.
‡Date on which cases self-reported the appearance of either fever (≥37.3℃) or any respiratory symptom during epidemiological investigation. Date of hospital visit was the earliest date that cases sought medical service for COVID-19 related illness.
§A composite variable involving the primary case's knowledge on the infectivity of SARS-CoV-2, contagious population, transmission route, susceptible population, incubation period, common symptoms and preventive measures.
¶Refers to the primary case or family members wearing a face mask at home, regardless of whether it was a N95 mask, disposable surgical mask or a common mask, including cloth mask. Wearing masks all the time means the primary case wears a mask all the time except when having dinner or sleeping at home.
**A composite variable involving the primary case's hand washing practice, including using running water, washing frequency, using sanitiser and under what conditions.

mild and 1/13 was asymptomatic. Of 64 secondary adult cases, 82.8% (53/64) were mild, 10.9% (7/64) were severe, 1.6% (1/64) was critical and 4.7% (3/64) were asymptomatic. No statistically significant difference was observed in clinical severity between 41 index adult cases (table 1) and 64 secondary adult cases for the secondary transmission group (p=0.18).

The univariable analysis for association with secondary transmission of SARS-CoV-2 within families is shown in tables 1–3. Significant associations were:

1. Characteristics, behaviours and knowledge of the primary case: having diarrhoea, interval from illness onset to medical isolation >2 days, self-awareness of being infected with SARS-CoV-2 when the primary case developed the illness, lack of knowledge of their own infectiousness, mask wearing in the home after illness onset, failing to self-isolate and not eating separately were associated with transmission (table 1).
2. Behaviours of family members: having daily close contact with the primary case at home, and number of family members wearing a mask in the home before and after the primary case's illness onset date were associated with transmission (table 2).
3. Household practices: frequency of using chlorine or ethanol based disinfectant for household cleaning and household ventilation duration were protective (table 3).

In multivariable logistic regression model, four factors remained significantly associated with secondary transmission. The primary case having diarrhoea in the home and daily close contact with the primary case in the home increased the risk. Transmission was significantly reduced

*Family members stay with the primary case at a short distance (within 1 m or 3 feet) for more than 10 min at a time. For example, they have dinner with the primary case around a table or watch TV sitting near.
†Before the primary case developed the illness, the primary case or his/her family contacts wear masks all the time at home.
‡When the primary case developed the illness, the primary case's family contacts wear masks all the time living with the primary case at home.

by frequent use of chlorine or ethanol based disinfectant in households and family members (including the primary case) wearing a mask at home before the primary case developed the illness (table 4).

DISCUSSION

This study confirms that the highest risk of household transmission is prior to symptom onset, but that precautionary NPIs, such as mask use, disinfection and social distancing in households can prevent COVID-19 transmission during the pandemic. This study is the first to confirm the effectiveness of mask use prior to symptom onset by family members, daily household disinfection and social distancing in the home. This could inform precautionary guidelines for families to reduce intrafamilial transmission in areas where there is high community transmission or other risk factors for COVID-19. Household transmission is a major driver of epidemic growth.[5 6] Further, in countries where health system capacity is exhausted, many people with infection are required to self-isolate at home, where their household contacts will be at risk of infection. In our study, the median family size of the 124 families was 4 (range 2–9), usually with children, parents and grandparents, which is similar to the social structure of most Chinese families.[9] Therefore, the risk of SARS-CoV-2 household transmission is high if a primary case was introduced and no measure was adopted. We showed that NPIs are effective at preventing transmission, even in homes that are crowded and small. UFMU is a low risk intervention with potential public health benefits.[3 4] The results suggest that community face mask use is likely to be the most effective inside the household during severe epidemics.

Almost a quarter of family members became infected, and the findings suggest that the risk was highest either before symptom onset or early in the clinical illness, as most primary cases were hospitalised after diagnosis, and interventions were not effective if applied after symptom onset. In the univariate analysis, wearing a mask after illness onset was significant, but in multivariate analysis, only wearing it before symptom onset was effective. Viral load is highest in the 2 days before symptom onset and on the first day of symptoms, and up to 44% of transmission is during the pre-symptomatic period in settings with substantial household clustering.[10 11] This supports UFMU, probably by reducing onward transmission from people in the pre-symptomatic phase of the illness[12 13] as well as protecting well mask users. Randomised clinical trials of face masks in the household have confirmed protection against other respiratory viruses if compliant, if used within 36 hours of the primary case symptom onset, and alone or in combination with hand hygiene.[14 15] This study now provides specific evidence for UFMU in settings of high epidemic growth to protect against COVID-19. In our study, 91.2% (103/113) of primary cases had a high score on hand hygiene, but it was not effective, confirming the results of previous randomised clinical trials which showed hand

Once a day or more	0.23	(0.07 to 0.84)	0.03

BMJ Glob Health: first published as 10.1136/bmjgh-2020-002794 on 28 May 2020. Downloaded from http://gh.bmj.com/ on January 23, 2021 by guest. Protected by copyright.

hygiene alone did not protect against respiratory transmissible viruses, but masks combined with hand hygiene did have effect.[16]

As the compliance of UFMU would be poor in the home, there was difficulty and also no necessity for everyone to wear masks at home. We recommended that those families with members who were at risk of getting infected with SARS-CoV-2 (such as ever having contact with a COVID-19 patient, medical workers caring for a COVID-19 patient or having a history of travelling to high risk areas) should apply UFMU to reduce the risk of household transmission.

This study showed that social distancing within the home is effective and having close contact (within 1 m or 3 feet, such as eating around a table or sitting together watching TV) is a risk factor for transmission. The study also provides evidence of effectiveness of chlorine or ethanol based household disinfection in areas with high community transmission, or where one family member is a health worker, or where there is a risk of COVID-19, such as during home quarantine, consistent with advice provided by local health authorities or organisations.[17] Diarrhoea as a symptom in the primary case is also a risk factor for SARS-CoV-2 transmission within families, which highlights the importance of disinfection of the bathroom and toilet, as well as closing the toilet lid when flushing to prevent aerosolisation of the virus.

Our study has limitations. Telephone interview has inherent limitations, including recall bias. It would take about 20 min to complete an interview, and 95% (118/124) of interviews were rated as informative by the interviewers. The evaluation results of mask wearing were reliable, but we did not collect data on the concentration of disinfectant used by families. The strengths of the study were that we had complete follow-up data and were able to accurately ascertain the incidence of secondary transmission in the cohort.

CONCLUSIONS

Household transmission in the pre-symptomatic or early symptomatic period of COVID-19 is a driver of epidemic growth and any measure aimed at reducing this can flatten the curve. This study reinforces the high risk of transmission in households but importantly shows that UFMU and hygiene measures can significantly reduce the risk of household transmission of COVID-19, independent of household size or crowding. This is the first study to show the effectiveness of precautionary mask use, social distancing and regular disinfection in the household, and can inform guidelines for prevention of household transmission. The results may also be informative for families of high risk groups, such as health workers, quarantined individuals or situations where cases of COVID-19 have to be managed at home.

Case-Control Study of Use of Personal Protective Measures and Risk for SARS Coronavirus 2 Infection, Thailand

Pawinee Doung-ngern, Rapeepong Suphanchaimat, Apinya Panjangampatthana, Chawisar Janekrongtham, Duangrat Ruampoom, Nawaporn Daochaeng, Napatchakorn Eungkanit, Nichakul Pisitpayat, Nuengruethai Srisong, Oiythip Yasopa, Patchanee Plernprom, Pitiphon Promduangsi, Panita Kumphon, Paphanij Suangtho, Peeriya Watakulsin, Sarinya Chaiya, Somkid Kripattanapong, Thanawadee Chantian, Emily Bloss, Chawetsan Namwat, Direk Limmathurotsakul

We evaluated effectiveness of personal protective measures against severe acute respiratory disease coronavirus 2 (SARS-CoV-2) infection. Our case-control study included 211 cases of coronavirus disease (COVID-19) and 839 controls in Thailand. Cases were defined as asymptomatic contacts of COVID-19 patients who later tested positive for SARS-CoV-2; controls were asymptomatic contacts who never tested positive. Wearing masks all the time during contact was independently associated with lower risk for SARS-CoV-2 infection compared with not wearing masks; wearing a mask sometimes during contact did not lower infection risk. We found the type of mask worn was not independently associated with infection and that contacts who always wore masks were more likely to practice social distancing. Maintaining ≥1 m distance from a person with COVID-19, having close contact for ≤15 minutes, and frequent handwashing were independently associated with lower risk for infection. Our findings support consistent wearing of masks, handwashing, and social distancing to protect against COVID-19.

Evaluation of the effectiveness of mask-wearing to protect healthy persons in the general public from infection with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the causative agent of coronavirus disease (COVID-19), is urgently needed (*1*,*2*). On February 27, 2020, during the early stages of the COVID-19 outbreak, the World Health Organization (WHO) announced that wearing a mask of any type was not recommended for asymptomatic persons (*3*). The rationale at that time was to avoid unnecessary cost, procurement burden, and a false sense of security (*3*). Several systematic reviews found no conclusive evidence to support widespread use of masks in public settings to protect against respiratory infectious diseases, such as influenza and severe acute respiratory syndrome (SARS) (*4*–*6*). However, China, South Korea, Japan, Thailand, and other countries in Asia have recommended the use of face masks among the general public since early in the COVID-19 pandemic (*7*). Evidence suggests that persons with COVID-19 can have a presymptomatic period, during which they can be contagious and transmit SARS-CoV-2 to others before symptoms develop (*8*). These findings led to a change in recommendations from the US Centers for Disease Control and Prevention on April 4, 2020, that advised all persons wear a cloth face covering when in public (*9*). On April 6 and June 5, 2020, WHO updated its advice on the use of masks for the general public and encouraged countries that issue the recommendations to conduct research on this topic (*8*).

Thailand has been implementing multiple measures against transmission of SARS-CoV-2 since the beginning of the outbreak (*10*,*11*). The country established thermal screening at airports on January 3, 2020, and detected an early case of COVID-19 outside China in a traveler from Wuhan, China, arriving at Bangkok Suvarnabhumi airport on January 8, 2020 (*10*). Thailand uses Surveillance and Rapid Response Teams (SRRTs), together with village health volunteers, to conduct contact tracing, educate the public about COVID-19, and monitor close contacts of persons with COVID-19 in quarantine (*11*). SRRTs are epidemiologic teams trained to conduct surveillance, investigations, and initial control of communicable diseases, such as SARS and influenza (*12*,*13*). More than 1,000 district-, provincial-, and regional-level SRRTs are working on COVID-19 contact tracing in Thailand.

By February 2020, public pressure to wear masks in Thailand was high. However, medical masks became difficult for the public to procure, and the government categorized medical masks as price-controlled goods. When the Ministry of Public Health (MoPH) designated COVID-19 a dangerous communicable disease, according to the Communicable Disease Act of 2015, government officials were empowered to quarantine case-contacts and close venues (*14*,*15*). On March 3, MoPH recommended public use of cloth face masks (*16*). On March 18, schools, universities, bars, nightclubs, and entertainment venues were closed (*17*). On March 26, when the country was reporting ≈100–150 new COVID-19 cases per day, the government declared a national state of emergency, prohibited public gatherings, and enforced wearing of face masks by all persons on public transport (*18*). On April 21, MoPH announced 19 new PCR-confirmed COVID-19 cases, bringing the total number of cases to 2,811 (*18*). Given the lack of evidence, we sought to evaluate the effectiveness of mask-wearing, handwashing, social distancing, and other personal protective measures against SARS-CoV-2 infection in public in Thailand.

Methods

Study Design

We conducted a retrospective case-control study by drawing persons with COVID-19 cases and noninfected controls from a cohort of contact tracing records of the central SRRT team at the Department of Disease Control (DDC), MoPH, Thailand. We included contact investigations of 3 large COVID-19 clusters in nightclubs, boxing stadiums, and a state enterprise office in Thailand.

Contacts were defined by DDC as persons who had activities with or were in the same location as a person with confirmed COVID-19 (*19*,*20*). The main aim of contact tracing was to identify and evaluate contacts, perform reverse transcription PCR (RT-PCR) diagnostic tests, and quarantine high-risk contacts, as defined by the MoPH (Appendix, https://wwwnc.cdc.gov/EID/article/26/11/20-3003-App1.pdf). RT-PCR was performed at laboratories certified for COVID-19 testing by the National Institute of Health of Thailand (*19*,*20*). Data on risk factors associated with SARS-CoV-2 infection, such as type of contact and use of mask, were recorded during contact investigations, but data sometimes were incomplete.

The central SRRT performed contact investigations for clusters of ≥5 PCR-confirmed COVID-19 cases from the same location within a 1-week period (*19*,*20*). We used these data to identify contacts who were asymptomatic during March 1–31, 2020. We used all available contact tracing records of the central SRRT in the study.

We telephoned contacts during April 30–May 27, 2020, and asked details about their contact with a COVID-19 index patient, such as dates, locations, duration, and distance of contact. We asked whether contacts wore a mask during the contact with the index patient, the type of mask, and the frequency of wearing a mask, which we defined as compliance with mask-wearing. We asked whether and how frequently contacts washed their hands while with the index patient. We asked whether contacts performed social distancing and whether they had physical contact with the COVID-19 index patient. If they did not know, or could not remember, contact with the index patient, we asked whether they had contact with other persons at the location. We asked whether the contact shared a cup or a cigarette with other persons in the place they had contact or had highest risk for contact with the index patient and whether the COVID-19 index patient, if known to the respondent, had worn a mask (Appendix, Additional Methods). We also asked, and verified by using DDC records, whether and when the contacts had symptoms and when COVID-19 was diagnosed.

For our study, we defined cases as asymptomatic contacts who later tested positive for SARS-CoV-2, on the basis of RT-PCR results available by April 21, 2020. We defined controls as asymptomatic contacts who did not have positive test results for SARS-CoV-2 by April 21, including those who tested negative and those who were not tested. We defined asymptomatic contacts as persons who had contact with or were in

the same location as a symptomatic COVID-19 patient and had no symptoms of COVID-19 on the first day of contact. We defined index patients as persons identified from contact tracing data as the potential source of SARS-CoV-2 infection; cases (as defined above) also could be index patients. We defined primary index patients as persons whose probable sources of infection were before the study period, March 1–31; for whom we were not able to identify the source of infection; or whose probable sources of infection were outside the contact tracing data included in the study. We defined high-risk exposure as that which occurred when persons lived in the same household as a COVID-19 patient; had a direct physical contact with a COVID-19 patient; were ≤1 m from a COVID-19 patient for >15 minutes; or were in the same closed environment, such as a room, nightclub, stadium, or vehicle, ≤1 m from a COVID-19 patient for >15 minutes.

We used 21 days after March 31 as a cutoff date based on evidence that most persons with COVID-19 likely would develop symptoms within 14 days (*21*) and that it could take ≤7 additional days for symptomatic persons under contact investigation to go to a healthcare facility and be tested for COVID-19. Our study follows the STROBE guidelines (*22*).

Statistical Analysis

To include only initially asymptomatic contacts in the study, we excluded persons who reported having symptoms of COVID-19 at the time of initial contact with an index patient. Because our study focused on the risk for infection in the community, we excluded contacts whose contact locations were healthcare facilities. We also excluded primary index patients if they were the first to have symptoms at the contact investigation location, had symptoms since the first day of visiting the location, or were the origin of infection based on the contact investigation.

We estimated secondary attack rates by using the percentage of new cases among asymptomatic contacts with high-risk exposure to enable comparison with other studies. We estimated odds ratios (ORs) and 95% CIs for associations between developing COVID-19 and factors evaluated. We used logistic regression with random effects for location and for index patients nested in the same location. If an asymptomatic contact had contact with ≥1 symptomatic COVID-19 index patient, the interviewer identified the index patient as the symptomatic COVID-19 patient with the closest contact. The percentage of missing values for the variable indicating whether the index patients wore a mask was 27%; thus, we did not include this variable in our analyses. For other variables, we assumed that missing values were missing at random and used imputation by chained equations (*23*,*24*). We created 10 imputed datasets and the imputation model included the case-control indicator and variables used in the multivariable models, including sex, age group, contact place, shortest distance of contact, duration of contact at ≤1 m, sharing dishes or cups, sharing cigarettes, handwashing, mask-wearing, and compliance with mask-wearing. We developed the final multilevel mixed-effect logistic regression models on the basis of previous knowledge and a purposeful selection method (*25*; Appendix, Additional Analyses). Because of collinearity between mask use and mask type, we conducted a separate analysis including mask type in the multilevel mixed-effects logistic regression model for SARS-CoV-2 infection. We also tested a predefined interaction between mask type and compliance with mask-wearing (Appendix, Additional Analyses).

To clarify patterns of behavior and factors related to compliance with mask-wearing, we used multinomial logistic regression models and the imputed dataset to estimated OR and 95% CI for associations between 3 mask-wearing compliance categories, never, sometimes, or all the time; and for other practices, including handwashing and social distancing during the contact period. We used logistic regression to estimate p values for pairwise comparisons.

To estimate the proportional reduction in cases that would occur if exposure to risk factors was reduced, we estimated the population attributable fraction by using the imputed dataset and a direct method based on logistic regression, as described previously (*26*,*27*; Appendix, Additional Analyses). We performed all analyses by using Stata version 14.2 (StataCorp, https://www.stata.com) and R version 4.0.0 (R Foundation for Statistical Computing, https://www.r-project.org).

Results

Characteristics of the Cohort Data

The contact tracing records of the central SRRT included 1,716 persons who had contact with or were in the same location as a person with diagnosed COVID-19 in an investigation of 3 large clusters (Figure 1). Overall, 18 primary index patients were identified: 11 from the nightclub cluster, 5 from the boxing stadiums cluster, and 2 from the state enterprise office cluster. Timelines of primary index patients from the 3 clusters varied (Appendix Figures

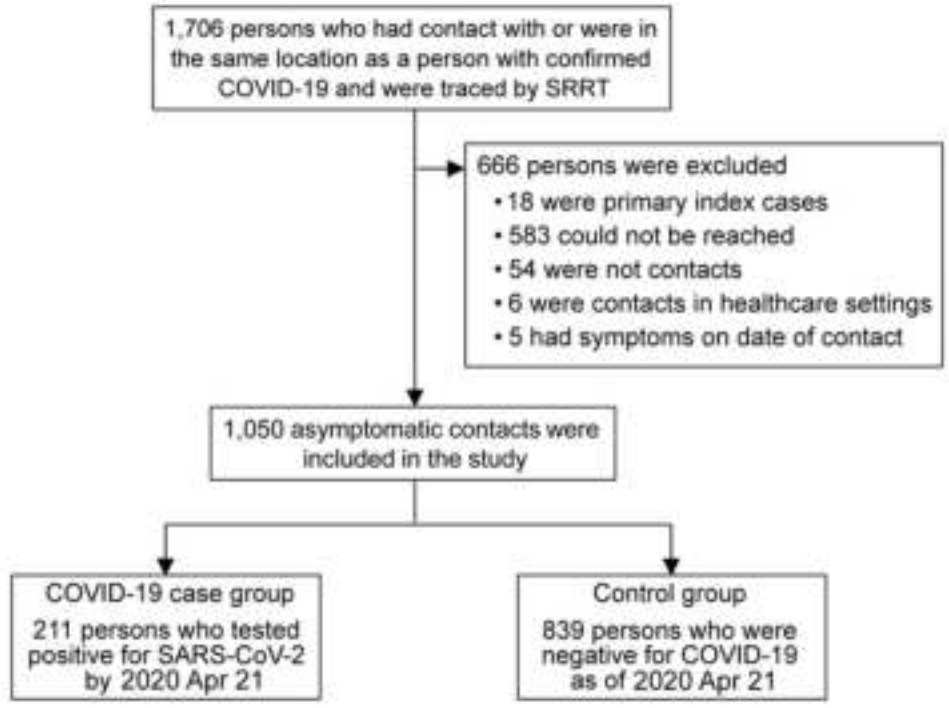

Figure 1. Flow diagram in case-control study of severe acute respiratory syndrome coronavirus 2 infections and contacts, Thailand, March–April 2020. COVID-19, coronavirus disease; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2; SRRT, Surveillance and Rapid Response Team of Ministry of Public Health.

1–3); we excluded the 18 primary index patients from our analyses.

Characteristics of Cases and Controls

After interviewing each contact by phone and applying the exclusion criteria (Figure 1), our analysis included 1,050 asymptomatic persons who had contact with or were in the same location as a symptomatic COVID-19 index patient during March 1–31, 2020. The median age of persons included was 38 years (IQR 28–51 years); 55% were male, and 45% were female (Table 1). Most (61%; n = 645) asymptomatic contacts included in the study were associated with the boxing stadiums cluster, 36% (n = 374) were related to the nightclub cluster, and 3% (n = 31) were related to the state enterprise office cluster. Overall, 890 (84.8%) contacts were considered to have high-risk exposure.

Among 1,050 asymptomatic contacts included in our analysis, 211 (20.1%) tested positive for SARS-CoV-2 by April 21, 2020, and were classified as cases; 839 (79.9%) never tested positive and were controls. Of the 211 cases, 195 (92.4%) had high-risk exposures and 150 (71.1%) had symptoms before COVID-19 diagnosis by RT-PCR (Appendix). The last date that a COVID-19 case was detected was April 9, 2020. Among the 839 controls, 695 (82.8%) had high-risk exposures and 719 (85.7%) were tested by PCR at least once.

Among asymptomatic contacts included in the study, 228 had contact with a COVID-19 index patient at nightclubs, 144 at boxing stadiums, and 20 at the state enterprise office (Figure 2). The others had contacts with a COVID-19 index patient at workplaces (n = 277), households (n = 230), and other places (n = 151). Among 890 asymptomatic contacts with high-risk exposures included in the study, the secondary attack rate from boxing stadiums was 86% (111/129), the secondary attack rate for nightclubs was 18.2% (34/187), the household secondary attack rate was 16.5% (38/230), the workplace secondary attack rate was 4.9% (10/205), and the secondary attack rate at other places was 1.4% (2/139).

Bivariate Analyses

Our analysis showed risk for SARS-CoV-2 infection was negatively associated with personal protective measures (Table 1). Crude odds ratio (OR) for infection was 0.08 (95% CI 0.02–0.31) for those maintaining a distance of ≥1 m from a COVID-19 patient; 0.13 (95% CI 0.04–0.46) for those whose duration of contact was ≤15 minutes; 0.41 (95% CI 0.18–0.91) for those who performed handwashing sometimes; 0.19 (95% CI 0.08–0.46) for those who washed hands often; and 0.16 (95% CI 0.07–0.36) for those wearing a mask all the time during contact with a COVID-19 patient. We noted a higher risk for SARS-CoV-2 infection among persons sharing dishes or cups (OR 2.71; 95% CI 1.48–4.94) and sharing cigarettes (OR 6.12; 95% CI 2.12–17.72) with other persons in general, not necessarily including a COVID-19 patient. In the bivariate model, type of mask was associated with risk for infection (p = 0.003).

Multivariable Analyses

We found a negative association between risk for SARS-CoV-2 infection and maintaining a distance of ≥1 m from a COVID-19 patient (adjusted odds ratio [aOR] 0.15; 95% CI 0.04–0.63); duration of contact ≤15 minutes (aOR 0.24; 95% CI 0.07–0.90); handwashing often (aOR 0.33; 95% CI 0.13–0.87); and wearing a mask all the time during contact with a COVID-19 patient (aOR 0.23; 95% CI 0.09–0.60) (Table 1). Wearing masks sometimes during contact with a COVID-19 patient was not statistically significantly associated with lower risk for infection (aOR 0.87; 95% CI 0.41–1.84). Sharing cigarettes with other persons was associated with higher risk for infection (aOR 3.47; 95% CI 1.09–11.02).

Compliance with mask-wearing during contact with a COVID-19 patient was strongly associated

*NA, not applicable; COVID-19, coronavirus disease.
†Data not available for all cases and controls for all factors.
‡Crude and adjusted odds ratios were estimated using logistic regression with random effects for location and for index patient nested within the same location.
§The state enterprise office was included as a workplace. Others included restaurants, markets, malls, religious places, and households of index patients or other persons in persons not living in that household. Location was included in the model as a random effect variable.
¶Sharing multiserving dishes and using communal serving utensils to portion food individually was not categorized as sharing dishes.
#Included sharing electronic cigarettes and any vaping devices.
**Included washing with soap and water, and by using alcohol-based solutions.
††Wearing masks incorrectly, such as not covering both nose and mouth, was considered the same as not wearing a mask for analyses. Crude odds ratios of wearing mask and of each factor evaluated were estimated using logistic regression with random effects for location and for index patient nested within the same location to take into account clustering; therefore, the crude odds ratios are not equal to dividing of the odds in the case group by the odds in the control group.

with lower risk for infection in the multivariable model. Because of collinearity with mask-wearing compliance, we did not include mask type in the final model. We included mask type in a separate multivariable model and found type of mask was not independently associated with infection (p = 0.54) (Appendix Table 1). We found no evidence of effect modification between mask type and mask-wearing compliance.

Association Between Mask-Wearing Compliance and Other Social Distancing Practices

Because mask-wearing throughout the contact period was negatively associated with COVID-19, we

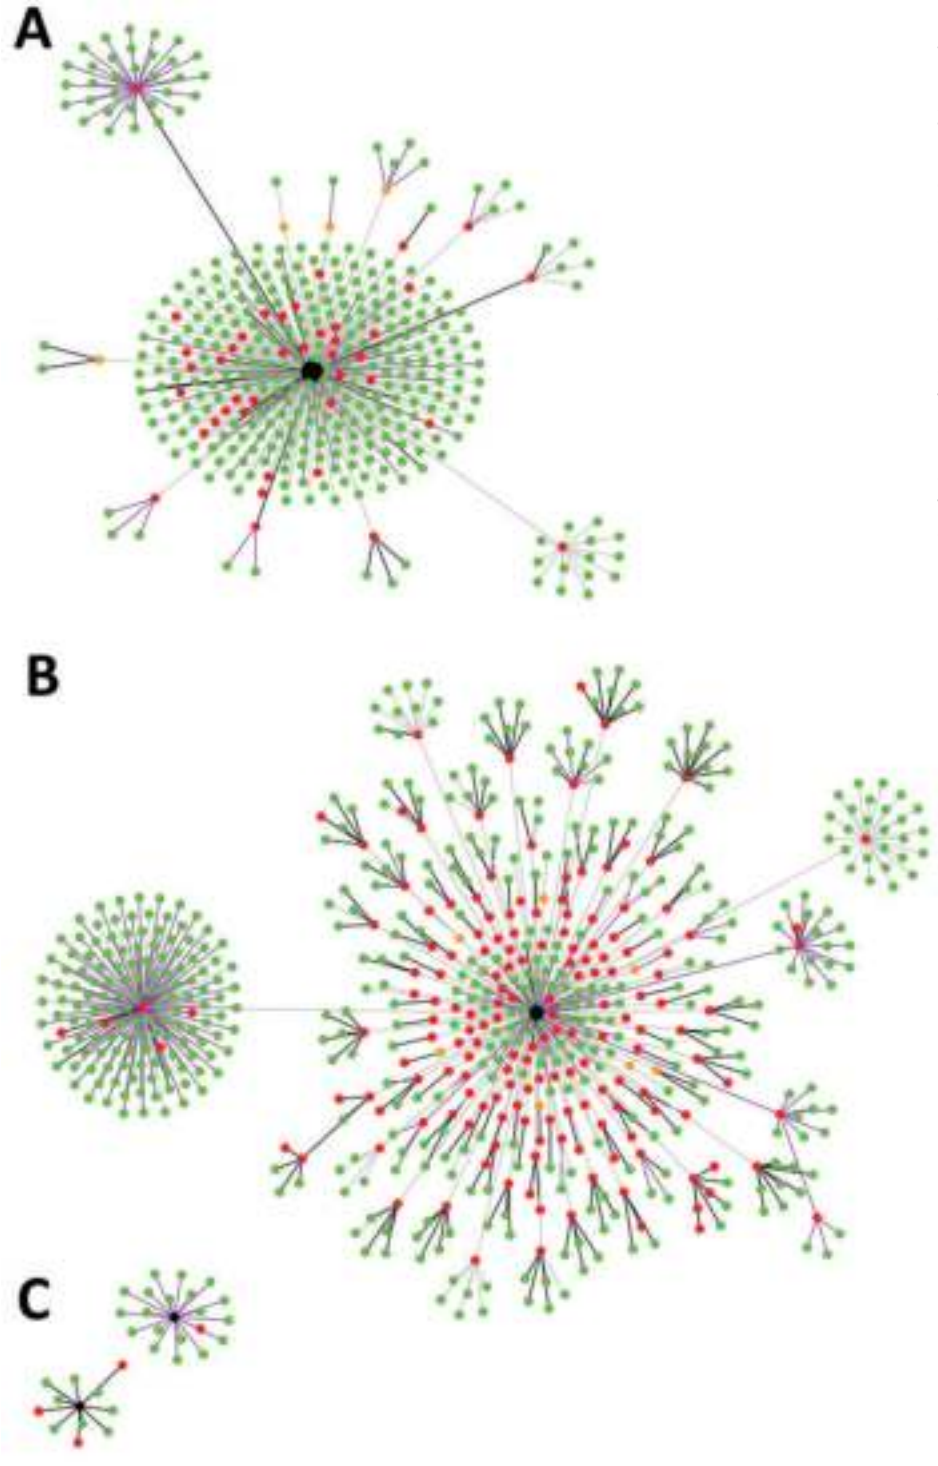

Figure 2. Development and transmission of severe acute respiratory syndrome coronavirus 2 among asymptomatic contacts, Thailand, March–April 2020. Clusters indicate coronavirus disease (COVID-19) contacts from nightclubs (A); boxing stadiums (B), and the state enterprise office (C). Black nodes represent primary index patients, red dots cases (contacts of primary index patients who had COVID-19), green dots noninfected controls, and orange dots patients with confirmed COVID-19 who could not be contacted by the study team. Black lines represent household contacts, purple lines contacts at workplaces, and gray lines contacts at other locations.

further explored characteristics of participants to ascertain whether wearing a mask produced a potential false sense of security. We found that during the contact period, 25% of persons who wore masks all the time reported maintaining ≥1 m distance from contacts compared with 18% of persons who did not wear a mask (pairwise p = 0.03). In addition, persons who wore masks all the time were more likely to report duration of contact ≤15 minutes (26% vs. 13% for those who did not wear a mask; pairwise p<0.001) and washing hands often (79% vs. 26% for those who did not wear a mask; pairwise p<0.001) (Table 2). We found that 43% of persons who wore masks sometimes were likely to wash their hands often compared with those who did not wear masks (26%; pairwise p<0.001), but they were more likely to have physical contact (50% vs. 42%; pairwise p = 0.03) and report duration of contact >60 minutes (75% vs. 67%; pairwise p = 0.04) compared with those who did not wear masks.

Discussion

Our findings provide evidence that mask-wearing, handwashing, and social distancing are independently associated with lower risk for SARS-CoV-2 infection in the general public in community settings in Thailand. We observed that wearing masks throughout the period of exposure to someone infected with SARS-CoV-2 was associated with lower risk for infection, but wearing masks only sometimes during the period was not. This evidence supports recommendations to wear masks consistently and correctly at all times in public (*2*,*7*–*9*).

The effectiveness of mask-wearing we observed is consistent with previous studies, including a randomized-controlled trial showing that consistent face

‡The state enterprise office was included as a workplace. Others included restaurants, markets, malls, religious places, and households of index patients or other persons but not living together (e.g., persons not living in that household).
§Sharing multiserving dishes and using communal serving utensils to portion food individually was not categorized as sharing dishes.
¶Included sharing electronic cigarettes and any vaping devices.
#Included washing with soap and water, and by using alcohol-based solutions.

mask use reduced risk for influenza-like illness (*28*), 2 case-control studies that found that mask-wearing was associated with lower risk for SARS infection (*29*,*30*), and a retrospective cohort study that found that mask-wearing by index patients or family members at home was associated with lower risk for SARS-CoV-2 infection (*31*). Previous studies found use of surgical masks or similar 12–16-layer cotton reusable masks demonstrated protection against coronavirus infection in the community (*32*), but we did not observe a difference between wearing nonmedical and medical masks in the general population. Our results suggest that wearing nonmedical masks in public can potentially reduce transmission of SARS-CoV-2. Another study found perception of risk of developing COVID-19 can increase a person's likelihood of wearing a medical mask in nonmedical settings (T.D. Huynh, unpub. data, https://www.medrxiv.org/content/10.1101/2020.03.26.20044388v1). However, given supply shortages, medical masks should be reserved for use by healthcare workers.

We found a negative association between risk for SARS-CoV-2 infection and social distancing, consistent with previous studies that found that ≥1 m physical distancing was associated with a large protective effect and distances of >2 m could be more effective (*32*). Our findings on effectiveness of hand hygiene also were consistent with reports in previous studies (*33*).

In this study, secondary attack rates at different venues varied widely. The household secondary attack rate in our study (16.5%) is comparable with ranges reported previously (11%–23%) (*34*,*35*), and relatively high compared with workplaces (4.9%) and other settings (1.4%). Although quarantine measures can be challenging and sometimes impractical, household members should immediately separate a person who develops symptoms of COVID-19; the sick person should stay in a specific room; use a separate bathroom, if possible; and not share dishes, cups, and other utensils (*36*). All household members should wear masks, frequently wash their hands, and perform social distancing to the extent possible (*37*).

The high number of COVID-19 cases associated with nightclub exposures in Bangkok is comparable to a COVID-19 outbreak associated with the Itaewon nightclub cluster in Seoul, South Korea, during May 2020 (*38*), in which persons visited several nightclubs in the same area during a short period of time. The secondary attack rate in boxing stadiums was high (86%) but similar to a cluster of COVID-19 cases associated with a football match in Italy during February 2020 (*39*). The secondary attack rate of COVID-19 at a choir practice in the United States was reported to be 53.3%–86.7% (*40*). Secondary attack rates in public gathering places with high densities of persons shouting and cheering, such as football and boxing stadiums, are still uncertain but appear to be high.

Clear and consistent public messaging from policy makers likely can prevent a false sense of security and promote compliance with social distancing in Thailand. We found that those who wore masks throughout the time they were exposed to a COVID-19 patient also were more likely to wash their hands and perform social distancing. Traditional and social media outlets can support public health responses by working with governments to provide consistent, simple, and clear messages (*41*). In Thailand, daily briefings from the Centre for COVID-19 Situation Administration provided clear, consistent messages on social distancing, how to put on a mask, and how to wash hands, which might have improved public confidence with the recommendations. Consistent public messages on how to wear masks correctly also are needed, particularly for those who wear masks sometimes or incorrectly, such as not covering both nose and mouth. We found that persons who only intermittently wore masks during exposure also did not practice social distancing adequately.

Our study has several limitations. First, because our findings were based on contacts related to 3 major COVID-19 clusters in Thailand during March 2020, they might not be generalizable to all settings. Second, estimated ORs were conditioned on reported contact with index patients; our study did not evaluate or consider the probability of having contact with other infected persons in the community, which could have occurred. Third, because only 89% of controls were tested, those not tested could have been infected; therefore, cases might have been missed in persons with mild or no symptoms or who did not report symptoms or seek care or testing. Nonetheless, we believe that misclassification likely was minimal because those who were not tested with RT-PCR were low-risk contacts; the small number likely would not change our main findings and recommendations on personal protective measures. Fourth, identifying every potential contact can be nearly impossible because some persons might have had contact with >1 COVID-19 patient. Hence, our estimated secondary attack rates among contacts with high-risk exposure could be overestimated or underestimated. Fifth, population attributable fraction is based on several assumptions, including causality, and should be interpreted with caution (*42*,*43*). Finally, findings were subject to

common biases of retrospective case-control studies, including memory bias, observer bias, and information bias (*44*). To reduce potential biases, we used structured interviews in which each participant was asked the same set of defined questions.

As many countries begin to relax social distancing measures, our findings provide evidence supporting consistent mask-wearing, handwashing, and adhering to social distancing recommendations to reduce SARS-CoV-2 transmission in public gatherings. Wearing nonmedical masks in public could help slow the spread of COVID-19. Complying with all measures could be highly effective; however, in places with a high population density, additional measures might be required.

Clear and consistent public messaging on personal protective recommendations is essential, particularly for targeting those who wear masks intermittently or incorrectly. Our data showed that no single protective measure was associated with complete protection from COVID-19. All measures, including mask-wearing, handwashing, and social distancing, can increase protection against COVID-19 in public settings.

SARS Transmission, Risk Factors, and Prevention in Hong Kong

Joseph T.F. Lau,* Hiyi Tsui,* Mason Lau,* and Xilin Yang*

We analyzed information obtained from 1,192 patients with probable severe acute respiratory syndrome (SARS) reported in Hong Kong. Among them, 26.6% were hospital workers, 16.1% were members of the same household as SARS patients and had probable secondary infections, 14.3% were Amoy Gardens residents, 4.9% were inpatients, and 9.9% were contacts of SARS patients who were not family members. The remaining 347 case-patients (29.1%) had undefined sources of infection. Excluding those ≤16 years of age, 330 patients with cases from "undefined" sources were used in a 1:2 matched case-control study. Multivariate analysis of this case-control study showed that having visited mainland China, hospitals, or the Amoy Gardens were risk factors (odds ratio [OR] 1.95 to 7.63). In addition, frequent mask use in public venues, frequent hand washing, and disinfecting the living quarters were significant protective factors (OR 0.36 to 0.58). In Hong Kong, therefore, community-acquired infection did not make up most transmissions, and public health measures have contributed substantially to the control of the SARS epidemic.

As of June 11, 2003, a total of 1,755 probable SARS cases were reported in Hong Kong (1). Some of the sources of SARS transmission are unknown. For instance, the first major SARS outbreak occurred in the Prince of Wales Hospital in March 2003, and 138 probable cases were reported from March 11 to March 25, 2003 (2). Another major outbreak occurred in the Amoy Gardens housing estate on approximately March 26, 2003, and a total of 321 residents were affected (3). A total of 381 hospital workers were affected as of May 29, 2003 (4). Other sources of infection are possible. Some inpatients were cross-infected by SARS case-patients, who were hospitalized for reasons other than SARS; others may have contracted the disease through known contacts with other SARS patients. The rest of the community-acquired case-patients contracted the diseases through less defined sources. The distributions of the "known" and "undefined" sources of infection have not been reported. Such an initiative would help assess the infectivity and modes of transmission of the virus in the community setting.

Also, reports that public health measures, such as wearing masks, frequent hand washing, avoidance of crowded places, disinfection of the living quarters had been practiced by most of the Hong Kong population during the SARS outbreak (>90%) (5). The efficacy of widespread use of masks was controversial (6), and evaluating the efficacy of such measures in controlling the epidemic is important.

Our study had two objectives. First, we sought to delineate the distribution of different sources of transmission of the SARS cases in Hong Kong. The number of cases with known and undefined sources was determined. Patients with known sources included those who were hospital workers, those who lived in the Amoy Gardens Estate, those who were probable secondary cases within a household (i.e., those with another household member who had SARS with an earlier date of onset), those who were inpatients and were cross-infected by other inpatients, and those persons who had contact with another SARS patient (who was not one of their household members) before the onset of fever. For the remaining cases, the virus was contracted through undefined sources.

The second objective was to identify the undefined source group. A number of hypotheses were tested to identify relevant risk and protective factors associated with contracting the disease. Risk factors were related to visiting places of potentially high risk and meeting at-risk people. Preventive factors were related to public health measures for prevention.

Methods

The study population comprised all probable SARS patients whose cases were reported to the Department of Health on or before May 16, 2003 (n = 1,690). The SARS case definition criteria, used by Hong Kong Hospital Authority, is as follows: radiographic evidence of infiltrates consistent with pneumonia and current temperature >38°C or a history of such at any time in the preceding 2 days, and

*Chinese University of Hong Kong, Hong Kong, China

at least two of the following: history of chills in the past 2 days, new or increased cough, breathing difficulty, general malaise or myalgia, typical signs of consolidation, and known exposure. These criteria for cases are equivalent to those in the World Health Organization's case definition for probable SARS cases (7).

Data Collection

Telephone numbers, as well as some demographic and clinical background information, for all probable SARS case-patients in Hong Kong (identified on or before May 16, 2003 [n = 1,690]) were obtained from the Department of Health. A team of trained interviewers called all these numbers, briefed the person answering the phone about the nature of the study, and invited their household to join the study. Informed consent was obtained directly from the respondents. The number of SARS patients in the household was ascertained, and the interviewer identified the index patient, the person who had the earliest date of onset of fever if the household had more than one SARS patient. The rest of the SARS patients, those with later onset of illness, were considered as having probable secondary or tertiary cases. When a household had had two or more SARS patients with the same fever onset date (11 households), both were treated as index patients rather than as having probable secondary cases. The information obtained was cross-checked with that obtained from the SARS registry. Ethics approval was obtained from the Ethics Committee of the Chinese University of Hong Kong.

The study was conducted from April 4, 2003, through June 10, 2003. Of the 1,690 probable SARS case-patients reported in Hong Kong as of May 16, a total of 1,214 (72%) SARS case-patients from 996 households were covered by our study. Of the remaining 476 case-patients not covered by this study, 140 case-patients (8.2%) did not have a correct telephone number, 163 (9.6%) could not be contacted after at least five attempts, 163 (9.6%) declined to participate, and 10 (0.6%) were either not in Hong Kong or could not communicate in Chinese or English.

Study Design

The study is part of a project that also includes an investigation of the secondary attack rate of household members. For the first part of this study, the index case-patients were asked whether they were hospital workers, inpatients before contracting SARS, or residents of the Amoy Gardens. The other respondents were asked whether onset of fever occurred within 10 days of contact with a SARS patient. These four types of SARS cases were classified into the known sources group. The rest of the index case-patients were classified into the undefined source group. In the second part of the study, a 1:2 matched case-control study was conducted for the undefined source group to identify risk and preventive factors associated with SARS transmission in the community setting.

Adults ≥16 years of age were included in the case-control study (17 case-patients were removed from the analysis). Potential geographically related risk factors studied included whether the case-patient had visited (but not lived in) Amoy Gardens, Prince of Wales Hospital, other hospitals or clinics, or crowded places within 10 days before onset of fever. Other risk factors were related to contact with other groups of people during the same reference period, including medical personnel, hospital visitors, and persons with influenzalike symptoms (who were not SARS case-patients). A number of protective factors were related to relevant public health measures, including the frequency of using a face mask in public venues, the frequency of washing hands each day, and disinfection of living quarters thoroughly during the same period. The same questions were asked to the control group, which was recruited by a random telephone survey. Members of the control group were matched for age and sex with the case-patient.

The reference period was the same as that of the matched case-patient. Random telephone numbers were selected from up-to-date local telephone directories. Interviews were conducted in the evening to avoid overrepresenting those who were not working during the daytime. At least three calls were made before an unanswered call was considered as a noncontact. Informed consent was obtained before the interviews were conducted. Almost all case-patients were interviewed within 14 to 28 days after their onset of fever, and the control group was interviewed accordingly. When a participant was unable to answer the questionnaire, a proxy, who was most familiar with the family situation, was interviewed.

Data Analyses

For the case-control study, odds ratios (OR) were first examined by using univariate logistic regression models. The significant univariate variables were then entered as input for the multivariate forward conditional logistic regression analysis; p values <0.05 were statistically significant. SPSS for Windows Release 11.0.1 (SPSS Inc., Chicago, IL) was used to analyze the data.

Results

Cases with Known Sources of Transmission

Of the 1,214 probable SARS cases covered by this study, 22 questionnaires (1.8%) were incomplete and did not allow us to classify the respondents into groups according to source of transmission. The rest (n = 1,192) were analyzed. A total of 192 (16.1%) had probable cases of secondary or tertiary household transmission (Table 1) (i.e.,

Table 1. Distribution of 1,214 severe acute respiratory syndrome cases covered by the study[a]

	n	%[b]
Known sources	727	61.0
Probable secondary/tertiary household infection	192[d]	16.1
Hospital care workers	317[d]	26.6

[e]PWH, Prince of Wales Hospital.

another household member had SARS but fever onset occurred earlier). All the names were verified as being reported to the SARS registry. Another 317 of 1,192 (26.6%) cases were hospital workers; 170 (14.3%) lived in the Amoy Gardens; 58 (4.9%) were inpatients who had been hospitalized for diseases other than SARS and kept on wards with SARS patients. Most infected inpatients were long-term chronic patients and had been hospitalized for >2 weeks before having SARS symptoms. These patients were likely to have been cross-infected. A total of 727 case-patients belonged in one of the four categories (61% of 1,192 cases). Another 118 (9.9%) had come into contact with a SARS patient within a 10-day period before onset of fever. For 347 (29.1%) participants, the source was undefined; these participants were included in the case-control analysis. After excluding 17 case-patients ≤16 years of age, 330 participants were included in the case-control study.

Univariate Case-Control Analysis

Of the 330 patients with an undefined source of infection, 48% were men and 52% were women. The mean age of the patient group was 47.1 years for both the male and female case-patients (standard deviation [SD] 18.8 and 19.9, respectively, $p > 0.05$, *t* test). The percentage of participants in the undefined source group in the three periods of the epidemic (before March 25, 2003, from March 26 through April 10, and after April 10) were 24.2%, 36.1%, and 43.5%, respectively.

Members of the patient group were more likely than the control group to have visited mainland China (12.7% vs. 6.5%, $p < 0.005$). One patient had visited Taiwan, another patient had visited Singapore, two controls had visited Taiwan, and none of the controls had visited Singapore (Singapore and Taiwan were listed as affected areas during the study period). Similarly, patients were also more likely than controls to have visited the Amoy Gardens (15% vs. 2%, OR = 9.10, $p < 0.005$) (keeping in mind that those who lived in the Amoy Gardens had already been removed from the analysis); patients were more likely than the controls to have visited the Prince of Wales Hospital (3.6% vs. 0.5%, OR = 8.27, $p < 0.005$) or other hospitals or clinics (40.7% vs. 17.0%, OR = 3.36, $p < 0.005$) (Table 2). A total of 212 cases of the undefined source group had visited at least one of the above-mentioned categories of places. Frequency of visiting crowded places was, however, not significant in the univariate analysis (21.91% vs. 20.8%, OR = 1.07, $p > 0.05$).

Members of the case-patient and control groups were not statistically different in the percentage of having come into contact with someone with influenzalike symptoms (those having made contacts with SARS patients were already removed, 9.0% vs. 6.4%, OR = 1.42, $p > 0.05$). The two groups were also not different in the likelihood of having social contact with someone who had visited a hospital (8.2% vs. 5.2%, OR = 1.66, $p > 0.05$) or having social contact with medical personnel (7.6% vs. 8.6%, OR = 0.87, $p > 0.05$). Also patients were not more likely to have a known SARS patient living in the same housing estate, after Amoy Gardens patients had already been removed from the analysis (such data were made available to the public by the government after April 12, 2003) (8).

Furthermore, matching for the reference period, members of the case group were less likely than members of the control group to have frequently worn a face mask in public venues (27.9% vs. 58.7%, OR = 0.36, $p < 0.005$), to have been washed their hands >10 times a day (18.4% vs. 33.7% OR = 0.44, $p < 0.005$), and to have disinfected their living quarters thoroughly (46.6% vs. 74.5%, OR = 0.30, $p < 0.005$).

Multivariate Analysis

When all the variables that were significant in the univariate analysis were used as input for the multivariate stepwise conditional logistic regression analysis, the results show that among the 330 patients with undefined sources, the following were significant risk factors: having visited mainland China (OR = 1.95, $p = 0.020$, Table 2), having visited the Amoy Gardens (OR = 7.63, $p < 0.001$), having visited the Prince of Wales Hospital (OR = 7.07, $p = 0.009$), and having visited other hospitals or clinics (OR = 3.70, $p < 0.001$) during the reference period. On the other hand, using a mask frequently in public places (OR = 0.27, $p < 0.001$), washing one's hands >10 times a day (OR = 0.58, $p = 0.008$), and disinfecting the living quarters thor-

oughly (OR = 0.41, $p < 0.001$) during the reference period were significant protective factors (Table 2).

Undefined Cases

After removing those case-patients who may have contracted SARS after visiting the Amoy Gardens, the Prince of Wales Hospital, other hospitals, or an affected country, including mainland China, Singapore, and Taiwan (212 cases of the 330 cases), 118 cases remained undefined. They were likely to be community-acquired cases of unknown sources of transmission. When univariate and multivariate conditional logistic regression analyses were repeated for the 118 cases with undefined sources (after 212 patients who had visited some particular places that were associated with risk for transmission were removed from the analysis) and their controls (n = 236), similar results were obtained. The three public health variables—frequently wearing a mask in public places (adjusted OR = 0.36, $p < 0.001$), washing hands >10 times a day (adjusted OR = 0.44, $p = 0.008$), and disinfecting the living quarters thoroughly (adjusted OR = 0.36, $p < 0.001$)—remained significant protective factors. Again, similar to the results of the previous analysis applied to the 330 cases, the other five variables (visiting crowded places, having contact with someone with influenzalike symptoms, having social contact with hospital visitors, having social contact with medical workers, and living with in the same housing estate as other SARS case-patients) were not significant risk factors.

Discussion

Of the 1,192 participants in this study, approximately 16.1% had probable secondary or tertiary transmission occurring within the household, 26.6% were hospital workers with nosocomial infections, 14.3% were Amoy Gardens patients, and 4.9% were cross-infected inpatients. In 9.9%, SARS might have been contracted when the participant came in contact with a SARS patient who was a nonhousehold member, which may have occurred in a hospital or community setting. SARS may have developed in 18.7% after they visited Amoy Gardens, hospitals or clinics, or affected countries. This computation leaves 9.9% as community-acquired cases of an unknown source.

The percentage of patients related to Amoy Gardens (someone who lived there or visited there) is 18.8% (224/1,192). The percentage of patients with a hospital connection (hospital workers, inpatients, and visitors) is 44% (525/1,192). The proportion of unknown community-acquired SARS infection among all SARS cases in this study was considerably lower than the proportion of nosocomial infection, which suggests that preventing hospital outbreaks is essential.

Of the 330 undefined transmissions, 44.2% of the transmissions occurred through hospital visitors. Another study on household transmission also indicated that hospital visits were a significant risk factor for predicting household secondary infection (9). Therefore, the severity of future outbreaks, if any, would depend on the ability of the hos-

pital system to control hospital cross-infection and infection of visitors.

Visits to mainland China were associated with SARS transmission, even after adjusting for other variables. Cross-border transmission played a role in the epidemic; although the absolute percentage is not high among the 1,192 case-patients (3.6% or 43/1,192), it is substantially larger among the undefined source group (12.4%). With a case-control design, we could not establish whether this 14.4% was associated with an inflated risk. Cross-border communication and prevention, such as those set in place (temperature screening and health declaration), need to be enforced strictly and consistently. Almost 70% of the 43 participants who visited mainland China had fever onset on or before April 1 (i.e., the early phase of the epidemic) (5). None of them had onset after May 3, which is understandable as visiting mainland China was perceived as a high risk by the general public in the late phase of the epidemic (5).

The variables related to social contacts (with medical personnel or hospital visitors, with persons with influenza-like symptoms, and with persons living in a housing estate with a reported SARS patient) were not significant. These findings should be interpreted with caution. On one hand, these case-patients should not be stigmatized. On the other, the results may have been confounded because all SARS cases contracted this way were excluded from the analysis. However, confirming that these variables could not account for transmission of the undefined source cases can be useful.

Evidence does not indicate that frequent visits to crowded places were associated with a higher likelihood of community-acquired infection. This finding may remove panic that arose during the epidemic, and daily life need not change as much as it had. Hong Kong is a densely populated city, and it had a large number of SARS cases. The number of community-acquired cases in less populated cities should be much lower than that of Hong Kong. This finding should be interpreted with care as >90% of the general public wore face masks in public places, and >85% avoided visits to public places during the epidemic in Hong Kong (5). Although visiting the Amoy Gardens was a risk factor, Amoy Gardens might be the only place where such a large-scale SARS outbreak was attributable to contamination of the environment.

We now have some empirical evidence to suggest that wearing a face-mask frequently in public places, frequent handwashing, and disinfecting one's living quarter were effective public health measures to reduce the risk for transmission (adjusted OR 0.58 to 0.36). The effectiveness of mask use was controversial (6). In another study, the prevalence of these three public health preventive public health measures increased significantly from March 21, 2003, to April 1, 2003, (i.e., wearing masks 11.5%–84.3%; frequent hand washing 61.5%–95.1%; home disinfection 36.4%–80%) (5). These practices played an essential role in limiting the spread of the virus in the community in Hong Kong.

That disinfecting the living quarter is a strong protective factor has a particular relevance. The reason behind the significance is not completely clear. During the epidemic, the Hong Kong government released frequent announcements of public interest to promote home disinfection using 1:99 bleach water solutions. Most respondents who disinfected their living quarters were probably following the government's suggestion. Keeping in mind that probable secondary cases had already been removed from the analysis, such protective effect is not referring to the effects that disinfecting the quarter reduced the chance of secondary infection. Environmental contamination (suspected to be related to the sewage system) was reported in the Amoy Gardens, and similar environmental contamination probably did not occur in other places. Such contamination-related infections might be on a small scale and not been noticed. In such circumstances, home disinfection might reduce the risk for transmission. The finding suggests that, in addition to the droplet theory, the fomites theory could not be dismissed.

Our study has a few limitations as well as strengths. First, approximately 72% of all SARS case-patients were included in the study (excluding patients whose contact numbers were incorrect or not available; approximately 78% of those with a valid contact telephone number were included, and the refusal rate was about 10%). The sample size was reasonably large. Second, data were collected retrospectively. Most of the data were, however, collected from the participants within 1 month after onset of fever. Since contracting the disease is a major life event for the patient and family, they should be able to recall whether such factual and benchmark behaviors had been practiced.

The study also has strength of matching for age, sex, and reference time of the behaviors in question, so that both the case and control in a pair were referring to relevant behaviors that occurred within the same 10-day period before the date of onset of fever of the patient. Third, some questions, such as those about disinfection of households or visiting crowed places were nonspecific (the questions asked were "Whether your living quarter had been disinfected thoroughly" and "Whether you had visited crowded places"). Different participants might have defined the terms differently. Further, a number of patients were unable to answer the questions, and a household member who was "most familiar with the household situation" was invited to serve as a proxy. The responses obtained from these informants were compared to those obtained from the patients themselves, and no statistical

significance was obtained (p 0.199 to 0.854) to all variables, except for the variable about visiting the Amoy Gardens ($p < 0.05$).

One particular strength of the study in its evaluation of the three public health measures is that transmissions due to various known sources of infection had been removed as much as possible. In conclusion, the study shows that public health measures may have contributed substantially to the control of SARS epidemic in Hong Kong.

This study was solely funded by the Chinese University of Hong Kong.

Dr. Lau is the director of the Center for Epidemiology and Biostatistics of the School of Public Health of the Chinese University of Hong Kong. His research interests include community research on behavioral aspects of infectious disease, such as HIV prevention studies.

Risk Factors for SARS among Persons without Known Contact with SARS Patients, Beijing, China

Jiang Wu,* Fujie Xu,†‡[1] Weigong Zhou,†‡[1] Daniel R. Feikin,†‡[1] Chang-Ying Lin,* Xiong He,* Zonghan Zhu,§# Wannian Liang,§¶ Daniel P. Chin,† and Anne Schuchat†‡[1]

Most cases of severe acute respiratory syndrome (SARS) have occurred in close contacts of SARS patients. However, in Beijing, a large proportion of SARS cases occurred in persons without such contact. We conducted a case-control study in Beijing that compared exposures of 94 unlinked, probable SARS patients with those of 281 community-based controls matched for age group and sex. Case-patients were more likely than controls to have chronic medical conditions or to have visited fever clinics (clinics at which possible SARS patients were separated from other patients), eaten outside the home, or taken taxis frequently. The use of masks was strongly protective. Among 31 case-patients for whom convalescent-phase (>21 days) sera were available, 26% had immunoglobulin G to SARS-associated coronavirus. Our finding that clinical SARS was associated with visits to fever clinics supports Beijing's strategy of closing clinics with poor infection-control measures. Our finding that mask use lowered the risk for disease supports the community's use of this strategy.

Severe acute respiratory syndrome (SARS) is a new disease caused by a previously unrecognized coronavirus (1,2). Investigations of SARS outbreaks in several countries suggest that the primary mode of transmission is close contact with a symptomatic patient. Indeed, most cases of SARS have occurred among persons who cared for or lived with someone with the disease, and this fact is reflected in the SARS case definition developed by the World Health Organization and in definitions developed by individual countries (3–7).

The SARS epidemic in Beijing, during which a total of 2,521 probable cases were reported from March through June 2003, was notable for its magnitude (8). Another distinguishing feature was the relatively high proportion of probable case-patients with no reported close contact with other SARS patients. Although the outbreaks in Hong Kong and Toronto were also large, most case-patients had healthcare-related or household links to other SARS patients (4,9). Beijing's epidemic began with importations of SARS-associated coronavirus (SARS-CoV) in travelers returning from Guangdong Province and Hong Kong (8), and the first phase of the epidemic involved hospitalized patients, family members, and healthcare workers exposed to these travelers. During this period (March 8–April 3, 2003), almost all (96%) probable SARS patients reported close contact with a known SARS patient. However, during the peak of the epidemic (April 4–May 4), the percentage of probable SARS patients who reported no contact with another SARS patient and who were not healthcare workers rose to 42%; as the number of cases fell during the last part of the epidemic (May 5–June), this percentage increased to 65%. The reasons for these apparently unlinked SARS cases were unknown. Possible explanations included acquisition of disease from unrecognized sources in the community or healthcare setting, incomplete collection or recording of contact histories, and clinical illness that met the SARS case definition but was caused by etiologic agents other than SARS-CoV.

To evaluate these hypotheses, we conducted a matched case-control study during the Beijing outbreak among a sample of SARS patients who had no reported contact with other SARS patients.

Methods

Definitions

Probable Cases

Probable and suspected SARS cases were defined according to the China Ministry of Health's definitions,

*Beijing Center for Disease Prevention and Control, Beijing, China; †World Health Organization–China Office, Beijing, China; ‡Centers for Disease Control and Prevention, Atlanta, Georgia, USA; §Beijing Municipal Health Bureau, Beijing, China; and ¶Beijing Joint SARS Expert Group, Beijing, China

[1]These authors served as temporary advisors to the World Health Organization–China Office SARS team.

which included clinical and epidemiologic components. The epidemiologic criteria changed during the course of the outbreak. Before April 3, 2003, only patients who had close contact with a known SARS patient or who had infected other persons could be diagnosed with SARS. From April 4 to May 3, the epidemiologic criteria were expanded to include persons with a history of visiting or residing in cities or areas where local transmission of SARS was occurring or with a history of contact with an outbreak or a healthcare facility. After May 3, Beijing was regarded as having local transmission of SARS, and visiting or residing in Beijing was considered sufficient to meet the epidemiologic criteria of the case definition. Laboratory testing for SARS-CoV was not part of the case definition.

Close Contacts

Close contacts of SARS patients were defined as persons who shared meals, utensils, a residence, a hospital room, or a transportation vehicle with a suspected SARS patient or as persons who visited such a patient in a period beginning up to 14 days before the patient's onset of symptoms. In addition, persons with potential contact with the bodily secretions of a SARS patient during the patient's treatment or care were considered close contacts.

Study Design

A matched case-control study design was used. Case-patients and controls were matched by sex and age group (≤17, 18–25, 26–45, 46–64, and ≥65 years). The goal was to enroll 100 case-patients matched with three controls each, which, if one assumes an α of 0.05 and 80% power, would allow detection of an odds ratio of >2.3 for exposures observed in 15% of controls. For the analysis, we excluded all controls <14 years of age because of potential biases in comparing them with matched case-patients aged 14–17 years. In addition, case-patients who were reclassified as healthcare workers after interview were excluded along with their matched controls.

Case-patients were eligible for the study if they met the probable case definition and reported no close contact with any known probable or suspected SARS patients. Only patients whose hospitalization occurred after April 28, 2003, were included in the study. A list of patients admitted to the 16 designated SARS hospitals in Beijing was obtained periodically, and we called patients at the hospital ward or their homes (after discharge) to invite them to participate. The latest date of hospitalization included in our study was June 9, 2003. Case interviews were completed June 3–16.

We selected controls by sequential digit dialing, using the case-patient's home telephone number as the index number. The last digit was added to or subtracted from by one digit in an alternating sequence until three controls matched by sex and age group were enrolled. Telephone prefixes are geographically clustered in Beijing, so this strategy was intended to provide neighborhood matching. Only one control was selected for each number dialed. Control interviews were completed by July 4.

Data Collection

Data from case-patients were collected in person or by telephone, by using a standardized questionnaire. Information was collected on potential risk factors for, or exposures to, SARS-CoV infection (such as having a chronic disease or visiting a healthcare facility), personal hygiene (such as washing hands), and the use of masks. The period of inquiry was the 2 weeks before the patient's onset of symptoms. For case-patients who reported visiting hospitals during the period of interest, a supplemental questionnaire was developed to collect detailed information on reasons for the visits and the hospitals and departments visited. Controls were interviewed by telephone and were queried about a reference period corresponding to the same 2-week period as the matched case.

Trained staff from the Beijing Center for Disease Prevention and Control interviewed all case-patients and approximately half of the controls. To accelerate enrollment, we used a commercial contractor to interview the remaining controls; the contractor received interviewer training by study staff before beginning the interviews. For quality control purposes, 10% of the contractor-interviewed controls were interviewed twice.

Laboratory Tests

Case-patients were asked to come to Beijing Center for Disease Prevention and Control so that a 5-mL blood specimen could be obtained. Blood samples were centrifuged, and serum samples were refrigerated at 4°C. Sera were tested at the Beijing Center for Disease Prevention and Control for immunoglobulin (Ig) G antibody to SARS-CoV, by using an enzyme-linked immunosorbent assay kit (Beijing Huada GBI Biotechnology Co. Ltd., Beijing). All serum samples were obtained ≥21 days after illness onset, and 80% of them were obtained 76–106 days after onset of symptoms.

Statistical Analyses

Matched univariate and multivariate analyses were conducted by conditional logistic regression. The PHREG procedure in SAS version 8 (SAS, Cary, NC) was used, with case status as the dependent variable. Factors associated with p values of <0.15 on univariate analysis were included in multivariable models. Collinearity and pairwise interactions were evaluated for all variables in the final model.

Results

A total of 373 patients were called from the master list until 100 were interviewed. Among patients who could be reached, the refusal rate was approximately 50%. The most frequent reasons for refusal were "tired of being interviewed" and being reluctant to disclose any personal information for fear of stigma and discrimination. Patients who agreed to participate in the study were similar in terms of age, sex, and temperature (on clinic presentation) to all probable SARS case-patients without a history of contact with another SARS patient (n = 1,091). Seven controls were excluded because they were <14 years of age, which resulted in the elimination of two matched sets. Four matched sets were also excluded because the case-patient was subsequently reclassified as a healthcare worker. A total of 94 case-patients and 281 matched controls were included in the final analyses.

Male patients accounted for 50% of case-patients. The median age was 29 years (range 14–84) for case-patients and 31 years (range 14–82) for controls. In univariate analyses, several health-related risk factors were significantly associated with an increased risk for clinically diagnosed SARS, including having visited any fever clinic (clinics established to separate patients who might have SARS from other persons being evaluated in emergency rooms or outpatient clinics) or any hospital or having a preexisting chronic disease, such as diabetes (Table 1). Eating out more than once a week and using several types of transportation, including taking a taxi or bus at least once a week, were associated with SARS (Table 1). Having visited a farmer's market, wearing a mask when going out, and washing hands when returning home were protective factors. Factors that were not associated with SARS included visiting a school or university, participating in large social gatherings outside the home, having mice or cockroaches in the home, and having stayed home from work or school. No case-patients or controls reported having traveled to SARS-affected areas, such as Guangdong, Hong Kong, or Toronto.

Factors associated with SARS in multivariable analysis are presented in Table 2. After other factors were controlled for, visiting a fever clinic and having a chronic medical condition remained significantly associated with a risk for SARS. After other variables were adjusted for, having visited a hospital was not associated with acquiring SARS. Other factors associated with an increased risk for SARS were eating outside the home and taking taxis more than once a week. Always wearing a mask when going out was associated with a 70% reduction in risk compared with never wearing a mask. Wearing a mask intermittently was associated with a smaller yet significant reduction in risk. Going to the farmer's market and owning a pet were both protective factors.

As of August 28, 2003, a total of 31 blood specimens had been tested for IgG to SARS-CoV, and 8 (26%) were positive. Of the eight seropositive case-patients, three had not visited a hospital or fever clinic in the 2 weeks before becoming ill.

Discussion

SARS-CoV transmission is now understood to involve close contact of symptomatic patients with others. Surveillance and case management in most parts of the world have focused on patients with clinically compatible illness who had had exposure to another SARS patient or had traveled to an affected area. Once SARS was recognized as widespread in Beijing hospitals, respiratory illness in any Beijing resident raised suspicion of SARS, and health authorities urged a low threshold for consideration of SARS to institute patient isolation, case reporting, and contact tracing. In the Beijing outbreak, the large number of patients who were diagnosed with probable SARS without a contact history led to concerns that overdiagnosis was occurring or, alternatively, that unrecognized sources of transmission existed in the community. Our study suggests that both factors were involved.

Thirty percent of case-patients in this study had a history of visiting a hospital in the 2 weeks before onset of SARS. By univariate analysis, persons with SARS were more than three times as likely as age- and sex-matched controls to have visited hospitals. After other factors, including the presence of chronic medical conditions, were controlled for, visiting a hospital was not independently associated with a higher risk for clinical SARS. The frequency of a history of hospital exposure among our case-patients was consistent with the epidemiology of SARS observed in other major outbreaks, where hospitals served as important amplifiers of transmission. Instituting effective infection-control measures in healthcare settings is the most critical step in controlling the spread of SARS.

Fever clinics were established in Beijing for triage of patients who might have SARS to separate them from other persons being evaluated in emergency rooms or outpatient clinics. Our study found that visiting a fever clinic was a very strong risk factor for SARS. Through a follow-up questionnaire administered to patients who reported having visited hospitals or clinics, we attempted to ensure that the reported visits were for reasons other than the first symptoms of the SARS illness. Our finding that visiting fever clinics increased the risk for probable SARS infection confirms the suspicions of public health authorities that, early in the epidemic response, some fever clinics had not implemented appropriate isolation and triage procedures and supports the public health decision to close dozens of problematic fever clinics and enhance infection-control measures at the 66 clinics that remained open.

Table 1. Selected potential risk and protective factors among cases and matched controls during the 2 weeks before the case-patient's onset of SARS-related symptoms, Beijing, 2003[a]

Potential risk or protective factor for SARS	% of cases with factor N=94	% of controls with factor N = 281	Matched OR (95% CI)[b]	p value

[d]Includes diabetes, cancer, immunosuppressive treatment, and other.
[e]A gathering of ≥10 persons for a party or other social event.
[f]Pets reported by case-patients included dogs (3 cases), cats (3 cases), fish (1 case), and pigeons (1 case).

In this investigation, persons with chronic medical conditions also had a significantly higher risk of clinical SARS developing. A disproportionate occurrence of the disease in persons who are elderly or who have a chronic disease was noted in other SARS outbreaks, but whether these factors were just markers for persons likely to have nosocomial exposure to other SARS patients was unclear. Our study found that the SARS risk associated with chronic disease was independent of recent exposure to healthcare facilities and suggests that, as is the case for other types of pneumonia (10,11), persons with chronic medical conditions are more vulnerable to clinically defined SARS. We had insufficient numbers of laboratory-confirmed cases to verify that this finding was specific for SARS-CoV infection.

Because a considerable proportion of SARS cases were reported in persons without a history of contact with another SARS patient and without exposure to healthcare facilities, we sought to identify unrecognized sources of community transmission that might help target control strategies and clarify whether widespread community transmission was indeed occurring. We found that certain

[b]Fever clinics were established for triage of patients who might have SARS to separate them from other persons being evaluated in emergency rooms or outpatient clinics.

community exposures were significantly more common among case-patients than controls, including eating out or taking taxis frequently. By univariate analysis, use of other common transport (e.g., buses, subways) was also associated with a risk for SARS. At least one well-publicized case of SARS in Beijing occurred in a taxi driver (12), but an increased risk among passengers had not previously been documented. Our findings regarding use of transportation bordered on statistical significance and will require validation by other studies.

We also used this investigation to quantify the impact of behaviors (i.e., mask wearing, handwashing) that were promoted to reduce the risk for SARS. Wearing masks outside the home in a reference period corresponding to the 2 weeks before symptom onset for cases was significantly protective against clinical SARS. Supporting the validity of this finding, there was a dose-response effect: by multivariable analysis, persons who always wore masks had a 70% lower risk of being diagnosed with clinical SARS compared with those who never wore masks, and persons with intermittent mask use had a 60% lower risk. Many persons who wore masks in the community did not use N-95 or similar highly efficient filtration devices, which have been recommended for use in the hospital setting. We sought details on the type of masks used but were unable to evaluate the protective efficacy for different mask types. We also were not able to differentiate protective efficacy for SARS-CoV versus efficacy against other pneumonia causes that met the clinical case definition.

Handwashing has been recommended to prevent SARS and other respiratory and diarrheal infections in which contact is an important mode of transmission. We found that consistently washing hands upon returning home was associated with a reduced risk for clinical SARS by univariate but not multivariate analysis. However, self-reported handwashing practices may be particularly prone to misclassification because respondents might provide the answer they believe is expected of them.

We also explored the role of domestic animals in relation to SARS infection among persons without contact with another SARS patient. An animal source for the origin of SARS-CoV in humans is suspected (13), and, using polymerase chain reaction, investigators identified SARS-CoV in household pets and cockroaches at the Amoy Gardens apartments in Hong Kong (14). Thus, we wondered whether certain household pets or rodents might be perpetuating disease-transmission cycles. One investigator recently hypothesized that a rodent vector may have amplified transmission of SARS at Amoy Gardens (15). In addition, rumors circulating during the Beijing SARS outbreak led to some calls for banning household pets or restricting them from common areas. We sought evidence to address this community fear and found that household rodents and cockroaches were not associated with a risk for clinical SARS. We also found that persons with pets had a significantly lower risk for clinical SARS. This finding might have occurred by chance or may be confounded by another factor more directly related to pneumonia. However, controls with pets might possibly have had exposure to other animal coronaviruses that provided cross-reacting antibody to the SARS-CoV. Of note, other investigators found IgG to SARS-CoV was common among animal traders in Guangdong (16), yet disease did not occur in this population, a finding consistent with the hypothesis that cross-reacting antibodies to a closely related virus may have protected these workers.

Another unexpected finding was that visiting a farmer's market was associated with a reduced risk for clinical SARS. Nevertheless, concern that farmers represented travelers from other provinces and that markets were crowded settings prompted us to ask about this exposure as a possible risk factor. Accounting for an association with lower risk is challenging. As with ownership of pets, this finding may relate to unmeasured lifestyle factors more directly related to pneumonia risk.

Among authorities in Beijing, a leading hypothesis for the occurrence of clinical SARS among patients without known contact with another SARS patient was that overdiagnosis was occurring. We sought to determine the proportion of case-patients in this study who could be confirmed by convalescent-phase serologic tests to be infected with SARS-CoV; however, we obtained serum samples

from an insufficient number of case-patients to analyze risk factors for laboratory-confirmed cases. Serologic testing for SARS may not be 100% sensitive, and the Huada test kit has had limited validation thus far. Nevertheless, a substantial portion of case-patients without contact with other SARS patients likely had pneumonia caused by pathogens other than SARS-CoV.

Certain limitations to this study should be mentioned. First, the study was conducted late in the Beijing epidemic, after patients had been hospitalized for several weeks, and the low participation rate might be attributable to patients having already been interviewed multiple times. Furthermore, recall bias might have influenced some of the factors we explored. Telephone-based public health studies were relatively new to Beijing, and the representativeness of our control population is not known. Because the rate of study participation by case-patients was not high, those who agreed to participate may have self-selected for unknown reasons that could have biased our findings. For instance, several patients responding to the open-ended comment section mentioned that they were certain their illness was "not SARS." Relatively few patients agreed to convalescent-phase serologic testing, and those who did agree may have been more skeptical about the cause of their pneumonia than were others, which may have skewed the sample for which we have serologic results.

In conclusion, we identified several explanations for the occurrence of clinically defined SARS in persons without contact with another SARS patient during Beijing's 2003 SARS epidemic. The nonspecific clinical definition for SARS led to reporting of many cases that were not confirmed to be caused by SARS-CoV. This apparent overdiagnosis probably helped ensure rapid control of the outbreak by introducing a wide net for contact tracing and patient isolation. Increased risk for clinically defined SARS was associated with attending fever clinics, having a chronic disease, and having certain community exposures. Consistent mask use lowered the risk for disease, thus providing some justification for the use of a strategy that was very popular in the general community. Our finding that pet owners had a lower risk for clinical SARS can help dispel fears that domestic pets were causing disease transmission in Beijing. Improved laboratory diagnostic tests (i.e., tests with high sensitivity early in the illness and with rapid turnaround) may eventually allow for more specific case reporting and management. Although human-to-human transmission of SARS has apparently been interrupted as of this writing, the factors associated with clinically defined SARS in this study may help target future efforts to control other respiratory infections, including pandemic influenza, and will provide valuable evidence for the control of SARS should the disease return.

Acknowledgments

We are grateful to the district and Beijing Center for Disease Prevention and Control staff who interviewed participants and collected serum specimens; Jiyong Guo, Ming-Yan Jia, Henk Bekedam, and Zhi-Jie Zheng for facilitating technical support; Elizabeth Zell for statistical advice; and Keiji Fukuda and Philippe Barboza for laying the groundwork for this investigation.

Financial support for this work was provided by the World Health Organization—China Office and Beijing Municipal Health Bureau. The U.S. Centers for Disease Control and Prevention provided financial support for the participation of their staff as technical consultants.

Dr. Wu is an epidemiologist with the Beijing Center for Disease Prevention and Control. His interests include infectious disease surveillance.

Outbreak investigation

ABSTRACT

Background: Between January 24, 2020 and February 15, 2020, an outbreak of COVID-19 occurred among 335 passengers on a flight from Singapore to Hangzhou in China. This study aimed to investigate the source of the outbreak and assess the risk of transmission of COVID-19 during the flight.
Method: Using a standardized questionnaire, we collected information on the travelers' demographic characteristics and illness before, during, and after the flight. We also collected data on factors potentially associated with COVID-19 transmission during the flight.
Results: A total of 16 COVID-19 patients were diagnosed among all passengers; the overall attack rate was 4.8%. The attack rate among passengers who had departed from Wuhan was significantly higher than that among those who had departed from other places. One passenger without an epidemiological history of exposure before boarding developed COVID-19. During the flight, he was seated near four infected passengers from Wuhan for approximately an hour and did not wear his facemask correctly during the flight.
Conclusions: COVID-19 transmission may have occurred during the flight. However, the majority of the cases in the flight-associated outbreak could not be attributed to transmission on the flight but were associated with exposure to the virus in Wuhan or to infected members in a single tour group.

1. Introduction

In December 2019, a cluster of acute respiratory illness, now known as coronavirus disease 2019 (COVID-19), occurred in Wuhan, Hubei Province in China [1,2]. By March 22, 2020, a total of 81,093 COVID-19 cases had been confirmed in China, of which 50,005 cases were from Wuhan City [3]. The condition rapidly spread globally, and on March 11, 2020 the World Health Organization declared a COVID-19 pandemic [4]. Epidemiological investigation has shown that COVID-19 is caused by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), which can be transmitted from human to human. The two primary transmission routes of SARS-CoV-2 are by contact (direct and indirect contact) or droplets, but the possibility of air-borne infection could not be totally excluded [5,6].

Air travel for leisure and business purposes has risen markedly in recent years due to economic growth and increased globalization [7,8]. Although infrequently reported and difficult to assess accurately, respiratory agents may be easily transmitted to passengers during air travel owing to limited ventilation, high occupant density and a long exposure time [9,10]. Multiple outbreaks of respiratory diseases, such as severe acute respiratory syndrome (SARS), measles, tuberculosis, and influenza, associated with air travel have been reported [11–14]. Recent studies suggest that SARS-CoV-2 may be more transmissible than severe acute respiratory syndrome (SARS) coronavirus and Middle East respiratory syndrome (MERS) coronavirus [15]. However, there have not yet been any reports of probable transmission of SARS-CoV-2 during air

travel.

On January 24, 2020, a flight originating from Singapore, and bound for Hangzhou, in China, was strictly managed after landing because approximately 100 passengers aboard the flight had visited Wuhan. Following a quarantine inspection in the airport, several passengers had already developed fever or upper respiratory infection symptoms. They were confirmed to have SARS-CoV-2 infections on the early morning of January 25. As in closed/semiclosed settings, on flight transmission of COVID-19 is facilitated by direct person-to person contact or contact with contaminated surfaces. Consequently, all passengers were required to spend at least 14 days under medical observation. By the end of the medical observation period on February 8, 2020, a total of 16 passengers had been confirmed with SARS-CoV-2 infection.

Here we describe the investigation of the outbreak of COVID-19 among passengers on this flight. The objectives of the investigation were to identify possible sources of exposure, and to evaluate whether transmission occurred during the flight. Because there are no published reports of transmission of SARS-CoV-2 during air travel, our investigation provides preliminary evidence of the risk of SARS-CoV-2 transmission on aircraft.

2. Methods

2.1. Flight

The flight left from Singapore Changi Airport on 24 January 2020, and landed at Hangzhou Xiaoshan Airport in China a few hours later. The aircraft was a Boeing 787-9. The total seat occupancy on the flight was 89% (335/375). The aircraft was equipped with air handling systems.

The boarding time of the flight was 16:30 local time, and the time of departure and landing were 16:50 and 21:40, respectively. A total of 346 people took the flight, of whom 335 were passengers and 11 were crew members. All crew members were Singaporean. Based on the departure records, we divided the passengers into two groups: Group A comprised those who departed from Wuhan to Singapore on 19 January 2020; and Group B comprised those who did not depart from Wuhan and did not have a history of travel to Wuhan.

2.2. Epidemiological investigations

All passengers were interviewed face-to-face or by telephone using a standardized questionnaire. We collected information on traveler demographics, health conditions, and symptoms (including fever, dry cough, shivering, expectoration and headaches) before, during, and after the flight, mask-wearing status, seat location, and activity during the flight. All passengers were required to take their temperature before deplaning.

2.3. Case definition

Infected passengers were categorized as symptomatic and asymptomatic. According to the national guidelines, a confirmed case of symptomatic COVID-19 was defined as a passenger who had a SARS-CoV-2 infection confirmed by real-time reverse-transcription polymerase chain reaction (RT-PCR) testing of a throat swab sample, and had symptoms of typical upper respiratory tract infection (such as runny nose, sore throat and dry cough) [16]. Asymptomatic cases were diagnosed based on positive RT-PCR test results but without any COVID-19 symptoms. The date of the positive RT-PCR test result was used as the onset date for asymptomatic cases, which was in line with a national study [17].

2.4. Laboratory testing

Consistent with a previous national study, all samples were tested for SARS-CoV-2 by use of RT-PCR with the Chinese Centers for Disease Control and Prevention recommended kit in accordance with the protocol established by the World Health Organization [18]. The RT-PCR was conducted at the Zhejiang Provincial Center for Disease Control and Prevention.

2.5. Medical isolation and observation

Since there were a large number of passengers originating from Wuhan and two passengers presented with a fever and upper respiratory infection symptoms, all passengers were regarded as close contacts and required to follow medical isolation and observation protocols for at least 14 days after deplaning on January 24. On arrival of the flight in Hangzhou, after preliminary investigation, passengers in Group A were accommodated in Hotel A near the Hangzhou Xiaoshan international airport; and passengers in Group B were transferred to Hotel B in the center of Hangzhou City; passengers (regardless of their group) who already had symptoms after preliminary investigation were sent to the infectious hospital designated for treatment of COVID-19 in Hangzhou. Except for children staying with a parent, the other passengers lived singly for medical isolation and observation in Hotel A or Hotel B. During the medical isolation and observation period, all passengers were required to take their temperature twice daily and report their health condition if they developed symptoms of an upper respiratory tract infection. If passengers isolated in Hotel A or Hotel B developed illness, they were to be transferred to the designated hospital immediately.

All crew members were isolated in Hotel B. They returned to Singapore on January 26, 2020. According to a message from the diplomatic department of Zhejiang Province, none of these crew members were infected with SARS-CoV-2.

2.6. Ethical considerations

According to the law on public health response in China, formal ethical review and approval of this outbreak investigation was not required.

2.7. Statistical analysis

A descriptive analysis was performed using R (Version 3.6.2) statistical software. Categorical variables were presented as frequencies and percentages. Because our study focused on passengers, crew members were excluded when we calculated the attack rate or performed the analysis of risk infection. Characteristics associated with the risk of infection were compared and tested for statistical significance using the chi-square or Fisher's exact tests.

3. Results

A total of 16 infected passengers, including 10 symptomatic passengers and 6 asymptomatic passengers, were diagnosed between 24 January and 15 February 2020. The overall attack rate among the passengers was 4.8% (16/335).

3.1. Temporal distribution

All infected passengers left for Singapore on January 19, 2020 (Fig. 1). Of the 10 symptomatic passengers, 2 (Cases 1 and 7) had developed symptoms before boarding and one (Case 2) developed symptoms on 24 January after the flight had landed in Hangzhou (Table 1). During the medical isolation and observation period, two passengers (Cases 5 and 6) developed symptoms on January 26 and 27 respectively. Six asymptomatic cases (Case 3 and Cases 11–15) were diagnosed on January 26 when all passengers were sampled and tested for the first time. On February 2, one week after the landing of flight, another two passengers (Cases 10 and 16) developed fever. On 6

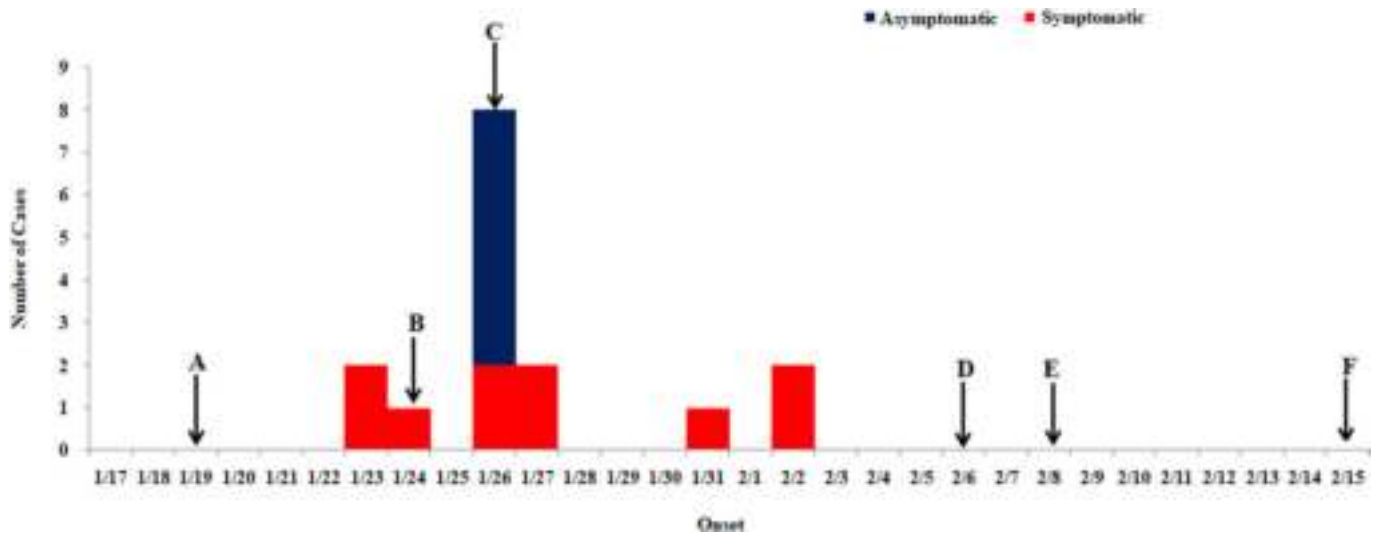

Fig. 1. Epidemic curve indicating the date of onset of COVID-19 cases among passengers on the flight, January to February 2020. (A): The case passengers flew from China to Singapore on 19 January (One passenger departed from Hangzhou; and the remaining 15 case passengers departed from Wuhan.). **(B):** The flight departed from Singapore to Hangzhou on 24 January and the passengers were placed in medical isolation and under observation on arrival in Hangzhou. **(C):** All passengers had samples collected for testing on 26 January. **(D):** All passengers had a second set of samples collected on 6 February. **(E)**: The passengers from places other than Wuhan ended their medical isolation on 8 February. **(F):** Those who departed from Wuhan ended their medical isolation one week later on 15 February.

16	44	M	Symptomatic	February 2	Hangzhou	D	Hangzhou	29B	None

F, female; M, male.
[a] Asymptomatic patients tested positive for SARS-CoV-2 using RT-PCR but did not have symptoms of COVID-19; Symptomatic cases tested positive for SARS-CoV-2 on RT-PCR and had symptoms of COVID-19 such as fever and dry cough.
[b] In the asymptomatic patients, the diagnosis date was used as the onset date.

February, we sampled and tested all passengers for the second time. However, no additional new cases were discovered during the second screening of all passengers. Moreover, no further cases were reported after 2 February. Passengers who had not departed from Wuhan ended their medical isolation and observation on February 8, and later, passengers who had departed from Wuhan ended their medical isolation and observation one week later, on 15 February (Fig. 1).

3.2. Seating

Fig. 2 shows seating locations on the airplane for all passengers. Two seating areas had a relatively high concentration of cases: six of the case passengers sat in Rows 11 and 12 and five case passengers sat in Rows 29 to 31. The remaining case passengers were scattered in the Row 6, Row 16, Row 18 and Row 44 (Fig. 2).

Case 16 originally sat in Seat 29B. There were no infected passengers in the first three rows close to Seat 29B; only one passenger who had departed from Wuhan was sitting in the aforementioned location. There was a wide aisle behind Seat 29B, where the toilet was located. However, during flight, Case 16 moved to Seat 30F and sat there for an hour. In the seats around Seat 30F, there were four infected passengers, with Case 11 and Case 12 sitting on the left side of him, and Case 7 and Case 8 sitting behind him on the right (Fig. 2).

3.3. Characteristics of the case passengers

Among the 16 cases, the median age was 37 years (range: 26–52 years). Six cases were female. The 16 cases belonged to four tour groups, with 12 cases in Tour Group A (TGA); one case in Tour Group B (TGB); two cases in Tour Group C (TGC); and one case in tour group D (TGD). Some cases were among passengers who were in a relationship with another case, e.g. Cases 2 and 3 were a couple (Table 1).

There were 15 tour members in TGA, of whom 12 were confirmed SARS-CoV-2 infection, an attack rate of 80%. All the cases in TGA, TGB

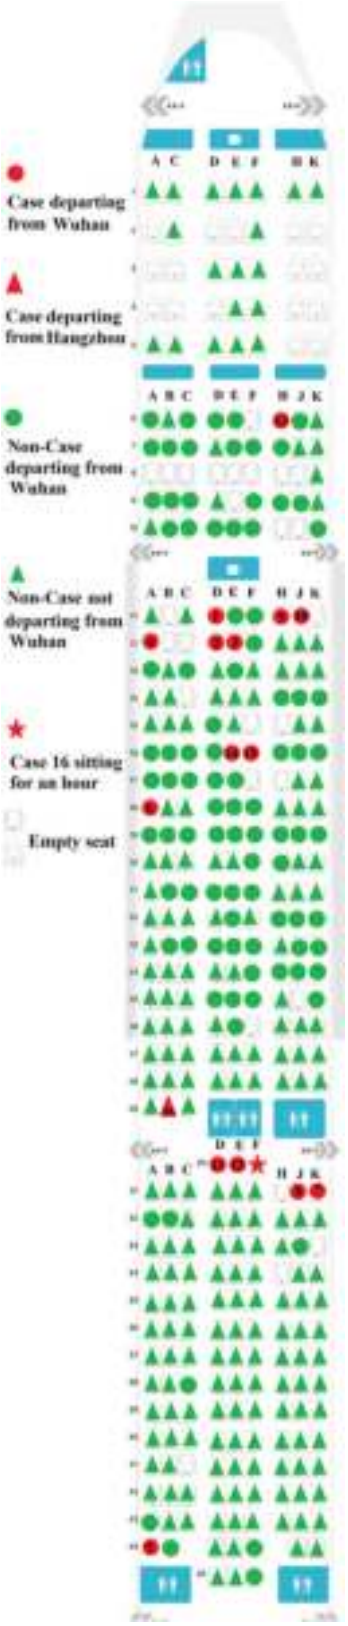

Fig. 2. Aircraft configuration and the location of the seats where the 16 case passengers sat during the flight. The numbers in the red background correspond to the Case number shown in Table 1. (For interpretation of the references to colour in this figure legend, the reader is referred to the Web version of this article.)

and TGC departed from Wuhan. In contrast, Case 16, who was a member of TGD, lived in Hangzhou, and departed from Hangzhou. The detailed information of all cases is listed in Table 1.

Table 2 summarizes the attack rates according to city of departure, age, and sex. The attack rate of passengers who departed from Wuhan was 13.8%, compared to 0.4% in passengers who did not depart from Wuhan ($p < 0.001$). The attack rate did not differ significantly by sex but was significantly higher among passengers aged 20–29 years, and 40–59 years, than in those aged<20 years and ≥60 years.

3.4. Exposure

According to the travel schedule, although TGA, TGB, and TGC all traveled to Singapore, there was no contact between the different groups before boarding the returning flight. All cases wore masks most of time and none of the cases visited a hospital or had contact with suspected or confirmed COVID-19 case during their travel.

Case 16 departed from Hangzhou to Singapore on 19 January 2020. None of the travelers in his tour group had visited Wuhan. Case 16 reported that he had not visited a hospital and had no contact with individuals suspected of having or confirmed with having COVID-19 before boarding the plane. Moreover, he stated he wore a mask while traveling in Singapore.

During air travel, all 16 case passengers wore masks. However, they removed their masks when they ate dinner or drank water provided during the flight. During the flight, Case 16 sat in Seat 30F for about an hour and talked to his wife and son in Seats 31E and 31F, respectively. While he talked, he reported that he did not wear his mask tightly, and his nose was outside of mask.

4. Discussion

We have described an outbreak of COVID-19 that affected 16 passengers who traveled on the same flight. The primary objective of our investigation was to determine possible sources of the outbreak and whether the transmission was occurred in the aircraft. We identified only one case (Case 16) who appears to have become infected during flight. The sources of infection in the remaining 15 passengers were complex and the passengers could have acquired their infections in Wuhan before their tour, or during the group tour before boarding.

Two cases (Cases 1 and 7) were infected before taking the flight because they were symptomatic before taking the flight. Previous research had suggested the SARS-CoV-2 is transmissible during the incubation period [19]. The high attack rate among the members of TGA indicates that SARS-CoV-2 infections occurred within TGA, which was the result of close exposure during their tour. Moreover, although TGA members drop off the mask during meals on the flight, they had donned a mask in most of other time. Considering that the median incubation period was 4 days (interquartile range: 2–7 days) [18], we hypothesize that the remaining 10 cases in TGA were probably infected before taking

Table 2
Attack rate according to characteristics of passengers involved in a flight-associated outbreak of COVID-19 in January–February 2020.

Characteristics	Total N = 335	Number of cases N = 16	Attack rate (%)	*P*
Departure city				<0.001
Wuhan	109	15	13.76	
Not Wuhan	226	1	0.44	
Sex				0.565
Male	149	6	4.03	
Female	186	10	5.38	
Age (years)				0.010
<20	69	0	0.00	
20–39	182	9	4.95	
40–59	71	7	9.86	
≥60	13	0	0.00	

the flight, rather than of during the flight. However, it was not possible to determine whether they had become infected in Wuhan, or during travel.

Case 13 in TGB and Cases 14 and 15 in TGC were asymptomatic and were diagnosed in the January 26 when we collected samples from passengers and tested them for the first time. Although they had left Wuhan on January 19, 2020, other studies have shown that transmission of SARS-CoV-2 in Wuhan on that day became widespread prior to their departure [17,20]. They also wore masks during air travel. Therefore, we believe they are most likely to have been infected in Wuhan, and not during flight.

With regard to Case 16, he did not have a history of exposure to Wuhan, or any suspected or confirmed cases of COVID-19 before boarding the flight in Singapore, and he wore a mask while traveling in Singapore. After boarding, he moved from seat 29B to 30F which was in the close proximity to the seats of Cases 7, 8, 11, and 12. Moreover, he talked to his wife (31E) and son (31F) with his mask loosened. After landing, he was immediately isolated and could not have any other source of exposure. The time from the flight landing to the onset of his symptoms fell within the accepted 1-to-14-day COVID-19 incubation period [16]. Therefore, he probably acquired SARS-CoV-2 infection during the flight. Our investigation further corroborated the probable transmission of SARS-CoV-2 on the flight recently reported by Eldin et al. [21].

Previous studies suggest that the basic reproductive number of COVID-19 ranges between 1.5 and 6.5. COVID-19 seems to be more transmissible than SARS and MERS [15]. However, in the present flight outbreak of COVID-19, the relative low number of the secondary cases that occurred due to transmission during the flight may be attributed to the wearing of masks, which have been shown to be effective in blocking the transmission of respiratory diseases at mass gatherings [22]. The low rate of transmission during the flight may also be attributed to the design of and equipment in the aircraft. The air recirculation system, with the highly efficient particulate filter equipment and laminar nature of airflow, may have effectively prevented or restricted the transmission of the virus [7,9]. In addition, after landing, all passengers were sent to designated places for medical isolation and observation. The strict management of all passengers further contributed to avoiding a larger travel-associated outbreak of COVID-19.

The atypical symptom onset of COVID-19 and the transmissibility of SARS-CoV-2 during incubation period make the prevention of SARS-CoV-2 transmission on aircraft challenging. Passengers are in close contact with one another in a confined space for hours during air travel. Numerous high-contact surfaces, such as armrests, tray tables, and seat controls, may serve as potential SARS-CoV-2 fomites [23]. Given these potential risks and those demonstrated by our investigation, development of appropriate prevention and control measures must take this into consideration. We suggest the key stakeholders should standardize aircraft disinfection protocols, train cabin crew for public health emergencies, implement technological solutions to reduce passenger contact with potentially contaminated surfaces, educate the general public to wear their masks closely and to wash their hands frequently. Fast reliable testing methods for detection of SARS-CoV-2 also need to be developed, to enable early diagnosis and to prevent infected passengers from boarding.

Our investigation had several limitations. Firstly, we collected exposure information by interview and telephone, and recall bias cannot be excluded. Moreover, we were unable to get a detailed and accurate trajectory of each case before boarding. Therefore, we cannot rule out the possibility that inapparent transmission between Case 16 and the other cases occurred in the shops, toilets, or airport lounge before boarding. Secondly, we did not perform virus isolation and genome sequencing of the virus, which could have provided evidence of whether viral transmission occurred during the flight. Thirdly, we did not perform surface swabs or take air samples in the aircraft cabin, and so do not have direct evidence of transmission occurring during the flight.

In conclusion, a flight-related outbreak of COVID-19 was investigated. The temporal, spatial, and exposure evidence suggests that SARS-CoV-2 transmission may have occurred during the flight. However, the majority of 16 cases in the outbreak were not attributed to transmission on the flight. Exposure to the virus in Wuhan or by infected members within the same tour group account for most cases in the outbreak. Our investigation suggests that it is important to take measures such as wearing a mask, temperature screening, and quarantine of close contacts to reduce the transmission of SARS-CoV-2 before, during, and after flights.

Funding

This work was financially supported by grants from Zhejiang province (Zhejiang Scientific and Technological Major Project) under the 2020 Emergency (Grant No. 2020C03124), Zhejiang University special scientific research fund for COVID-19 prevention and control (Grant No. 2020XGZX047) and Technology Project of Hangzhou Municipality (Grant No. 20202013A02).

Lack of COVID-19 transmission on an international flight

In response to the *CMAJ* news article, "Communication, transparency key as Canada faces new coronavirus threat,"[1] we would like to share the public health response to the first Canadian cases of coronavirus disease 2019 (COVID-19). Case details have been published.[2] The patients travelled from Wuhan to Guangzhou, then Guangzhou to Toronto, Canada, arriving on Jan. 22, 2020. The index patient was symptomatic with dry cough during the flight. His wife developed cough on Jan. 23. Both sets of throat and nasopharyngeal swabs collected were positive for COVID-19.

There were approximately 350 passengers on board the airplane. The public was notified through the media that the index case was symptomatic during the 15-hour flight. Close contacts included 25 individuals sitting within 2 m of the index case during the flight, flight crew members, and 1 close contact on arrival in Toronto. Close contacts received active daily contact monitoring by local public health officials for 14 days from the flight's arrival in Toronto. Passengers and crew members who were not from Ontario were referred to their home jurisdictions for follow-up. On Jan. 29, 1 close contact developed symptoms of cough; however, nasopharyngeal and throat swabs were negative for COVID-19. Non-close-contact passengers were advised to self-monitor and contact public health if they became symptomatic; 5 of these passengers became symptomatic, were tested and found by nasopharyngeal and throat swabs to be negative for COVID-19.

The United States Centers for Disease Control and Prevention recommend contact tracing 2 rows in front and behind symptomatic cases with respiratory infections owing to an elevated risk within close contact.[3] However, for both severe acute respiratory syndrome–associated coronavirus (SARS-CoV) and influenza, approximately 50% of airplane transmission occurred beyond these rows.[4]

Studies of airplane transmission are commonly biased by contacts sharing exposure risks before boarding the aircraft.[5] In our investigation, transmission may have been mitigated by mild symptoms and masking during the flight. However, the lack of secondary cases after prolonged air travel exposure supports droplet transmission, not airborne, as the likely route of spread of the COVID-19.

Absence of Apparent Transmission of SARS-CoV-2 from Two Stylists After Exposure at a Hair Salon with a Universal Face Covering Policy — Springfield, Missouri, May 2020

M. Joshua Hendrix, MD[1]; Charles Walde, MD[2]; Kendra Findley, MS[3]; Robin Trotman, DO[4]

On July 14, 2020, this report was posted as an MMWR *Early Release on the* MMWR *website (https://www.cdc.gov/mmwr).*

On May 12, 2020 (day 0), a hair stylist at salon A in Springfield, Missouri (stylist A), developed respiratory symptoms and continued working with clients until day 8, when the stylist received a positive test result for SARS-CoV-2, the virus that causes coronavirus disease 2019 (COVID-19). A second hair stylist (stylist B), who had been exposed to stylist A, developed respiratory symptoms on May 15, 2020 (day 3), and worked with clients at salon A until day 8 before seeking testing for SARS-CoV-2, which returned a positive result on day 10. A total of 139 clients were directly serviced by stylists A and B from the time they developed symptoms until they took leave from work. Stylists A and B and the 139 clients followed the City of Springfield ordinance* and salon A policy recommending the use of face coverings (i.e., surgical masks, N95 respirators,† or cloth face coverings) for both stylists and clients during their interactions. Other stylists at salon A who worked closely with stylists A and B were identified, quarantined, and monitored daily for 14 days after their last exposure to stylists A or B. None of these stylists reported COVID-19 symptoms. After stylist B received a positive test result on day 10, salon A closed for 3 days to disinfect frequently touched and contaminated areas. After public health contact tracings and 2 weeks of follow-up, no COVID-19 symptoms were identified among the 139 exposed clients or their secondary contacts. The citywide ordinance and company policy might have played a role in preventing spread of SARS-CoV-2 during these exposures. These findings support the role of source control in preventing transmission and can inform the development of public health policy during the COVID-19 pandemic. As stay-at-home orders are lifted, professional and social interactions in the community will present more opportunities for spread of SARS-CoV-2. Broader implementation of masking policies could mitigate the spread of infection in the general population.

Stylist A worked from day 0 to day 8 with COVID-19 symptoms before receiving a diagnosis of COVID-19 by polymerase chain reaction (PCR) testing. Although self-isolation was recommended after testing on day 6, stylist A continued to work until the test returned a positive result, at which time stylist A was excluded from work by salon A. On day 3, after working with stylist A, stylist B developed respiratory symptoms. During Stylist A's symptomatic period, the two stylists interacted while neither was masked during intervals between clients. Stylist B worked from day 3 to day 8 while symptomatic before self-isolating and seeking PCR testing, which returned a positive result for SARS-CoV-2 on day 10. Stylist A worked with clients for 8 days while symptomatic, as did stylist B for 5 days. During all interactions with clients at salon A, stylist A wore a double-layered cotton face covering, and stylist B wore a double-layered cotton face covering or a surgical mask.

The Greene County Health Department (Missouri) conducted contact tracing for all 139 exposed clients back to the dates that stylists A and B first developed symptoms. The 139 clients were monitored after their last exposure at salon A. Clients were asked to self-quarantine for 14 days and were called or sent daily text messages to inquire about any symptoms; none reported signs or symptoms of COVID-19. Testing was offered to all clients 5 days after exposure, or as soon as possible for those exposed >5 days before contact tracing began. Overall, 67 (48.2%) clients volunteered to be tested, and 72 (51.8%) refused; all 67 nasopharyngeal swab specimens tested negative for SARS-CoV-2 by PCR. Telephone interviews were attempted 1 month after initial contact tracings to collect supplementary information. Among the 139 exposed clients, the Greene County Health Department interviewed 104 (74.8%) persons.

Among the 139 clients, the mean age was 52 years (range = 21–93 years); 79 clients (56.8%) were male (Table 1). Salon appointments ranged from 15 to 45 minutes in length (median = 15 minutes; mean = 19.5 minutes). Among the 104 interviewed clients, 102 (98.1%) reported wearing face coverings for their entire appointment, and two (1.9%) reported wearing face coverings part of the time (Table 2). Types of face covering used by clients varied; 49 (47.1%) wore cloth face coverings, 48 (46.1%) wore surgical masks, five (4.8%) wore N95 respirators, and two (1.9%) did not know what kind of face covering they wore. Overall, 101 (97.1%) interviewed clients reported that their stylist wore a face covering for the entire appointment; three did not know. When asked about the type of face coverings worn by the stylists, 64 (61.5%) reported that their stylist wore a cloth face covering (39; 37.5%) or surgical mask

* Springfield, Missouri, city ordinance went into effect May 6, 2020, restricted seating in waiting areas to 25% of normal capacity and recommended social distancing and use of face coverings for employees and clients when social distancing was not or could not be followed. https://www.springfieldmo.gov/5140/Masks-and-Face-Coverings.

† Particulate-filtering facepiece respirators that filter ≥95% of airborne particles (https://www.cdc.gov/niosh/npptl/topics/respirators/disp_part/n95list1.html).

Summary

What is already known about this topic?

Consistent and correct use of cloth face coverings is recommended to reduce the spread of SARS-CoV-2.

What is added by this report?

Among 139 clients exposed to two symptomatic hair stylists with confirmed COVID-19 while both the stylists and the clients wore face masks, no symptomatic secondary cases were reported; among 67 clients tested for SARS-CoV-2, all test results were negative. Adherence to the community's and company's face-covering policy likely mitigated spread of SARS-CoV-2.

What are the implications for public health practice?

As stay-at-home orders are lifted, professional and social interactions in the community will present more opportunities for spread of SARS-CoV-2. Broader implementation of face covering policies could mitigate the spread of infection in the general population.

(25; 24.0%); 40 (38.5%) clients did not know or remember the type of face covering worn by stylists. When asked whether they had experienced respiratory symptoms in the 90 days preceding their appointment, 87 (83.7%) clients reported that they had not. Of those who did report previous symptoms, none reported testing for or diagnosis of COVID-19.

Six close contacts of stylists A and B outside of salon A were identified: four of stylist A and two of stylist B. All four of stylist A's contacts later developed symptoms and had positive PCR test results for SARS-CoV-2. These contacts were stylist A's cohabitating husband and her daughter, son-in-law, and their roommate, all of whom lived together in another household. None of stylist B's contacts became symptomatic.

Discussion

SARS-CoV-2 is spread mainly between persons in close proximity to one another (i.e., within 6 feet), and the more closely a person interacts with an infected person and the longer the interaction, the higher the risk for transmission (*1*). At salon A in Springfield, Missouri, two stylists with COVID-19 symptoms worked closely with 139 clients before receiving diagnoses of COVID-19, and none of their clients developed COVID-19 symptoms. Both stylists A and B, and 98% of the interviewed clients followed posted company policy and the Springfield city ordinance requiring face coverings by employees and clients in businesses providing personal care services. The citywide ordinance reduced maximum building waiting area seating to 25% of normal capacity and recommended the use of face coverings at indoor and outdoor public places where physical distancing was not possible. Both company and city policies were likely important factors in preventing the spread of SARS-CoV-2 during these interactions between clients and stylists. These results support the use of face coverings in places open to the public, especially when social distancing is not possible, to reduce spread of SARS-CoV-2.

TABLE 1. Characteristics* of clients (N = 139) who visited hair salon A and were exposed to stylists A and B with COVID-19 —Springfield, Missouri, May 2020

Characteristic	Value
Demographic characteristic	
Male, no. (%)	79 (56.8)
Age, yrs. mean (range)	52 (21–93)
Encounter information	
Appointment date range	May 12–20 (days 0–8†)
Exposure to stylist A, no. (%)	84 (60.4)

† After onset of symptoms in stylist A.
§ Among those tested.

Although SARS-CoV-2 is spread largely through respiratory droplets when an ill person coughs or sneezes (*1*), data suggest that viral shedding starts during the 2-to-3-day period before symptom onset, when viral loads are at their highest (*2*). Although the rate of transmission of SARS-CoV-2 from presymptomatic patients (those who have not yet developed symptoms) and asymptomatic persons (those who do not develop symptoms) is unclear, these persons likely contribute to the spread of SARS-CoV-2 (*3*). With the potential for presymptomatic and asymptomatic transmission, widespread adoption of policies requiring face coverings in public settings should be considered to reduce the impact and magnitude of additional waves of COVID-19.

Previous studies show that both surgical masks and homemade cloth face coverings can reduce the aerosolization of virus into the air and onto surfaces (*4*,*5*). Although no studies have examined SARS-CoV-2 transmission directly, data from previous epidemics (*6*,*7*) support the use of universal face coverings as a policy to reduce the spread of SARS-CoV-2, as does observational data for COVID-19 in an analysis of 194 countries that found a negative association between duration of a face mask or respirator policy and per-capita coronavirus-related mortality; in countries that did not recommend face masks and respirators, the per-capita coronavirus-related mortality increased each week by 54.3% after the index case, compared with 8.0% in those countries with masking policies (CT Leffler, Virginia Commonwealth University, unpublished data, 2020).§ Similar outcomes have been observed for other respiratory virus outbreaks, including the 2002–04 outbreak of Severe Acute Respiratory Syndrome

(SARS) (*6*) and the 2007–08 influenza season (*7*). A systematic review on the efficacy of face coverings against respiratory viruses analyzed 19 randomized trials and concluded that use of face masks and respirators appeared to be protective in both health care and community settings (*8*).

The findings in this report are subject to at least four limitations. First, whereas the health department monitored all exposed clients for signs and symptoms of COVID-19, and no clients developed symptoms, only a subset was tested; thus, asymptomatic clients could have been missed. Similarly, with a viral incubation period of 2–14 days, any COVID-19 PCR tests obtained from clients too early in their course of infection could return false-negative results. To help mitigate this possibility, all exposed clients were offered testing on day 5 and were contacted daily to monitor for symptoms until day 14. Second, although the health department obtained supplementary data, no information was collected regarding underlying medical conditions or use of other personal protective measures, such as gloves and hand hygiene, which could have influenced risk for infection. Third, viral shedding is at its highest during the 2 to 3 days before symptom onset; any clients who interacted with the stylists before they became symptomatic were not recruited for contact tracing. Finally, the mode of interaction between stylist and client might have limited the potential for exposure to the virus. Services at salon A were limited to haircuts, facial hair trimmings, and perms. Most stylists cut hair while clients are facing away from them, which might have also limited transmission.

The results of this study can be used to inform public health policy during the COVID-19 pandemic. A policy mandating the use of face coverings was likely a contributing factor in preventing transmission of SARS-CoV-2 during the close-contact interactions between stylists and clients in salon A. Consistent and correct use of face coverings, when appropriate, is an important tool for minimizing spread of SARS-CoV-2 from presymptomatic, asymptomatic, and symptomatic persons. CDC recommends workplace policies regarding use of face coverings for employees and clients in addition to daily monitoring of signs and symptoms of employees, procedures for screening employees who arrive with or develop symptoms at work, and posted messages to inform and educate employees and clients (https://www.cdc.gov/coronavirus/2019-ncov/community/organizations/businesses-employers.html).

Physical distancing, face masks, and eye protection to prevent person-to-person transmission of SARS-CoV-2 and COVID-19: a systematic review and meta-analysis

*Derek K Chu, Elie A Akl, Stephanie Duda, Karla Solo, Sally Yaacoub, Holger J Schünemann, on behalf of the COVID-19 Systematic Urgent Review Group Effort (SURGE) study authors**

Summary

Background Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) causes COVID-19 and is spread person-to-person through close contact. We aimed to investigate the effects of physical distance, face masks, and eye protection on virus transmission in health-care and non-health-care (eg, community) settings.

Methods We did a systematic review and meta-analysis to investigate the optimum distance for avoiding person-to-person virus transmission and to assess the use of face masks and eye protection to prevent transmission of viruses. We obtained data for SARS-CoV-2 and the betacoronaviruses that cause severe acute respiratory syndrome, and Middle East respiratory syndrome from 21 standard WHO-specific and COVID-19-specific sources. We searched these data sources from database inception to May 3, 2020, with no restriction by language, for comparative studies and for contextual factors of acceptability, feasibility, resource use, and equity. We screened records, extracted data, and assessed risk of bias in duplicate. We did frequentist and Bayesian meta-analyses and random-effects meta-regressions. We rated the certainty of evidence according to Cochrane methods and the GRADE approach. This study is registered with PROSPERO, CRD42020177047.

Findings Our search identified 172 observational studies across 16 countries and six continents, with no randomised controlled trials and 44 relevant comparative studies in health-care and non-health-care settings (n=25 697 patients). Transmission of viruses was lower with physical distancing of 1 m or more, compared with a distance of less than 1 m (n=10 736, pooled adjusted odds ratio [aOR] 0·18, 95% CI 0·09 to 0·38; risk difference [RD] –10·2%, 95% CI –11·5 to –7·5; moderate certainty); protection was increased as distance was lengthened (change in relative risk [RR] 2·02 per m; $p_{interaction}$=0·041; moderate certainty). Face mask use could result in a large reduction in risk of infection (n=2647; aOR 0·15, 95% CI 0·07 to 0·34, RD –14·3%, –15·9 to –10·7; low certainty), with stronger associations with N95 or similar respirators compared with disposable surgical masks or similar (eg, reusable 12–16-layer cotton masks; $p_{interaction}$=0·090; posterior probability >95%, low certainty). Eye protection also was associated with less infection (n=3713; aOR 0·22, 95% CI 0·12 to 0·39, RD –10·6%, 95% CI –12·5 to –7·7; low certainty). Unadjusted studies and subgroup and sensitivity analyses showed similar findings.

Interpretation The findings of this systematic review and meta-analysis support physical distancing of 1 m or more and provide quantitative estimates for models and contact tracing to inform policy. Optimum use of face masks, respirators, and eye protection in public and health-care settings should be informed by these findings and contextual factors. Robust randomised trials are needed to better inform the evidence for these interventions, but this systematic appraisal of currently best available evidence might inform interim guidance.

Introduction

As of May 28, 2020, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has infected more than 5·85 million individuals worldwide and caused more than 359 000 deaths.[1] Emergency lockdowns have been initiated in countries across the globe, and the effect on health, wellbeing, business, and other aspects of daily life are felt throughout societies and by individuals. With no effective pharmacological interventions or vaccine available in the imminent future, reducing the rate of infection (ie, flattening the curve) is a priority, and prevention of infection is the best approach to achieve this aim.

SARS-CoV-2 spreads person-to-person through close contact and causes COVID-19. It has not been solved if

Research in context

Evidence before this study

We searched 21 databases and resources from inception to May 3, 2020, with no restriction by language, for studies of any design evaluating physical distancing, face masks, and eye protection to prevent transmission of the viruses that cause COVID-19 and related diseases (eg, severe acute respiratory syndrome [SARS] and Middle East respiratory syndrome [MERS]) between infected individuals and people close to them (eg, household members, caregivers, and health-care workers). Previous related meta-analyses have focused on randomised trials and reported imprecise data for common respiratory viruses such as seasonal influenza, rather than the pandemic and epidemic betacoronaviruses causative of COVID-19 (severe acute respiratory syndrome coronavirus 2 [SARS-CoV-2]), SARS (SARS-CoV), or MERS (MERS-CoV). Other meta-analyses have focused on interventions in the health-care setting and have not included non-health-care (eg, community) settings. Our search did not retrieve any systematic review of information on physical distancing, face masks, or eye protection to prevent transmission of SARS-CoV-2, SARS-CoV, and MERS-CoV.

Added value of this study

We did a systematic review of 172 observational studies in health-care and non-health-care settings across 16 countries and six continents; 44 comparative studies were included in a meta-analysis, including 25 697 patients with COVID-19, SARS, or MERS. Our findings are, to the best of our knowledge, the first to rapidly synthesise all direct information on COVID-19 and, therefore, provide the best available evidence to inform optimum use of three common and simple interventions to help reduce the rate of infection and inform non-pharmaceutical interventions, including pandemic mitigation in non-health-care settings. Physical distancing of 1 m or more was associated with a much lower risk of infection, as was use of face masks (including N95 respirators or similar and surgical or similar masks [eg, 12–16-layer cotton or gauze masks]) and eye protection (eg, goggles or face shields). Added benefits are likely with even larger physical distances (eg, 2 m or more based on modelling) and might be present with N95 or similar respirators versus medical masks or similar. Across 24 studies in health-care and non-health-care settings of contextual factors to consider when formulating recommendations, most stakeholders found these personal protection strategies acceptable, feasible, and reassuring but noted harms and contextual challenges, including frequent discomfort and facial skin breakdown, high resource use linked with the potential to decrease equity, increased difficulty communicating clearly, and perceived reduced empathy of care providers by those they were caring for.

Implications of all the available evidence

In view of inconsistent guidelines by various organisations based on limited information, our findings provide some clarification and have implications for multiple stakeholders. The risk for infection is highly dependent on distance to the individual infected and the type of face mask and eye protection worn. From a policy and public health perspective, current policies of at least 1 m physical distancing seem to be strongly associated with a large protective effect, and distances of 2 m could be more effective. These data could also facilitate harmonisation of the definition of exposed (eg, within 2 m), which has implications for contact tracing. The quantitative estimates provided here should inform disease-modelling studies, which are important for planning pandemic response efforts. Policy makers around the world should strive to promptly and adequately address equity implications for groups with currently limited access to face masks and eye protection. For health-care workers and administrators, our findings suggest that N95 respirators might be more strongly associated with protection from viral transmission than surgical masks. Both N95 and surgical masks have a stronger association with protection compared with single-layer masks. Eye protection might also add substantial protection. For the general public, evidence shows that physical distancing of more than 1 m is highly effective and that face masks are associated with protection, even in non-health-care settings, with either disposable surgical masks or reusable 12–16-layer cotton ones, although much of this evidence was on mask use within households and among contacts of cases. Eye protection is typically underconsidered and can be effective in community settings. However, no intervention, even when properly used, was associated with complete protection from infection. Other basic measures (eg, hand hygiene) are still needed in addition to physical distancing and use of face masks and eye protection.

SARS-CoV-2 might spread through aerosols from respiratory droplets; so far, air sampling has found virus RNA in some studies[2–4] but not in others.[5–8] However, finding RNA virus is not necessarily indicative of replication-competent and infection-competent (viable) virus that could be transmissible. The distance from a patient that the virus is infective, and the optimum person-to-person physical distance, is uncertain. For the currently foreseeable future (ie, until a safe and effective vaccine or treatment becomes available), COVID-19 prevention will continue to rely on non-pharmaceutical interventions, including pandemic mitigation in community settings.[9] Thus, quantitative assessment of physical distancing is relevant to inform safe interaction and care of patients with SARS-CoV-2 in both health-care and non-health-care settings. The definition of close contact or potentially exposed helps to risk stratify, contact trace, and develop guidance documents, but these definitions differ around the globe.

To contain widespread infection and to reduce morbidity and mortality among health-care workers and others in contact with potentially infected people, jurisdictions have issued conflicting advice about physical or social distancing. Use of face masks with or

without eye protection to achieve additional protection is debated in the mainstream media and by public health authorities, in particular the use of face masks for the general population;[10] moreover, optimum use of face masks in health-care settings, which have been used for decades for infection prevention, is facing challenges amid personal protective equipment (PPE) shortages.[11]

Any recommendations about social or physical distancing, and the use of face masks, should be based on the best available evidence. Evidence has been reviewed for other respiratory viral infections, mainly seasonal influenza,[12,13] but no comprehensive review is available of information on SARS-CoV-2 or related betacoronaviruses that have caused epidemics, such as severe acute respiratory syndrome (SARS) or Middle East respiratory syndrome (MERS). We, therefore, systematically reviewed the effect of physical distance, face masks, and eye protection on transmission of SARS-CoV-2, SARS-CoV, and MERS-CoV.

Methods

Search strategy and selection criteria

To inform WHO guidance documents, on March 25, 2020, we did a rapid systematic review.[14] We created a large international collaborative and we used Cochrane methods[15] and the GRADE approach.[16] We prospectively submitted the systematic review protocol for registration on PROSPERO (CRD42020177047; appendix pp 23–29). We have followed PRISMA[17] and MOOSE[18] reporting guidelines (appendix pp 30–33).

From database inception to May 3, 2020, we searched for studies of any design and in any setting that included patients with WHO-defined confirmed or probable COVID-19, SARS, or MERS, and people in close contact with them, comparing distances between people and COVID-19 infected patients of 1 m or larger with smaller distances, with or without a face mask on the patient, or with or without a face mask, eye protection, or both on the exposed individual. The aim of our systematic review was for quantitative assessment to ascertain the physical distance associated with reduced risk of acquiring infection when caring for an individual infected with SARS-CoV-2, SARS-CoV, or MERS-CoV. Our definition of face masks included surgical masks and N95 respirators, among others; eye protection included visors, faceshields, and goggles, among others.

We searched (up to March 26, 2020) MEDLINE (using the Ovid platform), PubMed, Embase, CINAHL (using the Ovid platform), the Cochrane Library, COVID-19 Open Research Dataset Challenge, COVID-19 Research Database (WHO), Epistemonikos (for relevant systematic reviews addressing MERS and SARS, and its COVID-19 Living Overview of the Evidence platform), EPPI Centre living systematic map of the evidence, ClinicalTrials.gov, WHO International Clinical Trials Registry Platform, relevant documents on the websites of governmental and other relevant organisations, reference lists of included papers, and relevant systematic reviews.[19,20] We handsearched (up to May 3, 2020) preprint servers (bioRxiv, medRxiv, and Social Science Research Network First Look) and coronavirus resource centres of *The Lancet*, *JAMA*, and *N Engl J Med* (appendix pp 3–5). We did not limit our search by language. We initially could not obtain three full texts for evaluation, but we obtained them through interlibrary loan or contacting a study author. We did not restrict our search to any quantitative cutoff for distance.

Data collection

We screened titles and abstracts, reviewed full texts, extracted data, and assessed risk of bias by two authors and independently, using standardised prepiloted forms (Covidence; Veritas Health Innovation, Melbourne, VIC, Australia), and we cross-checked screening results using artificial intelligence (Evidence Prime, Hamilton, ON, Canada). We resolved disagreements by consensus. We extracted data for study identifier, study design, setting, population characteristics, intervention and comparator characteristics, quantitative outcomes, source of funding

Across studies, mean age was 30–60 years. SARS=severe acute respiratory syndrome. MERS=Middle East respiratory syndrome. *The Newcastle-Ottawa Scale was used for the risk of bias assessment, with more stars equalling lower risk.

Table 1: **Characteristics of included comparative studies**

and reported conflicts of interests, ethics approval, study limitations, and other important comments.

Outcomes

Outcomes of interest were risk of transmission (ie, WHO-defined confirmed or probable COVID-19, SARS, or MERS) to people in health-care or non-health-care settings by those infected; hospitalisation; intensive care unit admission; death; time to recovery; adverse effects of interventions; and contextual factors such as acceptability, feasibility, effect on equity, and resource considerations related to the interventions of interest. However, data were only available to analyse intervention effects for transmission and contextual factors. Consistent with WHO, studies generally defined confirmed cases with laboratory confirmation (with or without symptoms) and probable cases with clinical evidence of the respective infection (ie, suspected to be infected) but for whom confirmatory testing either had not yet been done for any reason or was inconclusive.

Data analysis

Our search did not identify any randomised trials of COVID-19, SARS, or MERS. We did a meta-analysis of associations by pooling risk ratios (RRs) or adjusted odds ratios (aORs) depending on availability of these data from observational studies, using DerSimonian and Laird random-effects models. We adjusted for variables including age, sex, and severity of source case; these variables were not the same across studies. Because between-study heterogeneity can be misleadingly large when quantified by I^2 during meta-analysis of observational studies,[21,22] we used GRADE guidance to assess between-study heterogeneity.[21] Throughout, we present RRs as unadjusted estimates and aORs as adjusted estimates.

We used the Newcastle-Ottawa scale to rate risk of bias for comparative non-randomised studies corresponding to every study's design (cohort or case-control).[23,24] We planned to use the Cochrane Risk of Bias tool 2.0 for randomised trials,[25] but our search did not identify any eligible randomised trials. We synthesised data in both narrative and tabular formats. We graded the certainty of evidence using the GRADE approach. We used the GRADEpro app to rate evidence and present it in GRADE evidence profiles and summary of findings tables[26,27] using standardised terms.[28,29]

For more on the **GRADEpro app** see https://www.gradepro.org

We analysed data for subgroup effects by virus type, intervention (different distances or face mask types), and setting (health care *vs* non-health care). Among the studies assessing physical distancing measures to prevent viral transmission, the intervention varied (eg, direct physical contact [0 m], 1 m, or 2 m). We, therefore, analysed the effect of distance on the size of the associations by random-effects univariate meta-regressions, using restricted maximum likelihood, and we present mean effects and 95% CIs. We calculated tests for interaction using a minimum of 10 000 Monte Carlo random permutations to avoid spurious findings.[30] We formally assessed the credibility of potential effect-modifiers using GRADE guidance.[21] We did two sensitivity analyses to test the robustness of our findings. First, we used Bayesian meta-analyses to reinterpret the included studies considering priors derived from the effect point estimate and variance from a meta-analysis of ten randomised trials evaluating face mask use versus no face mask use to prevent influenza-like illness in health-care workers.[31] Second, we used Bayesian meta-analyses to reinterpret the efficacy of N95 respirators versus medical masks on preventing influenza-like illness after seasonal viral (mostly influenza) infection.[13] For these sensitivity analyses, we used hybrid Metropolis-Hastings and Gibbs sampling, a 10 000 sample burn-in, 40 000 Markov chain Monte Carlo samples, and we tested non-informative and sceptical priors (eg, four time variance)[32,33] to inform

mean estimates of effect, 95% credibility intervals (CrIs), and posterior distributions. We used non-informative hyperpriors to estimate statistical heterogeneity. Model convergence was confirmed in all cases with good mixing in visual inspection of trace plots, autocorrelation plots, histograms, and kernel density estimates in all scenarios. Parameters were blocked, leading to acceptance of approximately 50% and efficiency greater than 1% in all cases (typically about 40%). We did analyses using Stata version 14.3.

Role of the funding source

The funder contributed to defining the scope of the review but otherwise had no role in study design and data collection. Data were interpreted and the report drafted and submitted without funder input, but according to contractual agreement, the funder provided review at the time of final publication. The corresponding author had full access to all data in the study and had final responsibility for the decision to submit for publication.

	Studies and participants	Relative effect (95% CI)	Anticipated absolute effect (95% CI), eg, chance of viral infection or transmission		Difference (95% CI)	Certainty*	What happens (standardised GRADE terminology)[29]
			Comparison group	Intervention group			
Physical distance ≥1 m *vs* <1 m	Nine adjusted studies (n=7782); 29 unadjusted studies (n=10 736)	aOR 0·18 (0·09 to 0·38); unadjusted RR 0·30 (95% CI 0·20 to 0·44)	Shorter distance, 12·8%	Further distance, 2·6% (1·3 to 5·3)	−10·2% (−11·5 to −7·5)	Moderate†	A physical distance of more than 1 m probably results in a large reduction in virus infection; for every 1 m further away in distancing, the relative effect might increase 2·02 times
Face mask *vs* no face mask	Ten adjusted studies (n=2647); 29 unadjusted studies (n=10 170)	aOR 0·15 (0·07 to 0·34); unadjusted RR 0·34 (95% CI 0·26 to 0·45)	No face mask, 17·4%	Face mask, 3·1% (1·5 to 6·7)	−14·3% (−15·9 to −10·7)	Low‡	Medical or surgical face masks might result in a large reduction in virus infection; N95 respirators might be associated with a larger reduction in risk compared with surgical or similar masks§

Table based on GRADE approach.[26–29] Population comprised people possibly exposed to individuals infected with SARS-CoV-2, SARS-CoV, or MERS-CoV. Setting was any health-care or non-health-care setting. Outcomes were infection (laboratory-confirmed or probable) and contextual factors. Risk (95% CI) in intervention group is based on assumed risk in comparison group and relative effect (95% CI) of the intervention. All studies were non-randomised and evaluated using the Newcastle-Ottawa Scale; some studies had a higher risk of bias than did others but no important difference was noted in sensitivity analyses excluding studies at higher risk of bias; we did not further rate down for risk of bias. Although there was a high I^2 value (which can be exaggerated in non-randomised studies)[21] and no overlapping CIs, point estimates generally exceeded the thresholds for large effects and we did not rate down for inconsistency. We did not rate down for indirectness for the association between distance and infection because SARS-CoV-2, SARS-CoV, and MERS-CoV all belong to the same family and have each caused epidemics with sufficient similarity; there was also no convincing statistical evidence of effect-modification across viruses; some studies also used bundled interventions but the studies include only those that provide adjusted estimates. aOR=adjusted odds ratio. RR=relative risk. SARS-CoV-2=severe acute respiratory syndrome coronavirus 2. SARS-CoV=severe acute respiratory syndrome coronavirus. MERS-CoV=Middle East respiratory syndrome coronavirus. *GRADE category of evidence; high certainty (we are very confident that the true effect lies close to that of the estimate of the effect); moderate certainty (we are moderately confident in the effect estimate; the true effect is probably close to the estimate, but it is possibly substantially different); low certainty (our confidence in the effect estimate is limited; the true effect could be substantially different from the estimate of the effect); very low certainty (we have very little confidence in the effect estimate; the true effect is likely to be substantially different from the estimate of effect). †The effect is very large considering the thresholds set by GRADE, particularly at plausible levels of baseline risk, which also mitigated concerns about risk of bias; data also suggest a dose–response gradient, with associations increasing from smaller distances to 2 m and beyond, by meta-regression; we did not rate up for this domain alone but it further supports the decision to rate up in combination with the large effects. ‡The effect was very large, and the certainty of evidence could be rated up, but we made a conservative decision not to because of some inconsistency and risk of bias; hence, although the effect is qualitatively highly certain, the precise quantitative effect is low certainty. §In a subgroup analysis comparing N95 respirators with surgical or similar masks (eg, 12–16-layer cotton), the association was more pronounced in the N95 group (aOR 0·04, 95% CI 0·004–0·30) compared with other masks (0·33, 0·17–0·61; $p_{interaction}$=0·090); there was also support for effect-modification by formal analysis of subgroup credibility. ¶Two studies[54,75] provided adjusted estimates with n=295 in the eye protection group and n=406 in the group not wearing eye protection; results were similar to the unadjusted estimate (aOR 0·22, 95% CI 0·12–0·39). ||The effect is large considering the thresholds set by GRADE assuming that ORs translate into similar magnitudes of RR estimates; this mitigates concerns about risk of bias, but we conservatively decided not to rate up for large or very large effects.

Table 2: **GRADE summary of findings**

Results

We identified 172 studies for our systematic review from 16 countries across six continents (figure 1; appendix pp 6–14, 41–47). Studies were all observational in nature; no randomised trials were identified of any interventions that directly addressed the included study populations. Of the 172 studies, 66 focused on how far a virus can travel by comparing the association of different distances on virus transmission to people (appendix pp 42–44). Of these 66 studies, five were mechanistic, assessing viral RNA, virions, or both cultured from the environment of an infected patient (appendix p 45).

44 studies were comparative[34–77] and fulfilled criteria for our meta-analysis (n=25 697; figure 1; table 1). We used these studies rather than case series and qualitative studies (appendix pp 41–47) to inform estimates of effect. 30 studies[34,37,41–45,47–51,53–56,58–61,64–70,72,74,75] focused on the association between use of various types of face masks and respirators by health-care workers, patients, or both with virus transmission. 13 studies[34,37–39,47,49,51,54,58,60,61,65,75] addressed the association of eye protection with virus transmission.

Some direct evidence was available for COVID-19 (64 studies, of which seven were comparative in design),[36,37,40,41,44,52,70] but most studies reported on SARS (n=55) or MERS (n=25; appendix pp 6–12). Of the 44 comparative studies, 40 included WHO-defined confirmed cases, one included both confirmed and probable cases, and the remaining three studies included probable cases. There was no effect-modification by case-definition (distance $p_{interaction}$=0·41; mask $p_{interaction}$=0·46; all cases for eye protection were confirmed). Most studies reported on bundled interventions, including different components of PPE and distancing, which was usually addressed by statistical adjustment. The included studies all occurred during recurrent or novel outbreak settings of COVID-19, SARS, or MERS.

Risk of bias was generally low-to-moderate after considering the observational designs (table 1), but both within studies and across studies the overall findings were similar between adjusted and unadjusted estimates. We did not detect strong evidence of publication bias in the body of evidence for any intervention (appendix pp 15–18). As we did not use case series data to inform estimates of effect of each intervention, we did not systematically rate risk of bias of these data. Therefore, we report further only those studies with comparative data.

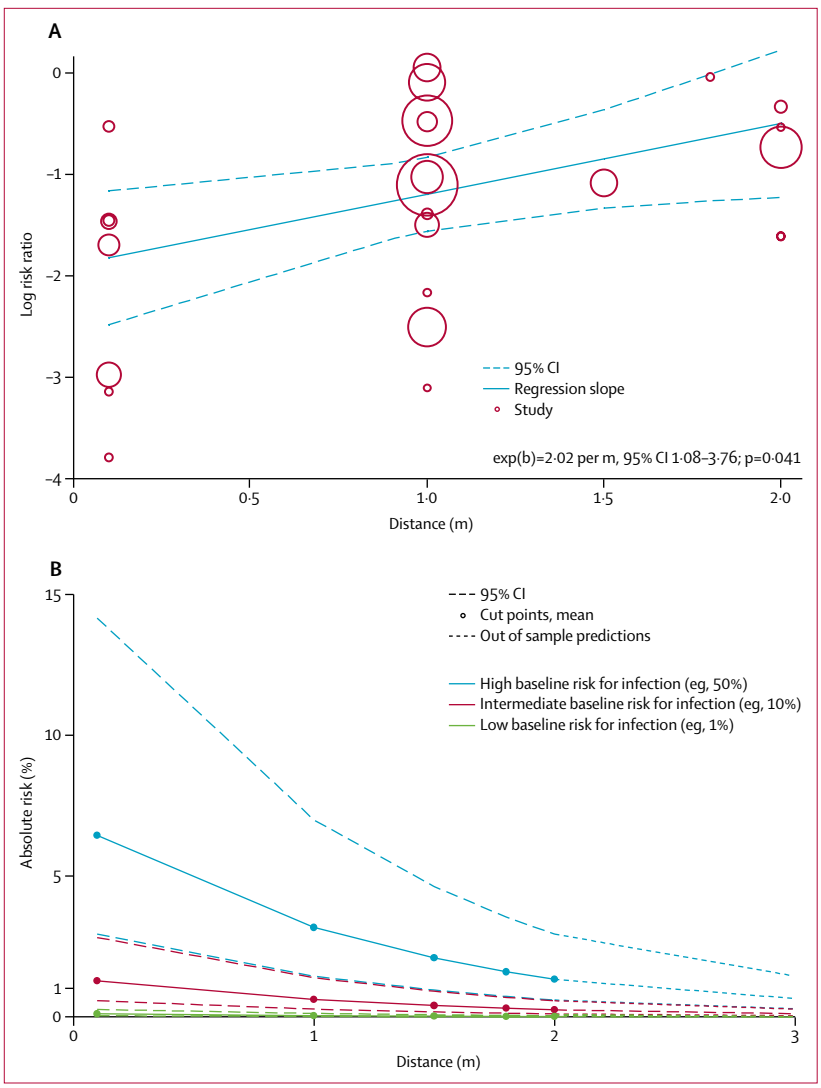

Figure 3: **Change in relative risk with increasing distance and absolute risk with increasing distance**
Meta-regression of change in relative risk with increasing distance from an infected individual (A). Absolute risk of transmission from an individual infected with SARS-CoV-2, SARS-CoV, or MERS-CoV with varying baseline risk and increasing distance (B). SARS-CoV-2=severe acute respiratory syndrome coronavirus 2. SARS-CoV=severe acute respiratory syndrome coronavirus. MERS-CoV=Middle East respiratory syndrome coronavirus.

Across 29 unadjusted and nine adjusted studies,[35–37,39,40,43,44,46,47,50–54,56,57,59–66,68,69,71,73,76] a strong association was found of proximity of the exposed individual with the risk of infection (unadjusted n=10 736, RR 0·30, 95% CI 0·20 to 0·44; adjusted n=7782, aOR 0·18, 95% CI 0·09 to 0·38; absolute risk [AR] 12·8% with shorter distance *vs* 2·6% with further distance, risk difference [RD] –10·2%, 95% CI –11·5 to –7·5; moderate certainty; figure 2; table 2; appendix p 16). Although there were six studies on COVID-19, the association was seen irrespective of causative virus ($p_{interaction}$=0·49), health-care setting versus non-health-care setting ($p_{interaction}$=0·14), and by type of face mask ($p_{interaction}$=0·95; appendix pp 17, 19). However, different studies used different distances for the intervention. By meta-regression, the strength of association was larger with increasing distance (2·02 change in RR per m, 95% CI 1·08 to 3·76; $p_{interaction}$=0·041; moderate credibility subgroup effect; figure 3A; table 2). AR values with increasing distance given different degrees of baseline risk are shown in figure 3B, with potential values at 3 m also shown.

Across 29 unadjusted studies and ten adjusted studies,[34,37,41–45,47–51,53–56,58–61,64–70,72,74,75] the use of both N95 or similar respirators or face masks (eg, disposable surgical masks or similar reusable 12–16-layer cotton masks) by those exposed to infected individuals was associated with a large reduction in risk of infection (unadjusted n=10 170, RR 0·34, 95% CI 0·26 to 0·45; adjusted studies n=2647, aOR 0·15, 95% CI 0·07 to 0·34; AR 3·1% with face mask *vs* 17·4% with no face mask, RD –14·3%, 95% CI –15·9 to –10·7; low certainty; figure 4; table 2; appendix pp 16, 18) with stronger associations in health-care settings (RR 0·30, 95% CI 0·22 to 0·41) compared with non-health-care settings (RR 0·56, 95% CI 0·40 to 0·79; $p_{interaction}$=0·049; low-to-moderate credibility for subgroup effect; figure 4; appendix p 19). When differential N95 or similar respirator use, which was more frequent in health-care settings than in non-health-care settings, was adjusted for the possibility that face masks were less effective in non-health-care settings, the subgroup effect was slightly less credible ($p_{interaction}$=0·11, adjusted for differential respirator use; figure 4). Indeed, the association with protection from infection was more pronounced with N95 or similar respirators (aOR 0·04, 95% CI 0·004 to 0·30) compared with other masks (aOR 0·33, 95% CI 0·17 to 0·61; $p_{interaction}$=0·090; moderate credibility subgroup effect; figure 5). The interaction was also seen when additionally adjusting for three studies that clearly reported aerosol-generating procedures ($p_{interaction}$=0·048; figure 5). Supportive evidence for this interaction was also seen in within-study comparisons (eg, N95 had a stronger protective association compared with surgical masks or 12–16-layer cotton masks); both N95 and surgical masks also had a stronger association with protection versus single-layer masks.[38,39,51,53,54,61,66,67,75]

We did a sensitivity analysis to test the robustness of our findings and to integrate all available information on face mask treatment effects for protection from COVID-19. We reconsidered our findings using random-effects Bayesian meta-analysis. Although non-informative priors showed similar results to frequentist approaches (aOR 0·16, 95% CrI 0·04–0·40), even using informative priors from the most recent meta-analysis on the effectiveness of masks versus no masks to prevent influenza-like illness (RR 0·93, 95% CI 0·83–1·05)[31] yielded a significant association with protection from COVID-19 (aOR 0·40, 95% CrI 0·16–0·97; posterior probability for RR <1, 98%). Minimally informing (25% influence with or without four-fold smaller mean effect size) the most recent and rigorous meta-analysis of the effectiveness of N95

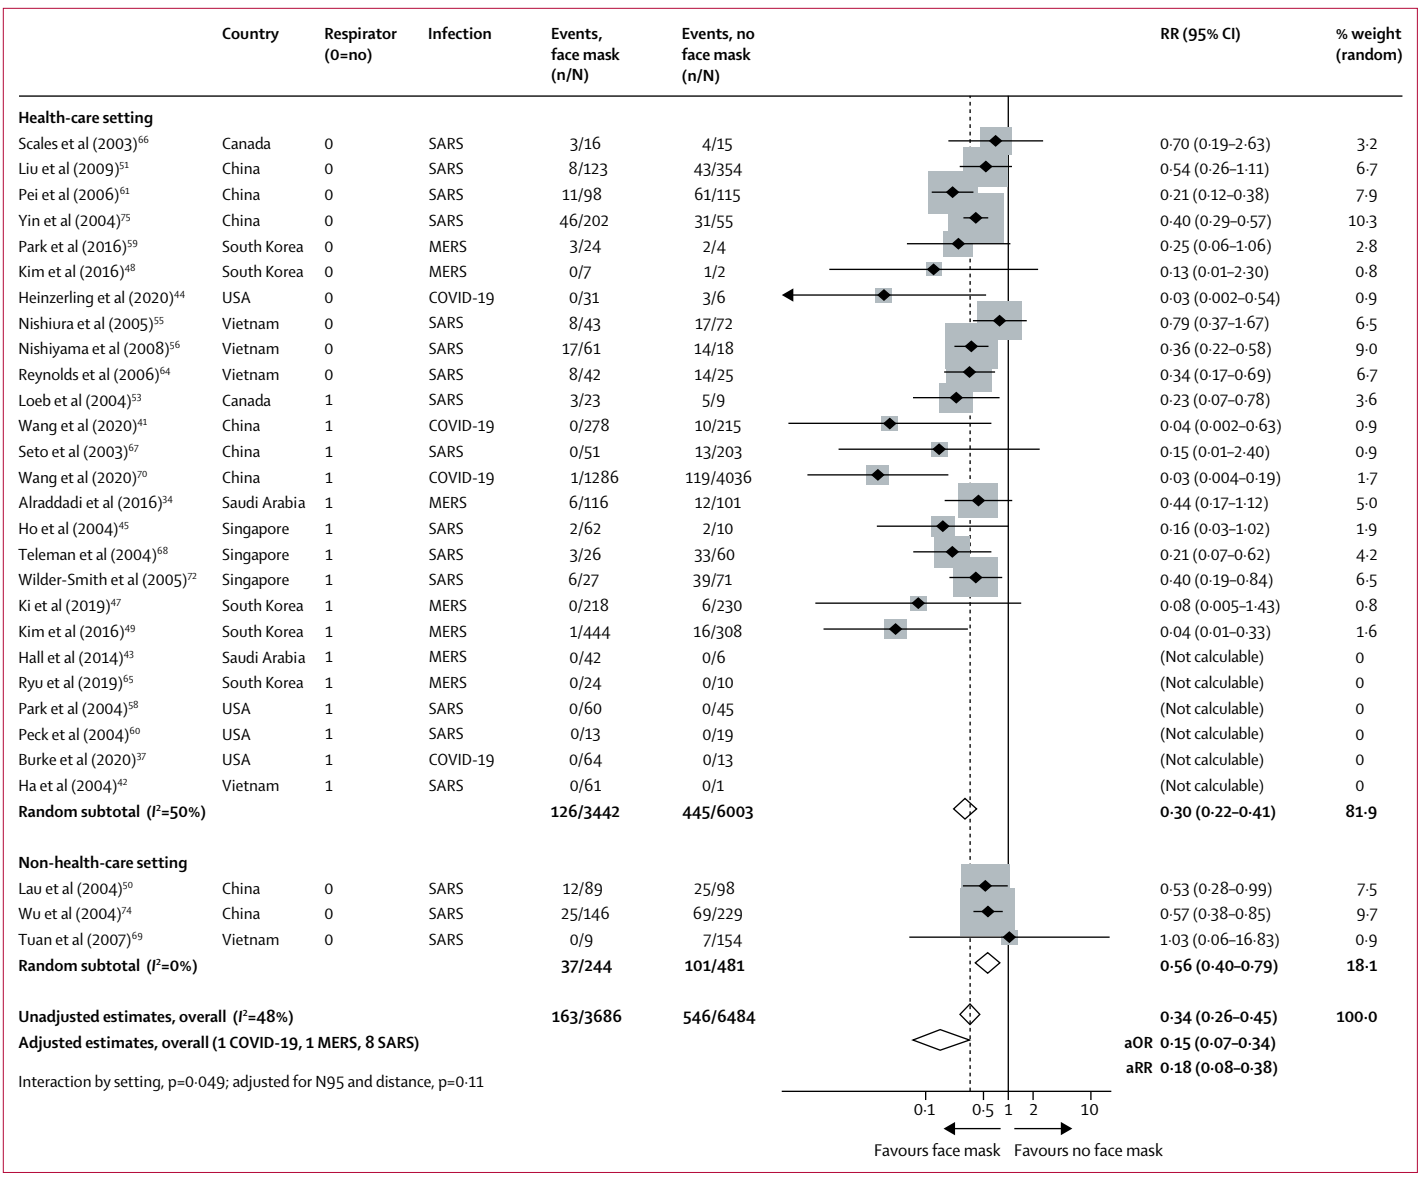

Figure 4: **Forest plot showing unadjusted estimates for the association of face mask use with viral infection causing COVID-19, SARS, or MERS**
SARS=severe acute respiratory syndrome. MERS=Middle East respiratory syndrome. RR=relative risk. aOR=adjusted odds ratio. aRR=adjusted relative risk.

respirators versus medical masks in randomised trials (OR 0·76, 95% CI 0·54–1·06)[13] with the effect-modification seen in this meta-analysis on COVID-19 (ratio of aORs 0·14, 95% CI 0·02–1·05) continued to support a stronger association of protection from COVID-19, SARS, or MERS with N95 or similar respirators versus other face masks (posterior probability for RR <1, 100% and 95%, respectively).

In 13 unadjusted studies and two adjusted studies,[34,37-39,47,49,51,54,58,60,61,65,75] eye protection was associated with lower risk of infection (unadjusted n=3713, RR 0·34, 95% CI 0·22 to 0·52; AR 5·5% with eye protection *vs* 16·0% with no eye protection, RD –10·6%, 95% CI –12·5 to –7·7; adjusted n=701, aOR 0·22, 95% CI 0·12 to 0·39; low certainty; figure 6; table 2; appendix pp 16–17).

Across 24 studies in health-care and non-health-care settings during the current pandemic of COVID-19, previous epidemics of SARS and MERS, or in general use, looking at contextual factors to consider in recommendations, most stakeholders found physical distancing and use of face masks and eye protection acceptable, feasible, and reassuring (appendix pp 20–22). However, challenges included frequent discomfort, high resource use linked with potentially decreased equity, less clear communication, and perceived reduced empathy of care providers by those they were caring for.

SARS=severe acute respiratory syndrome. MERS=Middle East respiratory syndrome. RR=relative risk. aOR=adjusted odds ratio. AGP=aerosol-generating procedures. *Studies clearly reporting AGP.

Discussion

The findings of this systematic review of 172 studies (44 comparative studies; n=25 697 patients) on COVID-19, SARS, and MERS provide the best available evidence that current policies of at least 1 m physical distancing are associated with a large reduction in infection, and distances of 2 m might be more effective. These data also suggest that wearing face masks protects people (both health-care workers and the general public) against infection by these coronaviruses, and that eye protection could confer additional benefit. However, none of these interventions afforded complete protection from infection, and their optimum role might need risk assessment and several contextual considerations. No randomised trials were identified for these interventions in COVID-19, SARS, or MERS.

Previous reviews are limited in that they either have not provided any evidence from COVID-19 or did not use direct evidence from other related emerging epidemic betacoronaviruses (eg, SARS and MERS) to inform the effects of interventions to curtail the current COVID-19 pandemic.[13,19,31,78] Previous data from randomised trials are mainly for common respiratory viruses such as seasonal influenza, with a systematic review concluding low certainty of evidence for extrapolating these findings to COVID-19.[13] Further, previous syntheses of available randomised controlled trials have not accounted for cluster effects in analyses, leading to substantial imprecision in treatment effect estimates. In between-study and within-study comparisons, we noted a larger effect of N95 or similar respirators compared with other masks. This finding is inconsistent with conclusions of a review of four randomised trials,[13] in which low certainty of evidence for no larger effect was suggested. However, in that review, the CIs were wide so a meaningful protective effect could not be excluded. We harmonised these findings with Bayesian approaches, using indirect data from randomised trials to inform posterior estimates. Despite this step, our findings continued to support the ideas not only that masks in general are associated with a large reduction in risk of infection from SARS-CoV-2, SARS-CoV, and MERS-CoV but also that N95 or similar respirators might be associated with a larger degree of protection from viral infection than disposable medical masks or reusable multilayer (12–16-layer) cotton masks. Nevertheless, in view of the limitations of these data, we did not rate the certainty of effect as high.[21] Our findings accord with those of a cluster randomised trial showing a potential benefit of continuous N95 respirator use over medical masks against seasonal viral infections.[79] Further high-quality research, including randomised trials of the optimum physical distance and the effectiveness of different types of masks in the general population and for health-care workers' protection, is urgently needed. Two trials are registered to better inform the optimum use of face masks for COVID-19 (NCT04296643 [n=576] and

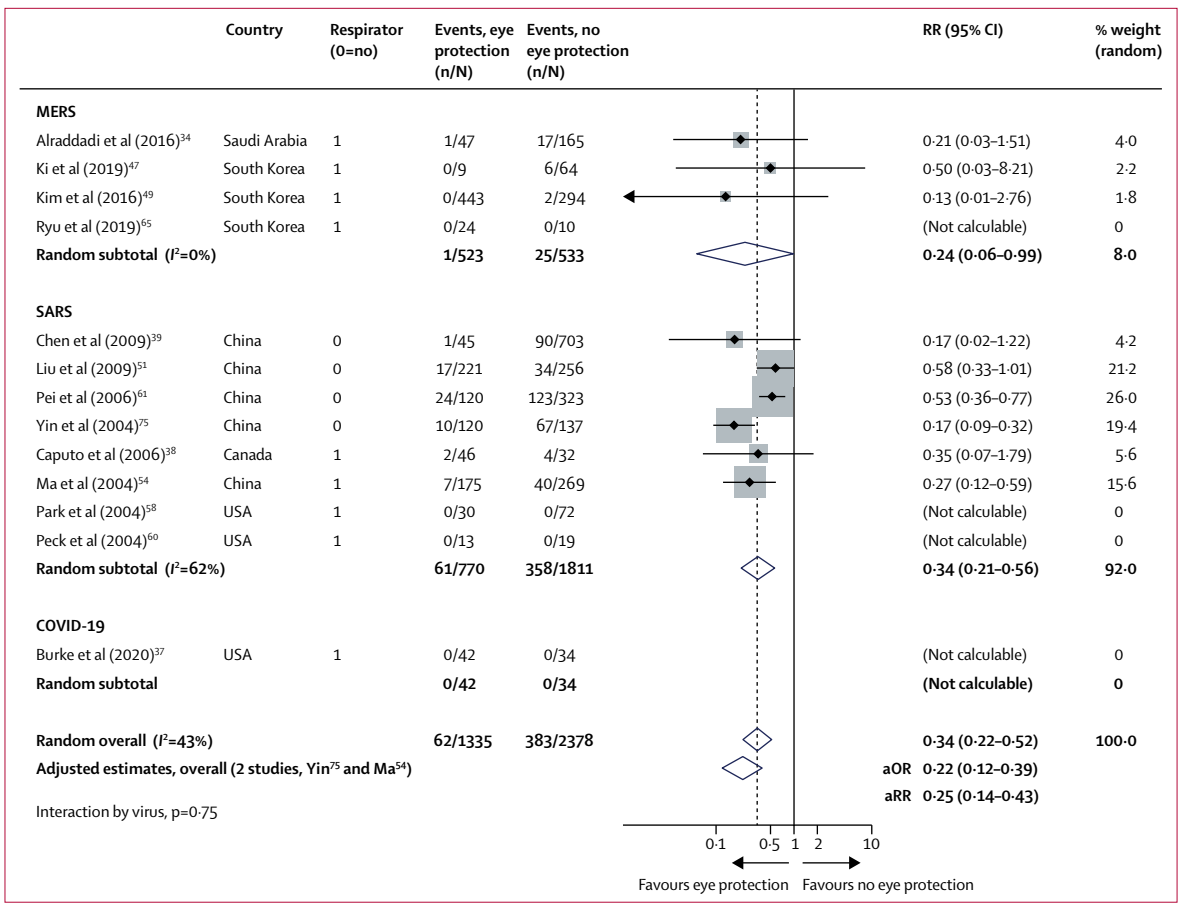

Figure 6: **Forest plot showing the association of eye protection with risk of COVID-19, SARS, or MERS transmission**
Forest plot shows unadjusted estimates. SARS=severe acute respiratory syndrome. MERS=Middle East respiratory syndrome. RR=relative risk. aOR=adjusted odds ratio. aRR=adjusted relative risk.

NCT04337541 [n=6000]). Until such data are available, our findings represent the current best estimates to inform face mask use to reduce infection from COVID-19. We recognise that there are strong, perhaps opposing, sentiments about policy making during outbreaks. In one viewpoint, the 2007 SARS Commission report stated:

> "…recognize, as an aspect of health worker safety, the precautionary principle that reasonable action to reduce risk, such as the use of a fitted N95 respirator, need not await scientific certainty".[80]

> "…if we do not learn from SARS and we do not make the government fix the problems that remain, we will pay a terrible price in the next pandemic".[81]

A counter viewpoint is that the scientific uncertainty and contextual considerations require a more nuanced approach. Although challenging, policy makers must carefully consider these two viewpoints along with our findings.

We found evidence of moderate certainty that current policies of at least 1 m physical distancing are probably associated with a large reduction in infection, and that distances of 2 m might be more effective, as implemented in some countries. We also provide estimates for 3 m. The main benefit of physical distancing measures is to prevent onward transmission and, thereby, reduce the adverse outcomes of SARS-CoV-2 infection. Hence, the results of our current review support the implementation of a policy of physical distancing of at least 1 m and, if feasible, 2 m or more. Our findings also provide robust estimates to inform models and contact tracing used to plan and strategise for pandemic response efforts at multiple levels.

The use of face masks was protective for both health-care workers and people in the community exposed to infection, with both the frequentist and Bayesian analyses lending support to face mask use irrespective of setting. Our unadjusted analyses might, at first impression, suggest use of face masks in the community setting to be less effective than in the health-care setting, but after accounting for differential N95 respirator use between health-care and non-health-care settings, we did not detect any striking differences in effectiveness of

face mask use between settings. The credibility of effect-modification across settings was, therefore, low. Wearing face masks was also acceptable and feasible. Policy makers at all levels should, therefore, strive to address equity implications for groups with currently limited access to face masks and eye protection. One concern is that face mask use en masse could divert supplies from people at highest risk for infection.[10] Health-care workers are increasingly being asked to ration and reuse PPE,[82,83] leading to calls for government-directed repurposing of manufacturing capacity to overcome mask shortages[84] and finding solutions for mask use by the general public.[84] In this respect, some of the masks studied in our review were reusable 12–16-layer cotton or gauze masks.[51,54,61,75] At the moment, although there is consensus that SARS-CoV-2 mainly spreads through large droplets and contact, debate continues about the role of aerosol,[2–8,85,86] but our meta-analysis provides evidence (albeit of low certainty) that respirators might have a stronger protective effect than surgical masks. Biological plausibility would be supported by data for aerosolised SARS-CoV-2[5–8] and preclinical data showing seasonal coronavirus RNA detection in fine aerosols during tidal breathing,[87] albeit, RNA detection does not necessarily imply replication and infection-competent virus. Nevertheless, our findings suggest it plausible that even in the absence of aerosolisation, respirators might be simply more effective than masks at preventing infection. At present, there is no data to support viable virus in the air outside of aerosol generating procedures from available hospital studies. Other factors such as super-spreading events, the subtype of health-care setting (eg, emergency room, intensive care unit, medical wards, dialysis centre), if aerosolising procedures are done, and environmental factors such as ventilation, might all affect the degree of protection afforded by personal protection strategies, but we did not identify robust data to inform these aspects.

Strengths of our review include adherence to full systematic review methods, which included artificial intelligence-supported dual screening of titles and abstracts, full-text evaluation, assessment of risk of bias, and no limitation by language. We included patients infected with SARS-CoV-2, SARS-CoV, or MERS-CoV and searched relevant data up to May 3, 2020. We followed the GRADE approach[16] to rate the certainty of evidence. Finally, we identified and appraise a large body of published work from China, from which much evidence emerged before the pandemic spread to other global regions.

The primary limitation of our study is that all studies were non-randomised, not always fully adjusted, and might suffer from recall and measurement bias (eg, direct contact in some studies might not be measuring near distance). However, unadjusted, adjusted, frequentist, and Bayesian meta-analyses all supported the main findings, and large or very large effects were recorded. Nevertheless, we are cautious not to be overly certain in the precise quantitative estimates of effects, although the qualitative effect and direction is probably of high certainty. Many studies did not provide information on precise distances, and direct contact was equated to 0 m distance; none of the eligible studies quantitatively evaluated whether distances of more than 2 m were more effective, although our meta-regression provides potential predictions for estimates of risk. Few studies assessed the effect of interventions in non-health-care settings, and they primarily evaluated mask use in households or contacts of cases, although beneficial associations were seen across settings. Furthermore, most evidence was from studies that reported on SARS and MERS (n=6674 patients with COVID-19, of 25 697 total), but data from these previous epidemics provide the most direct information for COVID-19 currently. We did not specifically assess the effect of duration of exposure on risk for transmission, although whether or not this variable was judged a risk factor considerably varied across studies, from any duration to a minimum of 1 h. Because of inconsistent reporting, information is limited about whether aerosol-generating procedures were in place in studies using respirators, and whether masks worn by infected patients might alter the effectiveness of each intervention, although the stronger association with N95 or similar respirators over other masks persisted when adjusting for studies reporting aerosol-generating medical procedures. These factors might account for some of the residual statistical heterogeneity seen for some outcomes, albeit I^2 is commonly inflated in meta-analyses of observational data,[21,22] and nevertheless the effects seen were large and probably clinically important in all adjusted studies.

Our comprehensive systematic review provides the best available information on three simple and common interventions to combat the immediate threat of COVID-19, while new evidence on pharmacological treatments, vaccines, and other personal protective strategies is being generated. Physical distancing of at least 1 m is strongly associated with protection, but distances of up to 2 m might be more effective. Although direct evidence is limited, the optimum use of face masks, in particular N95 or similar respirators in health-care settings and 12–16-layer cotton or surgical masks in the community, could depend on contextual factors; action is needed at all levels to address the paucity of better evidence. Eye protection might provide additional benefits. Globally collaborative and well conducted studies, including randomised trials, of different personal protective strategies are needed regardless of the challenges, but this systematic appraisal of currently best available evidence could be considered to inform interim guidance.

Contributors

DKC, EAA, SD, KS, SY, and HJS designed the study. SY, SD, KS, and HJS coordinated the study. SY and LH designed and ran the literature search. All authors acquired data, screened records, extracted data, and assessed risk of bias. DKC did statistical analyses. DKC and HJS wrote the report. All authors provided critical conceptual input, analysed and interpreted data, and critically revised the report.

The Polymerase Chain Reaction

History Methods, and Applications

Nancy Smyth Templeton, Ph.D.

The polymerase chain reaction (PCR) uses in vitro enzymatic synthesis to amplify specific DNA sequences. PCR amplification can produce approximately 100 billion copies of one molecule of DNA in a few hours. PCR has revolutionized research in the biological sciences and medicine, and has influenced criminology and law. Several major scientific discoveries, including purification of DNA polymerase and elucidation of the mechanism of DNA replication, were essential for development of the present PCR technology. An overview of these discoveries and early work on in vitro DNA synthesis are presented. Basic PCR methodology, instrumentation, advanced PCR techniques, and applications are also discussed in this review. Several new amplification systems are mentioned. PCR is an extremely important and simple technology for research and diagnostic analyses of DNA and RNA. PCR technology and other amplification procedures will continue to produce novel applications in basic research and clinical medicine.

Key Words: DNA polymerase—Amplification—DNA synthesis—Denaturation—Annealing—Primer extension.

Diagn Mol Pathol 1(1): 58–72, 1992.

The polymerase chain reaction (PCR) is defined as the in vitro enzymatic synthesis and amplification of specific DNA sequences (6). Several reviews and books have been written recently on the subject (5,6,8,10,13,23,27,31). PCR amplification can produce approximately 100 billion copies of one molecule of DNA in a few hours (23,24,29). Twenty cycles of PCR produce about a millionfold (2^{20}) amplification (6,23). Typically, PCR reactions begin using picogram quantities of template DNA which go through 30–40 cycles of amplification.

The present PCR technology is the end result of a series of major discoveries in basic science research, beginning with the discovery of the first DNA polymerase by Arthur Kornberg around 1955. DNA polymerase, the enzyme responsible for the synthesis of DNA, was purified in 1958. During the years 1955–70, scientists described the thermodynamics of DNA annealing and primer extension in the 5′ to 3′ direction. The idea of amplified synthesis of DNA was first described in a 1971 paper (17) based on the work of Dr. Har Gobind Khorana's group, which was studying synthesis of the gene that encodes the major Ala-tRNA from yeast. The final paragraph of this paper presents the theory of PCR in complete detail. At that time, the in vitro synthesis of DNA was called "DNA repair replication."

The first PCR experiment was performed by Dr. Kjell Kleppe, a postdoctoral fellow in Dr. Khorana's laboratory. This experiment was a reaction involving two cycles of amplification of a 30-nucleotide-long duplex DNA, using primers nine and 10 nucleotides long. Dr. Kleppe described his experiment publicly at the 1969 Gordon Conference on Nucleic Acids; his data are shown in Fig. 1 [Dr. Ruth Kleppe, personal communication on behalf of Dr. Kjell Kleppe (deceased 1988); previously unpublished data]. "The upper curve . . . shows the incorporation of dCTP-^{14}C into duplex II which was

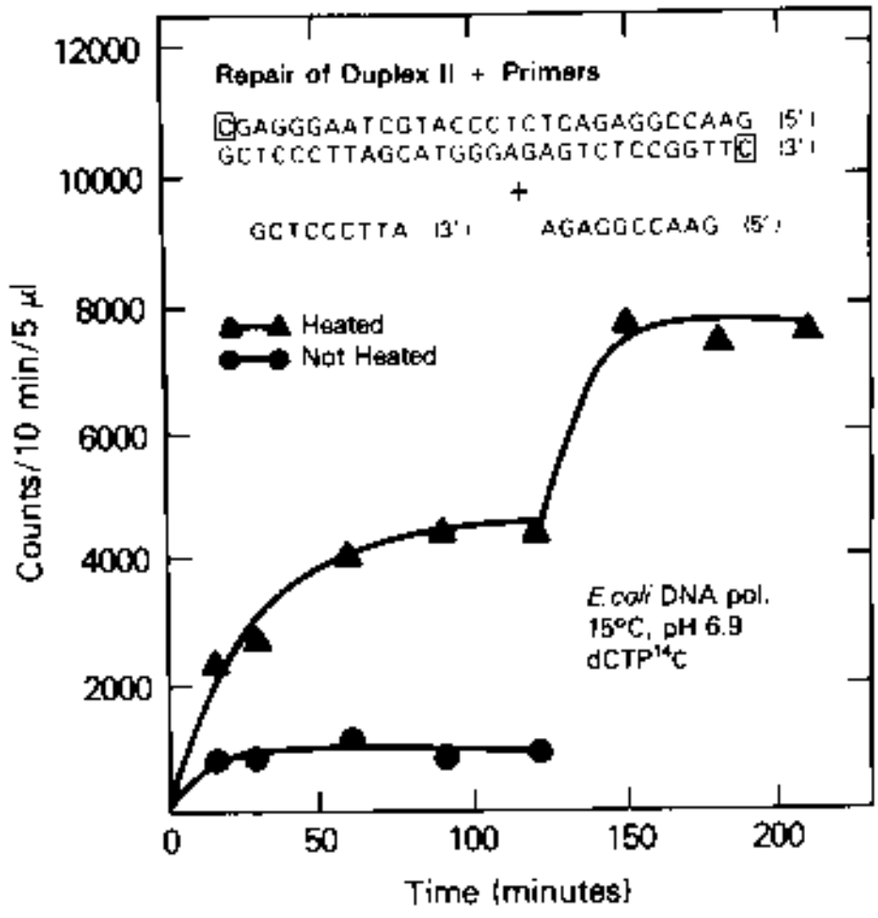

FIG. 1. Replication of duplex II by repair process. This figure represents the first PCR experiment performed by Dr. Kjell Kleppe in 1969.

heated at zero time in the presence of the primers, a deca- and a nona-nucleotide. The heating period was two minutes at 100°C, then the mixture was chilled and DNA polymerase and triphosphates added. After approximately two hours the incorporation levels off. If the mixture is heated again and new DNA polymerase added, more dCTP is incorporated and a new plateau is reached after approximately 1 hour. The theoretical amount of counts for one round of "repair" replication is approximately 7000 counts. The bottom curve represents the incorporation into duplex + the two primer pieces; the mixture in this case, has not been heated, and the incorporation is due to the two terminal C residues missing in this duplex. Several other control experiments, not shown confirm the above results. One must, therefore, conclude that the incorporation observed is due to repair processes of the new duplexes formed upon heating and chilling. The above results suggest that replication by this method might be feasible, but considerably more work is needed to perfect the method" (Dr. Ruth Kleppe, personal communication regarding the lecture presented by Dr. Kjell Kleppe at the Gordon Research Conference on Nucleic Acids on June 18, 1969).

Between 1970 and 1972, three rounds of amplification of four relatively short DNA duplexes were also achieved by Dr. Ian J. Molineux in Dr. Khorana's laboratory (26). Because the Klenow fragment was not available at that time, these experiments were all carried out using the intact DNA polymerase I molecule to synthesize DNA in vitro. To avoid degradation of the product DNA during synthesis, it was necessary to work at a pH far removed from the optimum for the enzyme. In turn, this made the reactions very slow. Incubations usually required 1–2 h at 15°C, and large amounts of the enzyme were required to sustain acceptable rates of synthesis.

In addition, it was technically impossible to perform many rounds of DNA amplification. DNA primers were extremely laborious and expensive to produce, and the millionfold excess of primers routinely used in modern PCR could not be made. In the late 1960s, it would take a trained postdoctoral organic chemist in Dr. Khorana's laboratory 6 months of full-time work to synthesize relatively small quantities of just two decanucleotides. The two icosanucleotides originally planned to be part of the synthetic yeast Ala-tRNA gene each took a postdoctoral fellow 2 years to synthesize. The successful synthesis of a defined sequence oligonucleotide usually led to a substantial publication in, for example, the *Journal of Molecular Biology* (see the complete issue of *J Mol Biol* 1972;72:209–474). It is

therefore not surprising that these valuable compounds were kept locked in the freezer. Two of the chemists and Dr. Khorana kept the only keys, and the biochemistry postdoctoral fellows in the laboratory had to fully justify any proposed use of oligonucleotides before they would be given out.

There were other hardships in performing PCR reactions in these early days of molecular biology. Template DNAs had to be made from the synthetic oligonucleotides, and the Khorana laboratory was instrumental in establishing the conditions for the use of DNA ligase on short DNA molecules. [γ-^{32}P]ATP (to monitor the progress of ligase reactions) and often [α-^{32}P]dNTPs (to follow kinetics of DNA polymerase reactions) were also chemically synthesized by the postdoctoral fellows in the Khorana laboratory. Because DNA polymerase was not commercially available, it was routinely purified. The Klenow fragment had only just been discovered; in 1971, it was actually still being characterized by Dr. Hans Klenow himself, while a visiting professor in the laboratory. Similarly, polynucleotide kinase and DNA ligase were not commercially available and had to be purified from T4-infected cells. These cells (and the phage to infect them!) had themselves to be grown in large quantities, often in 100-l or larger fermentors. All the foregoing was an integral part of the research projects using synthetic DNA. Indeed Dr. Molineux estimates that he spent the majority of his time in preparing and characterizing substrates and reagents, rather than doing PCR (repair replication reactions) or analyzing their products. Product analysis was also laborious; the technologies of gel electrophoresis of DNA molecules and DNA sequencing had not been developed. DNAs were usually purified using chromatography on meter-long (or greater) Sephadex columns and "sequenced" by a combination of nucleoside:nucleotide ratios and digestion to 5′ or 3′ mononucleotides, followed by paper chromatography and scintillation counting of the separated compounds.

Large-scale automation of DNA amplification was not pursued by the Khorana laboratory for several reasons (Drs. H.G. Khorana and I.J. Molineux, personal communications). Primarily, they believed that the goal of in vitro DNA synthesis had been achieved and therefore became interested in producing new discoveries in other areas. Furthermore, high temperature–stable DNA polymerases, which also transformed PCR from a method of last resort to one of first choice (6), were unknown; thus was automation precluded. In addition, DNA cloning, which had just begun, became the preferred method for producing large amounts of DNA. Finally, perhaps because it was so difficult to synthesize large amounts of primers, no one thought that the specific amplification of genomic DNA was feasible. Both Drs. Khorana and Molineux have stated that they would make the same choices again even with our current knowledge of PCR (personal communications); they preferred to leave the development of PCR technology in the hands of industry. Furthermore, Dr. Molineux does not think that it is ethical to patent a scientific discovery that is funded by government grants unless licenses are readily available and the discovery benefits only nonprofit organizations. He believes that his discoveries belong in the public domain.

Modern PCR technology was initially developed by Dr. Kary B. Mullis, a research scientist at the Perkin–Elmer Cetus Corporation in April 1983 (23). He was unfamiliar with the previous work of Drs. Khorana, Kleppe, and Molineux; despite a thorough search of the literature, he did not come across their publications on DNA repair replication (23). In 1985, Dr. Mullis first described the PCR technique at the American Society of Human Genetics meeting; the first publications utilizing PCR appeared in the same year (13). Since that time, over 1,000 research articles and reports including PCR data have been published. In 1988, only the subject of high-temperature superconductors was cited more frequently than PCR (8). In 1989, *Science* named DNA polymerase the Molecule of the Year because of its application to the PCR technique, and PCR was proclaimed the major scientific development of the year (10). Others have claimed that PCR represents one of the greatest technical advances of the last decade (5) and predicted that it will alter the course of scientific history. However, other methods of amplification have also been developed.

PCR will probably replace many conventional gene cloning techniques for the amplification of DNA for sequencing. In addition, PCR has had and will continue to have a major impact on the biological sciences, medicine, criminology, and law (31). Furthermore, PCR is a simple technique. In the words of Dr. Henry Erlich, a senior investigator at the Perkin–Elmer Cetus Corporation, "PCR allows people to practice molecular biology without a license" (6). Therefore, as Dr. Petr Karlovsky has warned us, intelligent application and critical utilization of PCR must be maintained (16). PCR has allowed us to address certain important questions that were out of our reach prior to the development of this technology.

METHODS AND INSTRUMENTATION

PCR resembles the in vivo process of DNA replication. It begins with one molecule of double-stranded DNA to be amplified, called "target," or "template," DNA. The target DNA is flanked by two primers. After one cycle, two molecules of identical double-stranded target DNA are produced (Fig. 2). Therefore, the number of DNA molecules doubles after each cycle. There is a geometrical increase in the number of DNA molecules produced after each cycle. After 30 cycles, over one billion (a 2^{30} amplification) copies of target DNA are produced.

Several basic goals have been achieved with PCR. A single molecule of DNA can be amplified to yield a 10^7–10^{11}-fold amplification. Approximately 2–3 μg DNA can be produced by one 100 μl PCR reaction mix. Target DNA up to 10 kilobases (kb) have been amplified, and protocols are being designed to amplify DNA up to 18 kb in length. Because it works successfully more often, most investigators find that target DNA about 4 kb and shorter are optimal for PCR amplification. It is difficult to amplify target DNAs greater than 4 kb in length. PCR can also detect one copy of DNA in 10^6 genomes. More specifically, if a gene is represented once in the genome, detection by PCR can be achieved using as few as 1 million cells.

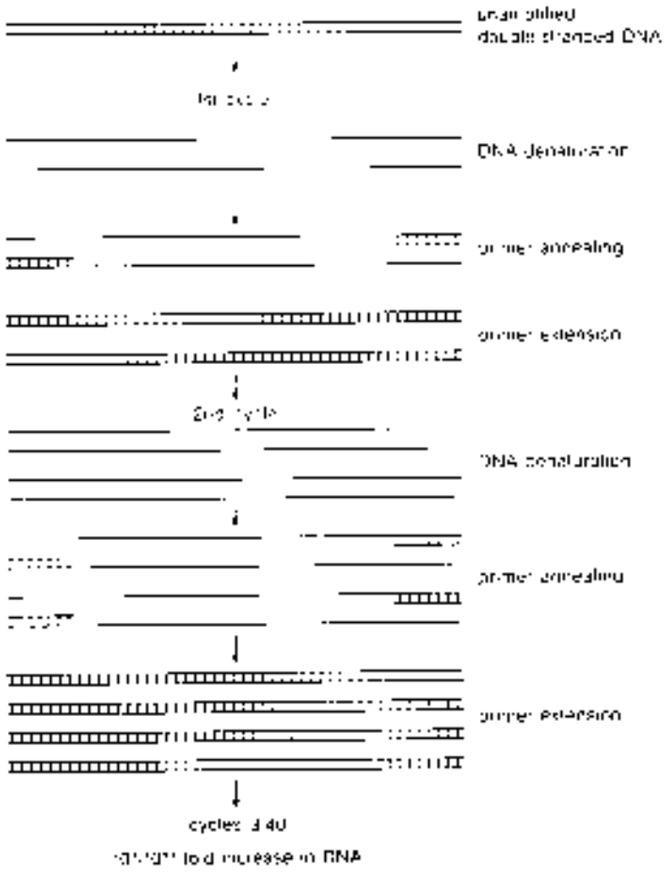

FIG. 2. Polymerase chain reaction.

PCR consists of several cycles in which three steps are repeated in the same order for each cycle. These steps are denaturation, annealing of oligonucleotide primers, and primer extension (Fig. 2). The first step is to heat the double-stranded DNA at 94°C in order to denature it into single-stranded DNA. The DNA remains single-stranded until the temperature is lowered for the next step of primer annealing. Single-stranded target DNA can then anneal to single-stranded DNA primers.

Two primers, generally 15–30 base pairs (bp) in length, are made that are complementary to each strand of the target DNA. Usually, this requires that the sequence of the ends of target DNA be known; however, exceptions to this requirement will be discussed. These primers are typically not complementary to each other. It is better to avoid using AT- and GC-rich primers, if possible, and to avoid primers containing internal secondary structure. The primers are hybridized to opposite DNA strands and bind at the 3′ ends of the complementary DNAs in the 5′ → 3′ orientation (Fig. 3). Thus, extension by DNA polymerase can proceed in the 5′ → 3′ direction, and the DNA strand is synthesized by the addition of deoxynucleoside triphosphates. The primers are added to the PCR reaction in huge excess in order to favor the binding of the primers to the target DNA and not the reassociation of the complementary target DNA strands.

The temperature used for annealing is in the range of 37–55°C. The lower temperature of annealing is used for amplifications in which high specificity or stringency is not required. For example, if the objective is to amplify genomic DNA to find new members of a gene family or DNA sequences that have partial homology to the target DNA, then a lower temperature should be used for hybridization. Also, if the complementarity between the primers and the target DNA is not 100% certain, a lower temperature for hybridization is used. A higher temperature is used for annealing in amplifi-

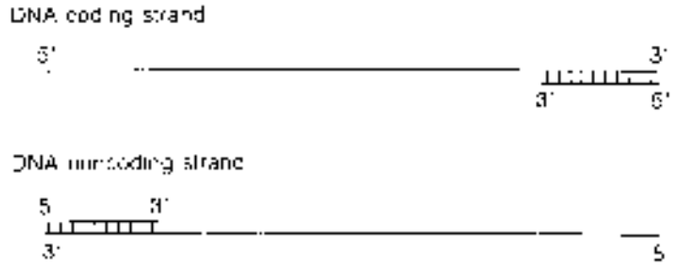

FIG. 3. Primer complementarity with denatured DNA.

cations requiring greater specificity or stringency. For instance, if the goal is to amplify one specific target DNA from genomic DNA, then a higher annealing temperature will produce fewer DNA fragments that are not of interest. It may take some trial and error to find the most appropriate temperature to use for a given experiment.

PCR specificity is also affected by factors other than the annealing temperature. The concentrations of deoxynucleoside triphosphates, primers, magnesium, and DNA polymerase can be varied. The times used for denaturation, annealing, and extension can be changed to allow a given specificity. The number, location, nature, and context of mismatches between the target DNA and primers will also influence PCR specificity.

After the primers are annealed to the target DNA, the appropriate DNA deoxynucleoside triphosphates are incorporated by the DNA polymerase starting at the 3' end of the primer and proceeding in the 5' → 3' direction. The extension continues until the entire target DNA has been replicated.

There are many types of DNA polymerases. The first PCR experiments performed by Perkin–Elmer Cetus used the Klenow fragment, the large fragment of DNA polymerase I, from *Escherichia coli* for primer extension at 37°C. This approach had several drawbacks because the Klenow fragment is not stable at high temperatures; therefore, it needs to be added after the denaturation step of every cycle. This enzyme is also less specific and yields high backgrounds. In addition, the Klenow fragment could amplify target DNAs no greater than a few hundred base pairs.

A breakthrough occurred upon the discovery that *Taq* DNA polymerase could be used in PCR (28). This polymerase is thermostable; it was first found in *Thermus aquaticus* (2), which live in the boiling geysers of Yellowstone National Park. *Taq* DNA polymerase was isolated and purified by several research laboratories (15,18,28). The PCR extension step is done at 72°C with *Taq* DNA polymerase, and this enzyme remains active at 72°C after repeated exposure to 94°C during the denaturation step. This polymerase is more specific, produces less background in PCR, and can amplify targets up to 10 kb. Presently, there are at least nine commercially available thermostable DNA polymerases that have been isolated from *Thermus flavis*, *Thermococcus litoralis*, and *Thermus aquaticus* (27). The use of thermostable DNA polymerases has allowed for the automation of PCR, thus making the PCR technique highly desirable.

As usually purified, *Taq* DNA polymerase does not appear to have an editing (proofreading) function to correct mistakes in the addition of deoxynucleoside triphosphates during extension. Editing removes any incorrect deoxynucleoside triphosphates that have been added by the polymerase. The estimated error rate for the *Taq* polymerase is less than one in 75,000 nucleotides polymerized, which is not a problem for most amplifications (6). For experiments requiring lower error rates, the T4 or T7 DNA polymerases can be used. However, these enzymes are not thermostable. It would be useful if thermostable enzymes that produce less error during DNA polymerization were available.

The most convenient method of performing PCR is to use a commercially distributed automated thermal cycler. Presently, there are 24 different types of thermal cyclers produced by 14 different corporations (27). The typical thermal cycler is a software-controlled heating/cooling system in which temperature and time are regulated. There is one heating/cooling block that holds 48–96 0.5 ml eppendorf tubes; this block is cycled through the various temperatures. The cycler is able to make the temperature changes very rapidly.

Some commercially available automated PCR machines use robotic work stations in which the samples are moved among three different temperature blocks, each set at a different temperature. These devices have several disadvantages and require a large bench space in the laboratory. Some laboratories have created their own homemade PCR machines, including a low-cost air-driven cycling oven (13), modification of a histokinette (13), a teacup/beaker device (13), and a do-it-yourself robotics work station (14). The cheapest, most labor intensive method is to set up three temperature blocks, each at a different temperature, and move the sample tubes manually using a timer to signal the end of each step. It is worth trying this method once in order to have a true appreciation of automated PCR.

Some laboratories use multi-channel automated liquid handlers for automation of pipetting in the preparation of PCR samples. Many investigators find that preparation and use of a master mix that includes all the reagents necessary for PCR, including the *Taq* DNA polymerase, is efficient and reduces pipetting errors. The master mix is added to the sample tubes containing the DNA to be amplified and the primers. Large numbers of samples can be prepared by this method, so that a sophisticated automated liquid handler is not necessary.

Because PCR is so sensitive, it is easy to amplify unwanted contaminants. In order to reduce contamination of PCR samples, many laboratories utilize positive displacement or motorized pipettors.

These pipettors allow for slow and even uptake of solutions, thereby decreasing the risk of DNA solutions becoming aerosolized during suction and contaminating the pipettors. However, many investigators are able to use the standard pipettors carefully with no contamination. It is best to set aside a set of pipettors that are used only for PCR. Contamination of PCR samples can also be avoided by aliquoting reagents that are used for PCR and including amplification of highly characterized positive and negative controls in all experiments.

The typical PCR sample contains 1 ng–1 μg of DNA to be amplified, 1.0 μM of each primer, 200 μM of each dNTP (dATP, dCTP, dTTP, dGTP), 10 μl of ×10 reaction buffer (500 mM KCl, 100 mM Tris-HCl pH 8.3, 15 mM $MgCl_2$, 0.1% gelatin), 2.5 units *Taq* polymerase, and double-distilled water to give a final volume of 100 μl. On top of the sample, 100 μl of high quality mineral oil is layered in order to prevent evaporation. A typical cycle will perform denaturation for 1.0–1.5 min, primer annealing for 1.5–2.0 min, and primer extension for 3.0 min. A total of 25–45 cycles are usually done. If RNA instead of DNA is used in the initial PCR sample, then it is necessary to produce the first strand cDNA with reverse transcriptase before starting PCR. A new thermostable DNA polymerase, rTth DNA polymerase (Cetus), functions as a reverse transcriptase and a DNA polymerase. This allows production of the first strand cDNA and cDNA amplification in the same tube with the same enzyme.

PCR conditions can be optimized for certain DNAs. Some DNAs require different conditions that are determined by trial and error. For instance, the concentration of $MgCl_2$ in the reaction buffer can be varied from 1.5 to 4.0 mM, the primer extension time can be shortened to 1.0–2.0 min, the amount of *Taq* polymerase used can be decreased, and the temperature for annealing of the primers can be increased. If too little $MgCl_2$ is used in the reaction buffer, no PCR product will be produced. Too much $MgCl_2$ will produce nonspecific DNA fragments during PCR. A new thermostable DNA polymerase, AmpliTaq DNA polymerase Stoffel fragment (Cetus), is available that minimizes optimization experiments for PCR. It is useful to amplify a control DNA utilizing control primers that produce a single DNA fragment of known size in order to determine if the PCR experiment has been successful (at least for the control DNA). Most PCR kits sold commercially include these control reagents along with all the necessary reagents needed for PCR. There are at least 21 different commercial PCR kits produced by six different corporations (27).

Another popular method called "fast," or "turbo," PCR has been used successfully by several investigators to amplify target genomic DNA that seems difficult to amplify or to increase the yield of amplification product. This procedure involves significantly decreasing the duration of all the steps in the cycle: Denaturation time is 15 sec (30 sec for cycle 1), primer annealing time is 15 sec, and primer extension time is 1.0 min. The total number of cycles of PCR performed is 60. Because the times for each step are decreased, the *Taq* polymerase can catalyze replication effectively throughout all 60 cycles. Under typical PCR conditions, with longer times for each step, there is no detectable increase in amplified DNA after cycle 40. Target DNA of up to 3.0 kb can be efficiently amplified by the fast PCR procedure.

After the last PCR cycle, the samples are placed at 4°C or the thermal cycler can be programmed to end with a 4°C cycle of indefinite length. The samples are analyzed to determine the products that were produced and to verify that the PCR was successful. This is done by removing 5.0 μl of the total 100 μl PCR sample by placing the pipette tip on the pipettor under the mineral oil layer and suctioning. The sample aliquots may be electrophoresed on agarose or polyacrylamide gels and stained with ethidium bromide. In order to distinguish short DNA fragments 20–250 bp in length, it is best to use a 2.5–3.0% agarose gel, a 20% polyacrylamide gel, or a 3.0% NuSieve/1.0% agarose gel for electrophoresis. If the results of gel electrophoresis are not clear or if the goal of PCR is to identify fragments of an unknown length, it may be necessary to perform a Southern blot analysis on the gel using the target DNA or target DNA oligonucleotides as probes.

In order to "clean up" PCR samples for use in other experiments, the following method is generally used if the PCR produced only one DNA fragment of expected size. The PCR sample is placed on dry ice for 5 min so that the sample is frozen and the mineral oil on top is not frozen. The oil is then removed; the sample is phenol-extracted, chloroform-extracted, precipitated in 100% ethanol, washed in 70% ethanol, dried, and resuspended in the appropriate volume of TE buffer. Other commercially available methods of purification include column chromatography or centrifugation. Alternatively, it is possible to perform certain procedures, such as restriction enzyme digestions, without cleaning up the PCR sample. In this case it is necessary to determine whether the components of the PCR reaction are or can be adjusted to be compatible with the conditions required for adequate activity of the restriction enzyme.

If more than one PCR fragment was produced, it is necessary to first separate the fragments on a polyacrylamide or a low-melting temperature agarose gel. The DNA fragments of interest are cut from the gel and purified. Some procedures, such as DNA ligations, can be performed on DNA fragments while they are embedded in certain gel matrices. Other protocols require that the DNA be eluted from the gel first and purified.

In order to produce PCR fragments for use in subcloning, restriction enzyme recognition sites are added at the 5' ends of the primers (Fig. 4). This methodology is possible because PCR is successful in the presence of a few nucleotides at the 5' end of the primers that are not complementary to the target DNA. The primer typically has 15–30 nucleotides that are complementary to the target DNA, preceded by 4–8 nucleotides at the 5' end to produce the restriction enzyme recognition site of choice; it also has 2–4 nucleotides at the outermost 5' end to allow for more efficient digestion by the restriction enzyme of choice at the recognition site (Fig. 4). Addition of extra nucleotides at the 5' ends of the primers does not interfere with PCR efficiency. In fact, *Taq* DNA polymerase adds extra nucleotides at the ends of template DNA during DNA synthesis. In order to produce a PCR fragment for directional ("forced") cloning, each primer is designed to have a different restriction enzyme recognition site. Both sites should have compatible ends with the sites found in the polylinker of the cloning vector. Thus, the investigator

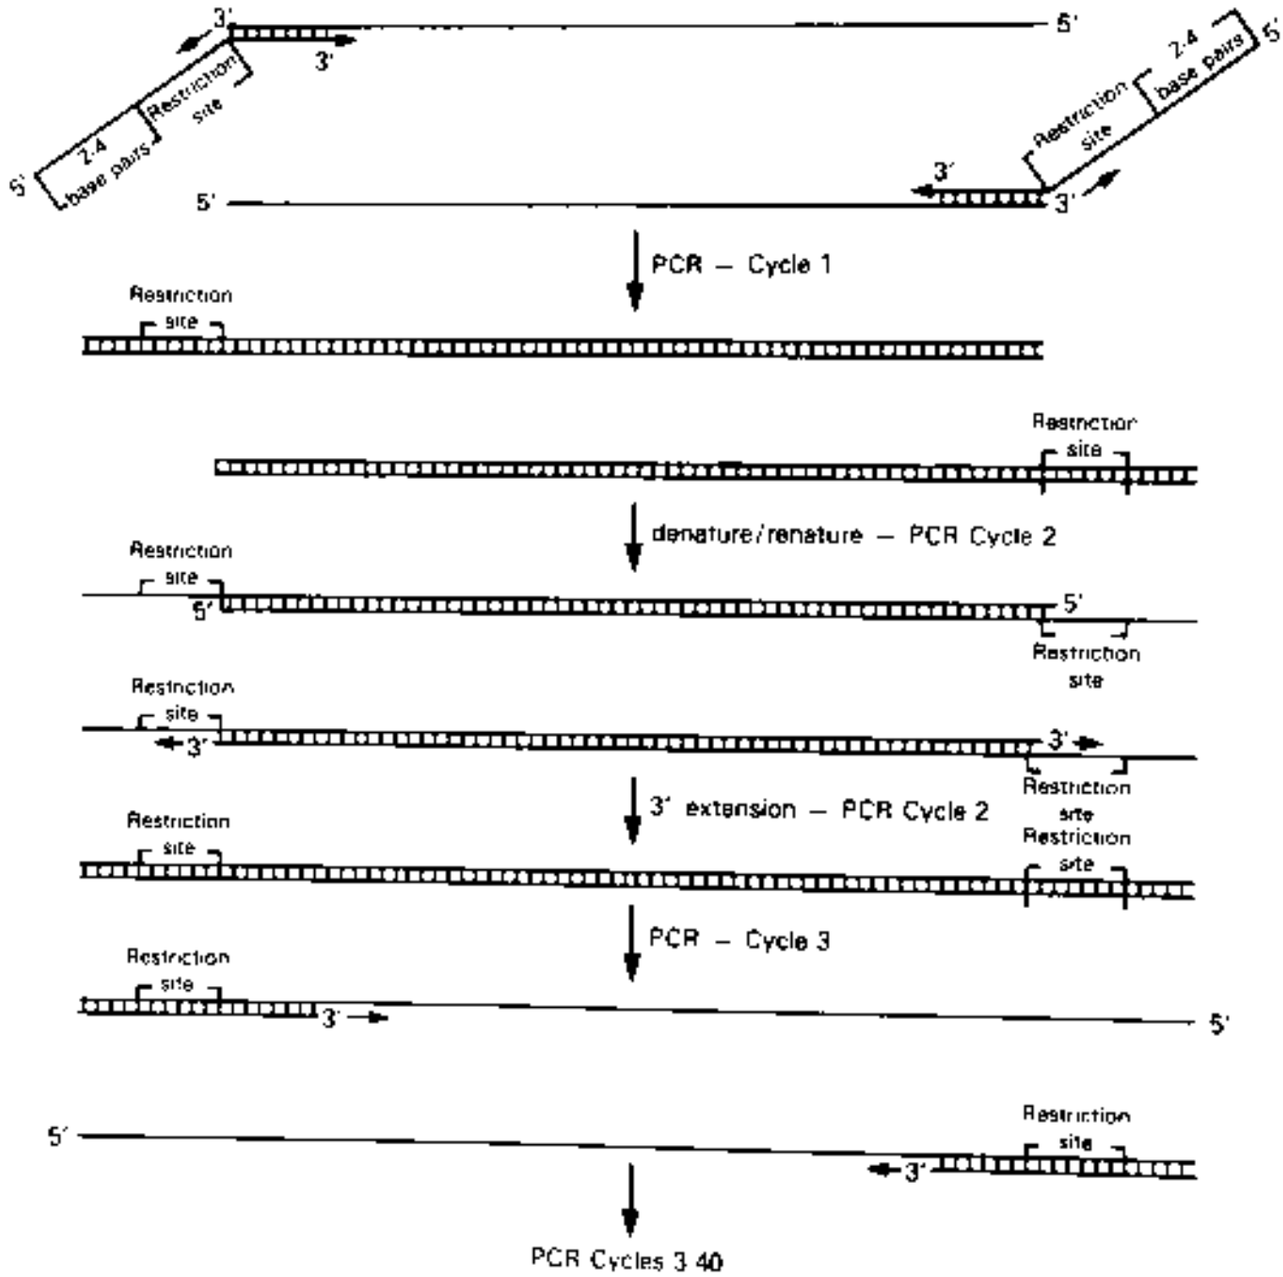

FIG. 4. Addition of restriction enzyme recognition sites in PCR.

can choose the orientation of the PCR fragment within the cloning vector. In addition to designing restriction enzyme recognition sites, this methodology can be used to introduce site-directed point mutations into amplified products of the target DNA by placing point mutations into the primers.

Inverse PCR allows amplification of DNA regions of unknown sequence that flank DNA of known sequence (Fig. 5). First the DNA is cut with restriction enzymes within the regions of unknown sequence so that the two DNA ends are compatible. Then the DNA is circularized by ligation. Primers are made to the known DNA sequence adjacent to the unknown DNA sequence, so that amplification occurs over the unknown sequence region. This method requires restriction enzyme recognition site information in the areas of unknown sequence. Therefore, restriction mapping must be done prior to PCR, and sites chosen for restriction enzymes must not cut within the vector or the region of known sequence. The optimal length for the target DNA is <4 kb. Inverse PCR is used for gene walking, identifying and amplifying transposable elements, for sequencing DNA flanking viral integration sites, and for analyzing genetic regulatory elements located outside or adjacent to genes of known sequence.

Anchor PCR allows amplification of DNA and RNA sequences that have variable termini and RNA whose 5' sequence is not known (7,20,25). Figure 6 demonstrates this technique starting with an mRNA with an unknown 5' sequence. The mRNA is transcribed into cDNA using reverse transcriptase. A poly (dG) tail is added at the 3' end of the cDNA using deoxynucleotidyl transferase. An anchor primer, a poly (dC) tail that could also contain a convenient restriction enzyme recognition site at the 5' end (for use in subsequent subcloning), and a specific primer are hybridized to the "tailed" cDNA. A typical PCR can then be performed to amplify this cDNA. Anchor PCR is significant because a cDNA, with unknown 5' sequence, could not be amplified by inverse PCR without subcloning into a vector first. Therefore, anchor PCR eliminates the requirement for subcloning.

Several methods are now used to sequence DNA fragments directly after PCR. These procedures include Sanger sequencing of single-stranded DNA fragments produced by asymmetric PCR (3,11,21), directly sequencing double-stranded PCR products (1,3) by the Sanger method, direct Sanger sequencing of single-stranded DNA produced by PCR using biotinylated primers (3,22), Maxam-Gilbert direct sequencing of PCR-amplified DNA (3,30), and

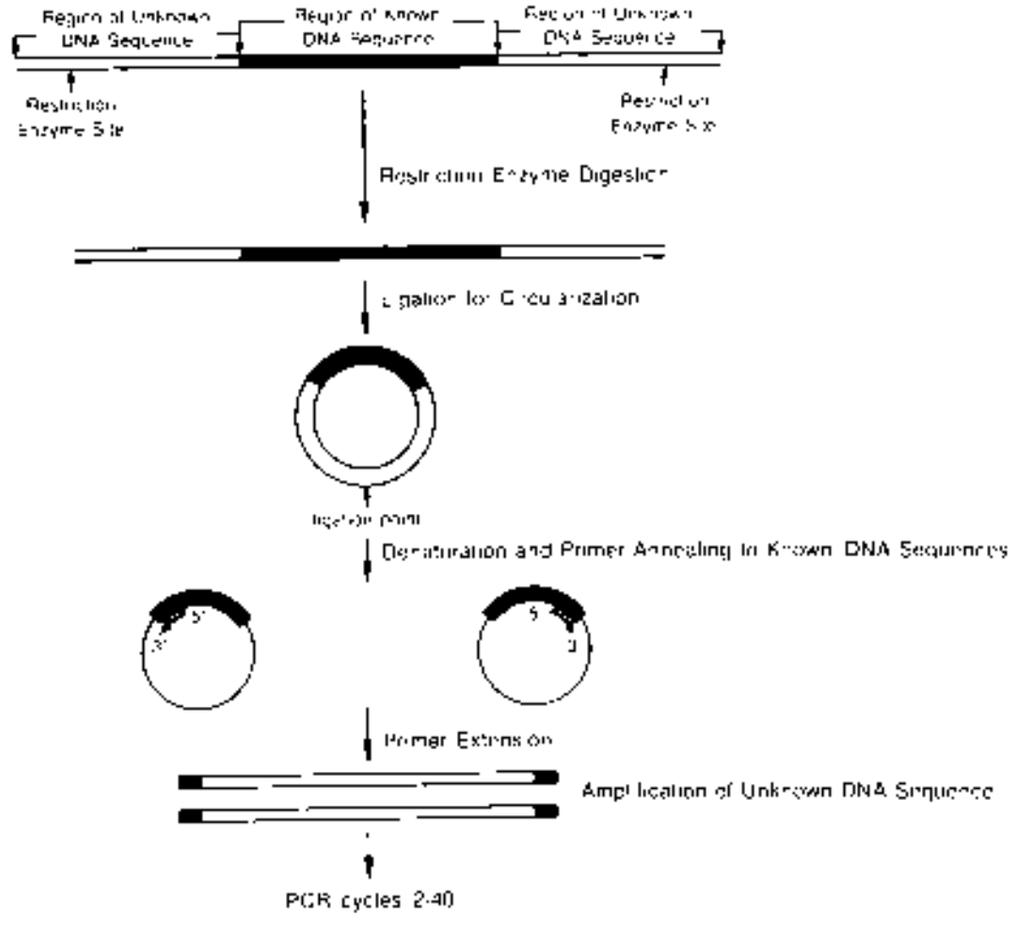

FIG. 5. Inverse PCR.

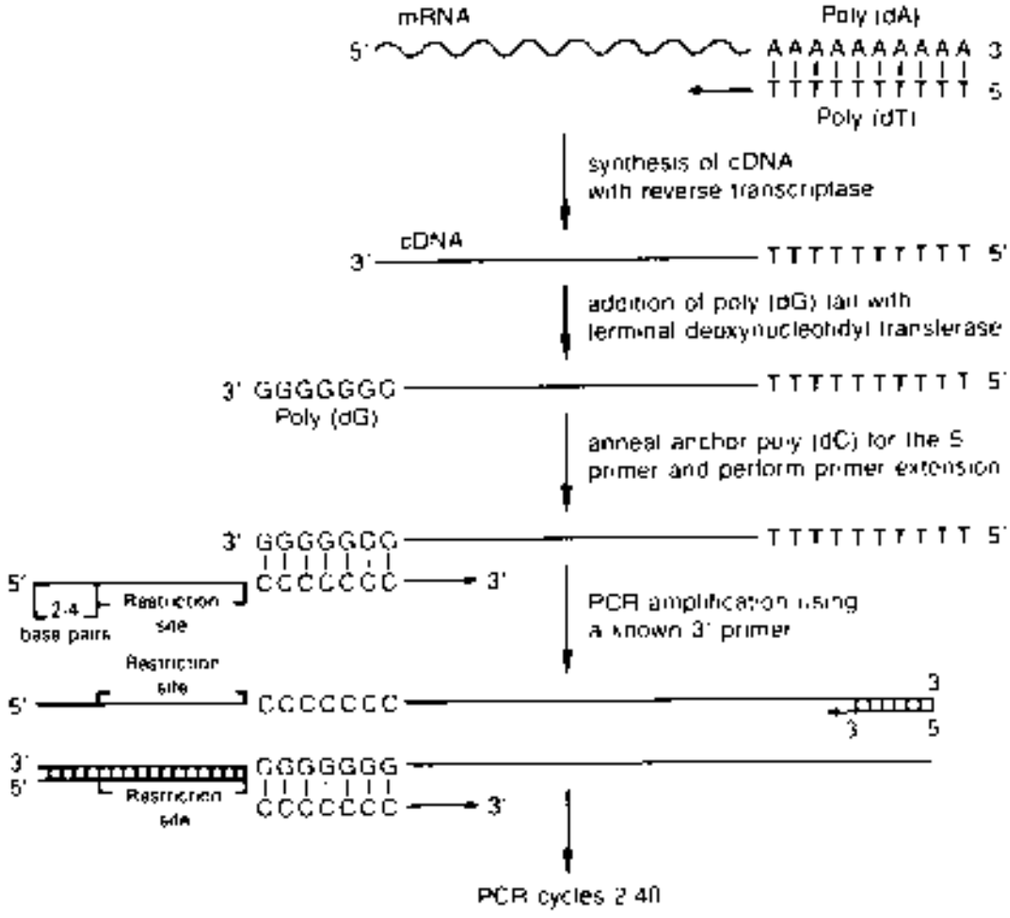

FIG. 6. Anchor PCR.

Sanger sequencing of single-stranded DNA generated by λ exonuclease digestion of double-stranded DNA products (3).

Because sequencing of PCR fragments is easier to do using single-stranded DNA, the basic strategy for direct sequencing of PCR products is to isolate or produce one DNA strand. Asymmetric PCR produces mainly single-stranded DNA fragments because the PCR samples contain primers in different molar concentrations (Fig. 7). Asymmetric primer ratios in the range of 50:1 to 100:1 are typically used. Double-stranded DNA is produced exponentially until cycles 10 to 15. The primer in lower concentration becomes depleted; therefore, the DNA strand that is primed with this primer is no longer produced. Only the DNA strand primed with the primer in greater concentration is produced linearly throughout the remaining cycles. Thus, 10–20 times more single-stranded than double-stranded DNA is produced during the amplification procedure.

Another way of isolating one DNA strand from the other is to purify one strand. This method makes use of biotinylated primers in PCR. By labelling the 5' end of one PCR primer with biotin-NSH (3,22), the target DNA strand synthesized from this primer contains biotin at its 5' end. The two PCR fragments produced are separated by purifying the heat-denatured sample on a streptavidin agarose column (22) or on magnetic/streptavidin beads (12) after PCR is completed. The biotinylated DNA strand will be bound to either the column or to the beads, respectively and the biotinylated DNA can be eluted. Sequencing can be performed on the biotinylated DNA while it is attached to the magnetic beads. This technique works extremely well. Good sequence data have also been produced on an

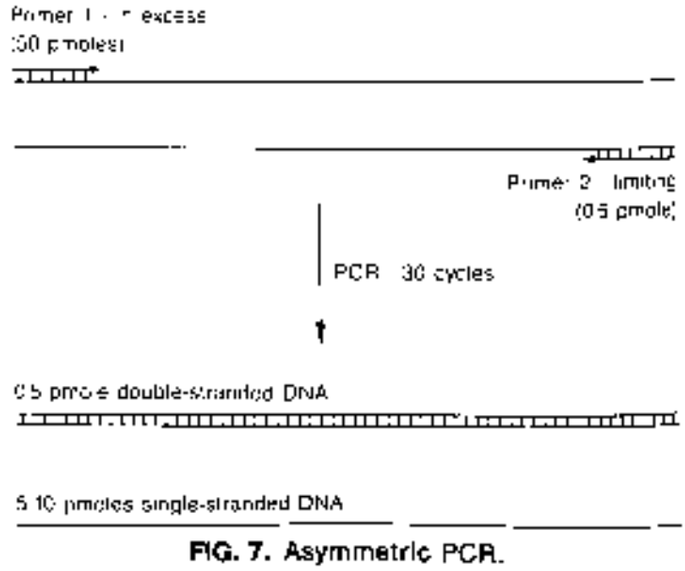

FIG. 7. Asymmetric PCR.

automated fluorescence DNA sequencer. The non biotinylated DNA strand can also be recovered and sequenced.

Internal site-specific mutagenesis can be produced by introducing point mutations into primers for PCR fragments that overlap in sequence (Fig. 8). A point mutation is introduced into the 3′ primer for the 5′ upstream DNA fragment. The same point mutation is placed into the 5′ primer for the 3′ downstream DNA fragment. The first PCR amplification is performed on the overlapping DNAs separately through about 40 cycles. The amplification products from both PCRs are combined, the primers are removed, and the DNA strands are denatured and renatured. A population of DNAs will anneal so that they will join only at the short region of overlap. Primer extension can then be performed in the 5′ → 3′ direction on the DNAs that overlap in a manner producing exposed 3′ ends. The extended DNA is denatured and renatured in the presence of primers from the outermost ends of the original overlapping DNA fragments, so that only the fully extended overlapping DNA will be amplified in the second PCR for about 40 cycles. The PCR product produced after the second PCR contains the internal site-directed mutation.

Internal insertions, internal deletions, and sequence recombination can be produced by PCR in a method similar to that described for introducing internal site-specific mutagenesis. For internal insertions, the insertion is placed into the 3′ primer for the 5′ upstream overlapping DNA fragment (Fig. 9). The same insertion is placed into the 5′ primer for the 3′ downstream overlapping DNA fragment. The first and second PCR amplifications are carried out as described for producing internal site-directed

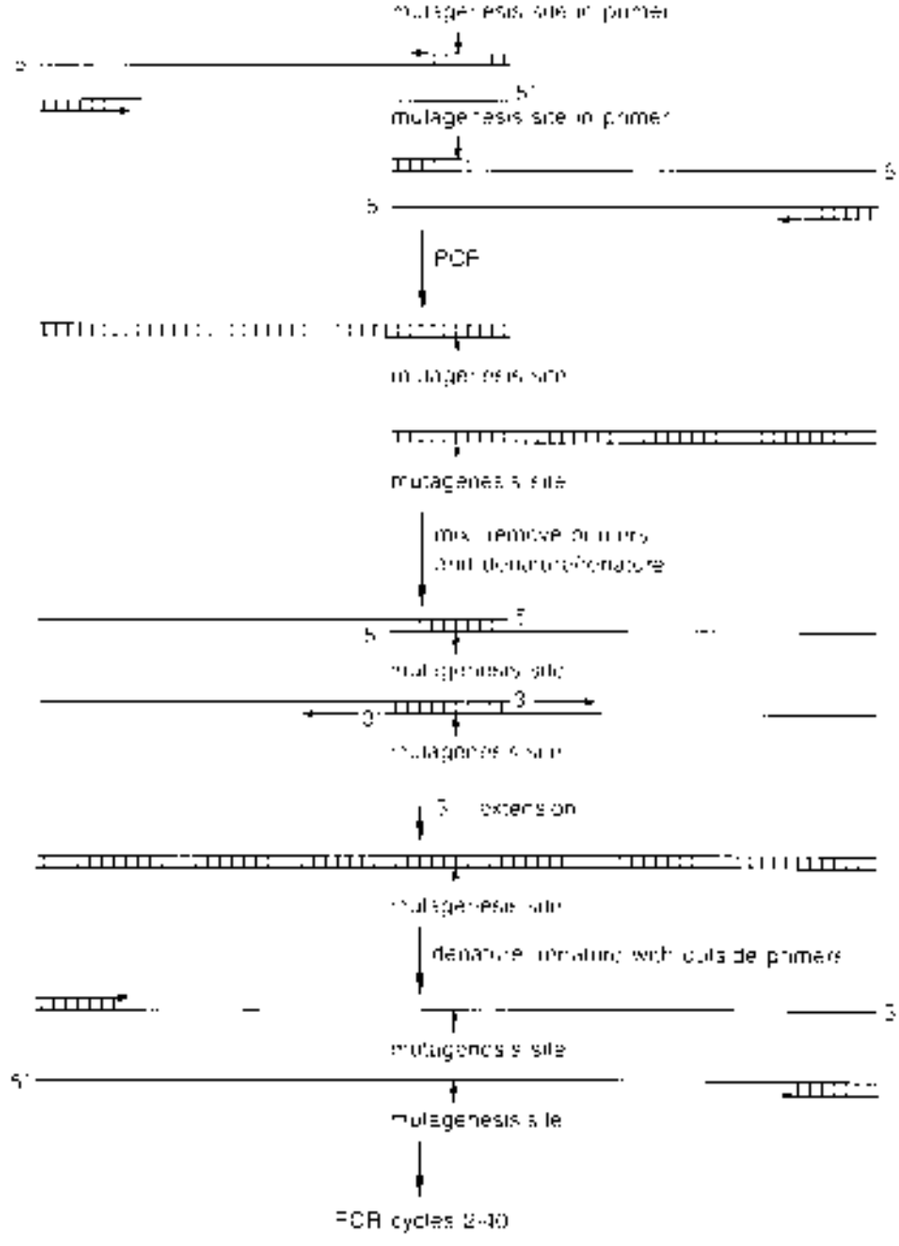

FIG. 8. Internal site-specific mutagenesis by PCR.

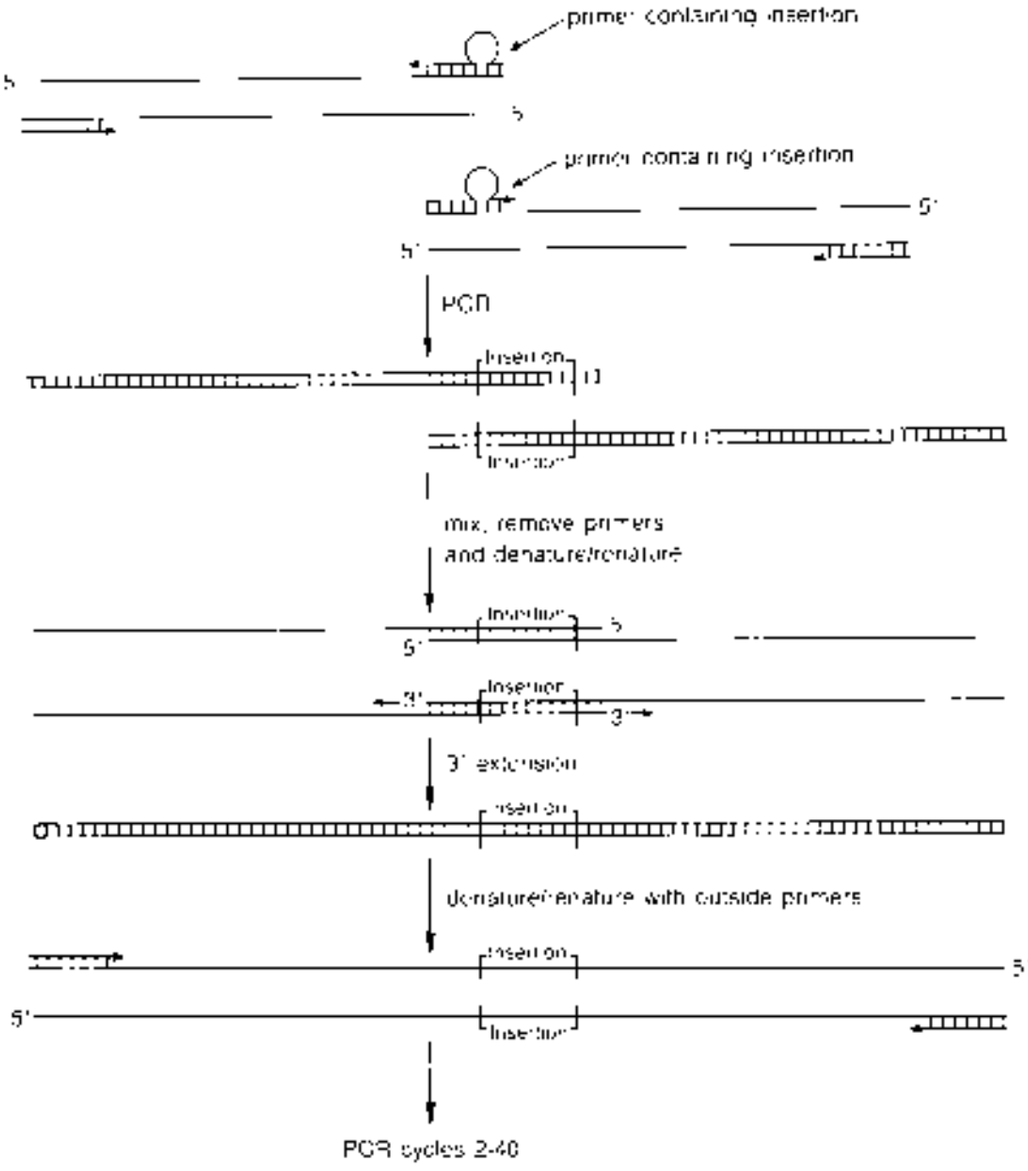

FIG. 9. Internal insertion by PCR.

mutagenesis. The PCR product produced after the second PCR contains the internal insertion of interest. The method is similar for introducing internal deletions by PCR (Fig. 10). The only difference is that a deletion is made in the 3′ primer for the 5′ upstream overlapping DNA fragment. A similar deletion is made in the 5′ primer for the 3′ downstream overlapping DNA fragment. The first and second PCR amplifications are performed as described for producing internal site-directed mutagenesis. The PCR product created after the second PCR contains the desired internal deletion.

Sequence recombination by PCR is a method that joins two unrelated DNA fragments (Fig. 11). This is done by placing a short sequence complementary to the 5′ end of DNA 2 onto the 3′ primer for DNA 1. Also, a short sequence complementary to the 3′ end of DNA 1 is placed onto the 5′ primer for DNA 2. This procedure creates a region of complementarity between DNAs 1 and 2. The first and second PCR amplifications are performed as described for producing internal site-directed mutagenesis. The PCR product produced after the second PCR is a fusion of DNAs 1 and 2.

Other systems for amplification besides PCR are presently available (see 4,9,19,27 for more detailed information). These systems include the ligation amplification reaction (LAR), Qβ replicase amplification, nucleic acid sequence-based amplification (NASBA), the transcription-based amplification system (TAS), and the self-sustained sequence replication system (3SR). LAR amplifies DNA sequences by ligation using bacteriophage T4 DNA ligase; a related method, LAS (ligase-based amplification system), uses *Escherichia coli* DNA ligase. In these two methods, primers that hybridize to adjacent regions of DNA of known sequence are brought together through ligation. These methods, which amplify target DNA no longer than about 50 bp, are used to distinguish normal alleles of genes

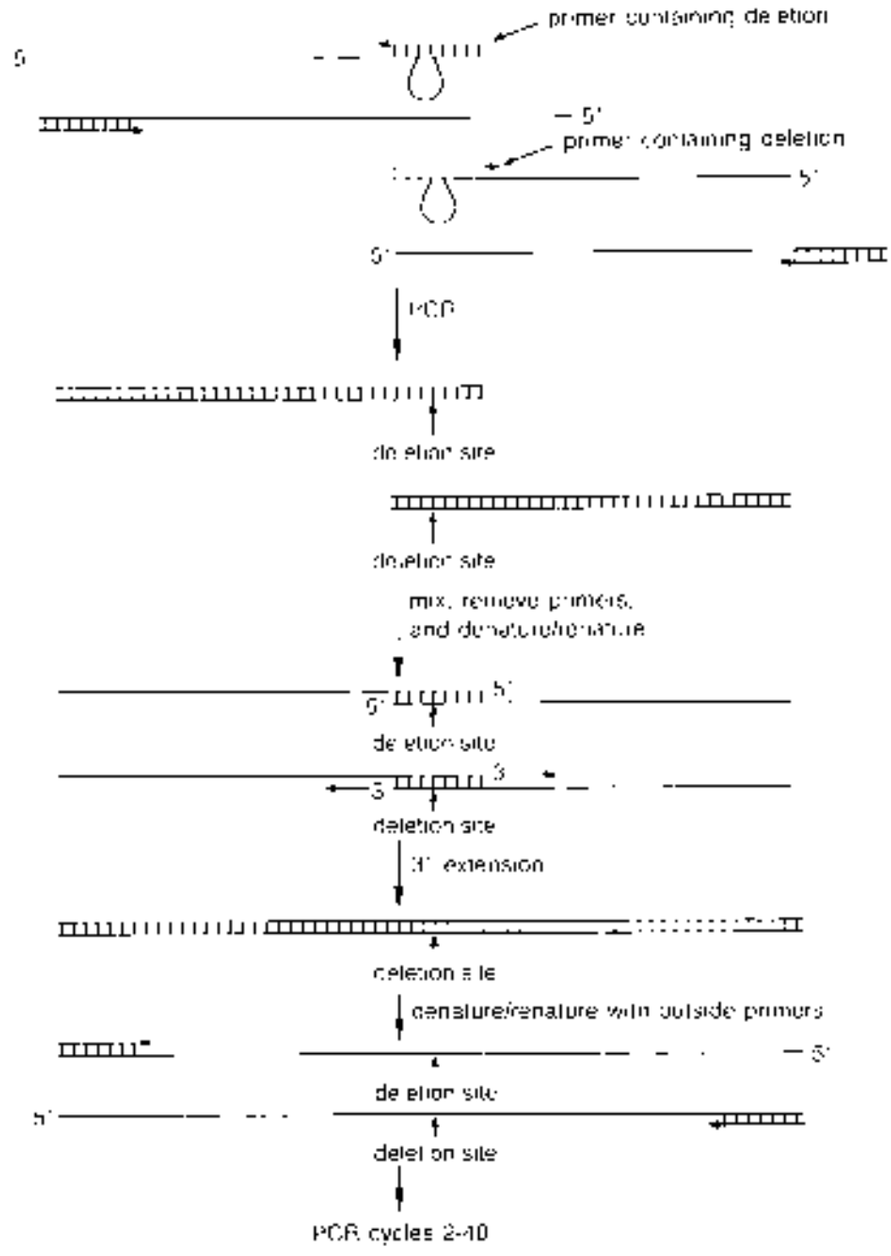

FIG. 10. Internal deletion by PCR.

from alleles containing point mutations. Primers that do not complement the target DNA exactly cannot be ligated. The advantages of ligase-based amplification are speed, reliability, and consistency. Also, there is no requirement for characterization of the amplified product, because evidence that the ligation occurred is proof that the sequence of interest is present.

Qβ replicase amplifies the signal of an RNA probe and is useful in determining the presence of a certain DNA or RNA. Qβ replicase is an RNA polymerase isolated from the RNA bacteriophage Qβ. This polymerase can also copy an RNA named midivariant (MDV-1) which is found in *Plasmodium falciparum*, a protozoan parasite. The probe of interest is first subcloned into MDV-1; therefore, the MDV-1 RNA and the probe are amplified in the presence of an activated Qβ replicase. Some advantages of this system are that (a) all steps of the reaction are performed at 37°C and no thermal cycling is required; (b) amplification is so great (10^9-fold in 30 min) that products can be detected colorimetrically; and (c) the amount of RNA produced within a given period of time can be used to determine the initial number of target sequences. Disadvantages of this amplification system are that Qβ replicase is extremely unstable, produces many errors during replication, and produces many false positives.

There are several systems that use RNA transcription to produce more amplified product. These systems are more efficient than PCR because transcription produces hundreds of copies of the RNA target from one cDNA. NASBA amplifies DNA and RNA without changing temperature and cycles DNA and RNA synthesis evenly. This system uses T7 RNA polymerase, RNase H, and AMV reverse

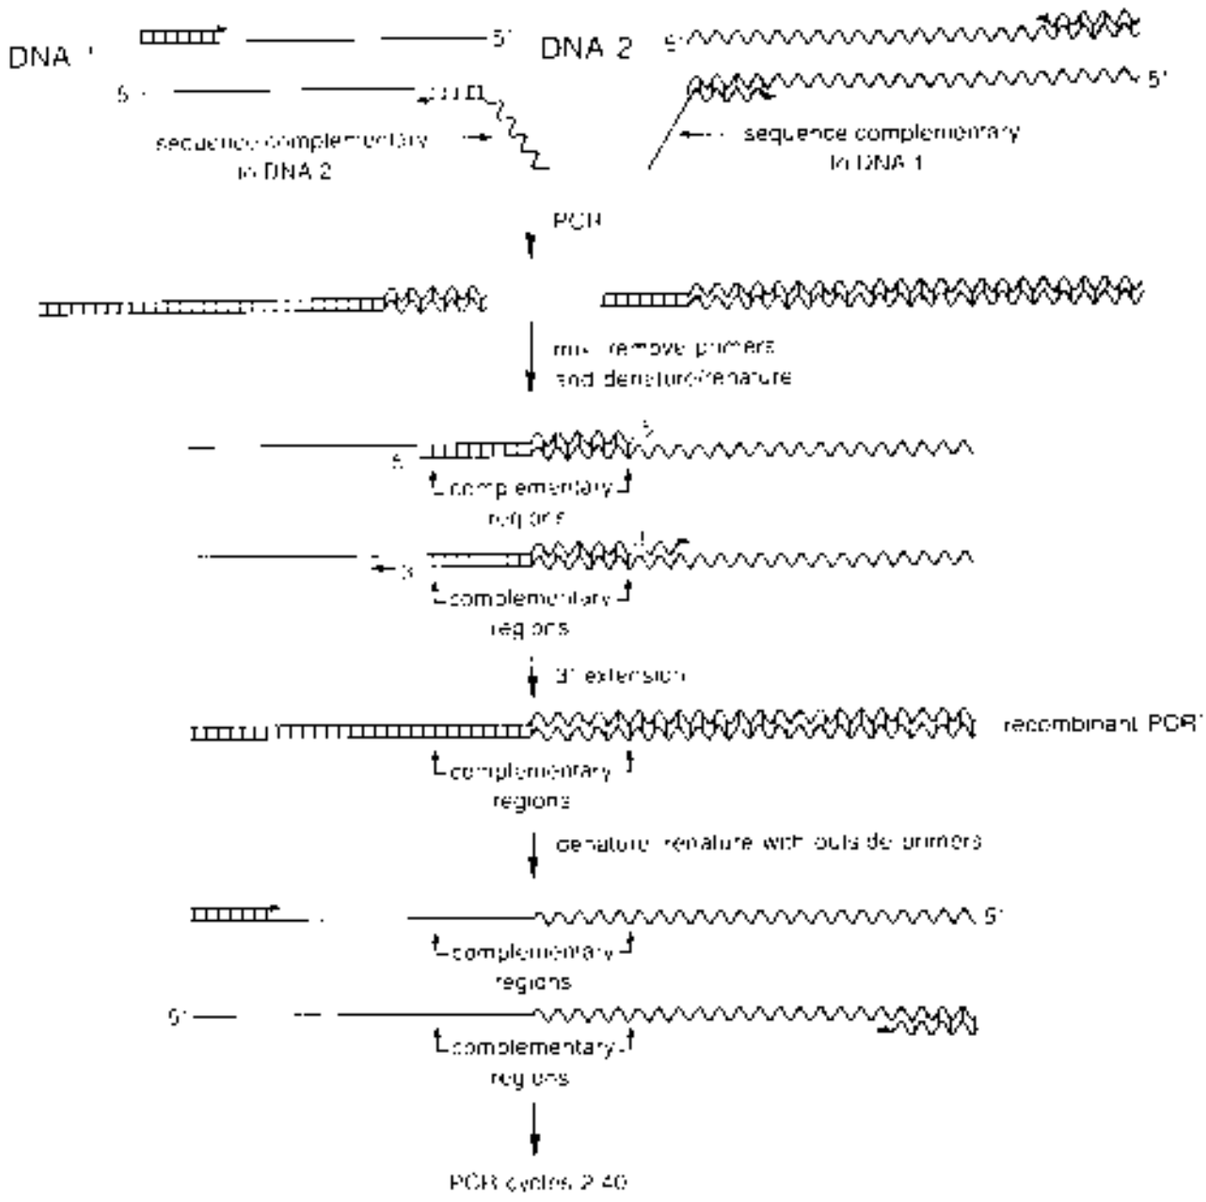

FIG. 11. Sequence recombination by PCR.

transcriptase to produce amplification in a series of many steps (4). The reaction is performed at 42°C for 1–2 h and produces about a 10^9-fold amplification. The amplification products are analyzed on an agarose gel, a slot blot, or a dot blot. As few as 10 molecules in a mix of 10^{10} molecules can be detected (19). TAS amplifies DNA or RNA targets by RNA transcription using T7, T3, or SP6 RNA polymerase (13,27). cDNA synthesis and RNA transcription occur at each cycle. Complementary strands for both RNA and cDNA are produced by the reverse transcriptase when it is added after the RNA-DNA hybrid is denatured. An advantage of this system is that RNA produced after amplification can be directly sequenced. 3SR is an amplification system similar to TAS except that the RNA-DNA hybrids are separated by RNase H and not by heat denaturation (9,27). Thus, all steps can be done at one temperature, and a thermal cycler is not required.

PCR APPLICATIONS

One of the most significant applications of PCR technology is the identification and analysis of mutations in eukaryotic DNA (21). DNA deletions and insertions can be detected by a change in size of the PCR product. Failure to produce any PCR fragment indicates that the primer is found in an area of deletion. Mutations can be identified by hybridizing PCR-generated DNA fragments to radioactively labelled RNA probes and digesting the DNA-RNA complex with RNase A. Digestion will occur if the complex contains any mismatches. Localization of mutations has also been achieved by examining

PCR products using denaturing gradient gel electrophoresis (DGGE). DGGE separates about 50% of DNA strands <1,000 bp in length that have single base changes (6). This technique separates DNA strands by electrophoresis through a polyacrylamide gel containing a linear gradient of DNA denaturants. The DNA strands migrate differently because they have slightly different melting properties. In addition, differences in a single DNA base can be detected by competitive nucleotide priming. In this procedure, two different primers that differ in one DNA base are used in PCR to prime one DNA strand. Thus, there are three primers used in the entire PCR sample. One of the two similar primers is radioactively labelled, allowing the amount of PCR products yielded by each primer to be determined. The sequence of the amplified target DNA is that of the primer that produced the greatest amplification.

Over 23 different human gene mutations and allele-linked disorders have been diagnosed using PCR (5). Some of these diagnoses have been performed prenatally or on embryos before they are implanted for in vitro fertilization. In addition, detection of amplified oncogenes has been achieved by differential PCR. In this procedure, the oncogene of interest and a single-copy reference gene are coamplified in the same PCR tube. Gene amplification is determined by comparing the intensity of the oncogene PCR product with that of the amplified reference single-copy gene. This method can detect even twofold differences and has been used to study gene amplifications of the *neu* oncogene and the epidermal growth factor (EGF) gene.

PCR has been used to identify over 22 different pathogenic organisms in clinical samples (5,13). A dispute in the field of AIDS research was settled by a critical PCR experiment. Some investigators questioned HIV-1 as the cause of AIDS because this virus could not be detected in late-stage AIDS patients. PCR was performed on CD4+ T cells from the circulatory systems of late-stage AIDS patients. The result of this experiment demonstrated that these cells contain large amounts of HIV-1.

PCR has been used for identification of biological and forensic samples (5,13); however, extreme care must be taken to eliminate DNA contaminants that may be erroneously amplified. DNA has been amplified from a single hair, one sperm, semen stains, blood, blood stains, saliva, buccal epithelial cells, and paraffin-embedded tissues. DNA fingerprint analysis can be performed on the PCR-amplified DNA in order to identify a specific individual. These analyses have been able to identify criminals involved in murder, sexual assault, etc., and have been used to settle paternity cases. PCR has been used in HLA analysis and tissue-typing for organ transplantation. DNA from certain organelles, such as the mitochondria, has been amplified by PCR for further analysis. Advances in the identification and screening of transgenic mice have also been possible with PCR technology. PCR-amplified DNA has been used in studies of gene polymorphisms; these studies have made major contributions to the field of evolution. DNA has been amplified from ancient archeological specimens, including Egyptian mummies, bone, teeth, 7,000-year-old brain tissue, etc.

PCR has had a major impact on developmental biology research (5,13). DNA from certain organisms that do not grow rapidly, such as some fungi, can now be amplified by PCR and analyzed. PCR has contributed to the analyses of expression of growth factors in small quantities of macrophages during wound healing; gene expression during embryogenesis; examination of site-directed homologous recombination of genes in embryonic cells; detection of nucleotide changes resulting from RNA processing events; quantitation of gene expression in specific organs, such as dystrophin gene expression in muscle; and studies of gene rearrangements that occur during development, such as the V-J region rearrangements in the T-cell receptor α-chain.

In conclusion, PCR is an extremely important yet simple technology for research and diagnostic analyses of DNA and RNA. It will be exciting to witness the new applications that arise in the future from this technology or other amplification procedures. The major advantages of PCR are the ability to utilize minute samples to produce a high yield of amplified target DNA, the specificity of the reaction, the flexibility of the method, and the simplicity and speed of the automated procedure. □

Acknowledgment: I thank Dr. Ian J. Molineux for his contribution to the historical section and for review and revision of the manuscript. I thank Drs. H. Gobind Khorana and Ian J. Molineux for helpful discussions, and Dr. Ruth Kleppe for the donation of Fig. 1, which demonstrates the first PCR reaction performed by the late Dr. Kjell Kleppe. I am also grateful to Perkin–Elmer Cetus for their support and sharing of educational materials.

Polymerase chain reaction: A landmark in the history of gene technology

Joe G. N. Garcia, MD; Shwu-Fan Ma, PhD

Definitions

The polymerase chain reaction, known worldwide by the abbreviation PCR, was defined by Kary B. Mullis, the 1993 Nobel laureate, not only as a specific technique or cluster of techniques but also as a concept. Mullis invented the PCR technique in 1985 while working as a chemist at the Cetus Corporation, a biotechnology firm in Emeryville, California. Basically, PCR uses a naturally occurring nuclease enzyme, polymerase, to catalyze the regeneration of DNA with a chain reaction, consisting of three steps (Fig. 1) that are repeated over and over to exponentially amplify the target DNA (1).

History of Development

The Klenow fragment of *Escherichia coli* DNA polymerase I was first used to catalyze the formation and amplification of DNA in 1983 (2). When PCR was conducted manually, the process was time consuming and labor intensive because the heat denaturation step, which is required for the separation of the newly synthesized strands of DNA, also denatured the polymerase. Therefore, fresh enzyme had to be added to the reaction mixture after the completion of each cycle. Fortunately, nature helped to overcome this disadvantage when a thermostable and heat-resistant DNA polymerase derived from *Thermus aquaticus* was purified (*Taq* DNA polymerase) (3–5). Using this heat-resistant polymerase, the amplification reaction could run through heat cycles without interruption. Cetus scientists and others automated the PCR process and developed the first thermocycling machine, "Mr. Cycle," in 1992. Employment of *Taq* DNA polymerase significantly improved the specificity and sensitivity of the reaction and increased yield and length of products. Novel technologies that significantly shorten the chain reaction time have also propelled the efficiency of PCR to a new level. Thus, PCR has allowed genetic material that was once scarce to be extremely abundant for analysis.

How Does PCR Work?

PCR requires placement of a small amount of a gene or segment of DNA (template) and an excessive amount of the DNA building blocks (i.e., the deoxynucleotides, deoxyadenosine triphosphate, deoxycytidine triphosphate, deoxyguanosine triphosphate, deoxythymidine triphosphate) into a PCR tube. A pair (sense and antisense) of synthesized short DNA segments (primers) that flank the sequence of the template are then added. These "primers" anneal to the right portion (complementary sequence) of the template and serve as starting points for the DNA polymerase to begin template copying. On addition of DNA polymerase to this mixture, DNA polymerase builds new complementary DNA (cDNA) strands dictated by the sequence of the target gene located between the two primers. The PCR tube is then heated, and the DNA's double helix separates into two strands (denaturation). The DNA sequence of each strand of the helix is thus exposed, and as the temperature is lowered, the primers again automatically bind to their complementary portions of the DNA sample (annealing). At the same time, the DNA polymerase links the loose deoxynucleotides to the primer and to each of the separated DNA strands in the appropriate sequence (extension). The three steps of denaturation, annealing, and extension are repeated 30–40 cycles, resulting in the exponential accumulation of the specific target fragment, approximately 2^n, where n is the number of cycles (6–7) (Fig. 1).

The concept and technology of reverse transcriptase (RT)-PCR and real-time PCR are similar to PCR with some modification. In RT-PCR, RNA and not DNA is used as the template and the RT is needed to transcribe RNA to cDNA before the initiation of PCR. Both PCR and RT-PCR can be used to quantitate the concentration of a particular target by amplifying the target sequence and a reference sequence, commonly referred to as a housekeeping gene, to a more readily detectable quantity. By comparing the amount of amplified product (amplicon) generated by the reference and the target sequences, one can estimate the relative amounts of the target sequence produced in a particular situation. However, this assay measures end-products without precisely knowing the saturation phase, thus rendering this approach less accurate (8). Quantification is more accurate if, during the exponential phase of the chain reaction, the reference and target sequence are present in approximately equal concentrations and both sequences amplify with equal efficiency (9).

The technique of real-time PCR employs similar concepts to quantify the amount of the target sequence throughout all cycles but uses a template-specific fluorescent reporter. This reporter increases the sensitivity of detection of the PCR product and is thus more accurate and reproducible (10). The fluorescence signal increases in direct proportion to the amount of PCR product in a reaction during each cycle (i.e., in real time) as opposed to at the end point detection (Fig. 2). By recording the amount of fluorescence emission at each cycle, it is possible to monitor the PCR reaction during the exponential phase, where the first significant increase in the amount of PCR product correlates with the initial amount of target template. The higher the starting copy number of the DNA target, the sooner a significant increase

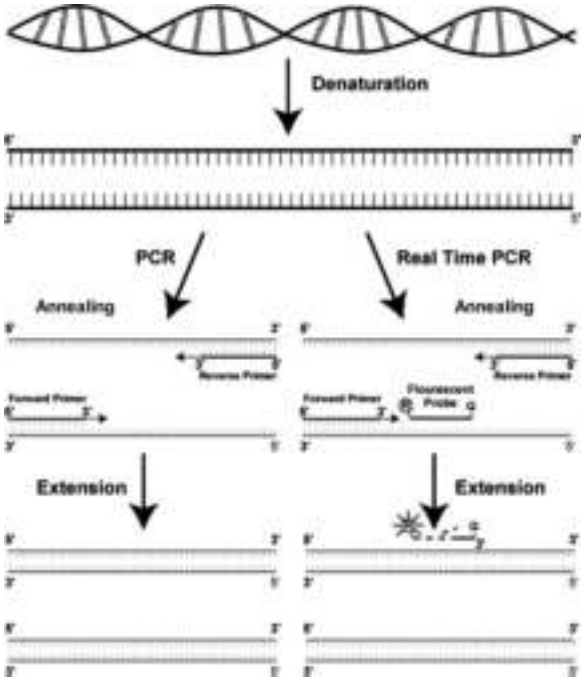

Figure 1. Three steps in polymerase chain reaction (*PCR*) and real-time PCR. Step 1, Denaturation: Template DNA mixture is heated to 90–95°C, allowing the DNA double strand to denature and separate into two single strands. Step 2, Annealing: Template DNA mixture is cooled to 50–60°C to allow primers (for PCR) and primers plus the TaqMan probe, which consists of an oligonucleotide with a 5'-reporter dye (R) and a downstream, 3'-quencher dye (Q) (for real-time PCR), to anneal to the single-stranded DNA. Step 3, Extension: The temperature is raised to 72°C to allow *Taq* polymerase to add deoxynucleotides to the target DNA (for PCR) and complete the amplification. For real-time PCR, the TaqMan probe containing a reporter dye at the 5' end and a quencher dye at the 3' end is separated on cleavage by DNA polymerase, resulting in increased fluorescence of the reporter as well as the newly amplified target DNA. These three steps are repeated 30–40 times to replicate 2^n copies of DNA region of interest where n = cycle number.

in fluorescence indicates the detection of PCR product accumulation. Similar to the RT-PCR, RNA can also be used as target source and termed real-time RT-PCR. In comparison to conventional RT-PCR, real-time RT-PCR offers a much wider dynamic range of ratios of target and reference (up to 10^7-fold) with equal sensitivity and specificity compared with conventional RT-PCR (1000-fold).

Why It Is Important

Why has PCR become a landmark for gene technology? Nobel laureate Mullis said, "The thing that was the 'Aha!', the 'Eureka!' thing about PCR, wasn't just putting those [things] together. . .the remarkable part is that you will pull out a little piece of DNA from its context, and that's what you will get amplified and that is the genius thing." Based on this key point, PCR has been used in examining nucleotide sequence variations to localize the genetic alterations and chromosomal rearrangements (11) underlying hereditary diseases, for high-efficiency cloning of genomic sequences (12), for direct sequencing of mitochondrial (3) and genomic DNAs in the Human Genome Organization (HUGO) project (13), and for detecting viral pathogens and HIV infections (14). Obviously, in crime investigation, PCR provides decisive information since it is now possible to analyze the DNA in a single drop of blood or in a hair found at the scene of a crime (15). Thanks to PCR, it became possible to mass-produce DNA from fossil remains. Researchers have succeeded in amplifying genetic material from insects that have been extinct for >20 million years by applying the PCR method to DNA extracted from amber. This prospect has inspired authors of science fiction such as *Jurassic Park* by Michael Crichton.

How It Is Presented

Agarose gel electrophoresis is the universal way of separating and analyzing the PCR products (Fig. 2). With the addition of ethidium bromide, which binds strongly to DNA by intercalating between the bases, the amplicon (~20 ng or 10–20 μL of post-PCR mixture) can be visualized by fluorescence, since ethidium bromide converts invisible ultraviolet light to the visible orange light spectrum. Visualization of the PCR products allows immediate evaluation and conclusion regarding whether the resulting product is the correct size and whether other products were amplified as well. Most agarose gels are made between 0.7% and 2% to separate two groups of amplicons based on size (5–10 kb and 0.2–1 kb) with 1% gels usually used for general purpose (16).

Its Importance in Critical Illness

Real-time PCR/RT-PCR protocols have been widely applied to facilitate the diagnosis in critical illness. Prucha et al. (17) hypothesized that gene expression profiling is applicable to sepsis diagnosis and used a microarray approach to identify 50 randomly chosen transcripts that were significantly differentially expressed in sepsis patients. Followed by PCR validation, they observed a striking correlation between the conventional diagnostic classification and the microarray approach, regardless of the heterogeneity of the patients. In addition to a global microarray approach, PCR was also applied to single gene validation. To study the expression levels of nitric oxide synthase and heme oxygenase, Reade et al. (18) isolated mesenteric arterial smooth muscle and peripheral blood mononuclear cell RNA from patients with early septic shock and from control individuals. Based on real-time RT-PCR data, they reported that messenger RNA for inducible and endothelial nitric oxide synthase was reduced in both arterial smooth muscle and peripheral blood mononuclear cells from septic patients. In contrast, inducible heme oxygenase messenger RNA was increased in sepsis in both cell types. Similarly, Kalkoff et al. (19) used real-time RT-PCR to quantify the pattern of inflammatory mediator messenger RNA expression in circulating leukocytes from adult patients diagnosed with severe sepsis and found distinct gene expression patterns, concluding that real-time RT-PCR is a useful tool to monitor the immune response in septic patients. Our group (20) recently identified a novel biomarker, pre-B-cell colony-enhancing factor, asso-

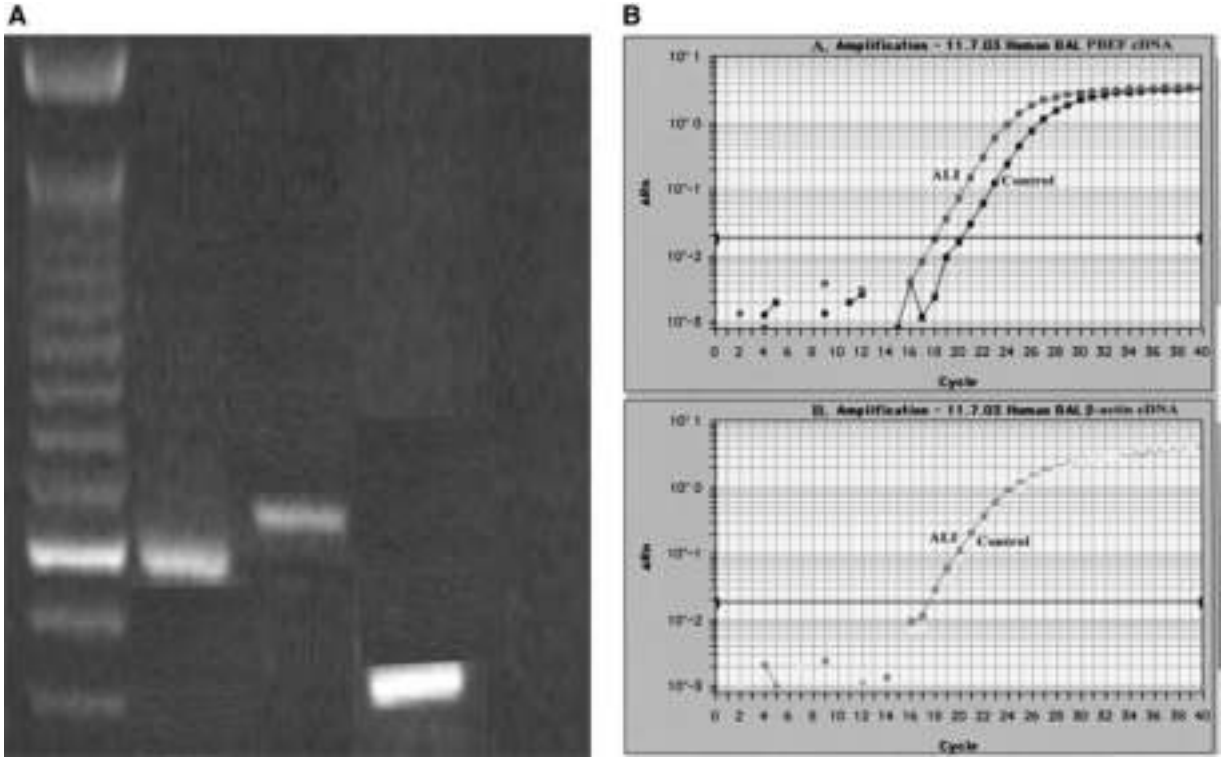

Figure 2. Visualization of polymerase chain reaction (*PCR*) and real-time PCR products. *A*, agarose gel (1%) electrophoresis of PCR products. *Lane 1*, 100 base-pair ladder. *Lanes 2–4*, PCR products of template DNA of interest. *Lane 5*, negative control. *B*, real-time PCR amplification plots comparing gene of interest in patients with acute lung injury (*ALI*) and control subjects. Actin was used as a housekeeping gene control. Accumulation of PCR products is detected by monitoring the increase in fluorescence of the reporter dye and is a direct consequence of target amplification during PCR. Since the variable C_T (threshold cycle) is defined as the cycle number at which the fluorescence emission exceeds the fixed threshold (baseline), the higher the initial amount of template, the sooner accumulated product is detected in the real-time PCR process, and the lower the C_T value. ΔRn, the difference between the normalized reporter signal and baseline signal; BAL, bronchoalveolar lavage; *PBEF*, pre-B-cell colony-enhancing factor; *cDNA*, complementary DNA.

ciated with lung pathophysiology. Real-time RT-PCR validates the significant increase of pre-B-cell colony-enhancing factor in both bronchoalveolar lavage fluid and serum of acute lung injury models and in cytokine- or cyclic stretch-activated lung microvascular endothelium. Pre-B-cell colony-enhancing factor single-nucleotide polymorphisms in a well-characterized sample of white patients with sepsis-associated acute lung injury, patients with severe sepsis, and healthy subjects detected by PCR further support the association between these single-nucleotide polymorphisms and susceptibility to acute lung injury.

Tips and Caveats

Since PCR amplifies a target DNA sequence from only a few molecules to >10 million copies, samples should be extremely well guarded from contamination with other DNA or previously amplified products (amplicons) that may reside in the laboratory environment. It is therefore recommended to always run both a negative control to verify that no contaminants are present in any of the reagent stocks and a positive control to verify that the PCR amplification reaction was successful for every round of amplification performed. The standard PCR protocol can only be followed as a guideline, and the optimal condition for each component or condition must be determined empirically.

WHO Information Notice for IVD Users 2020/05

Nucleic acid testing (NAT) technologies that use polymerase chain reaction (PCR) for detection of SARS-CoV-2

20 January 2021 | Medical product alert | Geneva | Reading time: 1 min (370 words)

Français Español

Related

Product type: Nucleic acid testing (NAT) technologies that use polymerase chain reaction (PCR) for detection of SARS-CoV-2

Date: 13 January 2021

WHO-identifier: 2020/5, version 2

Target audience: laboratory professionals and users of IVDs.

Purpose of this notice: clarify information previously provided by WHO. This notice supersedes WHO Information Notice for In Vitro Diagnostic Medical Device (IVD) Users 2020/05 version 1, issued 14 December 2020.

Description of the problem: WHO requests users to follow the instructions for use (IFU) when interpreting results for specimens tested using PCR methodology.

Users of IVDs must read and follow the IFU carefully to determine if manual adjustment of the PCR positivity threshold is recommended by the manufacturer.

WHO guidance Diagnostic testing for SARS-CoV-2 states that careful interpretation of weak positive results is needed (*1*). The cycle threshold (Ct) needed to detect virus is inversely proportional to the patient's viral load. Where test results do not correspond with the clinical presentation, a new specimen should be taken and retested using the same or different NAT technology.

WHO reminds IVD users that disease prevalence alters the predictive value of test results; as disease prevalence decreases, the risk of false positive increases (*2*). This means that the probability that a person who has a positive result (SARS-CoV-2 detected) is truly infected with SARS-CoV-2 decreases as prevalence decreases, irrespective of the claimed specificity.

Most PCR assays are indicated as an aid for diagnosis, therefore, health care providers must consider any result in combination with timing of sampling, specimen type, assay specifics, clinical observations, patient history, confirmed status of any contacts, and epidemiological information.

Actions to be taken by IVD users:

1. Please read carefully the IFU in its entirety.
2. Contact your local representative if there is any aspect of the IFU that is unclear to you.
3. Check the IFU for each incoming consignment to detect any changes to the IFU.
4. Provide the Ct value in the report to the requesting health care provider.

Contact person for further information:

Abstract

The viral load of SARS-CoV-2 in clinical samples as measured by the primary diagnostic tool of RT-PCR is an imperfect readout for infection potential as most targeted assays designed for sensitivity, indiscriminately detect short and long RNA fragments, although infectivity is embodied only in the whole virus and its intact genome. Here, we used next-generation sequencing (NGS) to characterize 155 clinical samples and show sensitive and quantitative detection of viral RNA which confirmed subgenomic RNA in 57.6% of samples and provided a novel method to determine relative integrity of viral RNA in samples. The relative abundance of long fragments quantified as a viral fragmentation score was positively associated with viral load and inversely related to time from disease onset. An empirically determined score cut-off for presence of substantially fragmented RNA was able to identify 100% of samples collected after 8 days of illness with poor infection potential in line with current clinical understanding of infectiousness of SARS-CoV-2. The quantification of longer fragments in addition to existing short targets in an NGS or RT-PCR-based assay could provide a valuable readout of infection potential simultaneous to the detection of any fragments of SARS-CoV-2 RNA in test samples.

Introduction

In March 2020, the World Health Organization (WHO) declared a pandemic of the coronavirus disease 2019 (COVID-19), an infection caused by severe acute respiratory

syndrome coronavirus 2 (SARS-CoV-2)[1]. By end of 2020, 82 million infections have been reported worldwide with 1.79 million deaths (https://coronavirus.jhu.edu). Diagnostic tools for detection of present and past infection of SARS-CoV-2 have been crucial for the management of this public health emergency, and include an array of molecular tests and immunoassays[2]. Direct detection of nucleic acids via reverse-transcription-polymerase chain reaction (RT-PCR) is the most widely deployed modality. Next-generation sequencing (NGS) is a related molecular method, and is characterized by the ability to identify polymorphisms and to define interrelatedness of virus strains[3,4], facilitated by the whole-genome interrogation of the virus.

Sensitive methods for detecting SARS-CoV-2 have been paramount in the identification and isolation of infected individuals and their close contacts, reducing viral transmission. Releasing infected persons prematurely from isolation carries the risk of fuelling transmission, while prolonging isolation unnecessarily can adversely affect resource allocation and cause undue disruptions[5]. While RT-PCR assays are widely regarded as the most sensitive of diagnostic methods, the inability to distinguish intact viral RNA – packaged in virions and able to cause onward transmission – from products of degradation of viral RNA ineffectual at further infection, has led to considerable debate on the dichotomous interpretation of RT-PCR results as positive/negative, and the in-depth analysis of the period of infectiousness[6,7]. Positive detection of virus RNA does not prove presence of infectious virus, as persistent detection of viral RNA in samples has been reported up to 35 days from symptom onset[8–12], and after resolution of clinical symptoms of both mild and severe disease[13–16]. As large-scale vaccination is deployed across countries[17–19], the uncertain impact of vaccination on potential contagiousness[20,21], further highlights the need for means to quantify contagiousness accurately.

The isolation of whole virions in cultured cells, in contrast to RNA fragments provides evidence of the isolate's replicative potential and more closely reflects the true infection potential[6]. Duration of live virus detection is much shorter than viral shedding and no live virus has been isolated in samples taken more than 8 days since symptom onset in immunocompetent patients [8,11,22]. In accordance with this, in a hamster model, transmissibility of SARS-CoV-2 correlated with detection of infectious virus by culture, but not by RT-PCR-positivity alone, and the communicable period was less than 6 days for inoculated donor animals[23]. Viral load dynamics also differ between upper respiratory tract samples, where highest viral loads were reported at the time of symptom onset or soon after at 3-5 days of illness followed by consistent decline, and in lower respiratory tract samples where peak viral load is in the second week of illness[7]. It is at present unclear if this dynamic is related to dynamic infection potential of transmitted material from each site.

Detection of subgenomic RNA (sgRNA) has been used as a proof of viral replication, which can only happen in infected cells, and declines over days 10-11 from infection[8]. sgRNA does not get packaged into virions therefore detection of sgRNA is indicative of actively infected cells in a sample, and complements the detection of infectious viral RNA packaged into virions. SgRNA have been detected in cultured cells and in limited clinical samples most commonly by NGS and by RT-PCR for specific sgRNA fusion products, but are not routinely studied [8,24,25].

Prompted by the limitations of the most commonly used diagnostic device for SARS-CoV-2 for informing contagiousness, and by the urgent need to address this crucial parameter, in this study we employed whole-genome NGS with molecular barcoding and sequencing error-correction to characterize clinical samples collected from a cohort of migrant workers in Singapore. As a comprehensive tool with full genome targeting, NGS can inform presence of any SARS-CoV-2 RNA, the presence of sequence variants and sgRNA, and as we show for the first time, this method can also characterize the lengths of fragments of RNA in a sample. We go on to show that fragment lengths, characterized as a viral fragmentation score, are related to intactness of viral RNA, which is a prerequisite for infectiousness in the form of whole virus, and is correlated in with other clinical parameters of potential infectiousness such as viral load, sgRNA and duration of illness.

Materials and Methods

Sample collection

Samples used in this study were collected as part of a previous study conducted in a large cohort of migrant workers in Singapore, and evaluated and approved by the Director of Medical Services, Ministry of Health, under Singapore's Infectious Disease Act[26]. A total of 155 samples, corresponding to 48 individuals were analyzed by NGS. The samples included 37 nasopharyngeal (NP) swabs collected in 3 mL of viral transport medium, 60 self-nasal swabs, and 58 oropharyngeal saliva samples collected in 2 mL of viral RNA stabilization fluid (SAFER™ VTM, Lucence, Singapore). The majority of the cases (35 of 48, 72.9%) were symptomatic at the time of first sample collection, one case was presymptomatic at time of first sampling, and 12 cases (25%) were asymptomatic through the study. For asymptomatic cases, the day of the first diagnostic test was used to determine days since diagnosis. For 17 cases (35.4%), only a single sample was available for sequencing, and for the remaining 31 (64.5%) of cases, between 2 and 9 samples were studied. For 5 cases (10.41%), samples from different sites (NP, nasal swab or saliva) were available but from the same timepoint (not longitudinal). All samples had previously been characterized for presence of SARS-CoV-2 using an RT-PCR assay using primers and probes sequences from the CDC 2019-nCoV Real-Time RT-PCR Diagnostic Panel[26,27], henceforth referred to as CDC RT-PCR assay. Samples were selected for NGS based on SARS-CoV-2 positivity at at least one of 2 or 3 timepoints of sample collection and relatively high viral loads as estimated by the RT-PCR assay. Archived extracted RNA from anonymized samples were used for this study.

Sample processing

Viral nucleic acid is extracted from the specimens (200 or 400 µl) using Viral Nucleic Acid Extraction Kit II (Geneaid Biotech Ltd., Taiwan) or QIAsymphony DSP Virus/Pathogen Kit (QIAGEN). For each sample, aliquots of extracted nucleic acid (RNA) was screened for presence of SARS-CoV-2 RNA using real-time reverse transcription-polymerase chain reaction (RT-PCR) targeting the N1 and N2 markers as specified by Centers for Disease Control and Prevention (CDC), and also processed for library preparation for NGS. Samples were processed in a College of American Pathologists (CAP) accredited and a Clinical Laboratory Improvement Amendments (CLIA) licensed laboratory (Lucence).

Analytical validation of SARS-CoV-2 NGS method

Lower limit of detection (sensitivity) of the NGS method was determined using synthetic SARS-CoV-2 RNA spiked into pooled clinical matrix that tested negative for the virus by a RT-PCR method. For the analytical validation of NGS, synthetic SARS-CoV-2 RNA

medRxiv preprint doi: https://doi.org/10.1101/2021.01.11.21249265; this version posted January 15, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

genomes (Twist Bioscience, San Francisco, USA) of known concentrations were spiked in to pooled negative clinical matrix (nasopharyngeal swab specimens) at known copy numbers prior to RNA extraction. The synthetic controls corresponded to these GenBank IDs of various published SARS-CoV-2 genome isolates. MT007544.1 (SKU: 102019), MN908947.3 (SKU: 102024), LC528232.1 (SKU: 102860), MT106054.1 (SKU: 102862), MT188340.1 (SKU: 102917), MT118835.1 (SKU: 102918). The threshold for detection of SARS-CoV-2 was determined by comparing the genome coverage (%) resulting from confirmed negative samples (by RT-PCR), and no-template controls and that resulting from known positive samples (by RT-PCR).

Design of multiplex PCR panel for SARS-CoV-2 genome

A multiplex amplicon-based next generation sequencing (NGS) platform was developed to sequence the entire SARS-CoV-2 genome. Primers for 327 amplicons were designed to span the entire SARS-CoV-2 genome in tiled configuration, and alternately assigned to two separate primer pools (Pool 1 and Pool 2) to allow amplification of the whole genome while minimizing formation of short overlapping amplicons. Five primer pairs designed to target five different human housekeeping genes (*TBP*, *MYC*, *LRP1*, *ITGB7*, and *HMBS*) are used as control in both pools. Each forward primer additionally includes on the 5' end, a random 10 nucleotide sequence to serve as molecular barcode. Each designed primer was checked against published SARS CoV-2 genomes as of April 15 2020, and base degeneracy was incorporated when required to achieve coverage of >99% of Asian, USA, Europe and Chinese genomes published.

Preparation of library for NGS of SARS-CoV-2

Based on the CDC RT-PCR results, extracted nucleic acid were diluted 10-fold for samples with cycle threshold (Ct) ≤20 or undiluted for samples with Ct>20, followed by reverse transcription using High-Capacity cDNA Reverse Transcription Kit (Applied Biosystems, USA) to generate complementary DNA (cDNA). A synthetic spike-in RNA control was added to the sample just before cDNA synthesis. The RNA control comprises a nucleotide sequence which is not found in a genome or a transcriptome of the virus, and is further not found in a genome or a transcriptome of a human, and is further not found in a genome or a transcriptome of a microorganism. Each cDNA was split into two reactions for target capture and enrichment of Pool 1 and Pool 2 using Platinum SuperFi II DNA Polymerase (Invitrogen, USA) under the following thermocycling conditions: Denaturation at 98^0C for 30s, followed by 5 to 15 cycles (5 cycles for samples with Ct <15, 10 cycles for samples with Ct 15-30, 15 cycles for samples with Ct >30) of 98^0C for 1 min, 60^0C for 1 min, and 72^0C for 1 min, with final extension at 72^0C for 5 min. At the end of the reaction, excess primers were removed

medRxiv preprint doi: https://doi.org/10.1101/2021.01.11.21249265; this version posted January 15, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

by purification two times with 1.5x AMPure XP beads (Beckman Coulter,USA). Purified products were subjected to a final PCR to amplify targets and to complete the library with indexed sequencing adaptors for sequencing on the Illumina platform. Briefly, purified product was amplified with indexed P5 adapter sequence and indexed P7 adapter sequence using KAPA HiFi HotStart ReadyMix under the following thermocycling conditions: Denaturation at 98^0C for 45 s, followed by 18 cycles of 98^0C for 15 s, 60^0C for 30 s, and 72^0C for 30 s, with a final extension at 72^0C for 1 min. The amplified library was purified twice with 0.7x AMPure XP beads to remove non-specific products. The quality and quantity of the sequencing library is assessed using the 4200 Tapestation system (Agilent Technologies, USA) and KAPA Library Quantification Kit for Illumina® Platforms (Kapa Biosystems Inc., USA) respectively. Paired-end sequencing (2x151bp) of the final dual-indexed libraries is performed on the Illumina platform as per manufacturer's instructions.

Primary sequencing data analysis

FASTQ files were processed using a custom pipeline. First, expected amplicons were identified and labeled in the FASTQ files based on the expected primer sequences in Read 1 and paired Read 2. Primer sequences and upstream molecular barcode sequences were trimmed using cutadapt, primer trimmed sequences were mapped to the reference genome SARS-CoV-2 reference genome (NCBI Reference Sequence: NC_045512.2) using bwa-mem. Molecular tag (or barcode) sequences were included in the trimmed "primer" sequences of read 1, and can be extracted given the unique structure of primer sequences in read 1. Barcode sequences were clustered based on sequence and amplicon identity, and consensus calling was done for each molecular tag (or barcode) cluster, by first performing global alignment among all associated reads using MAFFT. The consensus base in each aligned position was called by determining the majority representative base type, the percentage of which should be no less than an automatically determined threshold. The threshold is a function of the total number of reads for that barcode sequence. If no representative base could be called, the position was assigned N (as opposed to one of A, C, T, G). An overall quality score, of either 90^{th} percentile of all the quality values from the representative base type in that position (if a consensus base is found), or 10^{th} percentile of all quality values in that position (if no consensus bases is found) is assigned. The consensus reads are then written to a new FASTQ file.

Variant calling, subgenomic RNA analysis and phylogenetic analysis

First, consensus FASTQ files from two pool 1 and pool 2 were merged to create a single FASTQ file. Consensus FASTQ reads are mapped to the SARS-CoV-2 reference genome (NCBI Reference Sequence: NC_045512.2) using bwa-mem[28]. Samtools[29] was used to

medRxiv preprint doi: https://doi.org/10.1101/2021.01.11.21249265; this version posted January 15, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

calculate depth per base and coverage metrics. Variant calling was performed on consensus BAM files using snippy and freebayes. For variants to be called, a minimum of 10x coverage is required. With molecular barcoding, the sequencing is error-free and can enable detection of quasispecies and increase confidence of variant calls due to the high quality of sequencing data.

Detection of subgenomic RNA (sgRNA) was done by analysis of split reads supported by multiple consensus reads. Chimeric reads in which non-contiguous regions of the genome are captured within a read are identified as split reads and have 1) unexpected combination of primers which resulted in the amplicon, 2) presence of junction sites at which fusion occurs and 3) presence of a junction core sequence for coronaviruses which is exemplified by the sequence – CTAAACGAAC – within the read[30,31]. The detection of canonical sgRNA was defined by the presence of the 5' end leader sequence of the genome and downstream ORFs on the 3'end of the genome. Due to the design of the primers and full coverage inherent in the primer panel design, all canonical sgRNA can be detected. The frequency of each sgRNA was calculated as the number of split reads supporting sgRNA/number all reads supporting the location spanning the junction 3' to the junction. For comparison across samples and across different species of sgRNA, the sgRNA split read count was normalized to the mean depth of coverage for the sample. For comparing total sgRNA, the sum of all sgRNA read counts was normalized to the mean depth of coverage for the sample.

FASTA file of the assembled genome are used to construct phylogenetic trees. The phylogenetic tree building process and parameters follows the NextStrain team's repository at https://github.com/nextstrain/ncov[32].

Insert length analysis and calculation of viral fragmentation score

For each positive sample with sequencing data, SAMtools was used to capture insert sizes from alignment files with the following specifications: samtools view -f65 -F2048 SampleXYZ_consensus.bam | cut -f 1,4,9 > SampleXYZ_f65F2048.txt where f65 = filter in read paired, first in pair (Reads which are paired and insert sizes for first read in read pair and second in read in read pair will have same same insert size with "negative" length); F2048 = filter out reads with supplementary alignment (removes most subgenomic RNA reads which have part of reads with supplementary alignment and removes chimeric reads. Finally inserts of size 70 to 1000 are retained to get representation of expected insert sizes as no insert is expected to be shorter than 72 bp (design of inserts) and remove extremely long inserts.

Binning of inserts was done based on the expected and observed insert sizes into 0-150 bp (short) and 151-350 bp (long) ranges. Short and long insert counts were determined for each

medRxiv preprint doi: https://doi.org/10.1101/2021.01.11.21249265; this version posted January 15, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY-NC-ND 4.0 International license .

sample, representing short and long viral fragments, respectively. The viral fragmentation score is then derived as (number of fragments of size 151-350bp)/(number of fragments of size 0-150bp).

Multiplex RT-PCR assay for simultaneous detection of fragments of different lengths

A multiplex three-target RT-PCR assay was designed for the simultaneous detection of two short targets of 70 bp each in the N gene region (in two separate detection channels), and one long amplicon of 240 bp in the S gene of the SARS-CoV-2 genome. An internal housekeeping control target was included as fourth target in the multiplex reaction. Briefly, extracted RNA (5 µl) was mixed with the primers/probes for the multiplexed targets with Luna® Universal Probe One-Step RT-qPCR Kit (New England Biolabs, USA) and RT-PCR was performed using recommended protocol for the Luna master mix on a BioRad CFX96. Cycle threshold (Ct) values for each target were collected from respective channels and compared.

Statistical Methods

All datapoints are described individually with median and interquartile ranges, where appropriate. For comparison between groups, the Mann-Whitney unpaired t-test was used. Regression analysis and curve fitting was done using Prism 8.0.1.

Results

Detection of SARS-CoV-2 in clinical samples by whole-genome sequencing

Whole-genome sequencing was performed on RNA extracted from 155 samples corresponding to 48 individuals in this study. The samples included 37 nasopharyngeal swabs, 60 self-nasal swabs, and 58 saliva samples. An amplicon-based next-generation sequencing (NGS) panel covering the whole SARS-CoV-2 genome except the first 25 bases and 30 bases upstream of the final polyA tail was used. All samples had been previously characterized by the CDC RT-PCR assay, of which 11 (7.09%) of 155 samples were negative for SARS-CoV-2 and were included in the study to demonstrate the specificity of detection of SARS-CoV-2 by sequencing. The negative samples were from 6 cases which had at least one other matched positive sample from the same or different timepoint. Due to the high rate of positivity (92.9%) among the samples in this study, a set of 25 unrelated samples from the community confirmed to be negative by the same RT-PCR assay were also subjected to sequencing to establish a true threshold for calling positive based on the percentage of genome coverage obtained from sequencing. Additionally, 24 no-template

medRxiv preprint doi: https://doi.org/10.1101/2021.01.11.21249265; this version posted January 15, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY-NC-ND 4.0 International license .

controls (NTC) were included to demonstrate the specific detection of SARS-CoV-2 in samples, unaffected by background rates of formation of non-specific products from highly multiplexed amplicon-based sequencing. The cut-off of 1.8% genome coverage correctly classified 100% of positive cases, while 2 samples called negative by RT-PCR were just above the cut-off at 2% and 3% genome coverage, respectively (Fig. 1A.) No false positives were seen among the community negative and NTC samples. The genome coverage percentage for positive samples was closely related to the sample's cycle threshold (Ct) value from RT-PCR assay (Fig. 1B). A large proportion of samples (62 of 144, 43.1%) had >99% genome coverage which corresponded to a median Ct value of 23.61 (inter-quartile range, IQR: 18.37-26.26). Average depth of coverage was slightly higher in saliva samples compared to upper respiratory tract (URT) samples (nasopharyngeal and nasal swabs) ($p = 0.0281$) (Fig. 1C), but dependent mainly on the viral load in the sample represented by the Ct value (Fig. 1D). Limit of detection studies with synthetic SARS-CoV-2 reference genomes for sequencing-based detection of SARS-CoV-2 was determined to be 50 copies/ml (Fig. S1) and expected detection of variants from synthetic reference genome was also validated using this method (Fig. S2).

Variant analysis and phylogenetic classification

Comparative variant analysis on the SARS-CoV-2 genomes assembled from sequencing data was done for samples with >95% genome coverage (69 of 144, 47.9%) using the Wuhan/Hu-1/2019 genome as reference. Comparing samples originating from a single individual, samples from multiple timepoints, and those from differing sampling sites (upper respiratory tract or saliva), variants confidently detected (supported by >20x depth of coverage) were completely identical (Fig. 2A). This is contrast to a study in which throat swab and sputum from a patient sampled on the same day showed the presence of a unique variant in the throat swab, suggestive of independent replication in the two tissue sites[8]. Among the variants identified, a stop codon in ORF8 gene c.175G>T p.Glu59* - 28068G>T was observed in 6 samples coming from one individual, and 2 samples and one sample from two other individuals, respectively. Premature stop mutations in ORF8 have been reported among SARS-CoV-2 sequences in GenBank and GISAID initiative[33].

As the identity of variants among multiple samples from the same case were conserved, a single representative sequence from each case was used for the phylogenetic tree construction. A total of 28 cases (58.3%) were analyzed, as they had at least one sample satisfying the >92% genome coverage lacking stretches of N's required for phylogenetic analysis[34]. All sequences were identical or highly similar to sequences reported in previous analyses of SARS-CoV-2 cases in Singapore, and belonged to Clade O by GISAID

medRxiv preprint doi: https://doi.org/10.1101/2021.01.11.21249265; this version posted January 15, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY-NC-ND 4.0 International license .

nomenclature[35], and lineage B.6 by PANGOLIN system of nomenclature[36] and with respect to each other the 28 cases fit into 3 main clusters (Fig. 2B). One Case-28 which formed a single-case branch, harboured three unique variants M c.120C>T p.Ala40Ala - 26642C>T and ORF3a c.377G>A p.Arg126Lys - 25769G>A and orf1a c.6267G>T p.Glu2089Asp - 6532G>T in four different samples collected for this case.

Frequent detection of subgenomic RNA in clinical samples

The panel of primers for whole-genome sequencing of SARS-CoV-2 was specifically designed to also capture subgenomic RNA (sgRNA) sequences involving the fusion of the 5' leader sequence (first 72 nt of the genome) of the SARS-CoV-2 genome with the 5' end of each mRNA coding sequence, called the "body". The tiled design of primer pairs and inclusion of the primer targeting the 5' leader in both primer pools allows the capture of sequences corresponding to canonical sgRNA containing a consensus core sequence[24]. The relative abundance of each sgRNA was normalized by the mean genome depth of coverage of a sample to make comparisons across samples and sgRNA species. Among individuals with symptoms, sgRNA was found be relatively more abundant when found in URT (NP and nasopharyngeal) samples relative to saliva samples (unmatched) and was mostly detectable between -1 to 7 days since symptom onset (Fig. 3A). In both URT samples and saliva, the three most abundant sgRNA species were N, M genes and ORF3a. ORF10 was detected in only one of 68 evaluable positive URT samples, and was not detected in any of 59 positive saliva samples from symptomatic cases. This is in accordance with previous findings which found almost no subgenomic reads corresponding to ORF10[24,25,31]. Presence of sgRNA is considered an indicator of active viral replication[8,11] with more frequent detection in samples collected <8 days after symptom onset[11] and has been reported to persist up to 22 days[37] after onset of clinical symptoms Among samples in the present study, the persistence of sgRNA detection was observed in samples from 8-12 days since symptom onset and up to day 13 in saliva (Fig. 3A). Samples from asymptomatic cases also had prevalent sgRNA detection in URT samples 0-3 days since diagnosis (Fig. 3B). In contrast to URT samples, in saliva from asymptomatic cases, sgRNA could be detected in up to 5-6 days since diagnosis. No sgRNA was detected at 8 days since diagnosis. Individually assessed, detection rate of sgRNA progressively decreased over time (Fig. S3). Across all types of samples and cases, when detected, the relative total amount of sgRNA (sum of individual sgRNA) did not appear to be related to the viral load of samples as measured by the Ct values (Fig. 3C). However, for samples with Ct ≥28.67 (n = 80), 61 (76.25%) had no sgRNA expression while 100% of samples with Ct <28.67 (n = 64), had some sgRNA expression, for an overall sgRNA detection rate of 57.6% in all samples (Fig.

medRxiv preprint doi: https://doi.org/10.1101/2021.01.11.21249265; this version posted January 15, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY-NC-ND 4.0 International license .

3C). These results suggest that sgRNA is frequently detected in multiple samples types containing a minimal viral load related to Ct value in both symptomatic and asymptomatic cases. However, there is no relation between the abundance of sgRNA and Ct; following an approximate dichotomy of detection around Ct 28.7.

SARS-CoV-2 RNA fragments of differing lengths are captured by NGS

We observed that one of the consequences of tiling multiple primer pairs (in subsequence) to capture the entire known target template of SARS-CoV-2 in a highly multiplexed PCR-based NGS method, was the capture of longer inserts in addition to the inserts expected to be formed from amplicons of length 130-178 bp for which primer pairs were originally designed (Fig. S4A). The origin of the longer inserts was the formation of amplicons between a given forward primer and a reverse primer that is 1-, 2-, 3-, 4- and so on-displaced in the subsequence of primer pairs in the pool of primers (Fig. S4B). We reasoned that the more degraded the viral RNA template, the more the capture of short inserts (representing short fragments) would be favoured, due to the unavailability of intact RNA template for longer amplicons to form (Fig. S4C). Analysis of the sequencing data for the distribution of insert lengths per sample, showed that 2 to 3 distinct ranges of insert lengths could be captured per sample, and the number of sequencing reads supporting inserts in each insert length group could vary substantially between samples (Fig. 4A). Based on the dominance of inserts of lengths either 70-150 bp or 220-350 bp in sequencing data (and not other longer insert length groups), we chose these two insert length groups for further study and refer to them as “short” and “long” fragments, respectively. The cumulative number of short and long fragments (all reads mapping to SARS-CoV-2 from all potential primer combinations across the targeted genome) for samples were determined. It is noted that the sizes of the amplicons for N1 and N2 targets from the CDC RT-PCR assay initially used to characterize the samples are 72 bp and 67 bp, allowing sensitive detection of even very small fragments of virus RNA. It follows that such an RT-PCR assay would not be able to distinguish between long and short fragments that may exist in a given sample, but would give a cumulative read-out comprising all fragments. In 144 samples positive for SARS-CoV-2 by the CDC RT-PCR assay, the sequencing read counts for long and short fragments were each correlated with Ct value as expected, diminishing as the Ct value increased or presumed viral load decreased. However, the longer fragments had a steeper change in abundance relative to Ct value, become disproportionately fewer relative to short fragments in samples with low viral load reflected by later Ct values (Fig. 4B). We hypothesize, given a mass of viral RNA (a mix of intact and degraded RNA), measurable as a Ct value by an assay like the CDC RT-PCR assay with very short amplicons, that at later Ct values, previously long fragments have been converted to short fragments due to degradation of viral RNA, and contribute in turn to the

medRxiv preprint doi: https://doi.org/10.1101/2021.01.11.21249265; this version posted January 15, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY-NC-ND 4.0 International license .

observed read counts for short fragments which continue to maintain a relatively higher count from this contribution. Consequently, degradation of viral RNA more rapidly leads to the diminishing read counts for long fragments observed at late Ct values. This suggests that counting long fragments or the relative distribution of long to short fragments would provide a more accurate read-out for presence, if any, of intact viral RNA in samples.

We devised a viral fragmentation score, VFS (long to short fragment count ratio) to capture this variability in distribution of fragment lengths. VFS showed a moderate correlation with Ct (R^2 = 0.65 in NP and nasal swabs, and R^2 = 0.74 in saliva), suggesting relative abundances of long and short fragments within a sample are not captured fully by its Ct value, despite detection of long fragments diminishing with increasing Ct values (Fig. 4C). For 5 samples sequencing libraries were repeated from RNA extracts and VFS were shown to be within reproducible range for the same sample (Table S1). To rule out a fully Ct value-dependent behaviour of VFS, we made use of intact synthetic SARS-CoV-2 RNA genomes and prepared sequencing libraries from serial dilutions of synthetic RNA spiked in to negative clinical matrix and extracted via routine procedures. Synthetic RNA mimics SARS-CoV-2 genome but is composed of 6 fragments of 5000 bp each representing the genome, which we take as a relatively intact starting material. For the amounts of synthetic RNA spiked in- 250000, 25000, 2500 and 500 copies/ml - the Ct values measured by the same CDC RT-PCR assay were on average 24.4, 27.97, 31.73 and 33.45, respectively. Since the RNA in the serial dilutions are similarly intact, being derived from the same stock of synthetic RNA, the increase in Ct values are attributable only to the total copy numbers of RNA detectable by the RT-PCR assay. However, the VFS for the serial dilutions of synthetic RNA, do not show the same degree of decrease as the trend for increasing Ct values and ranged with a median: 0.384 (IQR: 0.289-0.449) across all 4 serial dilutions (Fig. 4C, Fig. S5). This experiment shows that factors besides total viral RNA amount measured by a Ct value (with short PCR amplicons) determine the VFS, which depends on the presence of long fragments, more of which is likely to be present in a sample with more intact. This is supported by the wide variation in VFS that was observed in clinical samples, which was higher in saliva relative to URT samples (p = 0.0035) and ranged from 0.0433 to 184.9 in saliva (n =58, median: 0.267, IQR: 0.113-0.68) and from 0.02073 to 14.38 in URT samples (n =81, median: 0.124, IQR: 0.074-0.246) (Fig. 4D). On the basis of VFS, on average, saliva samples in this study had less fragmented SARS-CoV-2 RNA. However, a relation with the disease time-course, symptomatic/asymptomatic status as an explanation for this observation cannot be ruled out. Importantly, what constitutes a high enough VFS score to be considered clinically relevant as infectious virus with intact RNA is not established.

Overall, these results support the presence of a wide range of fragmentation profiles in clinical samples which is readily detectable by NGS.

Correlation of viral fragmentation scores (VFS) with clinically relevant measures of infectiousness

As our NGS method was able to quantify relative abundances of short and long fragments representing less and more intact virus, respectively, next we determined if VFS was related to other clinical correlates of infectivity. This is particularly relevant as it is well-recognised that RT-PCR positivity alone, particularly from a test designed for short targets, does not translate to viable virus with infection potential[5,6]. We have already shown that VFS is moderately correlated with Ct value (Fig. 4C), which in itself is considered a proxy for infectious potential of SARS-CoV-2 in clinical samples based on the culturability of virus isolates[8,11,12,22,38,39] although with widely differing Ct cut-offs. In multiple studies, no live virus has been culturable after eight days in non-immunocompromised patients[2,10,14]. The typical clinical profile of the symptomatic cases in our study was immunocompetent with presentation of mild to moderate respiratory symptoms. Compared directly, VFS and days since symptom onset was not strongly correlated in both URT and saliva samples over the full duration of the symptom onset (days -1 to day 14) (Fig. 5A and 5B). However, transposing a VFS derived from a sample with known integrity i.e. synthetic RNA (refer to Fig. 4C), subject to the same extraction and sequencing procedure as the clinical samples, we selected a cut-off of 0.382 to separate samples with intact RNA from those without. We noted that with this cut-off value, no URT samples (total 69) collected >8 days since symptoms (n= 36) qualified as having intact RNA (Fig. 5A, top left quadrant). In saliva samples (total 46), only 1 (5.26%) of 19 samples collected >8 days since symptoms had a VFS indicative of intact viral RNA (Fig. 5B). Of 37 URT samples collected ≤8 days, 15 (40.5%), and of 29 saliva samples collected ≤8 days, 16 (55%) had VFS greater than 0.382 suggesting intact RNA profiles. These results suggest about 50% of samples collected ≤8 days have relatively fragmented RNA, in accordance with observations made in previous studies where about 29%-42% of samples with high viral load inferred from low Ct or from ≤8 days did not recover live virus[9,11,22]. Among asymptomatic cases, 25 (96%) of 26 samples had low VFS below 0.382 cut-off, from 0 to 8 days from diagnosis, suggesting that viral RNA from most asymptomatic cases is fragmented (Fig. 5C). For one case, VFS 3.36 of saliva sample collected on the day of diagnosis was matched with URT samples (NP and nasal swabs) from the same case with VFS of 0.79 and 0.14, suggesting a less fragmented SARS-CoV-2 RNA in saliva even at same timepoint. Overall, VFS differed significantly between samples collected ≤8 days from symptoms and those after 8 days for cases with information on symptom onset (Fig. 5D, left), but it was difficult to find a time measure that trended with

medRxiv preprint doi: https://doi.org/10.1101/2021.01.11.21249265; this version posted January 15, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

VFS for asymptomatic cases (Fig. 5D, right). For cases with multiple longitudinal samples, VFS were tracked with respect to time from symptom onset and were generally observed to be higher early between days -1 to 6 and generally decreased with time reaching levels similar to those seen asymptomatic cases through the course of the asymptomatic infection (Fig. 5E).

We observed no linear correlation between increasing VFS and total sgRNA abundance (Fig. 6A), but there was a significant difference in VFS of samples with any sgRNA compared to those with none, showing a dichotomous distribution ($p<0.0001$) (Fig. 6B). The dichotomy of distribution was related to the VFS cut-off of 0.382 determined earlier. All 33 samples with VFS ≥0.382 had some sgRNA expression, whereas 58 (54%) of 107 samples with VFS <0.382 had no sgRNA (Fig. 6A, 6B). When individual species of sgRNA were separately considered, interestingly, there was an inverse correlation with the VFS for S and N genes only, and not for other most abundant sgRNA M gene and ORF3a (Fig. 6C). No other sgRNA species showed a correlation with VFS (not shown), suggesting a specific effect of intact RNA on the abundance of S and N genes expression in clinical samples.

Finally, we demonstrate that the viral fragmentation score (VFS) can be translated into a simple multiplexed RT-PCR assay deliberately composed of a long amplicon of 240 bp and short amplicon of 70 bp to detect the long and short fragments observed in clinical samples using NGS. In a set of 20 clinical samples, a good correlation was seen between VFS from NGS and from the difference in Ct signal of short 70 bp and Ct signal of long 240 bp amplicon, here referred to as a viral fragmentation index (VFI) (Fig. 7A). For 7 samples with low VFS, 240bp amplicon was not detectable by PCR, potentially reflecting the higher sensitivity of NGS for detection due to the interrogation of the whole genome with multiple targets, but still in line with the expectation of continued detection of short 70 bp amplicon in these samples. For 13 samples with detection of both 70 and 240 bp by RT-PCR, the delta Ct (70bp-240bp) VFI was correlated with the VFS (R^2 =0.79, $p<0.0001$) (Fig. 7A, right). Over days since symptom onset, the VFI became more negative, indicating the increasingly greater abundance of short 70 bp amplicon, likely due to increasing fragmentation of viral RNA over clinical course of the disease (Fig. 7B).

Discussion

We used next-generation sequencing (NGS) to characterize clinical samples related to the spread of SARS-CoV-2 infection in a cohort of migrant workers in Singapore, collected from different tissue sites and over serial timepoints. The design of the NGS panel allowed virus

medRxiv preprint doi: https://doi.org/10.1101/2021.01.11.21249265; this version posted January 15, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

detection, genomic variant and sgRNA analysis. Further exploiting the design of the NGS panel for whole-genome sequencing of the virus, we have shown for the first time to our knowledge that NGS can be used for the detection of differential fragment lengths of viral RNA in clinical samples, potentially related to the integrity and transmissibility or infectiousness of the virus. We present a novel measure of fragmentation of viral RNA, which could be translated to a test for transmission potential of a current infection.

We show that relative to the gold-standard RT-PCR assay, NGS is a sensitive and specific method of detection of SARS-CoV-2, with 100% detection of virus in clinical samples known to be positive by RT-PCR. Additional detection of virus fragments spanning ~3% of the virus genome in two RT-PCR negative samples, highlights that NGS may be a more sensitive diagnostic method for low levels of SARS-CoV-2. This is attributable to the targeting of the whole genome of the virus in NGS compared to RT-PCR assays targeting specific loci which may not be present among the virus fragments in a sample low levels of SARS-CoV-2. In agreement with other NGS-based detection methods[40–42], sensitivity was high with analytical limit of detection determined to be 50 copies/ml. The detection of SARS-CoV-2 was quantitative, as the genome coverage % and the mean depth of coverage of a sample which was closely related to a Ct value from an orthogonal RT-PCR assay. As this method incorporates molecular barcodes in the primer sequences, the number of consensus reads corresponding to various regions of the genome are representative of the copy number of viral RNA fragments that are present during library preparation. Other SARS-CoV-2 NGS methods do not report similar quantitative capacity[40–42]. The quantitative feature of the method allows counting of reads to correlate with other parameters as described further on. Genomic variant analysis showed complete similarity of variants in multiple samples derived from a single case, suggesting no independent replication or generation of minor variants over time course of infection, in contrast to previous reports[8,9]. Phylogenetic analyses was possible on assembled SARS-CoV-2 genomes from 28 cases and showed that all cases were infected with virus belonging to the Clade O, lineage B.6, known to be circulating in Singapore and India.

Besides the sensitive detection of virus and identification of genomic variants, the method provided novel insights into two aspects of SARS-CoV-2 infection which have become increasingly more relevant in the context of predicting the onward transmission potential of an infection. In this work, we were able to elicit information on the presence of subgenomic RNA in clinical samples as well as the relative degree of fragmentation of the viral RNA in a sample.

Detection of sgRNA has been used as a proof of viral replication in infected cells and decline over days 10-11 from infection[8]. sgRNA detection outlasted successful virus culture and was a poor predictor of successful virus culture[14], or showed moderate agreement with virus culture, and was detected in 18 (81.8%) of 22 specimens collected <8 days after symptom onset and in 1 (9.1%) of 11 specimens collected ≥9 days after symptom onset[11]. Due to the prolonged detection of sgRNA in clinical samples including up to 22 days since start of illness, sgRNA may not be a marker of active replication but remain detectable in clinical samples due their stability[37].

In this study, abundant sgRNA was detected in clinical samples including prolonged detection in a saliva sample taken 13 days from illness onset from a symptomatic case. In samples with high viral loads, sgRNA was consistently detected, but became undetectable in ~75% of samples with low viral loads (Ct≥28.67), suggesting that both viral load and sgRNA stability account for its detection. This study, to our knowledge, is the first one to demonstrate direct sgRNA detection in samples from immunocompetent asymptomatic individuals[43] although at lower levels than symptomatic cases, in line with the non-zero but reduced transmission potential of asymptomatic carriers[44] .

It is increasingly becoming apparent that positive detection of virus RNA by RT-PCR is unrelated to presence of infectious virus, as viral RNA shedding can persist even after resolution of clinical symptoms of both mild and severe disease[8–16]. While more ill patients have generally longer detection of RNA, persistent positivity by PCR is seen in patients with mild illness as well as in asymptomatic cases[5]. A better measure of infectiousness is the culture of live virus from clinical specimens as successful virus growth is reliant on the presence of intact whole virions with complete RNA genomes. By this measure, samples taken more than 8 days since symptom onset in immunocompetent patients, do not have infectious virus as no live virus could be cultured from them[8,11,22]. In immunocompromised patients or those with severe illness, live virus could be isolated up to 14 days[12], 20 days[14] and much longer in severely immunocompromised patients[45]. Ability to culture live virus has been shown to be similar in asymptomatic and symptomatic indivduals [46–48]. Some studies have correlated viral loads measured by Ct value with ability to culture live virus[8,11,14,22,38,46], and no viral growth was reported based on a Ct value cut-off (varying between >24 and ≥35)[22,38,48]. Intriguingly, a number of studies have reported limited correlation between Ct value (or viral load) and success of virus isolation[49,50]. Samples with low Ct values (Ct<23), constituted 28.6% of samples with unsuccessful viral culture [50], and conversely, samples with low viral loads (Ct >35) could harbor viable virus[49,50].

The observation that not all samples with high viral loads generate live virus, suggest that factors other than viral genome copies are important. The topmost factor would be viral integrity, whether for a small or large viral load. Only the full-length intact viral RNA would represent the virus fragment that is capable of infection. It is understood that the processing of sample in the laboratory (extraction, enzymatic reactions) would lead to some degree of fragmentation, and the use of primer-limited amplicons would artificially limit fragment lengths but relative to a sample with highly fragmented viral RNA, a sample with intact viral RNA would contain more long fragments relative to short fragments.

In this work we have shown for the first time that NGS data can not only provide total viral RNA abundance information, it can also characterize the viral RNA fragments by length. This was possible due to combination of consensus read counting (related to the original copy numbers of virus RNA in a sample undergoing library preparation) and the tiled configuration of the primer panel which could capture long fragments, if present. In other words, the more intact or full-length RNA that is present in a sample, the more long fragments would be captured by the method. The relative abundances of long and short fragments was converted to a viral fragmentation score (VFS), representing the relative integrity of the virus RNA in the sample and was shown to be related to the viral load measured as Ct value by an RT-PCR assay. It is important to highlight that the CDC RT-PCR assay targets particularly short amplicons of about 70 bp, which means it would accurately detect intact RNA when present, but would continue give an abundant signal even when largely fragmented RNA was present in a sample. At early Ct values (representing abundant viral load), the relative abundance of long fragments were as much as 100-185 times more than short fragments (very high viral fragmentation score) and could not have resulted simply as a result of the specific sequencing method.

To further address if the observed relative abundances were simply a function of the copy number of template subject to sequencing, irrespective of its starting length, we showed using synthetic SARS-CoV-2 RNA, that for relatively intact RNA template molecules the VFS remains constant even over 500-fold reduction in starting copy numbers. An empirically determined cut-off from synthetic RNA applied to clinical samples was able to separate all samples collected >8 days since illness onset as having predominantly fragmented RNA. This correlated very well with the failure to culture live virus from clinical samples collected after 8-9 days of illness in immunocompetent patients [8,11,22,38,47,51]. Conversely, based on the cut-off, about 50% of case with VFS <0.382 (hence lesser intact RNA) were collected ≤ 8 days from symptom onset. This fraction mirrors those observed previous studied with about 29%-42% of samples high viral inferred from low Ct or from ≤8 days did not recover live virus[9,11,22].

Another variable to consider is the sample type. Viral load and duration of positivity tends to be greater in lower respiratory tract samples (sputum) compared to throat and nasal swabs[5,52]. Accordingly, prolonged ability to culture virus has been reported for samples from severely ill patients with mostly lower respiratory tract samples[14], compared to the success rate in upper respiratory tract samples[46]. In the present study, upper respiratory tract samples (nasopharyngeal and nasal swabs) and oropharyngeal saliva samples were compared. Oropharyngeal saliva contains secretion of the salivary glands mixed with sputum from lower respiratory tract[53], hence is more akin to lower respiratory tract samples. In line with this, we observed higher VFS (more long fragments) in saliva samples on average compared to URT samples.

One study has looked at the potential of RT-PCR assays to determine the integrity of viral RNA and suggested that strong correlation between the levels of detection of multiple amplicons spanning the intact genome is indicative of viral integrity (and demonstrated this with live virus culture)[39], as opposed to non-correlated levels. In the light of findings in this study and especially with the evidence that both high viral load samples and low viral load samples can produce unexpected live virus culture results, another direct measure of viral integrity is urgently needed.

Despite the large body of knowledge surrounding viral infectiousness, several gaps and hurdles remain. First, Ct value as a surrogate measure of infectivity is variably correlated with success of viral culture and multiple RT-PCR assays with Ct scales that are not directly comparable are in clinical use (evidenced from the dramatically different Ct cut-offs derived based on culture positivity [22,38,48]). Second, typical RT-PCR assays are designed to detect short target templates and will readily amplify small amounts of fragmented viral RNA, precluding any consideration of integrity of the viral RNA. Third, duration since symptom onset has been shown to correlate with success of viral culture, however, all measures suffer from recall bias [22,46,54]. Fourth, the viral culture test is labor intensive and requires the Biosafety Level 3, which precludes it from being established in all diagnostic laboratories, and suffers from variations in accuracy and permissiveness of cell lines. Accurate measurement of infection potential becomes particularly relevant as vaccines against SARS-CoV-2 that immunize against COVID-19 disease become available, but transmission capacity of an immunized individual remains unknown[55,56].

We emphasize that the viral fragmentation scores (VFS) determined in this study are relative and post-laboratory processing and no determination of absolute fragment lengths contained in a sample has been attempted. The viral culture assay is the closest surrogate of this measure. Further work to correlate the insert length or an RT-PCR-based measurement of

integrity to virus culture is necessary to further these findings. There are important limitations to this study. The use of the exact cut-off of VFS to categorize samples into clinical groups may not universally apply. Nonetheless, the basic premise of the argument that more intact virus would reflect in more longer fragments in a clinical sample would universally apply. As the study's main conclusions are based on NGS, with some comparison to RT-PCR results, without evidence from virus culture studies it cannot be ruled out that some of the observed infectivity measures are correlated and result from a feature of the specific NGS method.

In conclusion, we have applied NGS to comprehensively characterize longitudinal samples collected from different sites. NGS is an enabling tool that provides sequence-related information for which it is primarily designed, and also information from size and length dimensions. Based on this, we identify fragment length differences among clinical samples which are correlated to clinical features of infectiousness of SARS-CoV-2, quantification of which could be incorporated as relevant and straightforward measure to determine infection potential.

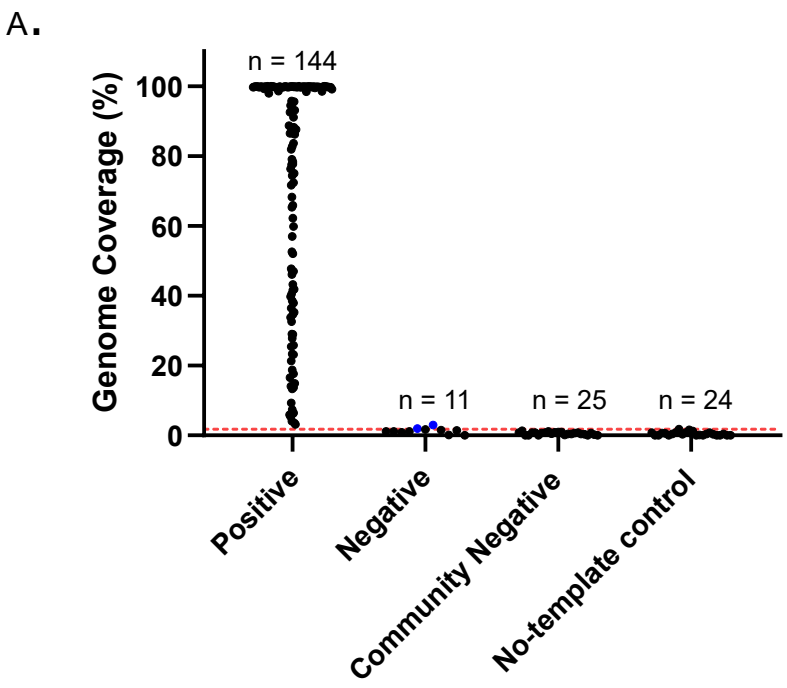

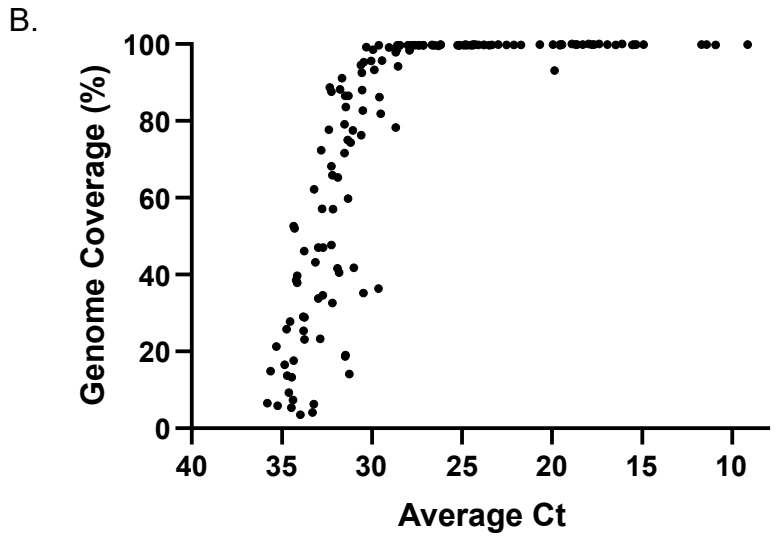

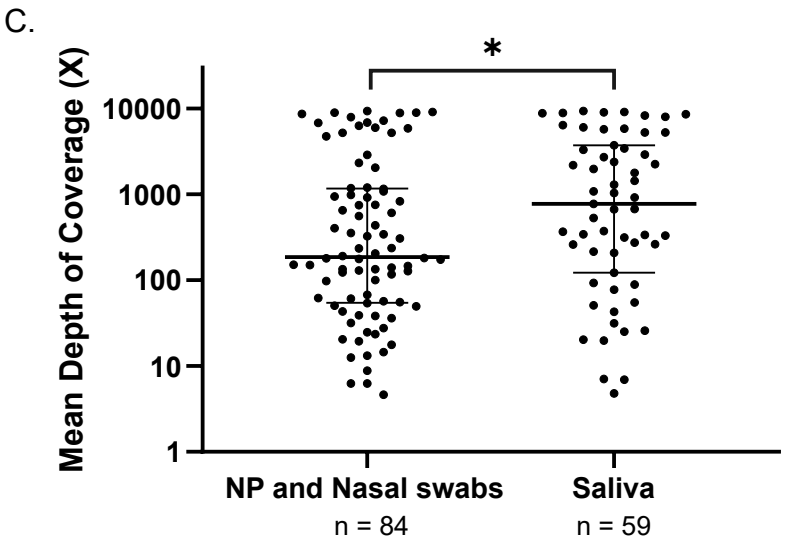

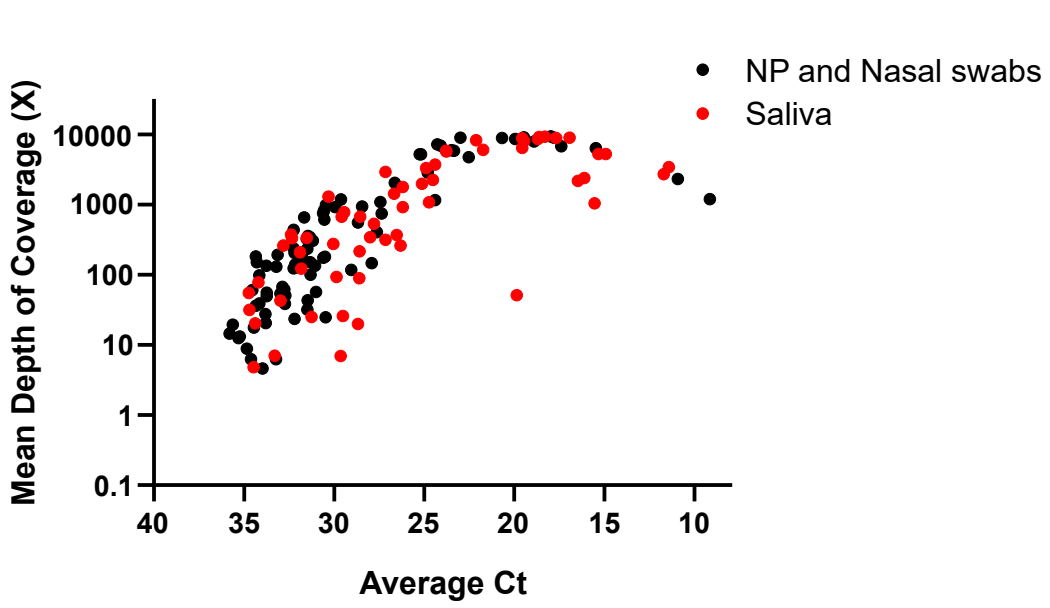

Figure 1. Next-generation sequencing (NGS) allows quantitative, sensitive and specific detection of SARS-CoV-2 in clinical samples (A) Grouped plot showing the breadth of genome coverage for samples including positive and matched negative samples from this study, confirmed negative samples from the community, which are unlikely to have any SARS-CoV-2 and no-template control (NTC) samples run parallelly with the samples over multiple batches of library preparation for sequencing. The cut-off genome coverage for positive samples was determined to be ~1.8% based on confirmed negative samples from the community (indicated by the red dotted line). Two of 11 samples negative by RT-PCR were just above the cut-off qualifying as positive for SARS-CoV-2 by sequencing. It remains possible that samples testing negative RT-PCR from the present study have very low-level positivity, which is at the limit of detection of the PCR assay. **(B)** The genome coverage (%) of SARS-CoV-2 by NGS (≥1x depth of coverage) is related to the original viral load in the clinical sample as measured by Ct value in RT-PCR. For clinical samples (n = 144) as Ct decreases, the % genome coverage reduces. **(C)** Mean depth of coverage is marginally higher in saliva samples (median: 186.7x, IQR: 54.33-1175x) relative to upper respiratory tract samples (URT) -nasopharygeal (NP) and nasal swabs (median: 776.8x, IQR: 122.5-3731x). *Mann-Whitney test, p = 0.0281. **(D)** Mean depth of coverage achieved is related to the viral load of the sample as measured by Ct value and decreases with increasing Ct value in both saliva and NP and nasal swabs.

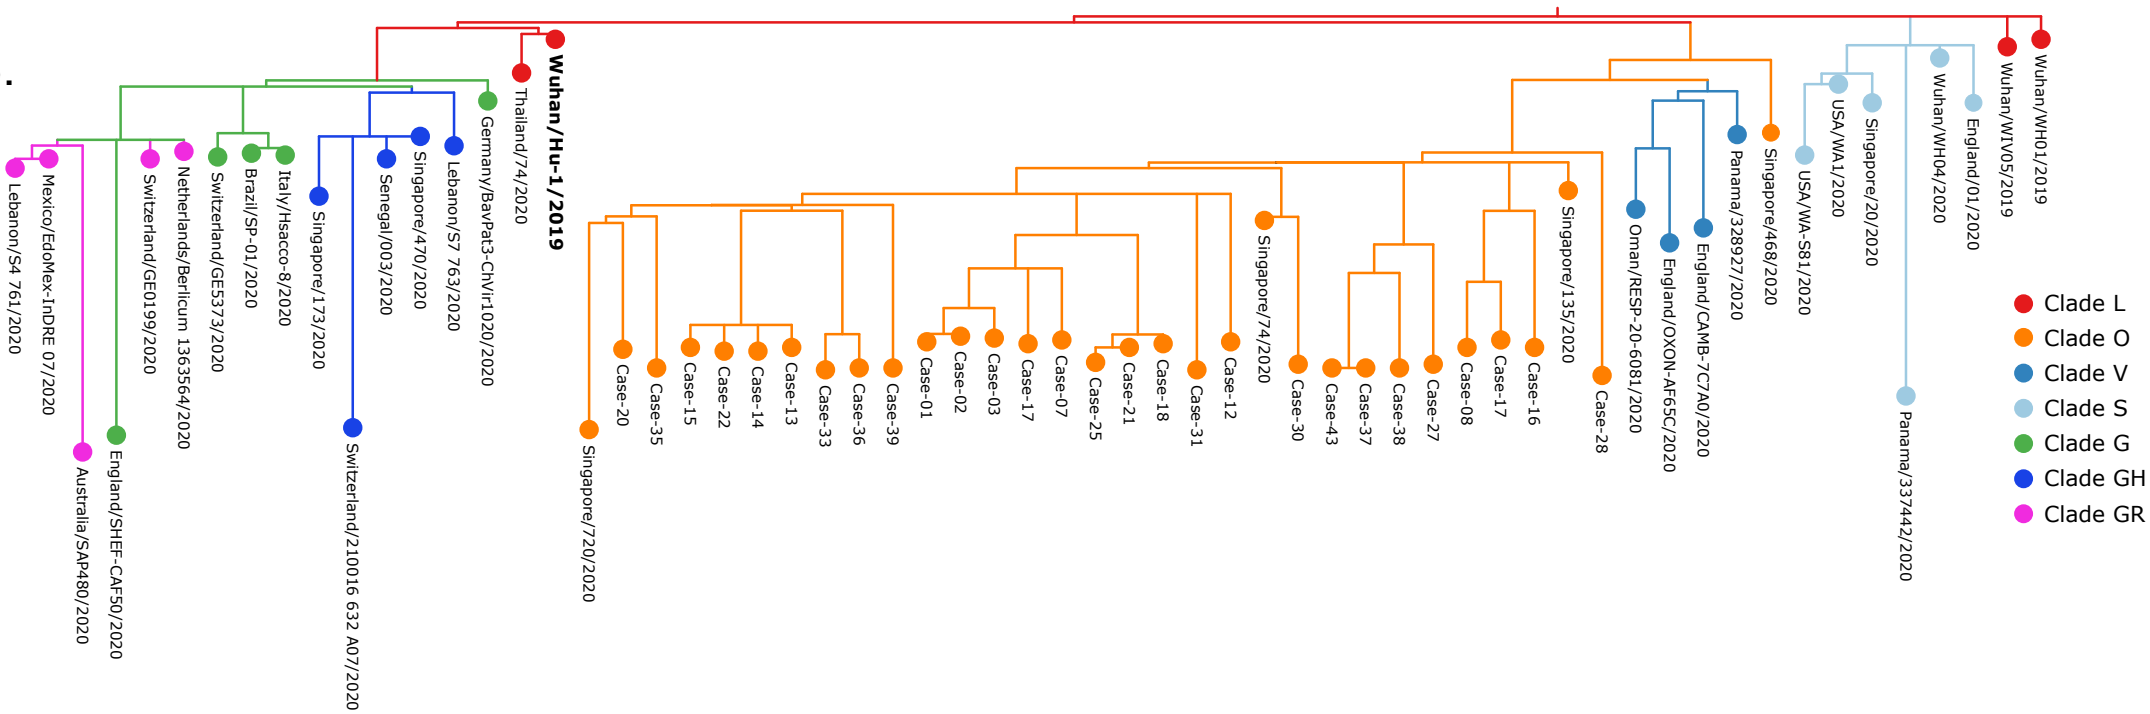

Figure 2. Genomic sequence analysis of SARS-CoV-2 in samples from multiple sites and over serial timepoints. (A) Genetic variant profiles of sequenced SARS-CoV-2 genome relative to the Wuhan/Hu-1/2019 reference from 4 representative cases with samples from multiple sites (NP or nasal swab or saliva) and over different time points since symptom onset (days). Genomic regions are depicted by shaded areas colored according to the case, and the grey lines represent the position of the detected variants. For each case with multiple samples each with >95% genome coverage (16 cases, not all depicted), identities of confidently called variants were conserved among the case's samples. **(B)** Phylogenetic tree of SARS-CoV-2 genomes from 28 cases relative to each other and to selected samples representing 7 GISAID clades (branches colored by clades). Cases from this study all belong to GISAID Clade O (orange branch) and cluster with each other and other Singapore samples. Phylogenetic reconstruction was performed using Nextstrain (https://nextstrain.org/) and GISAID (Global Initiative; https://www.gisaid.org).

Figure 3

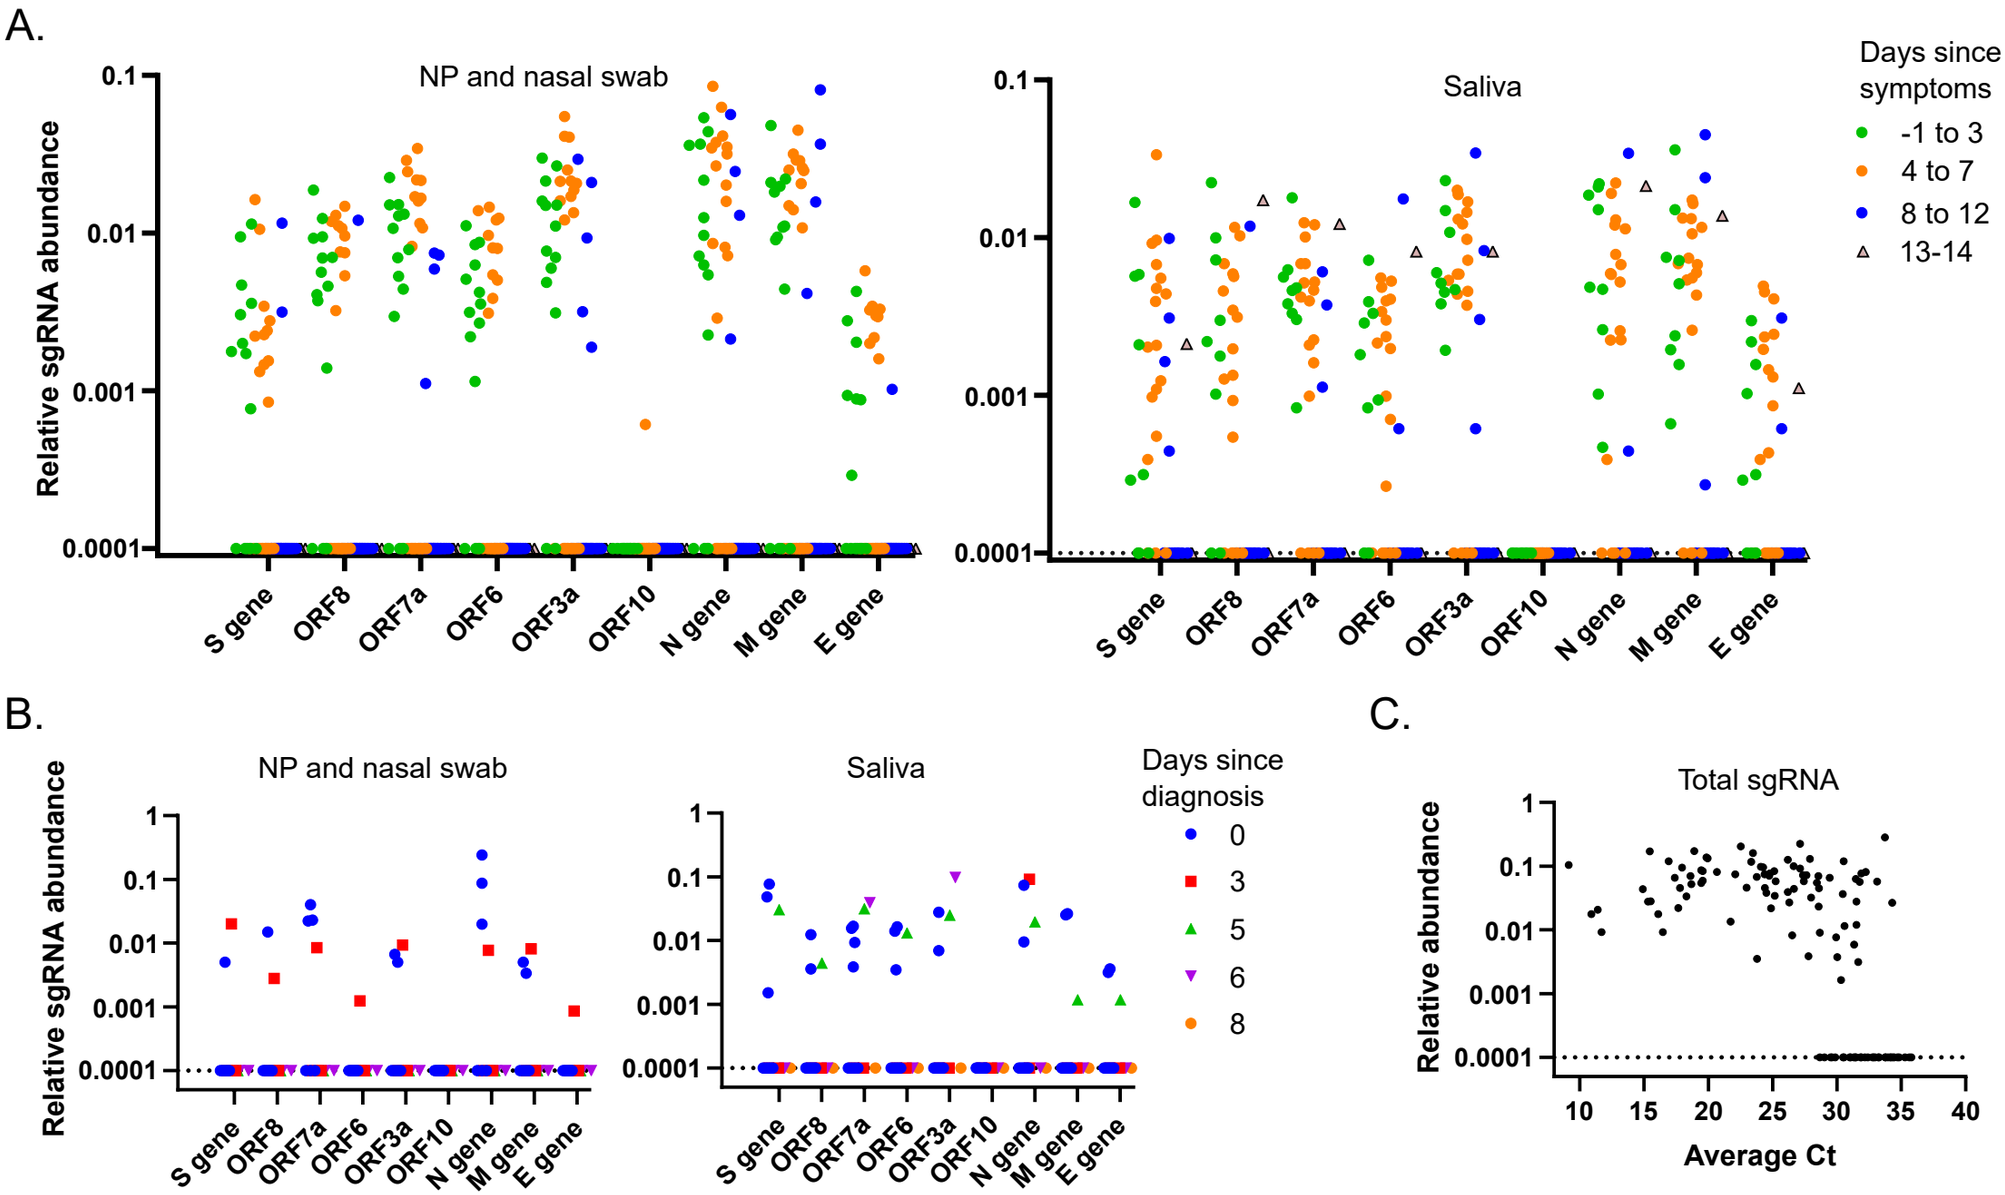

Figure 3. Detection of subgenomic RNA (sgRNA) in samples from symptomatic and asymptomatic cases over time. (A) In symptomatic cases, sgRNA species were abundantly detectable in both NP and nasal swab (URT) and saliva samples, and showed persistence up to 13 days since symptoms. Positive detection of sgRNA was largely within -1 to 7 days since symptom onset. N, M genes and ORF3a were the most abundant sgRNA in both sample types, while ORF10 was detected in only one sample. **(B)** In asymptomatic cases, sgRNA was most detectable in samples collected 0-3 days since diagnosis in both URT and saliva and was seen to persist up to 5-6 days since diagnosis in saliva. (C) Amount of total sgRNA, when detected, was not correlated with Ct value, but showed a Ct-related drop-off in detection, where 76.25% (61 of 80) samples with Ct≥28.67 did not have any sgRNA. Graph combines URT and saliva samples from symptomatic and asymptomatic cases. Zero values have been converted to 0.0001 to allow plotting on logarithmic scale and cluster on y-axes line at 0.0001.

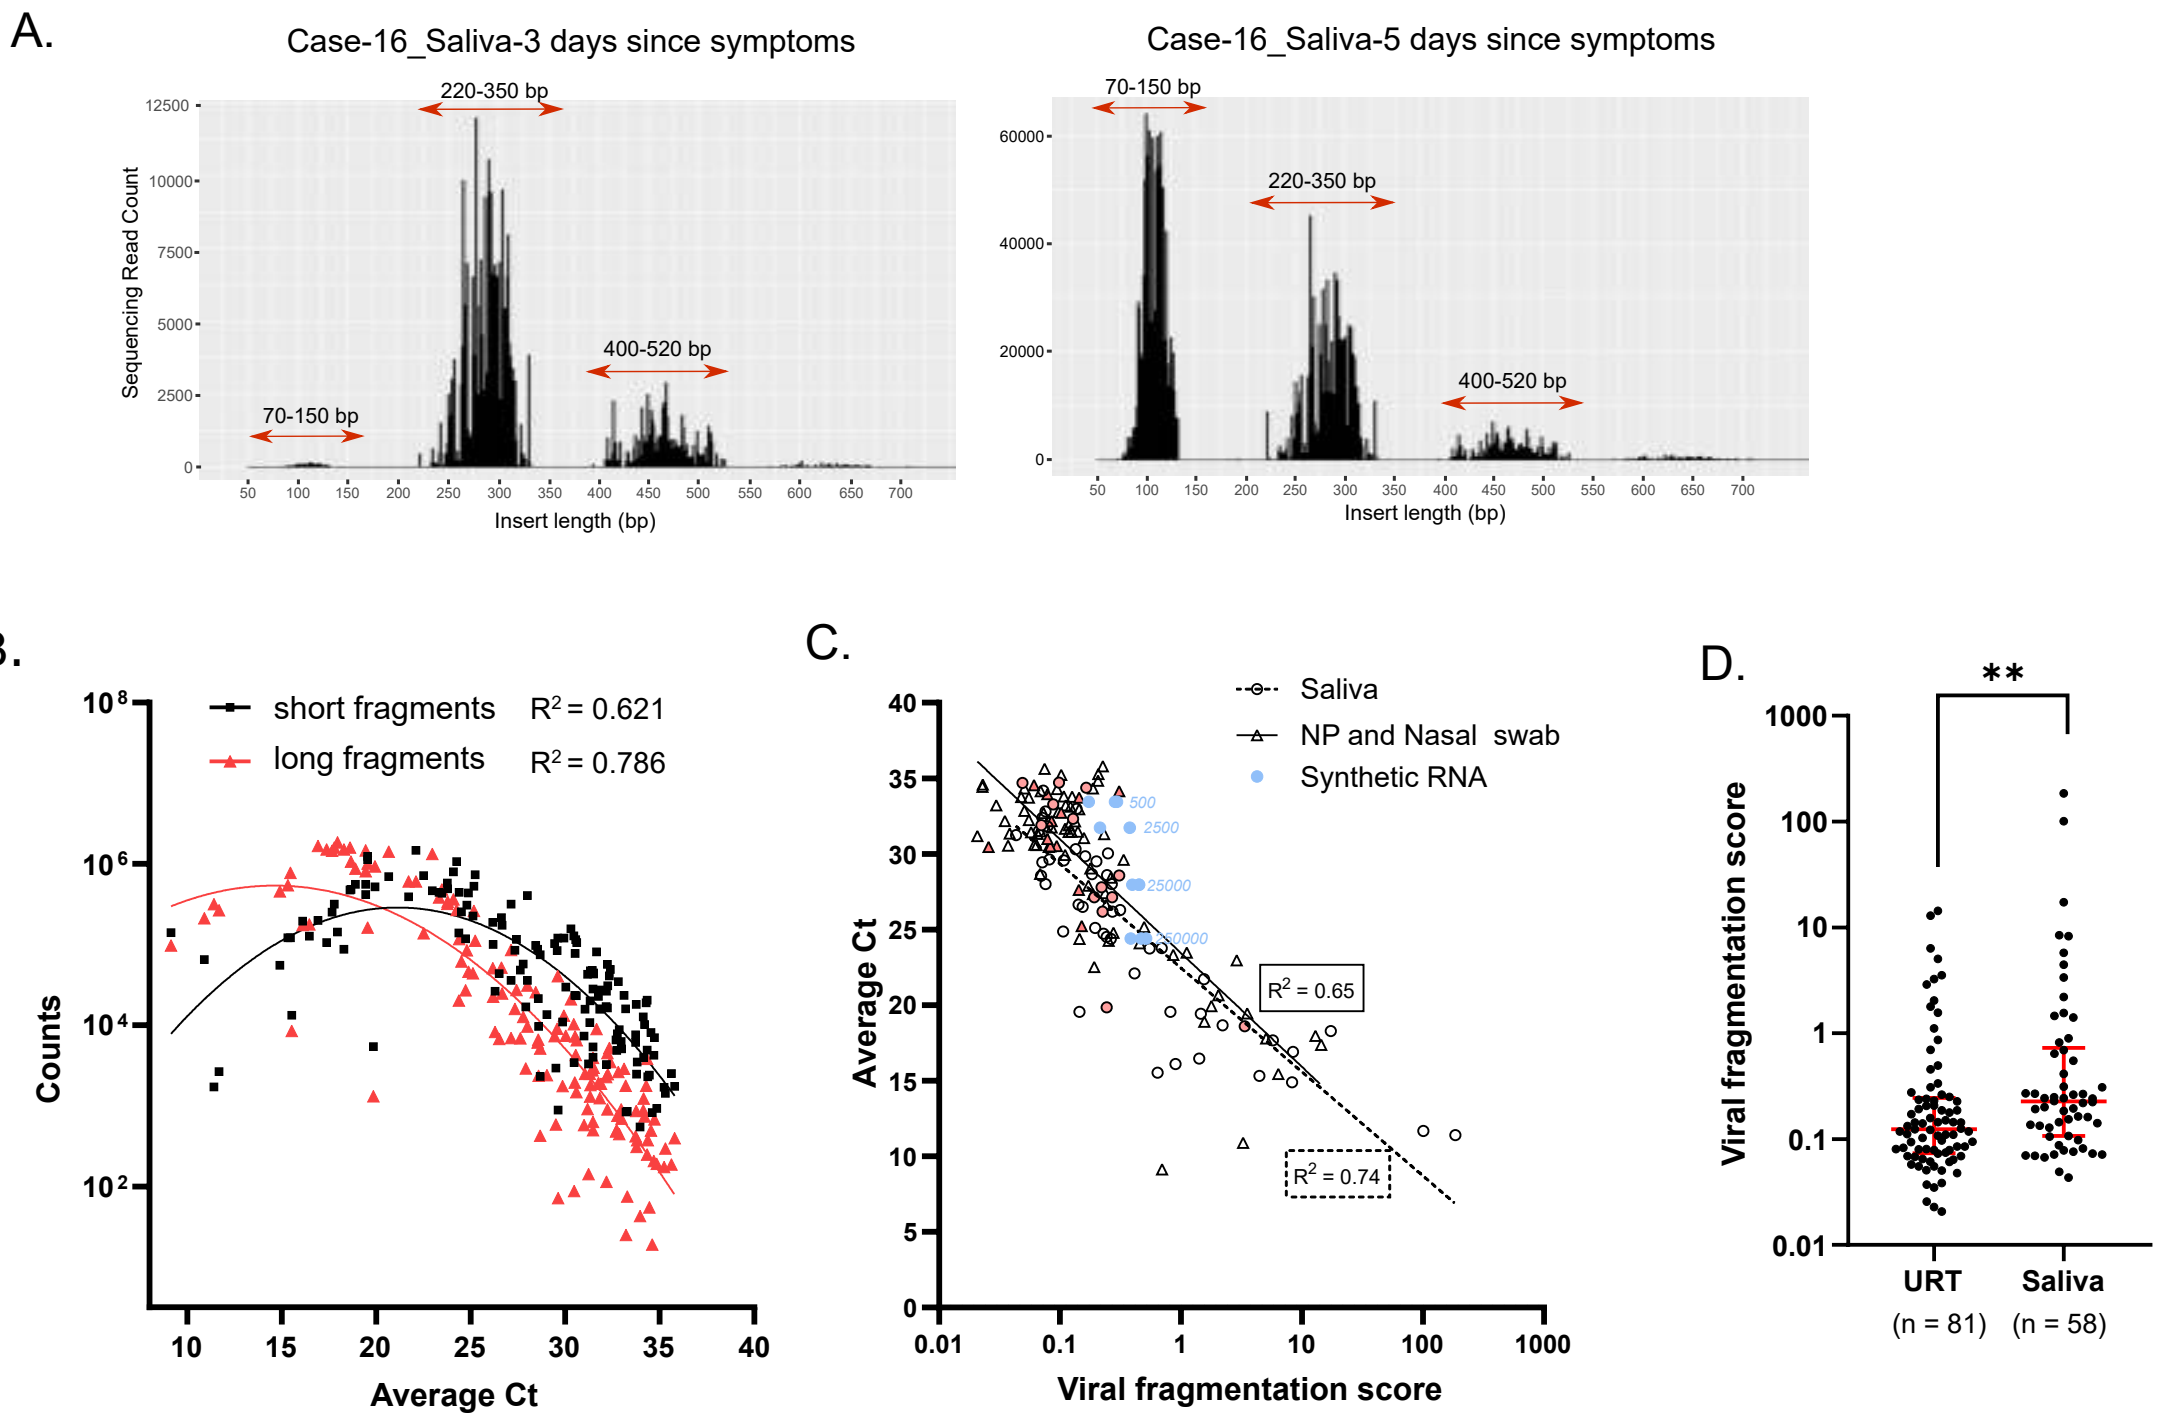

Figure 4. SARS-CoV-2 fragments of differing lengths can be detected by NGS as short or long inserts with varying relative abundances. (A) Histogram of sequencing read counts supporting insert lengths of ranges 70-150 bp, 220-350 bp, and 400-520 bp. Insert length distributions in longitudinal saliva samples from a single case are shown as examples. The relative abundance of insert lengths changes from a dominant 220-350 bp (long inserts) distribution in a sample taken 3 days from symptom onset, to a more abundant 70-150 bp (short inserts) distribution prominent in a sample taken 5 days from symptom onset. Insert lengths are representative of viral RNA fragments lengths. **(B)** Long and short fragment counts are each correlated with the Ct value of the sample measured by the CDC RT-PCR assay. Long fragments have a steeper decline in abundance, becoming differentially fewer compared to short fragments at Ct values greater than 25. URT (NP and nasal swab) and saliva samples are plotted together. **(C)** Long fragments count/short fragments count = viral fragmentation score (VFS) is moderately correlated with Ct value of a sample, in both URT and saliva samples. R2 values of correlation are shown. Pink-filled circles represent asymptomatic cases. Blue circles represent synthetic RNA samples of known integrity that generate a considerably constant VFS (median: 0.384, IQR: 0.289-0.449) across Ct values 24.4-33.45 over 500-fold serial dilution of synthetic RNA. Numbers next to blue circles are the concentrations in copies/ml of synthetic RNA. **(D)** Viral fragmentation scores are significantly higher across saliva samples compared to URT samples. Red lines represent median and interquartile ranges. **Mann-Whitney test p = 0.0035.

Figure 5

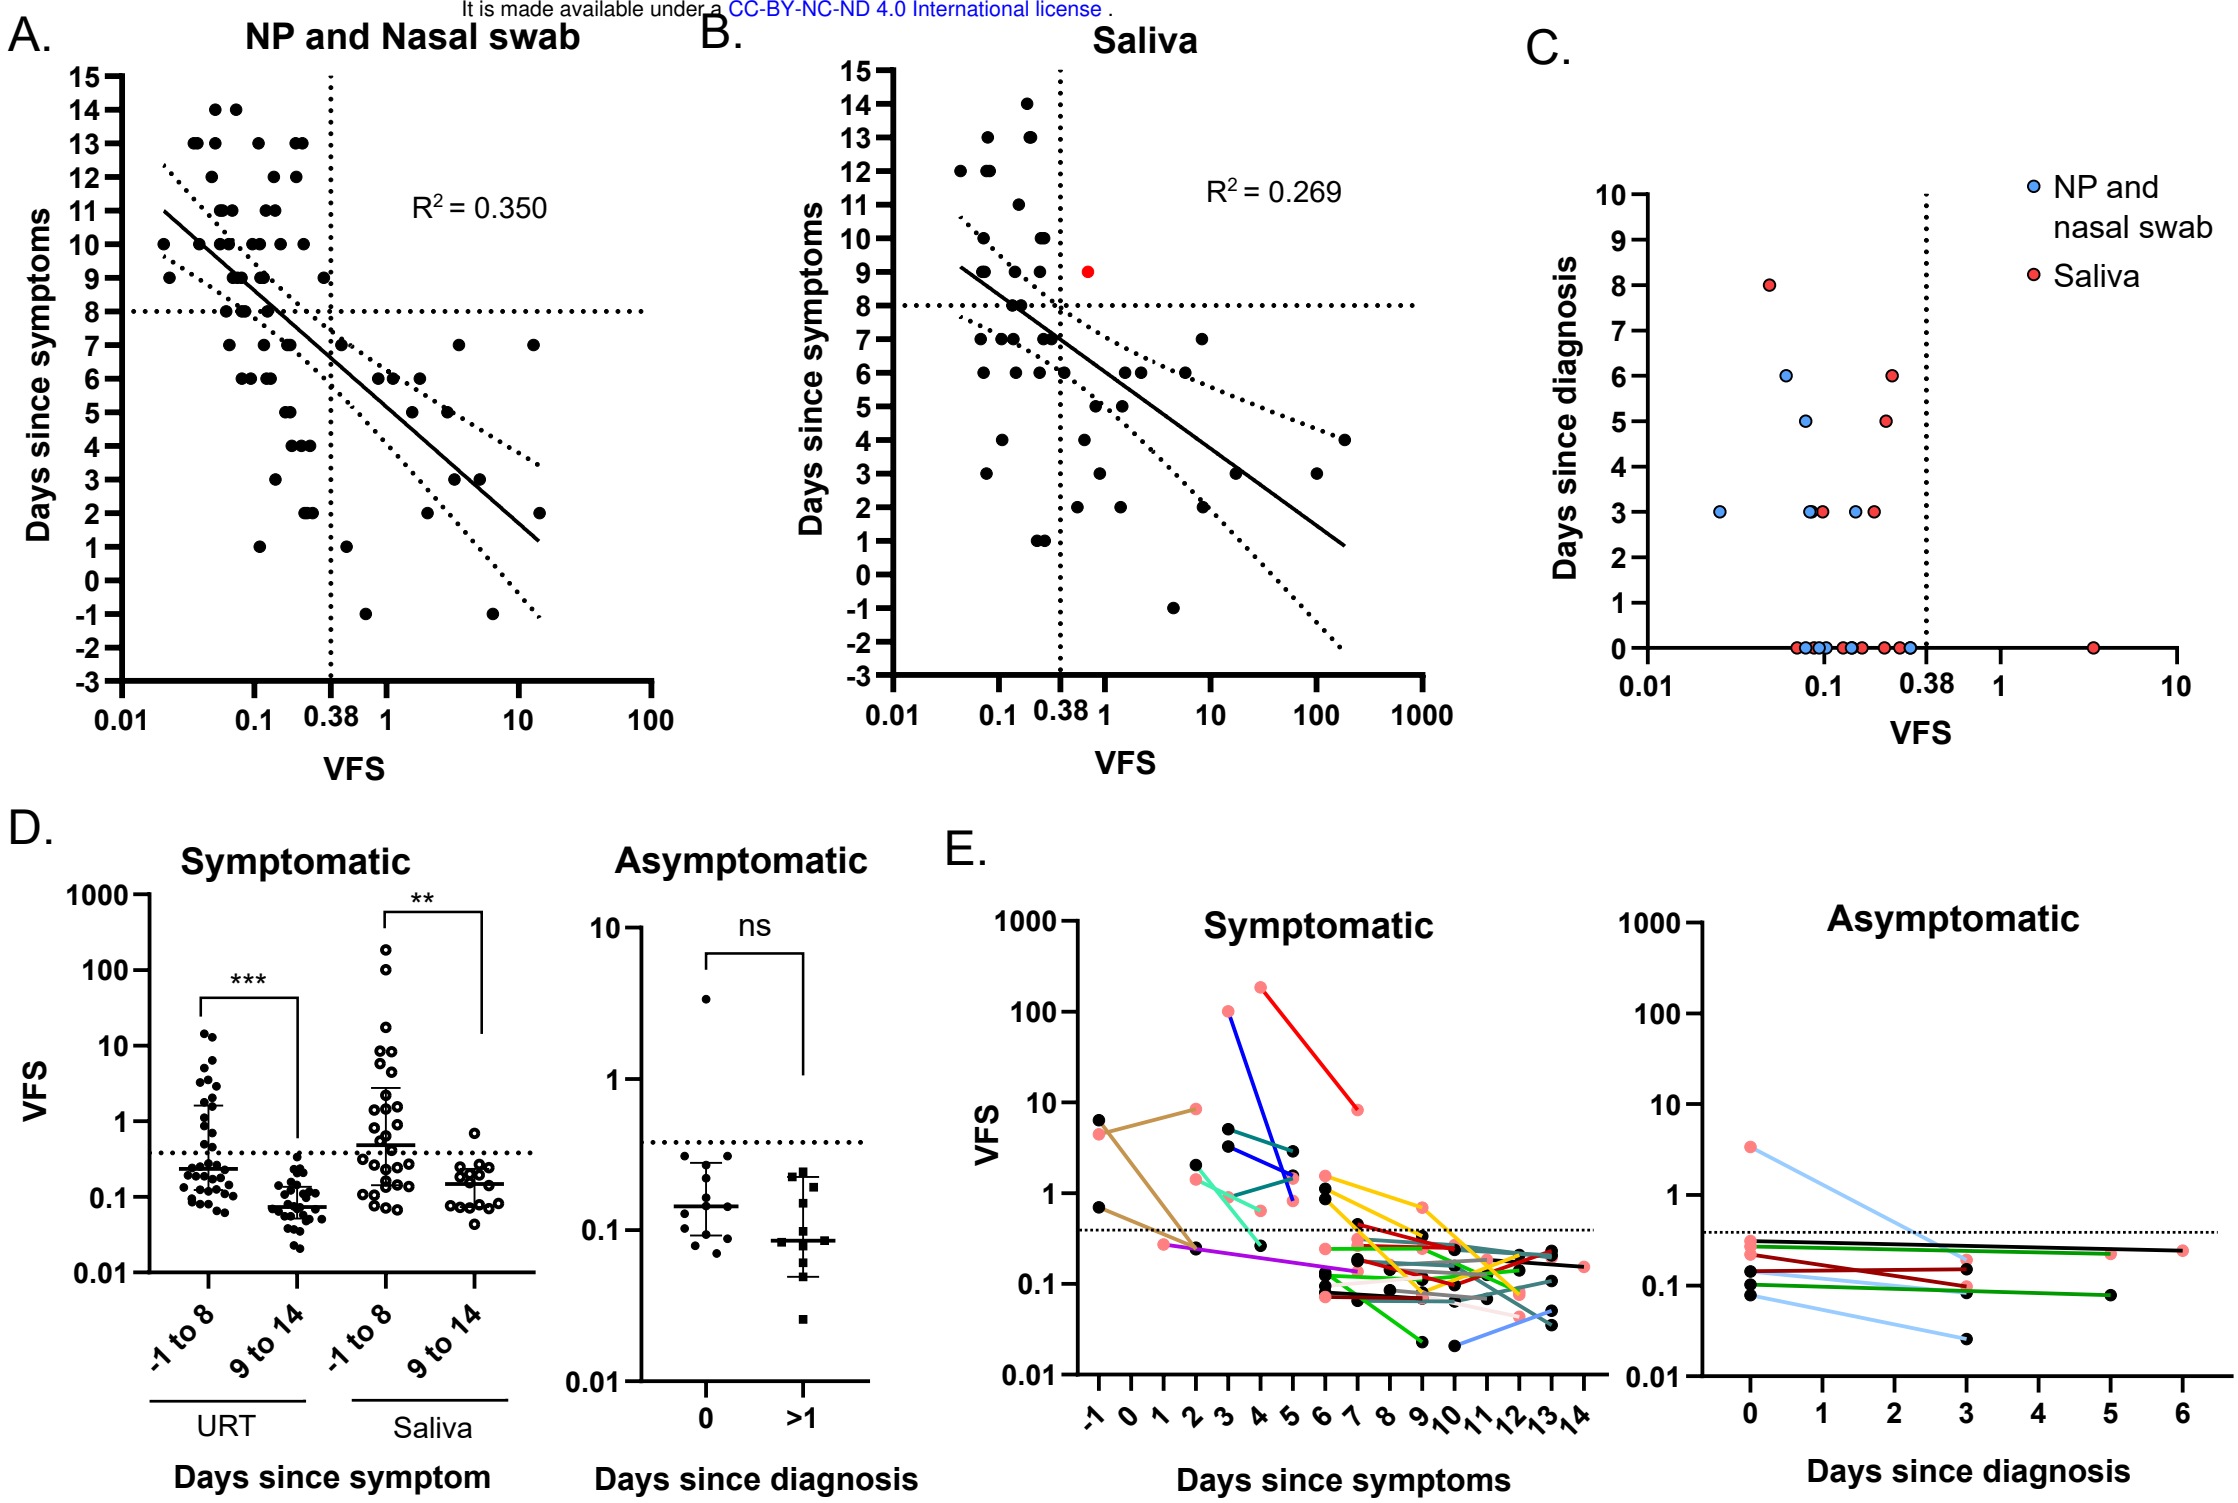

Figure 5. Viral fragmentation score is related to the clinical time-course of SARS-CoV-2 infection. In symptomatic cases, the relative amount of long fragments (viral fragmentation score, VFS) decreases with days since symptoms in both **(A)** URT and **(B)** saliva samples. With the exception of one saliva sample (red circle), beyond 8 days since symptoms, VFS does not exceed the cut-off of 0.38 (dotted line) estimated for intact RNA based on synthetic SARS-CoV-2 (upper left quadrants). For samples collected ≤8 days since symptoms onset, 15 (40.5%) of 37 URT samples and 16 (55%) of 29 saliva samples exceeded the cut-off (lower right quadrant). The fitted regression lines and 95% CI error are shown on graphs. **(C)** Most (96%) samples from asymptomatic cases had low VFS. **(D)** (Left) VFS differ significantly in URT and saliva between samples collected ≤8 days after symptoms onset and later samples.***Mann-Whitney test $p<0.0001$, **$p=0.0017$. (Right) No significant difference between VFS from samples collected on day 0 of diagnosis and later samples in asymptomatic cases (URT and saliva samples combined). Median and IQR lines are shown. **(E)** Matched longitudinal samples from 15 symptomatic cases (left) and 4 asymptomatic cases (right) and VFS. Each case is colored by a different line. Lines marked by pink ends are saliva samples while the rest are URT samples.

Figure 6

medRxiv preprint doi: https://doi.org/10.1101/2021.01.11.21249265; this version posted January 15, 2021. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

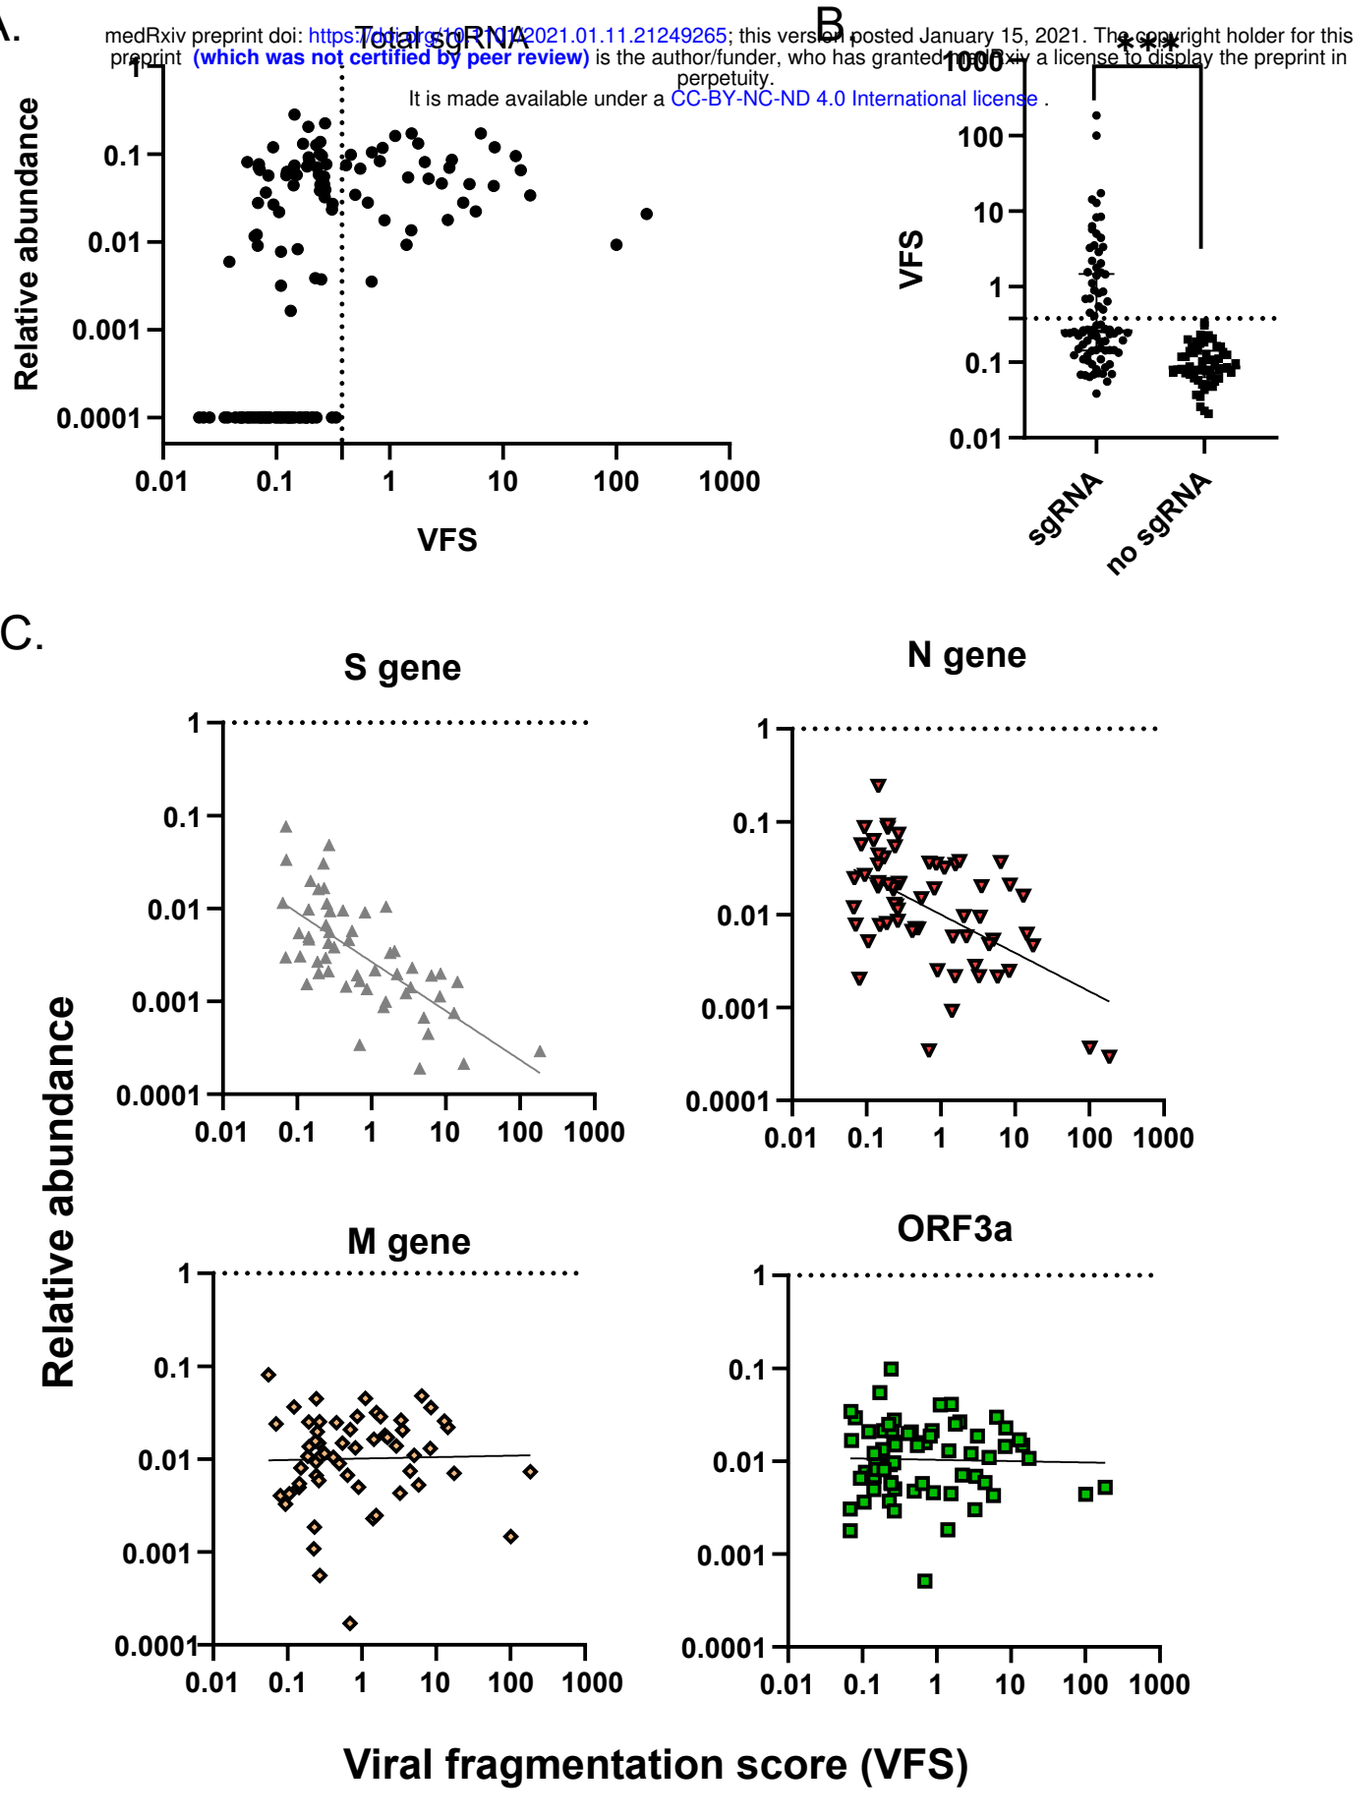

Figure 6. Profiles of subgenomic RNA (sgRNA) with relation to viral fragmentation score. (A) Across all sample types, sgRNA expression begins to tend to zero when VFS is low and a cut-off of 0.382 (dotted line) separates, 33 samples, all of which have VFS ≥0.382 and sgRNA detected, and 58 (54%) of 107 samples with VFS <0.382 having no sgRNA. **(B)** Significant difference in VFS between samples with zero or any sgRNA detected. ***Mann-Whitney test p<0.0001. Dotted line is VFS cut-off of 0.382. **(C)** S gene and N gene abundances are inversely related to the VFS, but other abundant sgRNA E gene and ORF3a are not.

Figure 7

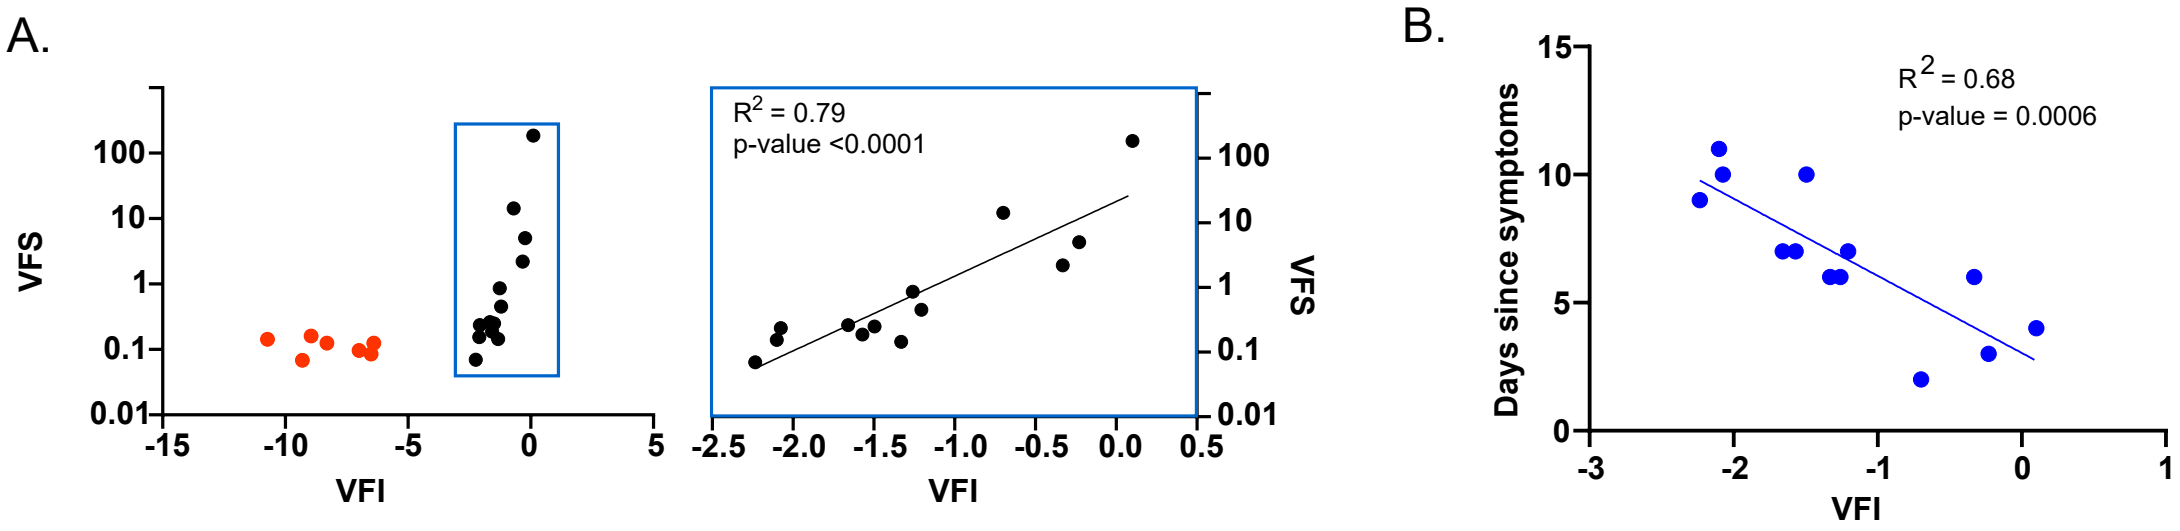

Figure 7. Viral fragmentation score can be captured in a multiplex RT-PCR assay for long (240 bp) and short (70 bp) amplicons. (A) Translation of the VFS obtained from NGS to an RT-PCR assay with calculation of difference in Ct value of short to long amplicon (Ct_70bp-Ct_240bp) for 20 clinical samples. The deltaCt value is referred to as the viral fragmentation index (VFI). (Left) Red dots are samples with no detection of 240 bp amplicon, for which Ct values are assigned to 40. (Right) Correlation of VFS and VFI for samples within blue margin is shown. **(C)** VFI from RT-PCR assay shows a correlation with days since diagnosis and for 7 samples not plotted due to non-detection of 240 bp, the days from diagnosis were ≥ 7.

SUMMARY

Objectives: To summarise the evidence on the duration of infectiousness of individuals in whom SARS-CoV-2 ribonucleic acid is detected.
Methods: A rapid review was undertaken in PubMed, Europe PubMed Central and EMBASE from 1 January 2020 to 26 August 2020.
Results: We identified 15 relevant studies, including 13 virus culture and 2 contact tracing studies. For 5 virus culture studies, the last day on which SARS-CoV-2 was isolated occurred within 10 days of symptom onset. For another 5 studies, SARS-CoV-2 was isolated beyond day 10 for approximately 3% of included patients. The remaining 3 virus culture studies included patients with severe or critical disease; SARS-CoV-2 was isolated up to day 32 in one study. Two studies identified immunocompromised patients from whom SARS-CoV-2 was isolated for up to 20 days. Both contact tracing studies, when close contacts were first exposed greater than 5 days after symptom onset in the index case, found no evidence of laboratory-confirmed onward transmission of SARS-CoV-2.
Conclusion: COVID-19 patients with mild-to-moderate illness are highly unlikely to be infectious beyond 10 days of symptoms. However, evidence from a limited number of studies indicates that patients with severe-to-critical illness or who are immunocompromised, may shed infectious virus for longer.

Introduction

Severe acute respiratory syndrome coronavirus, type 2 (SARS-CoV-2) is a highly infectious virus that is responsible for tens of millions of cases of coronavirus disease 2019 (COVID-19) worldwide.[1] SARS-CoV-2 constitutes a significant public health concern due to its high basic reproduction rate (R_0 of 4–5 in the unmitigated setting), the absence of immunity in the human population, the lack of effective treatment or vaccination approaches, the high SARS-CoV-2 viral loads detectable in respiratory samples, and the occurrence of transmission early in the disease course, often pre-symptomatically, or by those asymptomatic or paucisymptomatic.[2-7] Due to the lack of effective antiviral therapy or a vaccine, the rapid diagnosis, contact tracing, and isolation of suspected COVID-19 cases are of critical importance in the control of this pandemic.[3]

Isolation is defined as separating those with symptoms of, or diagnosed with, COVID-19, from people who are not infected.[8] This is distinct from quarantine, which is defined as separating and restricting the movements of people who were exposed or potentially exposed to COVID-19, as a precautionary measure to prevent transmission should they later become infected.[8] In circumstances in which cases are confirmed, isolation should continue until a patient is no longer expected to be infectious. However, recommendations regarding the appropriate duration of isolation for those who test positive for SARS-CoV-2 ribonucleic acid (RNA) have evolved since the emergence of the virus in China in December 2019, and vary across jurisdictions, generally ranging from 7 days[9] to 14 days.[10]

SARS-CoV-2 infection is primarily diagnosed based on detecting the presence of viral RNA by molecular testing, usually by re-

verse transcription polymerase chain reaction (RT-PCR) in a specimen from an individual's respiratory tract. However, detection of viral RNA does not necessarily mean that a person is infectious, i.e. that they are capable of transmitting the virus to another person.[3] Several factors determine viral transmission risk: these include whether a virus is still replication-competent (or viable); the amount of replicative virus; the presence of symptoms, such as a cough which can spread infectious droplets; the individual's local mucosal immune response to the virus; and the behavioural and environmental factors associated with the infected individual and their contacts.[11] Determination of the presence of viable virus may be accomplished by monitoring the ability of SARS-CoV-2 to replicate in laboratory-based cell culture. Such virus culture serves as a marker of potential viral infectivity.[12] Therefore, for the purpose of determining the infectiousness of a patient, and the duration of isolation required to minimise the risk of onward transmission, virus culture is significantly more informative than simple detection of viral RNA which could reflect non-replicative virus.[11,13–15] It is important to note that cells used to culture SARS-CoV-2 in the laboratory have been developed to be susceptible to, and enhance replication, of a wide range of viruses and therefore do not necessarily "mimic" the susceptibility of cells in a patient.[16] In addition, virus culture is usually used to identify the causative agent of an infection, and not to infer the infectivity of the individual from whom the sample was collected.[12] Therefore, the culture of SARS-CoV-2 derived from a patient's clinical sample does not necessarily prove that the patient is infectious at the time of sampling, but rather that they were potentially infectious due to the presence of viable virus. Evidence from epidemiological investigations can supplement the knowledge gained from virus culture studies by describing the transmission dynamics between index cases and their close contacts. Together, virus culture studies and epidemiological investigations (i.e., contact tracing studies) provide a more complete understanding of the duration of infectiousness.[15]

The aim of this rapid review was to summarise the evidence on the potential duration of patient infectiousness, as derived from virus culture and contact tracing studies, for those individuals in whom SARS-CoV-2 RNA is detected, and hence inform guidance on the duration of isolation.

Materials and methods

We conducted a rapid review to answer the following research question: *What is the duration of infectiousness in those in whom SARS-CoV-2 RNA is detectable?* This rapid review followed a standardised protocol,[17] in keeping with Cochrane rapid review methodology guidance.[18] We searched PubMed, Europe PubMed Central and EMBASE from 1 January 2020 to 26 August 2020. The search combined terms for COVID-19 and SARS-CoV-2 with terms for infectiousness, virus culture, and contact tracing. Reference lists of systematic reviews were also screened. No language restrictions were applied. Only articles including human subjects were included. The search strategy is provided in the supplementary material (Appendix 1).

All potentially eligible papers, including non-peer-reviewed preprints, were exported to Covidence[19] and screened for relevance. Any study that addressed the research question and met the inclusion criteria was included (Table 1). Primary research studies presenting empirical data on duration of infectiousness of SARS-CoV-2 in human populations were included. Specifically, the included studies were laboratory studies where virus culture was performed, and contact tracing studies with case-contact pairs.

For each included study, data on the study design, participant demographics and relevant outcomes were extracted. For virus culture studies, outcomes included the days post symptom onset on which virus culture was attempted, the days on which SARS-CoV-2 culture was positive, and the viral load of the original samples (where reported). Where graphical distributions were presented to model the probability of a positive culture on each day post symptom onset, data from curves were extracted using WebPlotDigitzer, version 4.3.[20] In order to present the data specifically for the time period following symptom onset (as opposed to pre-symptomatic culture positivity), and to allow for visual comparison of curves using common axes, extracted data derived from individual studies were plotted on a common chart. Plotting of data was performed using RStudio version 1.1.442.

For contact tracing studies, outcomes included the number of days post symptom onset in the infector at which infection in contacts was observed to have occurred, and the secondary attack rate. As studies were predominantly case series or case reports in design, a *de novo* tool, adapted from related tools, was used for quality appraisal.[17] Screening, data extraction, and quality appraisal were undertaken by single reviewers, however studies excluded at full-text screening stage, extracted data, and quality appraisal judgments were double-checked for accuracy by another reviewer.[18] Given the inconsistent presentation of data across the studies, and the heterogeneity of methods used to culture SARS-CoV-2, a quantitative synthesis of results could not be reliably performed. However, a narrative synthesis, including graphical representation of findings, is presented.

Results

Search results

Of 4226 studies screened after duplicate removal, 15 were included (Fig. 1).[14,21–34] In addition, unpublished data linked to 1 of the included studies[28] were also included.[35] Thirteen of these studies attempted to culture SARS-CoV-2 (Appendix 2),[14,21–23,25–33] and 2 studies conducted contact tracing of case-contact pairs (Appendix 3).[24,34] All 15 studies reported results in relation to time since symptom onset. No studies were found that reported duration of infectiousness in asymptomatic individuals (i.e. patients that never develop symptoms).

Population characteristics of included studies

Two studies each were conducted in the United States (US),[21,28] Taiwan,[24,30] the United Kingdom (UK)[31,34] and Germany;[25,33] while 1 study each was conducted in Switzerland,[29] Australia,[22] Canada,[23] Spain,[26] South Korea,[27] Hong Kong,[14] and the Netherlands.[32]

Of the 13 SARS-CoV-2 virus culture studies, 11 were case series[14,21–23,26–29,31–33] and 2 were case reports.[25,30] The contact tracing studies were both described as prospective, case-ascertained studies.[24,34] Across all 13 virus culture studies, SARS-CoV-2 culture was attempted from samples collected from at least 808 COVID-19 patients, with SARS-CoV-2 isolated in at least 206 of these patients. A total of at least 1652 samples had SARS-CoV-2 culture attempted and at least 413 of these were positive. Five studies did not clearly provide information on the number of samples and/or patients included.[22,23,26,30,33]

Twelve studies included COVID-19 patients only after onset of symptoms.[14,22,23,25–30,32–34] Three studies additionally included patients before they become symptomatic (i.e., pre-symptomatic).[21,24,31] The earliest SARS-CoV-2 virus culture attempt was 13 days before symptom onset,[31] whereas the latest SARS-CoV-2 culture attempt was 67 days after symptom onset.[14] The contact tracing study by Cheng et al. included contacts who had their first day of exposure to the index case between day 4 before and up to day 26 after symptom onset in the index case. Contacts were subsequently followed for 14 days after the last expo-

Table 1
Inclusion and exclusion criteria.

Inclusion Criteria	Exclusion criteria
Primary studies presenting empirical data on duration of infectiousness of SARS-CoV-2 in human populations, including: Contact tracing studies involving case-contact pairs Laboratory studies where virus culture was performed.	• Animal studies • Non-primary research (e.g. editorials/opinion pieces/guidance documents/reviews) • Studies which do not report data on duration of infectiousness (e.g. no time since first positive or symptom onset reported) • Studies reporting solely on pre-symptomatic durations, incubation periods, serial intervals, or on results based on statistical modelling • Laboratory studies where virus culturing was not undertaken • Studies where virus presence was confirmed only by culturing of non-respiratory samples (e.g. blood, faecal) • Virus culture studies where the virus was only isolated for the purpose of whole genome sequencing

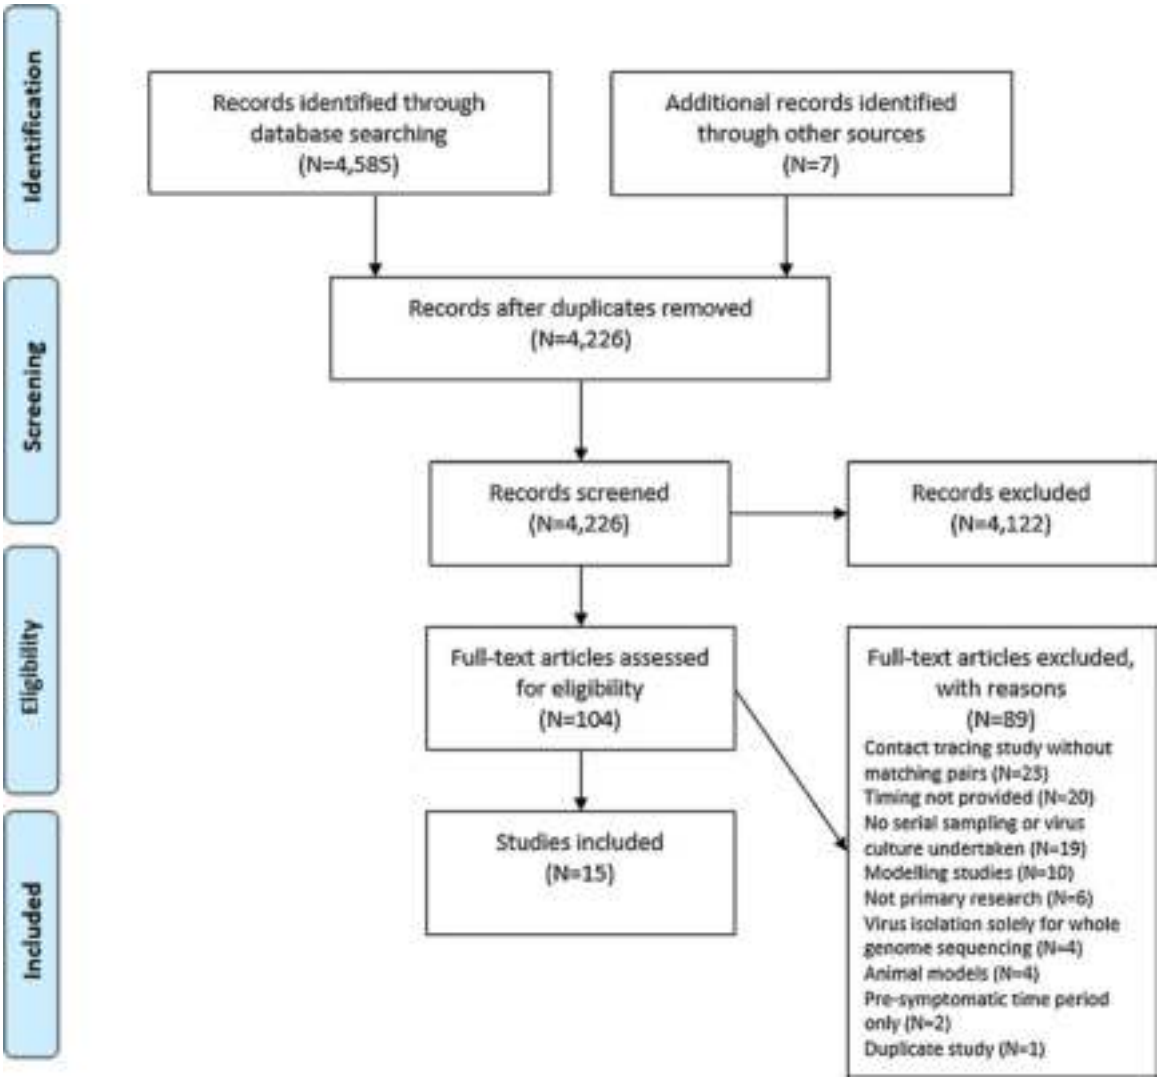

Fig. 1. PRISMA diagram indicating the flow of inclusion of studies for review.

sure to the index case.[24] The contact tracing study by Lopez Bernal et al. included household contacts who were exposed to the index case at any time between symptom onset and 14 days thereafter.[34] Follow-up of the contacts was limited to 14 days from onset of symptoms in the index case.[34]

Asymptomatic patients were included in 3 studies; however, no information was provided from these studies that could be used to inform the potential duration of infectiousness of asymptomatic patients. Results from serial sampling and attempted virus culture in asymptomatic patients were not reported,[21,31] and in 1 of the

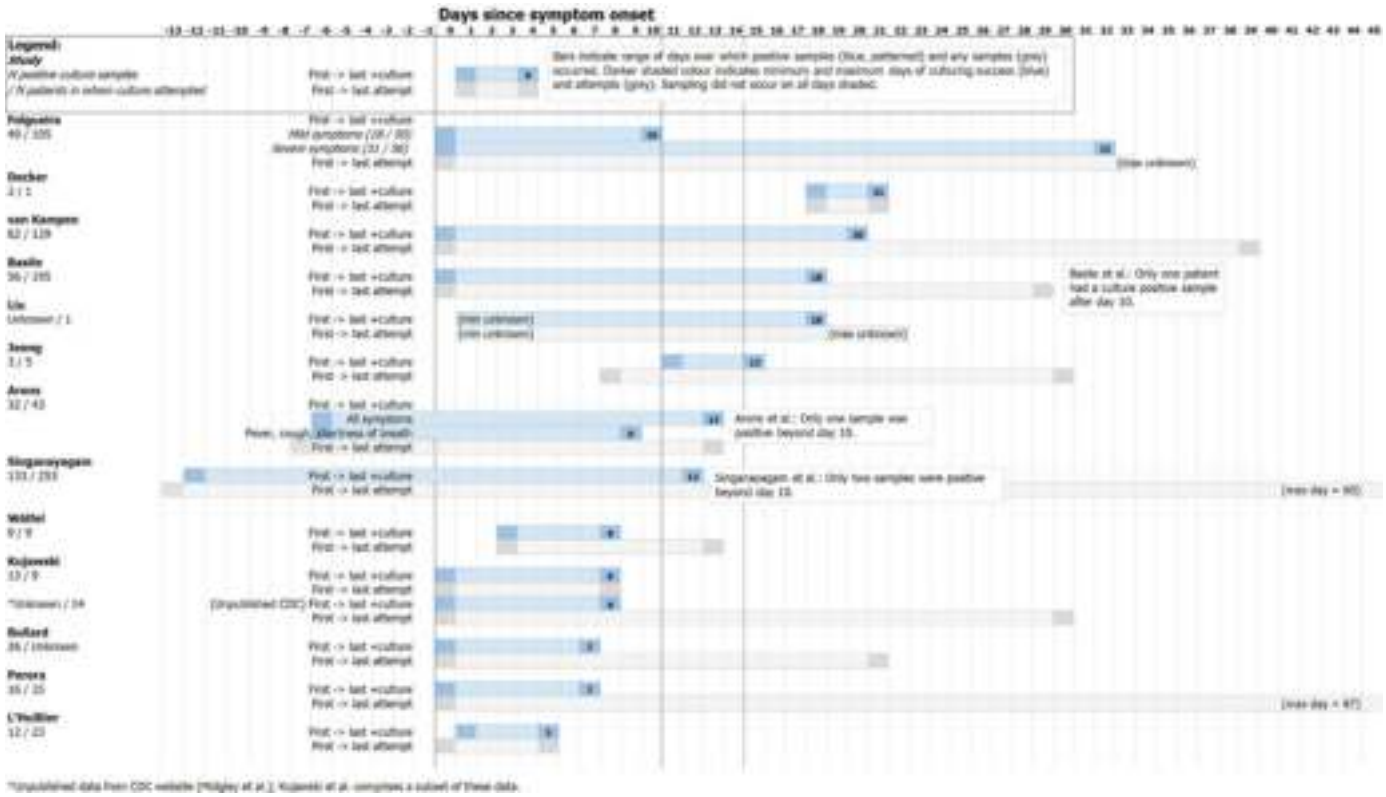

Fig. 2. Days since symptom onset at which SARS-CoV-2 virus culture was attempted (blue, patterned) and successful virus culturing (grey) took place in each study, displayed in descending order of last day of successful virus culturing.

contact tracing studies it was reported that no onward transmission occurred from the 9 asymptomatic patients included, despite 91 close contacts being identified for these patients.[24]

Virus culture study findings

Days post symptom onset on which SARS-CoV-2 could be cultured

Fig. 2 presents, for each individual study, the first and last days, post symptom onset, on which SARS-CoV-2 culture was attempted, and the first and last days on which SARS-CoV-2 culture was successful. These values are also listed in Table 2 alongside additional details of the studies.

For 5 of the 13 studies (with culture attempted in at least 76 patients), the last day on which SARS-CoV-2 could be cultured occurred within the first 10 days since onset of symptoms.[14,23,28,29,33] However, 1 of these studies, the sole study including only children, did not appear to attempt virus culture beyond day 5.[29] For the most part, the clinical severity of patients was mild-to-moderate in these 5 studies, though Perera et al. noted that 3 of the 35 patients in the study had been critically ill, while the remainder had mild disease or had been asymptomatic.[14]

In 2 studies, (with culture attempted in 296 patients) the last day on which SARS-CoV-2 culture was reported occurred between 10 and 14 days post onset of symptoms.[21,31] Singanayagam (with 133 SARS-CoV-2 culture positive samples from 253 patients) obtained only 2 culture positive samples between days 10 and 14 (1 on each of days 11 and 12). The authors also noted that more than half of the samples had been collected at least 8 days from symptom onset, and that 21% of these samples yielded SARS-CoV-2 in culture, the majority of which (25 of 27) was positive between 8 and 10 days after symptom onset. None of these late culture-positive samples included patients who were immunosuppressed or severely ill.[31] In Arons et al., 1 of 53 samples (for which the date of symptom onset was known) from 43 patients yielded SARS-CoV-2 on day 13; SARS-CoV-2 was not observed in other samples collected after day 10, though no virus culture was attempted beyond day 13.[21] There was also some uncertainty with regards to symptom onset in this study, with the longest time between the onset of typical COVID-19 symptoms (i.e., fever, cough or shortness of breath) and detection of SARS-CoV-2 culture positive recorded at 9 days, but 13 days after onset of less typical COVID-19 symptoms (i.e., chills, malaise, increased confusion, rhinorrhoea, nasal congestion, sore throat, myalgia, dizziness, headache, nausea or diarrhoea).

The remaining 6 studies, comprising 2 case reports and 4 case series (with culture attempted in 436 patients), reported successful SARS-CoV-2 culture between days 15 and 32 post symptom onset.[22,25–27,30,32] Three of the 4 case series included samples from over 100 patients.[22,26,32] Two of these studies included patients with severe disease.[26,32] Folgueira et al. ($N = 105$ patients) presented the maximum day on which SARS-CoV-2 was cultured for patients with mild symptoms (max day: 10) and severe symptoms (max day: 32).[26] Van Kampen et al. ($N = 129$ patients) reported SARS-CoV-2 culture results up until day 20. This study notably included only severely or critically ill patients, and included a large proportion of patients (23%) who were immunocompromised.[32] The third large case series, Basile et al. ($N = 195$), reported that the latest day on which a SARS-CoV-2 was cultured was day 10 for all but 1 patient (maximum day: 18).[22] The fourth case series, Jeong et al. ($N = 9$) reported positive cultures for 2 patients; the patient with SARS-CoV-2 cultured in saliva on day 15 was noted to be critically ill at the time of sampling.[27] Both of the case reports which identified SARS-CoV-2 in culture beyond day 14 were of hospitalised patients with mild disease,[25,30] although 1 of the

Table 2
Details of numbers of samples and patients for SARS-CoV-2 cultivation (positive cultures/attempted) and days on which culturing attempted and successful.

case reports described an immunocompromised patient who had recently had a heart transplantation.[25]

Viral load and duration of infectiousness

The assays used to detect SARS-CoV-2 RNA could be regarded as semi-quantitative, using the cycle threshold (Ct) value as a surrogate marker of the SARS-CoV-2 viral load. For each study, those samples collected on the maximum day on which SARS-CoV-2 was isolated in culture are outlined in Appendix 2. Of note, lower Ct values indicate a higher viral load.

Of the 6 included studies that examined the relationship between viral load and culture of SARS-CoV-2, all 6 found an inverse correlation.[14,22,23,31–33] Singanayagam et al. ($N = 324$ samples) estimated that the probability of successfully culturing SARS-CoV-2 from samples with a Ct value greater than 35 was 8.3% (95% CI: 2.8%–18.4%).[31] Basile et al. ($N = 234$ samples) concluded that any clinical sample with a Ct value of ≥37 was not indicative of replicative (or potentially transmissible) virus.[22] Bullard et al. ($N = 90$ samples) estimated that for every 1 unit increase in Ct value, the odds of culturing SARS-CoV-2 decreased by 32%.[23] While Folgueira et al. reported culturing SARS-CoV-2 on day 32 post symptom onset in a patient with severe COVID-19, they observed a very low viral load, with a Ct value of 39.1.[26] Hence it is probable (assuming the Ct value accurately reflects the amount of virus in the patient's respiratory tract) albeit not impossible, that the patient was not highly infectious at this particular time.

Summary estimates, including probability of culturing SARS-CoV-2

Three studies presented graphical estimates of the probability of culturing SARS-CoV-2 versus the number of days since symptom onset.[31–33] These probability distributions are reproduced in Fig. 3 in an amended form (data for days 0 to 20 presented only) with overlay of curves to allow visual comparison of the probability results. Van Kampen et al.[32] and Wölfel et al.[33] both presented probit (dose-response) distributions for this outcome and estimated the day post symptom onset on which the probability of culturing SARS-CoV-2 culture fell below 5%. These results were as follows: van Kampen et al., 15.2 days (95% CI 13.4–17.2);[32] Wölfel et al., 9.8 days (95% CI 8.5–21.8).[33] Singanayagam et al.[31] presented the results of a mixed effects logistic regression analysis (to account for the clustering of samples within patients); estimates of the percentage of samples with replicative SARS-CoV-2 were presented for each of days 7 to 15 post symptom onset, and are repro-

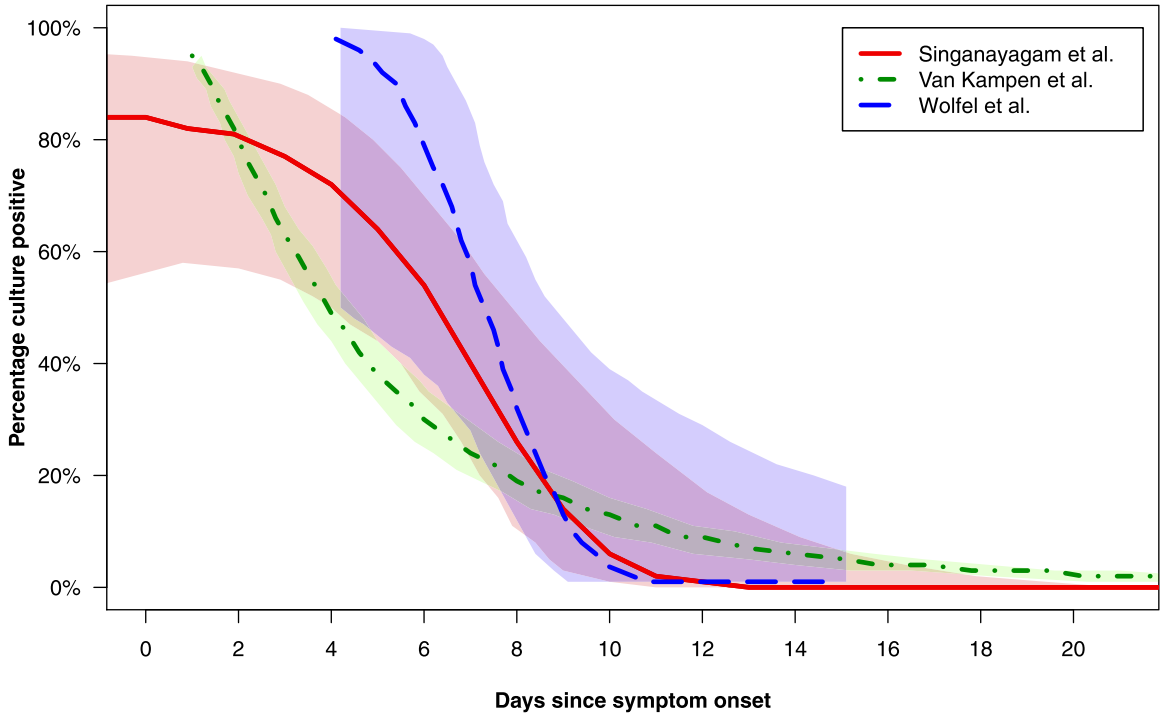

Fig. 3. Probability curves presented in 3 studies (Singanayagam et al., van Kampen et al., Wölfel et al.) which attempted to model the probability of successful virus culture versus duration of days of symptoms.[31–33] *Curves are presented with adaptation from the original presentation in the respective manuscripts in order to provide information for the first 20 days post symptom onset and to permit visual comparison of curves via overlay on a single plot. Lines (solid, dashed or dotted) depict estimated probability of positive virus culture* versus *days post symptom onset, while shaded areas depict 95% confidence intervals around these estimates.*

Table 3
Estimated percentage of samples with infectious SARS-CoV-2 for days 7–15 after symptom onset (adapted from Singanayagam et al.).

Day post symptom onset	Estimated% culture positive (95% CI)		Observed number of samples culture positive	Observed number of samples tested
7	40.1	(22.8 - 60.4)	10	14
8	25.8	(11.0 - 49.4)	9	33
9	13.7	(3.7 - 39.6)	10	34
10	6.0	(0.9 - 31.2)	6	23
11	2.2	(0.2 - 23.9)	1	6
12	0.7	(0.0 - 17.9)	1	3
13	0.2	(0.0 - 13.1)	0	4
14	0.03	(0.0 - 9.4)	0	2
15	0.006	(0.0 - 6.7)	0	2
			Total: 37	Total: 121

duced in Table 3. At 10 days post symptom onset, the probability of a sample with replicative SARS-CoV-2 was 6% (95% CI 0.9–31.2); however, these data carry a high degree of uncertainty, as shown by the wide confidence intervals.

While unpublished, Midgley et al. additionally presented a Kaplan-Meier analysis of time to a negative culture SARS-CoV-2 following illness onset.[35] This analysis represents an expanded analysis of the results reported by Kujawski et al.,[35] including a greater number of patients from the same setting ($n = 14$ versus $n = 12$ (9 of whom had samples collected for virus culture)), though the total number of samples tested is not known. Midgley et al. reported that the probability of successful SARS-CoV-2 culture fell from 50% at day 4 after illness onset, to 20% at day 8, and approached 0% after day 9.

Analysis and interpretation of virus culture study findings

Data for maximum day that SARS-CoV-2 was cultured

Several jurisdictions suggest a period of isolation for COVID-19 patients of a minimum of 10 days since the onset of symptoms.[11,15,36] As such, day 10 represents a relevant reference timepoint when considering the results of the SARS-CoV-2 culture studies included within this review.

While 8 of the 13 studies successfully cultured SARS-CoV-2 on days beyond day 10 post symptom onset, these results require contextualisation. Important aspects to consider include the number of samples and patients in whom this outcome occurred with respect to the overall number of samples and patients tested, and the patient populations included.

In total, these 8 studies included at least 337 SARS-CoV-2 culture-positive samples obtained from 732 patients.[22,25–27,30–32] In 4 of the 8 studies, only 1 patient was SARS-CoV-2 culture-positive beyond day 10,[21,22,25,30] and a further study identified only 2 samples (of 133 positive samples) yielding SARS-CoV-2 culture beyond day 10.[31] These 5 studies included at least 223 SARS-CoV-2 culture positive samples from 493 patients in whom culture was attempted (Table 2).[21,22,25,30,31] They reported a maximum of 6 patients who were SARS-CoV-2 culture-positive beyond day 10 (assuming conservatively that the 2 positive samples beyond day 10 in Singanayagam et al. arose from 2 unique patients).[31]

While these 5 studies in total reported a maximum of 6 patients from whom SARS-CoV-2 was cultured beyond day 10,[21,22,25,30,31] the total number of patients with positive samples is unknown (Table 2). However, amongst these 5 studies,

the proportion of patients from whom SARS-CoV-2 was cultured ranged from 44%[31] to 100%[25,30] (the latter representing case reports) (Table 2). Applying a worst-case scenario by adopting the lower proportion, i.e., assuming a positivity rate amongst patients of 44%, this results in an estimated minimum of 217 patients across these 5 studies. As such, 6 patients amongst 217 patients (maximum proportion of approximately 3%) are estimated to have had samples containing replicative SARS-CoV-2 in vitro beyond day 10 post symptom onset.

Within the remaining 3 studies (with culture attempted in 239 patients), wherein the latest day of successful culture exceeded day 10, it is less clear how many patients contributed to the samples resulting in this outcome.[26,27,32] Folgueira et al.[26] and Van Kampen et al.[32] noted that patients from whom SARS-CoV-2 could be isolated were severely or critically ill at the time of sampling. The remaining study, Jeong et al., included 2 patients with this outcome, 1 of whom was critically ill at the time of sampling (day 15), and the other of whom was severely ill, but recovering at the time of sampling (day 11).[27] As such, patients with severe and critical illness may represent a relevant subgroup within the data.

Probability estimate data

Two of the included studies (with culture attempted in 262 patients) which largely included patients with mild-to-moderate disease,[31,33] and additional unpublished estimates associated with 1 of the included studies,[28,35] estimated that the probability of culturing SARS-CoV-2 falls below 6% at day 10 (Fig. 3). A third study (with culture attempted in 129 patients) which modelled the probability of virus culturing versus time, suggested that the probability of a SARS-CoV-2 positive culture would fall below 5% at day 15[32] (Fig. 3). However, this latter study uniquely included only hospitalised patients with severe or critical illness.

Singanayagam et al., the virus culture study in our review with the greatest number of patients ($N = 253$ patients in whom culture was attempted), and which predominantly included patients with mild-to-moderate disease, reported numerical estimates of the probability of a sample producing a SARS-CoV-2 positive culture at each day from day 7 onwards (Table 3).[31] These data carry a high degree of uncertainty, as shown by wide confidence intervals, but showed a steep decline in the probability of culturing SARS-CoV-2 over time. For example, the estimated percentage of samples culture-positive on day 8 stood at 25.8% (95% CI 11.0–49.3) while the corresponding figure for day 10 was 6.0% (95% CI 0.9–31.2).

Contact tracing study findings

Two of the 15 included studies were contact tracing studies.[24,34] Cheng et al.[24] undertook a contact tracing study of 100 confirmed COVID-19 cases (ranging from asymptomatic to critical disease) in Taiwan. Amongst the 2761 close contacts of the 100 COVID-19 cases, there were 22 paired index-secondary cases. This study found that the overall secondary clinical attack rate was 0.7% (22 cases from 2761 contacts; 95% CI, 0.4%−1.0%). The attack rate was higher amongst the 1818 close contacts whose exposure to index cases started within 5 days of index case symptom onset (22 cases from 1818 contacts; 1.0%; 95% CI, 0.6%−1.6%) compared with those who were exposed later (0 cases from 852 contacts; 0%; 95% CI, 0%−0.4%). The 299 close contacts with exclusively pre-symptomatic exposure (up to 4 days before symptom onset in the index case) were also found to be at risk of infection (2 cases from 299 contacts; 0.7%; 95% CI, 0.2%−2.4%). The authors of this study concluded that there is a relatively short period of infectiousness of SARS-CoV-2, with higher transmissibility from 4 days before and up until 5 days after symptom onset. Based on the lack of onward transmission when close contacts were first exposed more than 5 days after symptom onset in the index case, the authors deduce that there is a lower transmission risk at the later stage of the disease.[24]

Lopez Bernal et al.[34] undertook a contact tracing study of 269 lab-confirmed COVID-19 cases in the UK, who lived with at least 1 other person. Local health protection teams contacted household contacts of these patients daily for 14 days after onset of symptoms in the index case. In total, 472 household contacts were identified. Of these 472 contacts, 65 (13.8%) had a laboratory-confirmed diagnosis of COVID-19 using RT-PCR testing, and another 96 (20.3%) had probable COVID-19 based on the onset of symptoms of fever, anosmia (i.e., loss of smell) or respiratory symptoms. The remaining 311 contacts were classified as non-cases as they did not experience any symptoms suggestive of COVID-19 within 14 days of symptom onset in the index case. The household secondary attack rate was found to be 37% (95% CI, 31%−43%) including both laboratory-confirmed and probable secondary cases.

Of the 161 laboratory-confirmed or probable secondary cases, 41 had a point source exposure (i.e., a maximum exposure window of 1 day) to an index case and data available to allow analysis of timing of exposure. Laboratory-confirmed and probable secondary cases considered together ($N = 41$) were exposed a mean of 2.37 days (standard deviation (SD) 3.36) and a median of 1 day (interquartile range (IQR) 0–4) after symptom onset in the index case; exposure ranged from 0 days to the maximum follow up of 14 days. As identification of contacts was limited to 14 days from onset of symptoms in the index case, no information was provided regarding secondary cases in household contacts outside this exposure window. Similarly, of the contacts identified in the 14-day window, follow-up was truncated at 14 days from symptom onset in the index case, so no information was provided regarding symptoms that may have arisen after this follow-up period.

Restricting to lab-confirmed secondary cases only ($N = 12$), exposure occurred a mean of 1.33 days (SD 1.61) and a median of 1 day (IQR 0–1.25) after symptom onset in the index case, ranging from 0 to 5 days. In contrast, non-cases were exposed a mean of 2.71 days (SD 2.74) and a median of 2 days (IQR 0–5) after symptom onset in the index case, ranging from 0 to 9 days. No analysis was undertaken in this study to determine whether these time differences were statistically significant.[34]

Methodological quality of included studies

There are some important methodological limitations associated with all of the included studies. All 13 SARS-CoV-2 culturing studies were retrospective in nature and were either case series[14,21–23,26–29,31–33] or case reports,[25,30] where patients do not appear to have been selected or sampled systematically. However, the contact tracing study by Cheng et al. was generally well-conducted due to its prospective nature, the systematic pairing of index cases and close contacts over time, and the follow up of contacts for 14 days after last exposure to the index case to assess for symptom onset.[24] Hence, the majority of evidence in this review comes from studies of low quality design. Importantly, it would appear that most studies did not specifically set out to identify the temporal relationship between time post symptom onset and presence of infectious virus, but rather reported culture positivity based on samples collected for other purposes.[23,26–29,31,33] Thereby, some uncertainty remains regarding the true duration of patient infectiousness, as the upper limit of outliers may not have been fully clarified. Recall bias is another issue which may have important implications on outcomes across all studies, as patients may not have been able to accurately determine when symptoms began, particularly if they were quite mild and non-specific.[37]

There are some concerns regarding the inconsistent approaches used for cell culture amongst studies, and the interpretation of

findings by the study authors. If, as noted in some studies,[14,29] a second passage of the sample is required to observe a cytopathic effect (CPE), and thereby to confirm culture positivity, this suggests a very low replicative viral load in the original sample and may reflect that the individual from whom the sample was collected is unlikely to have been infectious at the time of sampling.[38] Furthermore, given that longer periods for a CPE to develop are indicative of a lower viral replicative titre in the original sample,[16] where studies incubate the cell lines for prolonged periods, and only observe a CPE towards the end of this period, this may also lead to overestimation of the clinical significance of the findings.[31]

A *de novo* tool was also used to quality appraise case reports and case series.[39] This tool identified additional concerns regarding the limited reporting of demographic information,[22,23,30,31,33] the unclear criteria for selection of cases,[14,23,26,27,32,33] the non-consecutive inclusion of cases,[14,22,23,26,27,32,33] uncertainty regarding the appropriateness of statistical analysis[14,27,31–33] and the inconsistent use of RT-PCR testing for diagnosis.[34] Four of the studies included in this review are published as pre-prints, so have not yet been formally peer-reviewed, raising additional concerns about overall quality and the potential for results to change prior to formal publication.[22,26,32,34]

Discussion

Thirteen SARS-CoV-2 virus culture studies of various quality and size, and 2 large contact tracing studies, were included in this rapid review. The evidence to date from virus culture studies would appear to suggest that COVID-19 patients with mild-to-moderate illness are highly unlikely to be infectious beyond 10 days from symptom onset. Evidence from large contact tracing studies[24,34] appears to support this finding. However, evidence from a limited number of studies indicates that patients with severe-to-critical illness, and or those who are immunocompromised, may be infectious for a prolonged period, possibly for 20 days or more.[25,26,32] Virus culture studies suggested a steady decline in the probability of culturing SARS-CoV-2 in the first 10 days following symptom onset; the largest included study estimated the probability as falling from 40% on day 7 to 26% on day 8, 14% on day 9 and 6% by day 10. However, these results were subject to considerable uncertainty, and the clinical significance of these findings is unknown given potentially prolonged incubation of cultured cells.[31] Notably, there are important methodological limitations associated with all of the included studies. The number of studies for consideration remains few in number and sample sizes are often small; hence it is essential that the findings from these studies are interpreted in light of these caveats. Furthermore, virus culture studies determine if a sample contains replicative competent SARS-CoV-2; while a positive virus culture indicates *potential* infectiousness of the individual from whom the sample was collected, risk of transmission (i.e., clinical infectivity) is also influenced by the viral load, local immune response to SARS-CoV-2, clinical symptoms and environmental factors, and behaviour of the infected individual and their contacts.

One of the notable findings from 2 of the included studies was that patients who were found to be SARS-CoV-2 culture-positive for a prolonged period were immunosuppressed.[25,32] In particular, 1 of the case reports describes a mild clinical course of COVID-19 in a heart transplant recipient on immunosuppressant therapies (mycophenolate mofetil, ciclosporin and prednisone) from whom SARS-CoV-2 was cultured 21 days after symptom onset.[25] Although the evidence pertaining to prolonged infectiousness in immunosuppressed populations is very limited, these findings do raise important research and policy questions. Immunosuppressant therapies have been observed to delay the clearance of SARS-CoV-2 viral RNA in previous studies.[40,41] However, some of these agents are also being investigated as treatments for severe and critical COVID-19 to modulate the hyperinflammatory response (e.g., tocilizumab).[42,43] Little is known regarding the presentation and course of disease in patients who are immunocompromised; it is unknown whether all patients who are in an immunocompromised state necessarily present with severe COVID-19 disease, or how important the degree of immunosuppression is for clearance of the virus.[43] More evidence is required to understand the relationship between immunosuppression and the illness severity and duration of infectiousness of SARS-CoV-2. However, in these individuals it is very likely that any molecular investigations would indicate a significant SARS-CoV-2 viral load.

Only 1 study provided information on SARS-CoV-2 culture specifically in children.[29] However, as virus culture was only attempted once per patient, to a maximum of 5 days post symptom onset, this study provides insufficient information to inform policy decisions surrounding isolation requirements specifically for children testing positive for SARS-CoV-2 RNA. Children have generally been under-represented in COVID-19 studies to-date, although this may be a function of testing practices which initially typically prioritised those with more severe symptoms, healthcare workers and those residing in long term care settings. Given reports of milder symptoms in children, during the earlier stages of the pandemic they were less likely to be tested and diagnosed.[44] As children return to school en masse, increased testing and cases may occur in these settings, thus more data may emerge regarding the potential duration of infectiousness in this population.

The two included contact tracing studies both provide epidemiological evidence to support the findings from the virus culture studies.[24,34] Notably, there were substantial differences in the observed secondary attack rates between the 2 contact tracing studies (0.7% vs. 37%). These differences are likely to be explained by the different exposure settings at play; the study by Lopez Bernal et al. focused on transmission amongst household contacts,[34] a setting in which SARS-CoV-2 is known to be highly transmissible,[45] whereas Cheng et al. included all possible modes of transmission.[24] Differences in case or contact definitions and general approaches within the different public health systems may also explain this substantial disparity.[24,34] Despite these differences, both studies reported that when close contacts were first exposed greater than 5 days after symptom onset in the index case, there was no evidence of laboratory-confirmed onward transmission of SARS-CoV-2.

The findings from our rapid review are largely in agreement with 4 previous reviews conducted in this general area.[3,46–48] All of these reviews concluded that infectiousness generally declines 7–10 days after symptom onset, and point to uncommon outlier cases where this duration is exceeded. Another common finding across 3 of these reviews was the prolonged duration of SARS-CoV-2 RNA detection, sometimes for 2–3 months after onset of symptoms, along with cases of repeat SARS-CoV-2 RNA detection after a patient has clinically recovered.[3,46,48] Hence, patients are unlikely to be infectious for the entire duration of viral RNA detection as the presence of viral RNA may not represent transmissible or replication-competent virus.[3] Our rapid review is the first to attempt to quantify the proportion of COVID-19 patients that are potentially infectious beyond day 10 post symptom onset, and draws on more recent evidence, including both virus culture and contacting tracing studies. Hence, our rapid review adds greater clarity to this complex issue.

Evidence from our rapid review has directly informed the decision to reduce the duration of isolation in individuals who test positive for SARS-CoV-2 RNA in Ireland, from 14 to 10 days (with the additional clinical requirement of being fever-free for 5 days).[49,50] Though guidance still varies on this topic globally, several public health agencies have updated their recommendations

in recent times in light of the growing evidence of this rapid reduction in infectiousness post symptom onset, and a greater understanding of the prolonged shedding of non-transmissible SARS-CoV-2 RNA.[11,15,36,51]

The World Health Organization (WHO) currently recommends that a COVID-19 patient (regardless of symptom severity) can end isolation, without requiring re-testing, 10 days after symptom onset and at least 3 additional days without symptoms.[11] Previously, WHO recommendations published in January 2020 stated that COVID-19 patients could only be released from isolation if they were clinically recovered and received 2 negative RT-PCR results on sequential samples taken at least 24 h apart.[11] In contrast, the European Centre for Disease Prevention and Control (ECDC) issued a recommendation in April 2020, in the context of widespread community transmission, that COVID-19 patients in the community with mild or asymptomatic illness can end isolation 8 days after the onset of symptoms.[51] This recommendation is conditional on resolution of fever and clinical improvement of other symptoms for at least 3 days.[51] Previous recommendations issued by ECDC in March 2020 advised that mild cases of COVID-19 could be discharged from hospital, if clinically appropriate, with a further 14 days of isolation post-discharge.[52] The Centers for Disease Control and Prevention (CDC) in the United States (US) recommended in July 2020 that isolation can generally be discontinued (in patients with mild-to-moderate illness) 10 days after symptom onset and resolution of fever for at least 24 h (without the use of fever-reducing medications) and with improvement of other symptoms.[53] This may be contrasted with the previously recommended period of isolation of 14 days. However, the CDC also now recommends that isolation may be required for up to 20 days after symptom onset in a limited number of severe cases, and recommend that for patients who are severely immunocompromised, a test-based strategy (using RT-PCR) may be considered to discontinue isolation, in consultation with infectious diseases experts.[15] For all other patients, the CDC no longer recommend a test-based strategy to discontinue isolation.[15] The CDC also points to the lack of equivalent data from children and infants and the need for more data regarding immunocompromised individuals. As new evidence emerges for these subgroups of interest, recommendations regarding the duration of isolation in these populations may change.

It is important to note that the majority of evidence in this review is derived from studies of low quality design, where determining the duration of infectiousness may not have been the primary objective and SARS-CoV-2 culturing methods were not consistent. Furthermore, the inconsistent reporting of data precluded any meaningful quantitative synthesis. Notably, virus culture studies are inherently fraught with challenges,[54] but the requirement for biosafety level 3 (BSL-3) facilities is a particular barrier to research. Further work is required to develop standardised methods to optimise culturing of SARS-CoV-2.

Future research should ideally be prospective in design, following a large cohort of COVID-19 patients with a broad spectrum of disease and inclusive of subgroups of interest (such as children, asymptomatic and immunosuppressed patients). Patients should be regularly and systematically sampled and SARS-CoV-2 virus culturing attempted using standardised methods, until virus can no longer be successfully isolated.[47] The time between sample inoculation and the detection of viral growth should be reported for all studies, as this is a reflection of the viral load of infectious virus in the original sample. The findings of such virus culture studies should be supplemented with epidemiological evidence of onward transmission at different time points, as derived from well-conducted, large and prospective contact tracing studies. A core outcome set should be measured and reported, stratified by different subgroups, thus enabling better synthesis by systematic reviewers to better facilitate interpretation and decision-making by policy-makers.[55]

Conclusion

The evidence to date suggests that COVID-19 patients with mild-to-moderate illness are highly unlikely to be infectious beyond 10 days from symptom onset. However, evidence from a very limited number of studies indicates that patients with severe-to-critical illness or those who are immunocompromised, may shed infectious virus for longer than 10 days. Future research is required to confirm these findings and to provide information on the duration of infectiousness in subgroups such as children, and asymptomatic and immunosuppressed patients.

Acknowledgments

The authors would like to thank Executive Assistant Debra Spillane (HIQA) and Information Specialist Andrew Simpson (RCSI), and acknowledge the support of the Health Technology Assessment, the Health Information and Standards, and the Communications & Stakeholder Engagement Directorates at HIQA.

Correlation Between 3790 Quantitative Polymerase Chain Reaction–Positives Samples and Positive Cell Cultures, Including 1941 Severe Acute Respiratory Syndrome Coronavirus 2 Isolates

To the Editor—The outbreak of the coronavirus disease 2019 (COVID-19) pandemic due to severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) was declared a pandemic on 12 March 2020 by the World Health Organization [1]. A major issue related to the outbreak has been to correlate viral RNA load obtained after reverse-transcription polymerase chain reaction (RT-PCR) and expressed as the cycle threshold (Ct) with contagiousness and therefore duration of eviction from contacts and discharge from specialized infectious disease wards. Several recent publications, based on more than 100 studies, have attempted to propose a cutoff Ct value and duration of eviction, with a consensus at approximately Ct >30 and at least 10 days, respectively [2–5]. However, in an article published in *Clinical Infectious Diseases*, Bullard et al reported that patients could not be contagious with Ct >25 as the virus is not detected in culture above this value [6]. This limit was then evoked in the French media during an interview with a member of the French Scientific Council Covid-19 as a possible value above which patients are no longer contagious [7].

At the beginning of the outbreak, we correlated Ct values obtained using our PCR technique based on amplification of the E gene and the results of the culture [8]. Since the beginning of the pandemic, we have performed 250 566 SARS-CoV-2 RT-PCR for 179 151 patients, of whom 13 161 (7.3%) tested positive. Up to the end of May, 3790 of these samples, reported as positive on nasopharyngeal samples, were inoculated and managed for culture as previously described [8]. Of these 3790 inoculated samples, 1941 SARS-CoV-2 isolates could be obtained after the first inoculation or up to 2 blind subcultures. The correlation between the scanner values and the positivity of the culture allows us to observe that the image obtained with 10 times more isolates than in our preliminary work (1941 vs 129) does not change significantly (Figure 1). It can be observed that at Ct = 25, up to 70% of patients remain positive in culture and that at Ct = 30 this value drops to 20%. At Ct = 35, the value we used to report a positive result for PCR, <3% of cultures are positive. Our Ct value of 35, initially based on the results

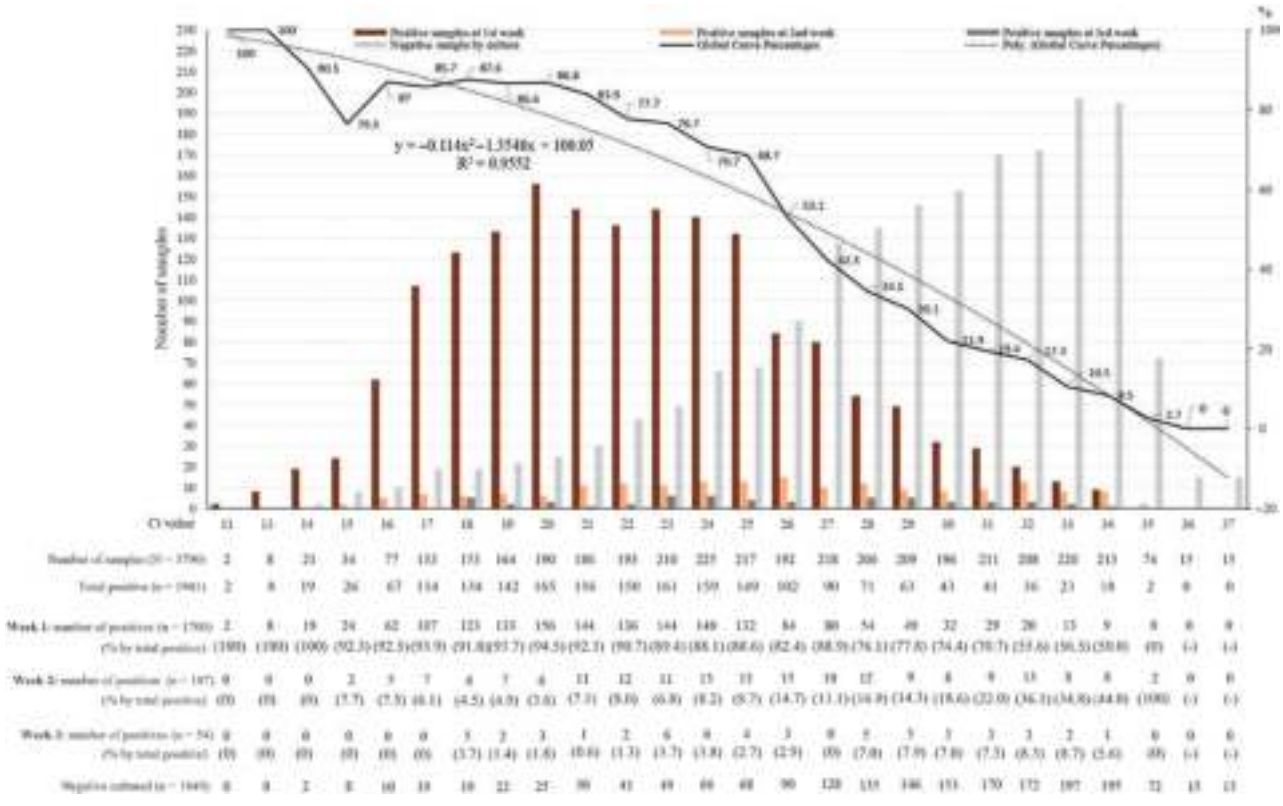

Figure 1. Percentage of positive viral cultures of severe acute respiratory syndrome coronavirus 2 polymerase chain reaction–positive nasopharyngeal samples from coronavirus disease 2019 patients, according to Ct value (plain line). The dashed curve indicates the polynomial regression curve. Abbreviations: Ct, cycle threshold; Poly., polynomial.

obtained by RT-PCR on control negative samples in our laboratory and initial results of cultures [8], is validated by the results herein presented and is in correlation with what was proposed in Korea [9] and Taiwan [10]. We could observe that subcultures, especially the first one, allow an increasing percentage of viral isolation in samples with Ct values, confirming that these high Ct values are mostly correlated with low viral loads. From our cohort, we now need to try to understand and define the duration and frequency of live virus shedding in patients on a case-by-case basis in the rare cases when the PCR is positive beyond 10 days, often at a Ct >30. In any cases, these rare cases should not impact public health decisions.

Notes

Ethical approval. The protocol was approved by the University Hospital Institute Méditerranée Infection Ethical Committee. All patients provided informed consent in accordance with the Declaration of Helsinki.

Financial support. This research was funded by the French Government under the Investissements d'avenir (Investments for the Future) program managed by the Agence Nationale de la Recherche (French National Agency for Research; reference: Méditerranée Infection 10-IAHU-03) and by Région Provence-Alpes-Côte d'Azur and European funding Fond Europen de Recheche et de developpement (FEDER) PRIMI.

Potential conflicts of interest. D. R. reports grants from the Hitachi High-Tech Corporation outside the submitted work. All other authors report no potential conflicts. All authors have submitted the ICMJE Form for Disclosure of Potential Conflicts of Interest. Conflicts that the editors consider relevant to the content of the manuscript have been disclosed.

Article submitted on 03 Aug 2020 / accepted on 12 Aug 2020 / published on 13 Aug 2020

Severe acute respiratory syndrome coronavirus 2 viral load in the upper respiratory tract peaks around symptom onset and infectious virus persists for 10 days in mild-to-moderate coronavirus disease (n = 324 samples analysed). RT-PCR cycle threshold (Ct) values correlate strongly with cultivable virus. Probability of culturing virus declines to 8% in samples with Ct > 35 and to 6% 10 days after onset; it is similar in asymptomatic and symptomatic persons. Asymptomatic persons represent a source of transmissible virus.

Since the emergence of coronavirus disease (COVID-19) at the end of 2019, rapid tracing and isolation of confirmed cases and close contacts with restrictions on social movement have played an important role in controlling onward spread of the virus. Understanding the duration of infectiousness in persons who test positive for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is critical to developing evidence-based public health policies on isolation, contact tracing and return to work. Virus detection by reverse transcription-PCR (RT-PCR) from respiratory samples is widely used to diagnose and monitor SARS-CoV-2 infection and, increasingly, to infer infectivity of an individual. However, RT-PCR does not distinguish between infectious and non-infectious virus. Propagating virus from clinical samples confirms the presence of infectious virus but is not widely available, requires biosafety level 3 facilities, and the results are not timely to inform public health actions. The aim of this work was to understand how RT-PCR detection relates to cultivable virus, which can be used as a proxy for infectiousness and can inform and support decisions on infection control.

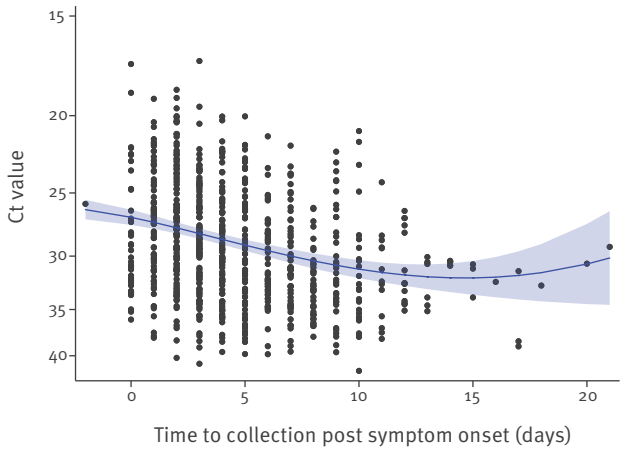
Kinetics of viral RNA detection from the respiratory tract

Upper respiratory tract (URT) samples from persons with suspected COVID-19 were tested at the national respiratory virus reference laboratory at Public Health England to support routine clinical care and surveillance activities during the COVID-19 pandemic. Samples included nose, throat, combined nose-and-throat and nasopharyngeal swabs, or nasopharyngeal aspirates; the majority were taken by clinical staff but some were self-sampled nose swabs.

In the first 3 months of the COVID-19 pandemic in the United Kingdom (UK) (late January to early April 2020), we received 754 URT samples from 425 symptomatic cases that tested positive for SARS-CoV-2 by RT-PCR targeting the RNA-dependent RNA polymerase (RdRp) gene [1] and that had a clear record of the dates of symptom onset and sample collection. These samples were collected as part of the First Few 100 surveillance study described in Boddington et al. [2]. Using RT-PCR cycle threshold (Ct) values as a semiquantitative measure of SARS-CoV-2 viral load identified that the level of SARS-CoV-2 RNA in the URT was greatest around symptom onset, steadily decreased during the first 10 days after illness onset and then plateaued (Figure 1). In the first week after symptom onset (days −2 to 7), geometric mean (GM) Ct was 28.18 (95% confidence interval (CI): 27.76–28.61). In the second week (days 8 to 14), GM Ct was 30.65 (95% CI: 29.82–31.52; $p < 0.001$ compared with week 1) and after 14 days, GM Ct was 31.60 (95% CI: 31.60–34.49; $p = 0.01$ compared with week 1). There was no significant difference in Ct values between days 8–14 and after 14 days ($p = 0.49$).

Figure 1

Detection of SARS-CoV-2 by RT-PCR targeting the RdRp gene, England, January–April 2020 (n = 754)



Ct: cycle threshold.

To capture the nonlinear relationship between days post symptom onset (days) and Ct value, a fractional polynomial model was used, indicating predictors days2 and days2ln(days). These were fitted in a random intercept regression model with ln(Ct value) as the outcome variable. Analysis accounted for multiple samples from the same individuals. The random intercept for individuals was not statistically significant, providing no evidence for dependencies within person, thus each individual sample was treated as being independent. The y axis was created in Stata 15.1 with reversed log scale*.

Isolation of infectious virus from respiratory samples

Virus culture was attempted from 324 URT samples (from 253 cases) that tested positive for SARS-CoV-2 by RT-PCR. Samples were obtained from a range of clinical scenarios including community and healthcare worker surveillance, symptomatic persons tested as part of the early epidemic response and samples acquired in outbreak investigations. Selection of asymptomatic cases was through swabbing of contacts or facility/family/household testing in the context of outbreak investigations; we cannot be certain of their date of exposure or start of infection. Vero E6 cells were inoculated with clinical specimens and incubated at 37°C, 5% CO_2. Cells were inspected for cytopathic effect daily up to 14 days. Presence of SARS-CoV-2 was confirmed by SARS-CoV-2 nucleoprotein staining by enzyme immunoassay on infected cells. Cultivable virus was isolated from 133 (41%) samples (from 111 cases).

Median Ct of all 324 samples was 31.15 (interquartile range (IQR): 27.50–33.86; range: 17.47–41.78). Some 233 cases (92%) were classified as non-severe (asymptomatic or mild-to-moderate) and 20 (8%) had severe illness (requiring intensive care admission and/or fatal). There was no difference in Ct values between those with asymptomatic (median Ct = 31.23; IQR: 28.21–32.97), mild-to-moderate (median Ct = 30.94; IQR: 27.08–34.57) or severe (median Ct = 32.55; IQR 28.39–33.66) illness (p = 0.79). A stratified comparison of the severe cases over time showed a similar result as described above: Ct values were lower (higher viral load) in week 1 than week 2. There were 62 samples from 61 asymptomatic cases and no difference in culture positivity rate was observed: 21 of 62 samples from asymptomatic individuals vs 112 of 262 samples from symptomatic individuals (estimated odds ratio (OR) = 0.66; 95% CI: 0.34–1.31; mixed effects logistic regression model, p = 0.23).

Relationship between Ct value and virus isolation

We observed a strong relationship between Ct value and ability to recover infectious virus. The estimated OR of recovering infectious virus decreased by 0.67 for each unit increase in Ct value (95% CI: 0.58–0.77) (Figure 2). Virus propagation was successful from five of 60 samples with Ct›35; all five were from symptomatic cases and none had severe illness. The estimated probability of recovery of virus from samples with Ct›35 was 8.3% (95% CI: 2.8%–18.4%).

Relationship between 'symptom to test' interval and virus isolation

There were 246 samples from 176 symptomatic cases where the date of symptom onset was known, of which 103 (42%) samples from 81 cases were culture-positive. Detection of cultivable virus peaked around the time of symptom onset (Figure 3). Median duration of virus shedding as measured by culture was 4 days (IQR: 1–8; range: –13 to 12, with symptom onset dates based on symptom recall). The culture positivity rate was significantly higher during week 1 than week 2 (74% vs 20%; p = 0.002). Ten days after symptom onset, the probability of culturing virus declined to 6.0% (95% CI: 0.9–31.2%) (Table 1). Where cases

Ct = cycle threshold. The y axis on Figure 3A was created in Stata 15.1 with reversed log scale*.

were followed up within outbreak investigations, 13 individuals who were asymptomatic at the time of sampling developed symptoms within 14 days of sampling and were classified as presymptomatic, of whom seven were culture-positive. Regression analysis indicates that presymptomatic samples were at least as likely to be culture-positive as samples taken during symptomatic phases.

More than half the samples (n = 130, 53%) tested (from 91 cases) were received more than 7 days after symptom onset and 21% of those (27 samples from 18 cases) were culture-positive; none of the 91 patients had severe illness or were immunosuppressed. Most of these late culture-positive samples (25/27) were taken between 8 and 10 days after symptom onset.

Comparison of virus detection by age group

There was no significant difference in Ct values (p = 0.12) or culture positivity (p = 0.63) from URT samples received across the different age groups, although this dataset included few children younger than 16 years. The proportion of asymptomatic cases was similar across age groups, except for 81–100 year-olds who were more likely to be asymptomatic than the other age groups (p = 0.006, cluster-adjusted logistic regression) (Table 2). There was no difference in the proportion of asymptomatic cases between males and females, with an estimated OR of 0.86 (95% CI: 0.46–1.90; p = 0.63).

Discussion

Readouts from semiquantitative RT-PCR using Ct values provide a valuable proxy for infectious virus detection and may help to inform decision-making on infection control. This study adds to the evidence base on duration of infectiousness following mild-to-moderate COVID-19, demonstrating that infectious virus can persist for a week or more after symptom onset, declining over time. At 10 days after symptom onset, in line with current guidance from the World Health Organization [3] and the UK [4] on release from isolation, probability of culturing virus declines to 6%. The findings concur with smaller studies that identified infectious virus shed for 8 or 9 days [5-9] and others demonstrating correlation between Ct value/viral load and cultivable virus [5,9-11]. Strengths include the comparatively large size of this dataset, inclusion of a large proportion (> 50%) of samples taken more than 7 days after symptom onset and that all analysis was performed in a single laboratory. Van Kampen et al. reported more prolonged detection of cultivable virus from 23 hospitalised cases, for up to 20 days after symptom onset [10]. However, their cohort included mostly lower respiratory tract samples from patients with more severe disease including nearly one in five who were immunocompromised, which is unlikely to be representative of the general population. Taken together with data presented here, the results of Van Kampen et al. indicate that more prolonged excretion of infectious virus could be associated with severe disease or an immunocompromised state.

This study identified that Ct values and the presence of infectious virus were similar in samples from asymptomatic and presymptomatic persons, compared with those who were symptomatic, and is one of the first reports of virus isolation from cases who remain completely asymptomatic. The findings suggest that asymptomatic and presymptomatic persons do represent a source of potentially transmissible virus. Extensive data on cultivable virus from asymptomatic or presymptomatic individuals are lacking, with one outbreak investigation in a care home reporting detection of cultivable virus in one asymptomatic and 17 presymptomatic cases [8]. Although we saw a higher proportion of asymptomatic cases in the age group 81–100 years, the reasons and significance of this are unclear. It may reflect sampling bias from care home outbreaks. However, it could also reflect real differences in response to infection in this age group (e.g.

lower response to fever, lower reporting of subjective symptoms in this age group).

Of note, recall bias may affect the interpretation of timing of virus detection in relation to symptom onset, particularly in elderly patients and those presenting with atypical symptoms. Duration and cessation of symptoms is also not well recorded. For asymptomatic cases, the time when infection was acquired is not known. A further limitation is that this dataset comprises real-world data and subjects were not sampled systematically; therefore, there may be bias in the timing of sampling related to the clinical scenario. Finally, the sensitivity of virus propagation from clinical samples is dependent on laboratory expertise, cell lines and protocols used, and may be affected by sample quality, storage and transport conditions, meaning it is difficult to directly compare data between laboratories described in other literature.

Conclusion

Based on the real-world data described here, we recommend that infection control measures for persons with mild-to-moderate COVID-19 be particularly focussed immediately after onset of symptoms and retained for 10 days. Asymptomatic and presymptomatic persons are likely to be a source of infectious virus. Detection of cultivable SARS-CoV-2 from URT samples is valuable as a proxy for infectiousness; however, as the human infectious dose remains unknown, the significance of low titres of infectious virus for human-to-human transmission remains uncertain. Correlation with observational epidemiological data analysing known infector–infectee pairs is required to fully understand the dynamics of infectiousness and viral transmissibility.

Abstract

In a preliminary clinical study, we observed that the combination of hydroxychloroquine and azithromycin was effective against SARS-CoV-2 by shortening the duration of viral load in Covid-19 patients. It is of paramount importance to define when a treated patient can be considered as no longer contagious. Correlation between successful isolation of virus in cell culture and Ct value of quantitative RT-PCR targeting E gene suggests that patients with Ct above 33–34 using our RT-PCR system are not contagious and thus can be discharged from hospital care or strict confinement for non-hospitalized patients.

Keywords SARS-CoV2 · Covid-19 · RT-PCR · Co-culture · Viral load · Correlation

Introduction

An outbreak of an emerging disease (Covid-19) due to SARS-CoV-2 started in Wuhan, China, then rapidly spread in China, and was declared pandemic on March 12, 2020, by the WHO [1–3]. Currently, the overall case fatality rate is about 2.3% in China, which is likely an overestimate because most patients have mild symptoms and are thus not tested [4]. Because of a study showing that chloroquine and hydroxychloroquine inhibit SARS-CoV-2 in vitro, we tested hydroxychloroquine as a treatment in Covid-19 patients [5, 6]. Our results show that in treated patients, the nasopharyngeal viral load of SARS-CoV-2-infected patients was cleared in only 3 to 6 days. Our results also suggest a synergistic effect of the combination of hydroxychloroquine and azithromycin, two molecules previously demonstrated to be active in vitro against Zika and Ebola viruses [7–10] and to prevent severe respiratory tract infections when administered to patients suffering viral infection [11]. These results are of great importance because a recent paper has shown that the median duration of viral RNA detection in patients suffering from Covid-19 in China was 20 days, with the longest duration being 37 days [12]. We are now facing a massive influx of patients in need of treatment and hospitalization, ideally in infectious disease wards equipped with NSB3 modules with negative pressure. Thus, in addition to obtaining complete disappearance of virus RNA in respiratory samples, having a PCR-based indicator of loss of contagiousness is a major priority for discharge from infectious diseases ward. Based on a set of 183 samples from 155 patients, we observed a significant relationship between viral RNA load and culture positivity.

The Méditerranée Infection University Hospital Institute in Marseille is the reference center for highly infectious diseases for Southeastern France. It was the only center in this region with diagnostic tests available during the first weeks of the epidemic in France and received patients' samples from this whole area. From the day of the first positive test, on February 27 until March 12, 4384 clinical samples were tested by RT-PCR for 3466 patients. Since the beginning of this crisis and until now, on March 26, we inoculated 1049 samples and could obtain in culture 611 SARS-CoV-2 isolates. A total of 183 samples testing positive by RT-PCR, including 9 sputum samples and 174 nasopharyngeal swabs from 155 patients, were inoculated in cell cultures. SARS-CoV-2 RNA positivity in patient samples was

assessed by real-time reverse transcription-PCR targeting the E gene, as previously described [13]. For all patients, 500 μL of nasopharyngeal swab fluid (Virocult, Elitech, France) or sputum sample were passed through 0.22-μm pore sized centrifugal filter (Merck Millipore, Darmstadt, Germany) and then were inoculated in 4 wells of 96-well culture microplates containing Vero E6 cells (ATCC CRL-1586) into Minimum Essential Medium culture medium with 4% fetal calf serum and 1% glutamine. All samples were inoculated between 4 and 10 h after sampling and kept at + 4 °C before processing. After centrifugation at 4000×*g*, microplates were incubated at 37 °C. They were observed daily for evidence of cytopathogenic effect. Two subcultures were performed weekly. Presumptive detection of virus in supernatant showing cytopathic effect was done using the SU5000 scanning electron microscope (Hitachi High-Tech Corporation, Tokyo, Japan) and then confirmed by specific RT-PCR targeting E gene. Variation of culture positivity rate was assessed statistically as the proportion of variance explained by Ct value and considered adequately fitted if the coefficient of determination (R^2 statistic) was > 50%.

Among the 183 samples inoculated in the studied period of time, 129 led to virus isolation. Of these, 124 samples had detectable cytopathic effect between 24 and 96 h. Blind subcultures allowed obtaining 5 additional isolates only. We observed a significant relationship between Ct value and culture positivity rate (Fig. 1). Samples with Ct values of 13–17 all led to positive culture. Culture positivity rate then decreased progressively according to Ct values to reach 12% at 33 Ct. No culture was obtained from samples with Ct ≥ 34. The 5 additional isolates obtained after blind subcultures had Ct between 27 and 34, thus consistent with low viable virus load.

In the present work, we observe a strong correlation between Ct value and sample infectivity in a cell culture model. On the basis of this data, we can deduce that with our system, patients with Ct values equal or above 34 do not excrete infectious viral particles. It was observed that SARS-CoV-2 was detected up to 20 days after onset of symptoms by PCR in infected patients but that the virus could not be isolated after day 8 in spite of ongoing high viral loads of approximately 10^5 RNA copies/mL of sample, using the RT-PCR system used in the present study [14]. Progressive decrease of viral load over time is observed in all studies conducted in Covid-19 patients with positive detection being observed until 17–21 days after onset of symptoms, independently of symptoms [15]. These previous observations suggested that isolation of patients after diagnosis was mandatory. However, due to prolonged shedding of RNA in respiratory samples, the criteria for ending the isolation of a patient were not clear, and there was a need to correlate viral load to cultivable viruses. Our results show that in our system of RT-PCR, we can assess that patients with Ct equal or above 34 may be discharged. In 6 patients under the current therapeutic protocol used at our institute (hydroxychloroquine and azithromycin), Ct values ≥ 34 were obtained between days 2 and 4 post-treatment [6]. There is no previous correlation demonstrated between level viral load in respiratory samples and infectivity. However, this reduction is the basis of all procedures used for the validation of disinfectants [16]. One limitation of our work is that it cannot be extrapolated to other hospital centers since they use different systems of sample transport, of RNA extraction, and of PCR with different primers and probes; i.e. it has been suggested that sensitivity of amplification based on Gene E detection

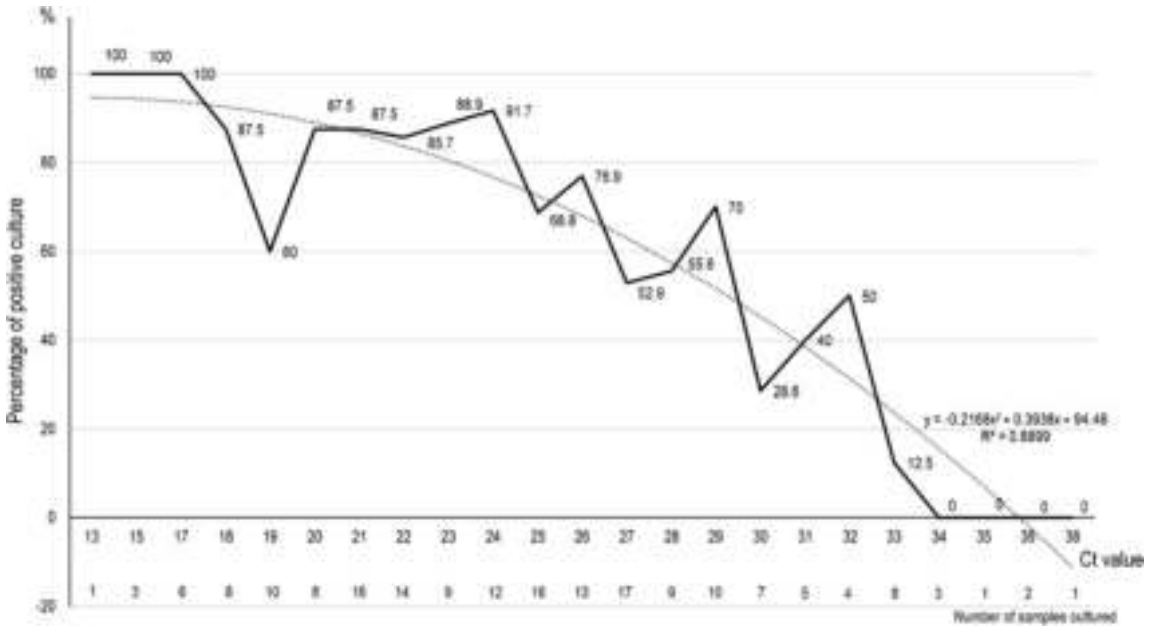

Fig. 1 Percentage of positive viral culture of SARS-CoV-2 PCR-positive nasopharyngeal samples from Covid-19 patients, according to Ct value (plain line). The dashed curve indicates the polynomial regression curve

would be less sensitive than ORF1ab or N genes. We propose that each center perform its own correlation between culture results and viral RNA load from patients' samples. Another potential limitation is that nasopharyngeal swab fluid might be less representative than sputum samples. However, from the data obtained from patients rather tested in sputum, the viral load follows the same reduction with time of evolution than upper respiratory specimens [17].

Abstract: Background: The coronavirus disease (COVID-19) pandemic, caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), has become a major global public health issue. SARS-CoV-2 infection is confirmed by the detection of viral RNA using reverse transcription polymerase chain reaction (RT-PCR). Prolonged viral shedding has been reported in patients with SARS-CoV-2 infection, but the presence of viral RNA does not always correlate with infectivity. Therefore, the present study aimed to confirm the presence of viable virus in asymptomatic or mildly symptomatic patients in the later phase of the disease, more than two weeks after diagnosis. Method: Asymptomatic or mildly symptomatic COVID-19 patients who had been diagnosed with the disease at least two weeks previously and admitted to a community treatment center (CTC) from 15 March to 10 April 2020 were enrolled in this study. Nasopharyngeal and salivary swab specimens were collected from each patient. Using these specimens, RT-PCR assay and viral culture were performed. Result: In total, 48 patients were enrolled in this study. There were no significant differences in baseline characteristics between the asymptomatic and mildly symptomatic patient groups. RT-PCR assay and viral culture of SARS-CoV-2 were performed using nasopharyngeal and salivary swabs. The results of RT-PCR performed using salivary swab specimens, in terms of cycle threshold (Ct) values, were similar to those of RT-PCR using nasopharyngeal swab specimens. In addition, no viable virus could be cultured from swab specimens collected from the late-phase COVID-19 patients with prolonged viral RNA shedding. Conclusions: In conclusion, our study suggests that even if viral shedding is sustained in asymptomatic or mildly symptomatic patients with later phase of COVID-19, it can be expected that the transmission risk of the virus is low. In addition, saliva can be used as a reliable specimen for the diagnosis of SARS-CoV-2 infection.

Keywords: coronavirus disease 2019; COVID-19; RT-PCR; viral culture; saliva

1. Introduction

The coronavirus disease (COVID-19) pandemic, caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), has become a major global public health issue. At the time of writing,

the massive viral outbreak has affected 216 countries, with more than 13 million people infected and 580,000 having died [1].

In South Korea, the number of patients has increased rapidly since February 2020. For the proper management of COVID-19 patients, asymptomatic or mildly symptomatic patients were admitted to community treatment centers (CTCs), which are non-medical facilities for isolation and monitoring.

However, patients with prolonged viral RNA detection after resolution of symptoms presented difficulties in terms of their safe discharge from isolation. For efficient distribution of medical resources, the revised WHO discharge guidelines recommend that symptomatic patients should be discharged 10 days after the onset of symptoms, following at least three additional days without symptoms, and that asymptomatic patients should be discharged 10 days after testing positive for SARS-CoV-2 [2].

Diagnosis of COVID-19 is achieved using a nasopharyngeal swab. At present, real-time reverse transcription polymerase chain reaction (RT-PCR) analysis of respiratory specimens is the gold standard test for detecting SARS-CoV-2 infection [3].

Over the course of infection, viral RNA has been identified in respiratory tract specimens 1–3 days prior to the onset of symptoms. The viral load is thought to persist for up to 7–10 days after the onset of symptoms in mild cases. In more severe cases, it tends to peak up to 11 days after the onset, followed by gradual decrease over time [4]. Viral RNA has been detected in various specimens of the human body, such as the upper and lower respiratory tract, blood, pharyngeal swabs, saliva, urine, and feces [5,6].

Prolonged viral shedding has been reported from nasopharyngeal swabs up to 63 days after the onset of symptoms among adult patients [7,8]. However, viral shedding of SARS-CoV-2 does not always indicate infectivity, unless the virus is isolated and cultured from the specimens. The revised WHO release criteria do not require additional examination prior to discharge. Therefore, there is a residual risk that the disease can still spread when these criteria are adhered to. Accordingly, in late-phase COVID-19 patients with prolonged viral RNA detection, it is important to determine the risk of transmission.

In this study, we attempted to confirm the presence of viable virus by performing RT-PCR assay and culture using salivary and nasopharyngeal swabs of asymptomatic or mildly symptomatic COVID-19 patients who had been diagnosed with the disease and admitted to a CTC at least two weeks previously.

2. Methods

2.1. Patients and Study Settings

Asymptomatic or mildly symptomatic COVID-19 patients who had been admitted to the CTC between March 15 and April 10, 2020 and had been diagnosed at least two weeks previously, were enrolled in the current study. Asymptomatic or mildly symptomatic COVID-19 patients were defined as those with an early warning score of <3 for SARS-CoV-2 infection [9]. Patients referred to other hospitals due to worsening of symptoms during isolation were excluded. Written informed consent was obtained from all study participants. Nasopharyngeal and salivary swab specimens were obtained from each patient. Ethical Statement: This study was approved by the Institutional Review Board (IRB number: 4-2020-0133) of Severance Hospital (Seoul, South Korea) and informed consent was obtained.

2.2. Definitions

RT-PCR assays targeting three genes of SARS-CoV-2, the E (envelope protein), RdRP (RNA-dependent RNA polymerase), and N (nucleocapsid protein) genes, were performed using the Allplex™ 2019-nCoV Assay (Seegene Inc., Seoul, South Korea) with nasopharyngeal and salivary swab specimens. Patients with negative RT-PCR results were tested again by RT-PCR the following day; those with positive RT-PCR results were re-tested by RT-PCR after a week; and those with inconclusive RT-PCR results were re-tested by RT-PCR after three days. The inconclusive result refers to a case in

which one or more, but not all genes included in the kit show an amplification curve after the cut-off when using a follow-up sample [10].

RT-PCR assay results were expressed as the cycle threshold (Ct) value. Ct values ≥ 40 were considered negative results. Negative conversion was defined as two consecutive negative RT-PCR results at a 24 h interval.

Rebound Ct value was defined as a negative (Ct value ≥ 40) from the single RT-PCR assay and positive (Ct value < 40) from the following RT-PCR result.

2.3. Nucleic Acid Extraction and RT-PCR for SARS-CoV-2

The nasopharyngeal swab sample was placed in 2 mL of viral transport medium. Saliva samples were collected in a sterile container and both specimens were stored frozen −70 °C. Nasopharyngeal swab specimens were subjected to total nucleic acid extraction using a viral RNA mini kit (QIAGEN, Hilden, Germany). After extraction, the total nucleic acid was recovered using 60 µL of elution buffer.

For salivary swab specimens, the same amount of PBS was added, and following the vortex process, RNA was extracted using the same process as for the nasopharyngeal swab samples. Using 8 µL of RNA, RT-PCR assay targeting the three genes of SARS-CoV-2 was performed using a Seegene Kit (Allplex 2019-nCoV Assay kit, Seegene, Korea). When the upper respiratory specimens including the nasopharyngeal swab were examined using the Allplex 2019-nCoV Assay, a Positive Percent Agreement (PPA) was 100% (95% CI: 92.75~100%), and a Negative Percent Agreement (NPA) was 93.07% (95% CI: 85.76~96.93%) [11].

2.4. SARS-CoV-2 Cell Culture

SARS-CoV-2 was cultured in a biosafety level 3 facility. Vero E6 cells were used for isolating SARS-CoV-2. Vero E6 cells were cultured in Eagle's minimum essential medium (EMEM) supplemented with heat-inactivated fetal bovine serum (FBS; 10%). Both nasopharyngeal and salivary swab specimens were used for virus isolation. Vero E6 cells were seeded with 1 mL of EMEM at a density of 1.5×10^4 cells/well in culture tubes and incubated at 37 °C in a carbon dioxide incubator for 24 h until confluence for inoculation was achieved.

The next day, each nasopharyngeal and salivary swab specimen was diluted at a ratio of 1:10 and inoculated into four wells containing EMEM (2% FBS, 1% P/S). Cells in the media were fixed with 10% formaldehyde and stained with 1% crystal violet dye.

The virus-induced cytopathic effect was examined daily for up to seven days [12,13].

3. Results

The analysis was performed on asymptomatic or mildly symptomatic COVID-19 patients who had been diagnosed and admitted to a CTC at least two weeks previously. In total, 48 patients were enrolled in this study. The mean age of all patients was 32.62 ± 14.59 years, and 14 of the patients were male (29.2%). Of all the patients, 11 (22.9%) were asymptomatic.

Baseline characteristics were similar between the symptomatic and asymptomatic patient groups. There was no statistically significant difference in terms of age, sex, comorbidities, and symptoms. The most common symptoms were myalgia (32.4%), fever (29.7%), and headache (24.3%); chest pain (2.7%) and vomiting (2.7%) were uncommon (Table 1).

Nasopharyngeal and salivary swab specimens were collected from the patients approximately 30.40 ± 5.71 days after initial diagnosis. The average Ct value of patients on the day of culture was over 30 in both the symptomatic and asymptomatic groups. A total of 17 cases (35.4%) showed rebound Ct values, which included 11 cases in the symptomatic group and 6 in the asymptomatic group (Table 2).

RT-PCR assay was performed using saliva specimens to determine the effectiveness of saliva as a diagnostic tool. As shown in Table 3, in the case of Patient 8, the saliva RT-PCR result was positive, although the RT-PCR result of the nasopharyngeal swab specimen was negative. Additionally, in eight patients, the mean Ct values of the nasopharyngeal and salivary swab specimens were

33.7 and 33.96, respectively, indicating that saliva swabs can serve as a reliable tool for diagnosing SARS-CoV-2 infection.

4. Discussion

In this study, we aimed to determine whether infectious viruses could be isolated using salivary and nasopharyngeal swab samples from patients with persistent positive RT-PCR results or rebound Ct values more than two weeks after diagnosis. SARS-CoV-2 could not be cultured from the patient specimens. Consequently, we surmised that there is no viral transmission risk in the later phase of SARS-CoV-2 infection. In addition, as indicated by the fact that the Ct values derived from salivary swab RT-PCR were similar to those of nasopharyngeal swab RT-PCR, saliva was shown to be an effective diagnostic tool for the detection of SARS-CoV-2.

SARS-CoV-2 infection is confirmed by detecting the presence of viral RNA through molecular testing, usually by RT-PCR [14]. The presence of viral RNA alone does not indicate that a patient is infectious or can transmit the virus to others. Factors affecting the transmission risk include whether the patient has symptoms, such as cough, which can spread droplets, whether a virus is infectious, and environmental factors or the behavior of the infected patient. Usually, 5 to 10 days after the initial SARS-CoV-2 infection, the patient begins to produce neutralizing antibodies. The binding of these neutralizing antibodies to the virus is expected to decrease the risk of viral transmission [4,15].

In many studies, viral shedding detected by RT-PCR from respiratory specimens has been found to persist for more than 20 days and sometimes up to 63 days after the onset of symptoms, and it appears to last beyond symptom resolution [6,8,16,17]. It has also been proven that transmission occurs in asymptomatic patients. In a study conducted by Zou et al., the viral loads of nasal and throat swabs

were similar in symptomatic and permanently asymptomatic patients [18]. In addition, in the present study, the Ct values of symptomatic and asymptomatic patients were not significantly different. This might be because in the late phase of infection the viral load is close to the detection limit, but there is evidence that viral shedding occurs in both symptomatic and asymptomatic patients after symptom improvement; however, the relationship between the detection of viral RNA and infectivity is still unclear. RT-PCR results do not necessarily indicate the possibility of viral transmission and cannot distinguish between infectious and non-infectious virus [7,15].

Viral RNA has been detected in the upper and lower respiratory tract, blood, pharyngeal swabs, saliva, urine, and feces, regardless of the severity of the disease [5,16]. The virus has also been detected in water gargled by patients diagnosed with COVID-19 [17]. We used saliva specimens for RT-PCR tests to confirm SARS-CoV-2 infection. It was confirmed that saliva showed a high concordance rate of 90% or more with the nasopharyngeal specimens in the detection of respiratory viruses including coronavirus [13,19,20].

A study by Zhou et al. indicated that angiotensin-converting enzyme II (ACE2) is likely the cell receptor for SARS-CoV-2; it was also the receptor for SARS-CoV and HCoV-NL63 [4]. According to a previous study, ACE2 is presented on the epithelial cells of oral mucosa, suggesting that the oral cavity might be at high risk of SARS-CoV-2 infection [21]. These findings suggest that ACE2-expressing cells may act as target cells and are therefore vulnerable to SARS-CoV-2 infection [22]. Since many viruses, including SARS-CoV-2, can be detected in saliva, saliva is considered a major factor in the risk of transmission of viruses that can cause respiratory infections [21]. In our study, a viral load was detected in saliva, therefore, saliva can also be expected to serve as an effective diagnostic tool.

Viral RNA tends to be detected for a longer period of time in more severe cases. According to several studies, viral RNA has been detected in respiratory tract specimens 1-3 days before the onset of symptoms. Viral load is thought to increase for up to 7–10 days after the onset of symptoms in mild cases. In more severe cases, it tends to peak up to 11 days after the onset, followed by gradual decrease over time [4,23]. Some studies have predicted that transmission risk is the highest at or around the time of symptom onset and during the first five days of disease [16].

Viral culture studies using patient specimens to confirm the presence of infectious SARS-CoV-2 are still limited. In some studies, viable viruses have been isolated from viral cultures using respiratory samples collected during the early stages of the disease or at least within eight days after the onset of symptoms [4]. According to a study investigating the relationship between the Ct value and culture positivity rate, all samples with Ct values of 13-17 led to positive culture; however, the culture positivity rate decreased as Ct values increased. Cultures could not be obtained from specimens with Ct values ≥ 34 [24]. In the present study, the mean Ct value of specimens was approximately >30, and no virus was isolated in cultures using these samples.

This study has several limitations. Firstly, the sample size of this study was small and larger studies are needed to confirm the relationship between infectivity loss and RT-PCR results. Secondly, the infectivity of individual cases and accuracy of our culture analysis may have individualized variations. Furthermore, subculture is known to improve the sensitivity of culture assays, but subculture was not performed in this study. Fourth, since serial saliva specimens were not available, serial viral load monitoring was not possible in this study. Finally, changes in the dynamics of viral shedding could have occurred due to the treatments administered to patients.

Although viral RNA can be detected in RT-PCR analyses even after the improvement of symptoms, the amount of viral RNA gradually decreases over time, eventually reducing below the level at which viable virus can be isolated. Therefore, based on the evidence that the virus is rarely detected in respiratory specimens after 10 days following the onset of symptoms, especially in mild or asymptomatic cases of SARS-CoV-2 infection, even if viral shedding is sustained in the later phase of COVID-19, it can be expected that the transmission risk of the virus is low. Accordingly, it seems safer to release patients from quarantine based on the revised WHO discharge criteria that require minimum isolation for 13 days, than to repeat RT-PCR assays. Although the transmission risk is thought to

be minimal in the later stages of COVID-19, it cannot be completely ruled out. Therefore, further investigations are warranted to understand the relationship between SARS-CoV-2 detection, viral culture, and transmission depending on the clinical course.

Key questions in COVID-19 are the duration and determinants of infectious virus shedding. Here, we report that infectious virus shedding is detected by virus cultures in 23 of the 129 patients (17.8%) hospitalized with COVID-19. The median duration of shedding infectious virus is 8 days post onset of symptoms (IQR 5–11) and drops below 5% after 15.2 days post onset of symptoms (95% confidence interval (CI) 13.4–17.2). Multivariate analyses identify viral loads above 7 $\log_{10}$ RNA copies/mL (odds ratio [OR] of 14.7 (CI 3.57-58.1; $p < 0.001$) as independently associated with isolation of infectious SARS-CoV-2 from the respiratory tract. A serum neutralizing antibody titre of at least 1:20 (OR of 0.01 (CI 0.003-0.08; $p < 0.001$) is independently associated with non-infectious SARS-CoV-2. We conclude that quantitative viral RNA load assays and serological assays could be used in test-based strategies to discontinue or de-escalate infection prevention and control precautions.

Coronavirus disease-2019 (COVID-19) is a new clinical entity caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)[1,2]. In particular, persons with underlying diseases, such as diabetes mellitus, hypertension, cardiovascular disease, and respiratory disease, are at increased risk for severe COVID-19, and case fatality rates increase steeply with age[3].

Understanding the kinetics of infectious virus shedding in relation to potential for transmission is crucial to guide infection prevention and control strategies[4]. Long-term shedding of viral RNA has been reported in COVID-19 patients, even after full recovery, putting serious constraints on timely discharge from the hospital or de-escalation of infection prevention and control practices[5–7]. Detection of viral RNA by reverse transcriptase-polymerase chain reaction (RT-PCR) is the gold standard for COVID-19 diagnosis and this technique is used in test-based strategies to discontinue or de-escalate infection prevention and control precautions[8–10]. However, there is no clear correlation between detection of viral RNA and detection of infectious virus using cell culture[5,11,12]. Detection of infectious virus, also called live virus or replication-competent virus, by demonstration of in vitro infectiousness on cell lines is regarded as a more informative surrogate of viral transmission than detection of viral RNA[8–10]. In a COVID-19 hamster model, the window of transmission correlated well with the detection of infectious virus using cell culture but not with viral RNA[13]. Key questions in COVID-19, like in any other infectious disease, are how long a person sheds infectious virus and what the determinants are of infectious virus shedding[5,11,12,14,15].

Two studies reported that infectious virus could not be detected in respiratory tract samples obtained more than 8 days after onset of symptoms despite continued detection of high levels of viral RNA[5,12]. For one patient, infectious virus shedding up to 18 days after onset of symptoms was reported[11]. Shedding of infectious SARS-CoV-2 has not been studied in larger groups of patients nor in patients with severe or critical COVID-19. Here, we show that patients with critical COVID-19 may shed infectious virus for longer periods of time compared to what has been reported for in patients with mild COVID-19. In addition, we show that infectious virus shedding drops to undetectable levels below a viral RNA load threshold and once serum neutralizing antibodies are present, which suggests that quantitative viral RNA load assays and serological assays could be used in test-based strategies to discontinue or de-escalate infection prevention and control precautions.

Results

We included 129 hospitalized individuals that had been diagnosed with COVID-19 by RT-PCR and for whom at least one virus culture from a respiratory tract sample was available (Table 1). Of these, 89 patients (69.0%) had been admitted to the intensive care and the remaining 40 patients (31.0%) were admitted to the medium care. Mechanical ventilation was only performed at the intensive care (81 or 91.0% of patients). Supplemental oxygen was given to 8 (9.0%) of the intensive care patients and to 35 (87.5%) medium care patients. Thirty patients were immunosuppressed (23%) of whom 19 (14.7%) were nonseverely immunocompromised and 11 (8.5%) were severely immunocompromised.

We tested 690 respiratory samples from the 129 patients for the presence of infectious virus using cell culture and determined the viral RNA load with RT-qPCR (Fig. 1). Infectious SARS-CoV-2 was isolated from 62 respiratory tract samples (9.0%) of 23 patients (17.8%). The median time of infectious virus shedding was 8 days post onset of symptoms (IQR 5–11, range 0–20) and probit analysis showed a probability of ≤5% for isolating infectious SARS-CoV-2 when the duration of symptoms was 15.2 days (95% CI 13.4–17.2) or more (Fig. 2A). The median viral load was significantly higher in culture positive samples than in culture negative samples (8.14 versus 5.88 Log_{10} RNA copies/mL, $p < 0.0001$) and the probability of isolating infectious SARS-CoV-2 was less than 5% when the viral load was below 6.63 Log_{10} RNA copies/mL (95% CI 6.24–6.91) (Fig. 2B).

For 27 patients, neutralizing antibody titers from 112 serum samples that were obtained on the same day as a respiratory tract sample were available in our diagnostic database (Table 2). The probability of isolating infectious virus was less than 5% when the neutralizing antibody titer was 1:80 or higher (Fig. 2C). In addition to these neutralizing antibody measurements, we performed RT-PCRs to detect SARS-CoV-2 subgenomic messenger RNA in the 112 corresponding respiratory tract samples. Detection of the subgenomic RNAs outlasted the detection of infectious virus (Supplementary Figs. 1 and 2), and predicted poorly if virus cultures were positive (positive predictive value of 37.5%). In addition, quantitative assessment of subgenomic RNA using cycle threshold (CT) values had no added value over measuring viral genomic RNA loads or serological response to predict infectious virus shedding (Supplementary Fig. 3).

Finally, the key parameters were compared using multivariate generalized estimating equations (Table 3). For this, timepoints for which all three data types (RT-qPCR, virus culture and serum neutralizing antibody titer) were available were included ($n = 112$). A viral load exceeding 7 Log_{10} RNA copies/mL, less than 7 days of symptoms, absence of serum neutralizing antibodies and being immunocompromised were all associated with a positive virus culture in univariate analysis. After submitting all these variables into a multivariate analysis, we found that only a viral load above 7 Log_{10} RNA copies/mL and absence of serum neutralizing antibodies were independently associated with isolation of infectious SARS-CoV-2 from the respiratory tract.

Discussion

In this study we assessed the duration and key determinants of infectious SARS-CoV-2 shedding in patients with severe and critical COVID-19. Such information is critical to design test-based and symptom-based strategies to discontinue infection prevention and control precautions. Both strategies only allow for discontinuation of infection prevention and control precautions after partial resolution of symptoms. Symptom-based strategies use as additional criterion that a certain time interval should have passed since onset of symptoms, while test-based strategies use negative SARS-CoV-2 RT-PCR results as main additional criterion.

The duration of infectious virus shedding found in this study was longer than has been reported previously[5,11,12]. Wölfel and colleagues showed for patients with mild COVID-19 that infectious virus could not be detected after more than eight days since onset of symptoms[5]. Bullard and colleagues obtained similar results, but disease severity was not reported[12]. Shedding of infectious virus up to 18 days after onset of symptoms has been reported for a single case of mild COVID-19[11]. The patients in this study had severe or critical COVID-19 and detection of infectious virus was common after eight days or more since onset of symptoms. For a single patient, infectious virus was detected up to 20 days after onset of symptoms. Higher viral loads have been reported for severe COVID-19 cases compared to mild cases, which may in part explain the longer duration of shedding found in this study[16–20]. Our findings imply that symptom-based strategies to discontinue infection prevention and control precautions should take diseases severity into account. For example, the CDC currently use a minimum disease duration of 10 days in their symptom-based strategy as the statistically estimated likelihood of recovering replication-competent virus approaches zero after ten days of symptoms[8,21]. Based on our findings, a longer disease duration could be considered for severely-ill patients.

High viral RNA loads were independently associated with shedding of infectious virus, but, upon seroconversion, shedding of

[a]Disease severity classification according to NIH criteria (https://www.covid19treatmentguidelines.nih.gov/overview/management-of-covid-19/): 81/129 (62.5%) critical disease, 43/129 (33.3%) severe disease, 5/129 (3.9%) moderate disease.
[b]Immunocompromised level was scored as described previously[25]. Patients with severe immunosuppression ($n = 11$): Lung transplantation, or other solid organ transplantation and treatment for rejection within the last 3 months ($n = 3$); Underlying disease treated with daily corticosteroid dosages (based on prednisone) >30 mg for >14 days and/or immunomodulating biologicals ($n = 4$); Allogeneic hematopoietic stem cell transplantation within the last 12 months, or allogeneic hematopoietic stem cell transplantation with with graft-versus-host-disease treated with immunosuppressive drugs, or acute leukemia ($n = 4$). Patients with nonsevere immunosuppression ($n = 19$): Untreated auto-immune disease or underlying disease treated with immunosuppressive drugs (excluding treatment with daily corticosteroid dosages (based on prednisone) >30 mg for >14 days and/or treatment with immunomodulating biologicals) ($n = 10$); At least 1 year after solid organ transplantation (excluding lung transplantation) and no rejection ($n = 3$); Hematological malignancies (excluding acute leukemia and leukemia treated with induction therapy or chemotherapy resulting in neutropenia for >7 days) ($n = 4$); Other nonsevere immunodeficiencies ($n = 2$).
[c]As of April 17th 2020. PRNT = plaque-reduction neutralization titer. Respiratory tract samples for virus culture and PCR were obtained from the lower respiratory tract (sputum) on the intensive care unit (538/690 samples, 78%) and from the upper respiratory tract (swabs) on the intensive care unit as well as on the medium care unit (152/690 samples, 22%). A total of 127 out of the 690 respiratory tract samples that were submitted for virus culture (18.4%) were obtained from immunocompromised patients. For categorical variables a two-sided Chi-square test was used and for continuous variables a two-sided student's *t*-test was used. No adjustments were made for multiple comparisons.

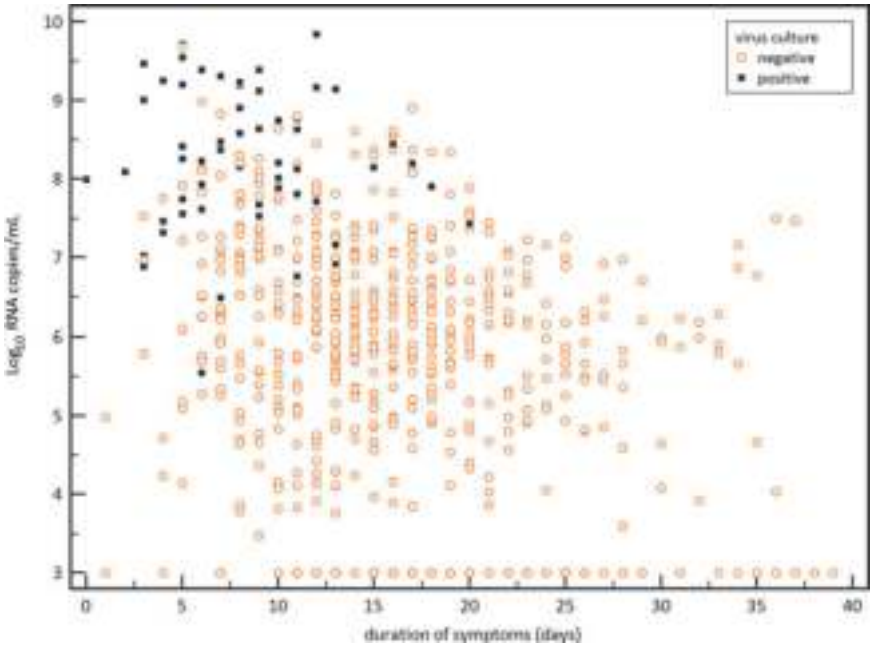

Fig. 1 Viral loads and duration of symptoms for infectious virus shedding. Viral RNA loads (Log_{10} RNA copies/mL) in the respiratory samples versus the duration of symptoms (days). Black boxes represent virus culture positive samples and open red circles represent the virus culture negative samples.

infectious virus dropped rapidly to undetectable levels. Infectious virus could not be isolated from respiratory tract samples once patients had a serum neutralizing antibody titer of at least 1:80. These results warrant the use of quantitative viral RNA load assays and serological assays in test-based strategies to discontinue or de-escalate infection prevention and control precautions. The probability of isolating infectious virus was less than 5% when viral RNA load was below 6.63 Log10 RNA copies/mL, which is strikingly similar compared to the cutoff of 6.51 Log10 RNA copies/mL reported by Wölfel et al.[5]. In addition, Bullard and colleagues used cycle threshold (ct) values as quantitative measure for viral RNA load and reported that infectious virus could not be isolated from diagnostic samples when ct values were above 24[12]. Together, these results indicate that viral RNA load cutoffs could be used in test-based strategies to discontinue infection prevention and control precautions. In addition, we report here a very strong association between neutralizing antibody response and shedding of infectious virus with an odds ratio of 0.01 for isolating infectious virus after seroconversion. Antibody responses were measured with a plaque-reduction neutralization test (PRNT)[22]. Neutralization assays, which are the gold standard in coronavirus serology, are labor-intensive and require a biosafety level 3 laboratory. We have recently cross-validated various commercial immunoassays using our PRNT50% as gold standard. Some commercial assays showed good agreement with our PRNT50%: For example, the

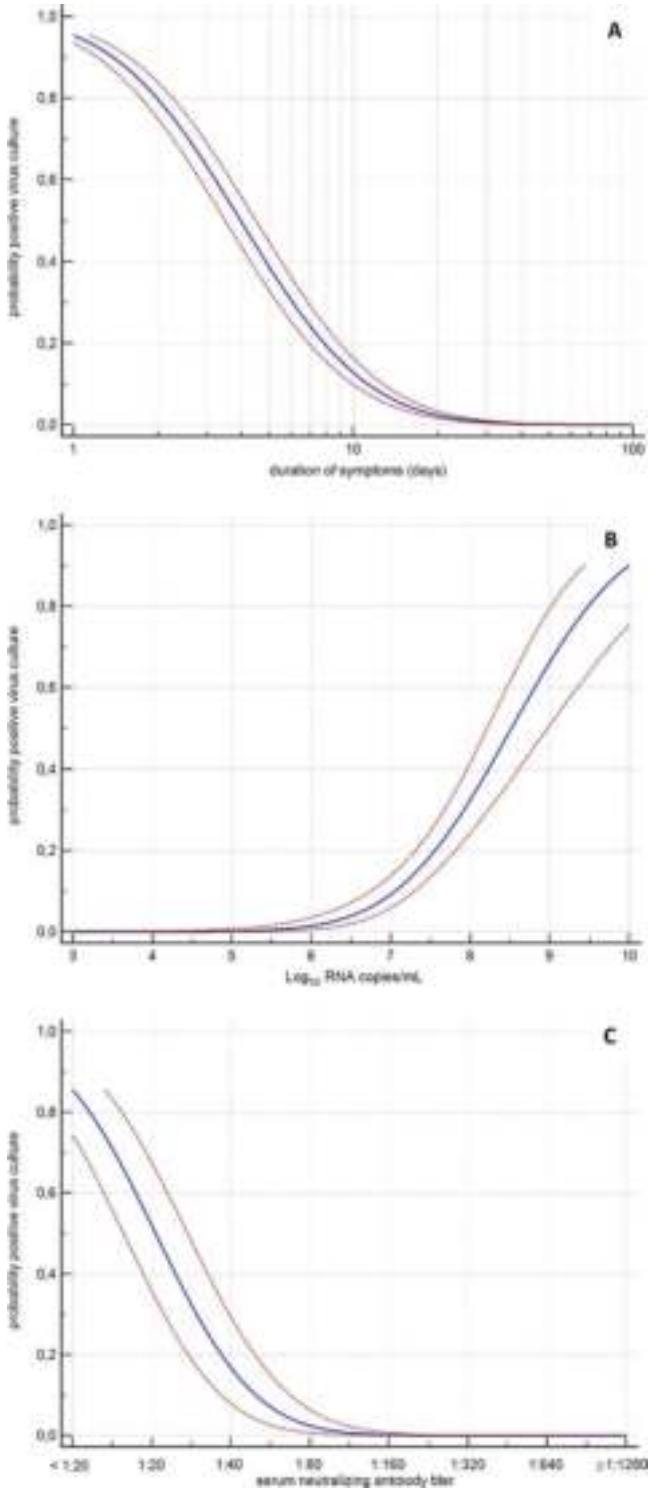

Fig. 2 Probabilities of infectious virus shedding. Probit analyses of the detection of infectious virus in respiratory samples with cell culture for duration of symptoms in days (**A**) ($n = 690$ samples), viral RNA load in Log10 copies per mL (**B**) ($n = 688$ samples), and serum neutralizing antibody titer (**C**) ($n = 112$ samples). Blue line represent the probit curve and the dotted red lines represent the 95% confidence interval. Serum neutralizing antibody titers are expressed as plaque-reduction neutralization titers 50% as described previously[27].

Table 2 Serum neutralizing antibody titers and isolation of infectious virus from the respiratory tract.

Serum neutralizing antibody titer	Total number samples	Number culture positive samples (%)	Number culture negative samples (%)
<1:20	31	27 (87%)	4 (13%)
1:20	10	4 (40%)	6 (60%)
1:40	7	2 (29%)	5 (71%)
1:80	2	0 (0%)	2 (100%)
1:160	4	0 (0%)	4 (100%)
1:320	11	0 (0%)	11 (100%)
1:640	9	0 (0%)	9 (100%)
1:1280	14	0 (0%)	14 (100%)
1:2560	16	0 (0%)	16 (100%)

Serum neutralizing antibody titers against SARS-CoV-2 were determined using a plaque-reduction neutralization assay[17]. Neutralizing antibodies (titers of 1:20 or higher) were detected in 72.3% (81/112) of the serum samples. For six patients, infectious SARS-CoV-2 was isolated from the respiratory tract despite the presence of neutralizing SARS-CoV-2 antibodies in the serum sample pairs. In four of these six patients, infectious virus was not isolated in the consecutive respiratory tract samples obtained after a virus culture positive sample (sampled from day +1, +1, +4, and +4 in respect to virus culture positive sample). For one patient, infectious virus was not isolated in the respiratory tract sample obtained one day after the virus culture positive respiratory tract sample, while the respiratory tract sample obtained 2 days after the virus culture positive respiratory tract sample was positive for infectious SARS-CoV-2. All respiratory tract samples obtained thereafter tested negative for infectious virus. For one patient, no follow-up respiratory tract samples were available.

Wantai SARS-CoV-2 Ig total ELISA has a sensitivity of 99% (95% CI 97–100%) and a specificity of 99% (95% CI 96–100%)[23]. These commercial immunoassays require less stringent biosafety measures and are amenable to high throughput use resulting in a broad application of our results to guide infection prevention strategies and discharge management for clinical cases being hospitalized.

Detection of viral subgenomic RNA correlated poorly with shedding of infectious virus. These RNAs are produced only in actively infected cells and are not packaged into virions. Subgenomic RNAs were still detected when virus cultures turned negative. This could indicate that active replication continues in severely-ill symptomatic COVID-19 patients after seroconversion and after shedding of infectious virus has stopped. Possibly, infectious virions are produced but are directly neutralized by antibodies in the respiratory tract. On the other hand, the half-life of viral subgenomic RNAs is not known in COVID-19 and these RNAs may still be detected once replication has stopped.

Our study has some limitations. Firstly, virological data were obtained from diagnostic samples only and samples were not prospectively collected at predefined timepoints. However, as many aspects of COVID-19 were still unclear, a sampling-rich diagnostic approach was applied in our institution with regular virological monitoring of confirmed COVID-19 patients. This approach resulted in a large high quality dataset from a considerable number of patients including patients with a immunocompromised status. The strikingly similar viral RNA load cutoff for a 5% probability of a positive virus culture found by us and by Wölfel et al. underpins the validity of the results[5]. Secondly, we used in vitro cell cultures as a surrogate marker for infectious virus shedding. The success of SARS-CoV-2 isolation is dependent on which cell lines is used[24]. Vero cells are currently regarded as the gold standard to detect infectious SAR-CoV-2, but the true limit of detection is unknown. Notwithstanding the above, experimental evidence from a COVID-19 hamster model showed that transmission of SARS-CoV-2 correlated well with detection of infectious SARS-CoV-2 from respiratory tract samples using in vitro Vero cell cultures while detection of viral RNA did not[13]. More data from experimental models, and epidemiological and modeling

Table 3 Univariate and multivariate analysis of key determinants for infectious virus shedding.

Variable	Positive virus culture ($n = 33$)	Negative virus culture ($n = 79$)	Univariate odds ratio (95% CI)	Multivariate odds ratio (95% CI)
Viral RNA load				
$>10^7$ RNA copies/mL	29 (87.9%)	22 (27.8%)	18.8 (5.5–64.2), $p < 0.001$	14.7 (3.7–58.1), $p < 0.001$
Duration of symptoms				
<7 days	20 (60.6%)	17 (21.5%)	5.6 (1.7–18.1), $p = 0.004$	2.1 (0.4–11.7), $p = 0.31$
Serum neutralizing antibody titer				
1:20 or higher	6 (18.2%)	75 (94.9%)	0.01 (0.003–0.05), $p < 0.001$	0.01 (0.002–0.08), $p < 0.001$
Immunocompromised				
Yes	10 (30.3%)	10 (12.7%)	3.00 (0.8–11.0), $p = 0.098$	2.0 (0.7–5.3), $p = 0.22$

Results of the univariate and multivariate generalized estimating equation analysis. The analyses were limited to the samples for which a viral RNA load and a serum neutralizing antibody titer were available from samples taken at the same day.

studies on transmission, which take viral RNA load and antibody response into account, are needed for further validation of this approach. It should be noted that, besides the infectious viral load, additional factors determine virus transmissibility. Finally, our study only included hospitalized symptomatic adults with severe or critical COVID-19 and important differences were noted in our study compared to what has been reported for in mild COVID-19. Thus, further studies are needed on the determinants and duration of infectious virus shedding in specific patient groups.

In conclusion, infection prevention and control guidelines should take into account that patients with severe or critical COVID-19 may shed infectious virus for longer periods of time compared to what has been reported for in patients with mild COVID-19. Infectious virus shedding drops to undetectable levels when viral RNA load is low and serum neutralizing antibodies are present, which warrants the use of quantitative viral RNA load assays and serological assays in test-based strategies to discontinue or de-escalate infection prevention and control precautions.

Methods

Samples and patients. Between March 8, 2020 and April 8, 2020, diagnostic respiratory samples of COVID-19 patients from the Erasmus MC that were send to our laboratory for SARS-CoV-2 PCR were also submitted for virus culture. From these patients, results from SARS-CoV-2 PCRs on diagnostic respiratory samples and results from SARS-CoV-2 neutralizing antibody measurements on serum samples were extracted from our diagnostic laboratory information management system (LabTrain version 3, bodegro, the Netherlands). The following information was extracted from the electronic patient files (HiX version 6.1, ChipSoft, the Netherlands): date of onset of symptoms, disease severity (hospitalized on ICU with mechanical ventilation, hospitalized on ICU with oxygen therapy, hospitalized to ward with oxygen therapy, hospitalized to ward without oxygen therapy), information to classify patients as immunocompetent, nonseverely immunocompromised (excluding diabetes mellitus), or severely immunocompromised as described previously[25], disease severity score according to the NIH classification (https://www.covid19treatmentguidelines.nih.gov/overview/management-of-covid-19/), and whether the patients were still alive or not as of April 17, 2020. Excel 2016 (Microsoft Corp, USA) was used as data collection software.

Sample processing and analysis. Swabs from the upper respiratory tract were collected in tubes containing 4 mL virus transport medium (Dulbecco's modified eagle's medium (DMEM, Lonza) supplemented with 40% FBS, 20 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES), NaCO3, 10 µg/ml amphotericin B, 1000 U/mL penicillin, 1000 µg/mL streptomycin). Supernatant was passed through a 45-µm filter and used for PCR analysis and virus culture. For sputum samples, 6 mL sample processing medium (DMEM supplemented with 17 mM HEPES, $NaCO_3$, 1000 U/mL penicillin, 1000 µg/mL streptomycin, 12.5 µg/ml amphotericin B) was added until the final volume was 6 mL. Subsequently, samples were vortexed, centrifugated, passed through a 45-µm filter, and 1 part FBS was added to 1.5 parts supernatant. Subsequently, processed samples were used for PCR analysis and virus culture.

Real-time RT-PCR detection of SARS-CoV-2 was performed using an in-house assay[26] or using the SARS-CoV-2 test on a cobas® 6800 system (Roche Diagnostics). Subsequently, cycle threshold (ct) values were converted to Log_{10} RNA copies/mL using calibration curves based on quantified E-gene in vitro RNA transcripts[5]. SARS-CoV-2 subgenomic RNAs were detected with RT-PCR[5].

Respiratory samples were cultured on Vero cells, clone 118, using 24-wells plates with glass coverslips[27]. Cells were inoculated with 200 µL sample per well and centrifugated for 15 min at 3500 × *g*. After centrifugation, inoculum was discarded, virus culture medium (Iscove's modified Dulbecco's medium (IMDM; Lonza) supplemented with 2 mM L-glutamine (Lonza), 100 U/mL penicillin (Lonza), 100 µg/mL streptomycin (Lonza), 2.5 µg/mL amphotericin B (department of hospital pharmacy, Erasmus MC), and 1% heat-inactivated fetal bovine serum (Sigma)) was added, and samples were cultured at 37 °C and 5% CO_2 for 7 days. Each sample was cultured in triplicate: Two replicates were fixed with ice-cold acetone after 24 and 48 h, respectively irrespective if cytopathic effect (CPE) was visible. The fixed samples were further analyzed with immunofluorescence (see below). The remaining replicate was scored for CPE on a daily basis for 7 days. When CPE was visible, the sample was fixed with ice-cold acetone and further analyzed with immunofluorescence (see below). Virus cultures were regarded as negative if no CPE was visible during 7 days. For immunofluorescence read-out, the fixed cells were washed with phosphate buffer saline (PBS), and incubated for 30 min at 37 °C with 25 µL 1000-fold diluted polyclonal rabbit SARS-CoV anti-nucleoprotein antibodies (Sino Biological, catalogue number 40143-T62). After incubation, samples were washed with three times with PBS and once with deionized water. Subsequently, cells were incubated for 30 min at 37 °C with 25 µL 2000-fold diluted Alexa Fluor 488-labeled polyclonal goat anti-rabbit IgG (Invitrogen, catalogue number A-11070). Subsequently, cells were washed three times with PBS. Finally, cells were incubated for 1 min with 25 µL Evan's Blue (counterstain), washed twice with deionized water, air dried and analyzed with a fluorescence microscope.

Serum neutralizing antibodies titers against SARS-CoV-2 (German isolate; GISAID ID EPI_ISL 406862; European Virus Archive Global #026V-03883) were determined using a plaque-reduction neutralization test[22]. A plaque-reduction neutralization titer 50% (PRNT50%) of 1:20 or more was considered to be positive and a PRNT50% below 1:20 negative.

Medical ethical approval. All patient samples and data used in this study were collected in the context of routine clinical patient care. Additional analyses were performed only on surplus of patient material collected in the context of routine clinical patient care. The institutional review board of the Erasmus MC (Rotterdam, The Netherlands) approved the use of these data and samples (METC-2015-306). METC-2015-306 is a generic protocol to study viral diseases. Informed consent for COVID-19 research was waived by the privacy knowledge office of the Erasmus MC (Rotterdam, The Netherlands). Instead, patients had the right to opt-out against the use of their surplus patient material and their medical data for research. The opt-out system of the Erasmus MC was checked for all patients included in this study, and none of the patients included in this study opted-out against the use of their surplus patient material and their medical data for research.

Statistical analysis. Categorical and continuous variables were compared using the Chi-square test the student's *t*-test, respectively. Generalized estimating equations were used to identify factors that are associated with a virus culture positive respiratory tract sample. The continuous data in the generalized estimating equations were dichotomized using various cutoff values. In the main paper we present the results of the best fitting generalized estimating equations using the levels of dichotomizing that had the best fit according to the quasi-likelihood under the independence criterion (QIC)[28]. Sensitivity analysis is shown in Supplementary Table 1 and Supplementary Table 2. All variables having a p value < 0.1 in univariate analysis were submitted into a multivariate general estimating equation to account for repeated measurements obtained from the same patient during hospitalization[29]. For this analysis we used the geepack package version 1.3-1 and R version 4.0.0[29]. Probit analyses were performed with MedCalc version 19.2.3 (MedCalc Software Ltd).

Role of the funding source. This work partially was funded through EU COVID-19 grant RECOVER 101003589. The study sponsors were involved neither in the study design, the collection, analysis and interpretation of the data, writing of the report, nor in the decision to submit the paper for publication. The corresponding author had full access to all the data in the study and had final responsibility for the decision to submit for publication.

Reporting summary. Further information on research design is available in the Nature Research Reporting Summary linked to this article.

Data availability

Background. Key knowledge gaps remain in the understanding of viral dynamics and immune response of Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) infection.

Methods. We evaluated these characteristics and established their association with clinical severity in a prospective observational cohort study of 100 patients with PCR-confirmed SARS-CoV-2 infection (mean age, 46 years; 56% male; 38% with comorbidities). Respiratory samples (n = 74) were collected for viral culture, serum samples for measurement of IgM/IgG levels (n = 30), and plasma samples for levels of inflammatory cytokines and chemokines (n = 81). Disease severity was correlated with results from viral culture, serologic testing, and immune markers.

Results. Fifty-seven (57%) patients developed viral pneumonia, of whom 20 (20%) required supplemental oxygen, including 12 (12%) with invasive mechanical ventilation. Viral culture from respiratory samples was positive for 19 of 74 patients (26%). No virus was isolated when the PCR cycle threshold (Ct) value was >30 or >14 days after symptom onset. Seroconversion occurred at a median (IQR) of 12.5 (9–18) days for IgM and 15.0 (12–20) days for IgG; 54/62 patients (87.1%) sampled at day 14 or later seroconverted. Severe infections were associated with earlier seroconversion and higher peak IgM and IgG levels. Levels of IP-10, HGF, IL-6, MCP-1, MIP-1α, IL-12p70, IL-18, VEGF-A, PDGF-BB, and IL-1RA significantly correlated with disease severity.

Conclusions. We found virus viability was associated with lower PCR Ct value in early illness. A stronger antibody response was associated with disease severity. The overactive proinflammatory immune signatures offer targets for host-directed immunotherapy, which should be evaluated in randomized controlled trials.

Keywords. COVID-19; cytokines; serology; viral culture; immunology.

The coronavirus disease 2019 (COVID-19) pandemic caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has caused great harm to health and the global economy [1, 2]. Understanding of SARS-CoV-2 pathogeneisis has advanced at an unprecedented speed, but key gaps remain and preliminary findings require validation.

Studies of patients with COVID-19 have described the inflammatory milieu in severe infections, with increased neutrophils, suppressed lymphocytes, and elevated inflammatory mediators [3, 4]. However, most studies are limited to comparing severe against nonsevere infections and lack serial data [5, 6]. A clearer definition of disease pathogenesis will support the development of risk-stratification tools and therapeutics targeting critical pathways in the inflammatory cascade.

Early seroconversion has been reported with immunoglobulin (Ig) G to the receptor binding domain (RBD) detected at day 7 [7–10]. However, evidence of correlation between antibody titers and disease severity is conflicting [8, 10–12]. There remains a need for more detailed assessment of antibody kinetics to help determine the impact of antibody-dependent enhancement in COVID-19 pathogenesis, as well as guide convalescent plasma harvesting and use of serological assays for diagnosis [13].

SARS-CoV-2 can be detected from the nasopharynx for a median of 2–3 weeks following onset of symptoms [14]. Several studies have reported that, in immunocompetent individuals, virus is typically only cultured from respiratory samples during the first week of illness when viral loads are highest [8, 15, 16]. This suggests transmission risk declines in the second

week. This finding requires confirmation in larger cohorts as it has important implications for infection-control and isolation protocols [17].

In this multipronged study, we describe the serologic evolution, inflammatory response, and pattern of viral shedding and viability in patients with virologically confirmed COVID-19 in Singapore, and analyze the contributions these make to severe infections.

METHODS

Patient Recruitment

All individuals confirmed to have COVID-19 by SARS-CoV-2 real-time reverse transcriptase–polymerase chain reaction (RT-PCR) and admitted to any of 7 public hospitals in Singapore were eligible for inclusion in this study. RT-PCR was performed on respiratory samples, as previously described [18] (details shown in the Supplementary Methods).

Data and Specimen Collection

Clinical information was extracted from the medical record using a standardized data-collection form adapted from the International Severe Acute Respiratory and Emerging Infection Consortium (ISARIC) case record form [19]. Serial blood and respiratory samples were collected during hospitalization and follow-up postdischarge (days 1, 3, 7, 14, 21, and 28 after enrollment). A stool and urine sample was also collected for SARS-CoV-2 PCR and culture on day 1.

Clinical Management

At the time of the study, all patients with COVID-19 in Singapore were admitted to airborne infection–isolation rooms regardless of disease severity. Supportive therapy, including supplemental oxygen and symptomatic treatment, was administered as required. Patients with moderate to severe hypoxia were transferred to the intensive care unit (ICU) for further management and invasive mechanical ventilation as required.

Patients were discharged from the hospital only after resolution of symptoms and when 2 consecutive nasopharyngeal swabs more than 24 hours apart were negative for SARS-CoV-2 by RT-PCR. Follow-up visits were arranged on day 28 of enrollment.

Virus Isolation

Material from nasopharyngeal swabs was collected in universal transport media and used to inoculate Vero-E6 cells (American Type Culture Collection: CRL-1586TM) for virus isolation in an Animal Biological Safety Level 3 laboratory. Urine and stool samples were collected and transported fresh for viral culture. Stools were filtered before inoculation. Cells were cultured at 37°C for 7 days or less if cytopathic effect (CPE) was observed, and 3 blind passages were performed. Cytopathic effect consisted of rounded cells and extensive cell death, usually by day 4 postinoculation. Positive isolation was confirmed by the observation of CPE and virus-specific PCR. Total RNA was extracted from all samples using the E.Z.N.A. Total RNA Kit I (Omega Bio-Tek, Inc) according to the manufacturer's instructions, and samples were analyzed by RT-PCR for the detection of SARS-CoV-2 as previously described [20].

Capture Enzyme-linked Immunosorbent Assay to Detect IgM and IgG

Serum collected during the acute and convalescent phases of infection were tested for SARS-CoV-2 receptor binding domain–specific IgM and IgG using capture enzyme-linked immunosorbent assay (ELISA) (details in the Supplementary Methods).

Multiplex Microbead-based Immunoassay

Plasma samples were collected during acute and convalescent phases and treated with a solvent/detergent based on Triton X-100 (1%) (Dow Chemical Company) for virus inactivation [21]. Immune mediator levels were measured using Cytokine/Chemokine/Growth Factor 45-Plex Human ProcartaPlex Panel 1 (ThermoFisher Scientific) (details in the Supplementary Methods). Cytokine levels were also measured in 23 healthy donor plasma samples as baseline controls.

Statistical Analysis

Patients were categorized into 3 groups for comparison: no pneumonia on chest radiographs (CXR) throughout admission, pneumonia on CXR without hypoxia, and pneumonia with hypoxia (desaturation to ≤94%) needing supplemental oxygen. Day 1 was defined as the first day of symptom onset.

Fold-changes (FCs) of antibody titers compared with negative controls were calculated. Kruskal-Wallis test followed by Dunn's multiple-comparison test was used to determine significance of antibody levels.

Unpaired *t* test was applied to ascertain significant differences in the immune mediator levels between the patients with COVID-19 and healthy controls at different time points post–illness onset. One-way analysis of variance (ANOVA) with post hoc *t* test corrected using the method of Bonferroni was used to discern the differences in immune mediator levels between the various disease-severity groups. One-way ANOVA results were corrected for multiple testing using the method of Benjamini and Hochberg.

TM4-MeV Suite (version 10.2) was used to compute hierarchical clustering and heat map on the immune mediators (details in Supplementary Methods). Biological processes and immune pathways were predicted and illustrated using the Search Tool for the Retrieval of Interacting Genes/Proteins database (STRING; version 11.0; available at: https://string-db.org). All interactions were derived from high-throughput laboratory experiments and previous knowledge in curated databases at a confidence threshold of 0.8.

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciaa1280/5898476 by guest on 20 March 2021

Student's *t* test or Mann-Whitney *U* test was used as appropriate for continuous variables and Fisher's exact test for categorical variables. *P* values less than .05 were considered statistically significant. Plots were generated using GraphPad Prism (version 7), MedCalc Statistical Software (version 19.2.1), or R (version 3.3.1).

Ethical Approval

Written informed consent was obtained from all participants. The study protocol at all sites was approved by the National Healthcare Group Domain Specific Review Board, study reference 2012/00917; additional study protocol at Singapore General Hospital was approved by the SingHealth Centralized Institutional Review Board, study reference 2018/3045.

RESULTS

Clinical Presentation, Treatment, and Outcome

A total of 130 patients with COVID-19 were diagnosed in Singapore from the first known case on 22 January 2020 to 6 March 2020 (Figure 1). Among the 100 (77%) enrolled in this study, viral pneumonia was diagnosed by CXR in 57, of whom 20 required supplemental oxygen for hypoxia and 12 required invasive mechanical ventilation (Table 1).

Following resolution of infection and viral shedding, 97 patients have been discharged, and after 90 days of follow-up no reinfection or recrudescence has been detected. Three patients have died. Deaths occurred 27 days or more after hospital admission, and while all were assessed by the managing clinician as related to COVID-19, they followed viral clearance and prolonged invasive mechanical ventilation.

Viral Shedding and Cultures

SARS-CoV-2 was detectable from nasopharyngeal swabs by PCR up to 48 days after symptom onset. The mean duration of viral shedding by PCR was 16.7 days (95% confidence interval [CI], 15.2–18.3 days). Cessation of viral shedding by PCR occurred in 4% by day 7, 30% by day 14, 78% by day 21, and 91% by day 28. There were no differences in the duration of viral shedding stratified by disease severity (Supplementary Figures 1 and 2).

Viral culture was attempted from 152 respiratory samples where SARS-CoV-2 was detected by PCR. These samples were collected from 74 patients and SARS-CoV-2 was isolated from 21 samples from 19 (26%) patients (Supplementary Table 1). No virus was isolated from samples where the cycle threshold (Ct) value was greater than 30, or when the sample was collected more than 14 days after symptoms onset (Figure 2, Supplementary Figures 2 and 3). There was no correlation between virus isolation by culture and infection severity, patient demographics, or symptomatology (data not shown). Viral culture was attempted from the stool of 34 patients and urine of 24 patients during acute infection; in all patients, virus was not isolated. Seven (21%) patients had virus detectable by PCR in stool.

IgM and IgG Titers Correlate With Disease Severity

Serial serum samples for ELISA were available for 30 patients. Anti–SARS-CoV-2 IgM was first detectable in 17.9% in the first week of illness, 39.3% in the second week, 35.7% in the third week, and 7.1% after the third week, and correspondingly for IgG, 7.7%, 26.9%, 50.0%, and 15.4%. The median time to seroconversion was 12.5 days (interquartile range [IQR], 9–18 days)

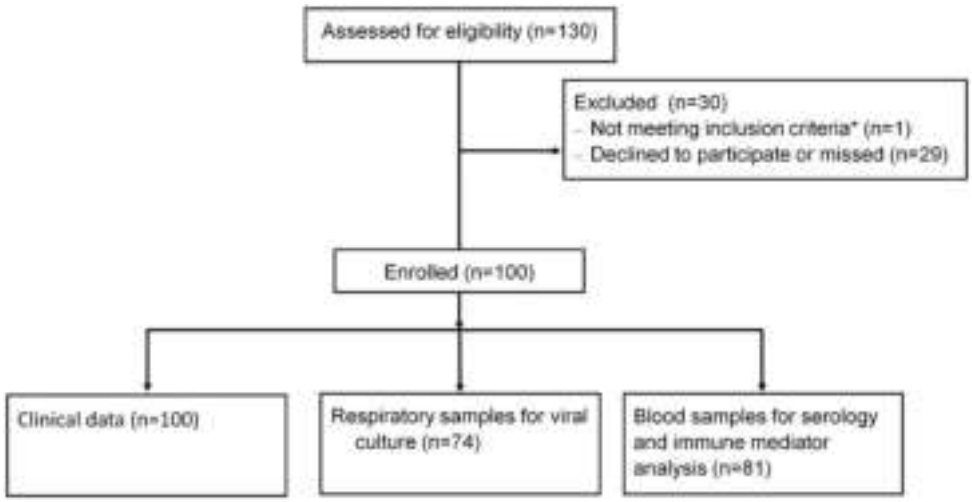

Figure 1. Flow diagram of study recruitment and follow-up in 130 patients diagnosed in Singapore as of 6 March 2020. *One excluded as diagnosis was retrospective via serology rather than PCR. The 100 patients were enrolled from the following hospitals in Singapore: National Centre for Infectious Diseases (77), National University Hospital (8), Singapore General Hospital (8), Ng Teng Fong General Hospital (3), Changi General Hospital (2), Alexandra Hospital (1), Khoo Teck Puat Hospital (1). Abbreviation: PCR, polymerase chain reaction.

Abbreviations: ALT, alanine aminotransferase; CRP, C-reactive protein; Ct, cycle threshold; IQR, interquartile range; LDH, lactate dehydrogenase; PCR, polymerase chain reaction.

for IgM and 15.0 days (IQR, 12–20 days) for IgG. The total seroconversion rate from 62 patients sampled on day 14 or later was 87.1%. Time to IgG seroconversion was significantly shorter for patients with pneumonia and hypoxia compared with less-severe infections (median, 12.5 vs 18 days; $P = .013$, Mann-Whitney). There was also a significant correlation between disease severity and peak IgM and IgG levels (Figure 3). However, IgM and IgG antibody levels were not associated with duration of viral shedding (Figure 3), baseline viral Ct values from respiratory samples, age, or comorbidities (Supplementary Figure 5).

Proinflammatory Signature of Severe COVID-19

A total of 321 plasma samples were available from 81 patients. Levels of interleukin (IL)-2, IL-18, interferon-γ (IFN-γ), tumor necrosis factor α (TNF-α), monocyte chemoattractant protein 1 (MCP-1), hepatocyte growth factor (HGF), brain-derived neurotrophic factor (BDNF), leukemia inhibitory factor (LIF), placenta growth factor-1 (PLGF-1), and beta-nerve growth factor (bNGF) were significantly elevated compared with healthy controls for their first plasma samples taken soon after admission (Figure 4A). Proinflammatory cytokines and chemokines (IL-2, IL-18, IFN-γ, and MCP-1) were elevated at the early phase of infection and were reduced to a healthy basal range at approximately 15 days post–illness onset. In contrast, the elevated levels of lung injury–associated growth factors (HGF, BDNF, LIF, PLGF-1, and bNGF) persisted throughout the infection course (Figure 4A). Stratification of patients with COVID-19 with plasma samples nearest to the onset of pneumonia and hypoxia revealed that the proinflammatory cytokines IFN-γ inducible protein (IP-10), HGF, IL-6, MCP-1, macrophage inflammatory protein-1α (MIP-1α), IL-12p70, and IL-18; growth

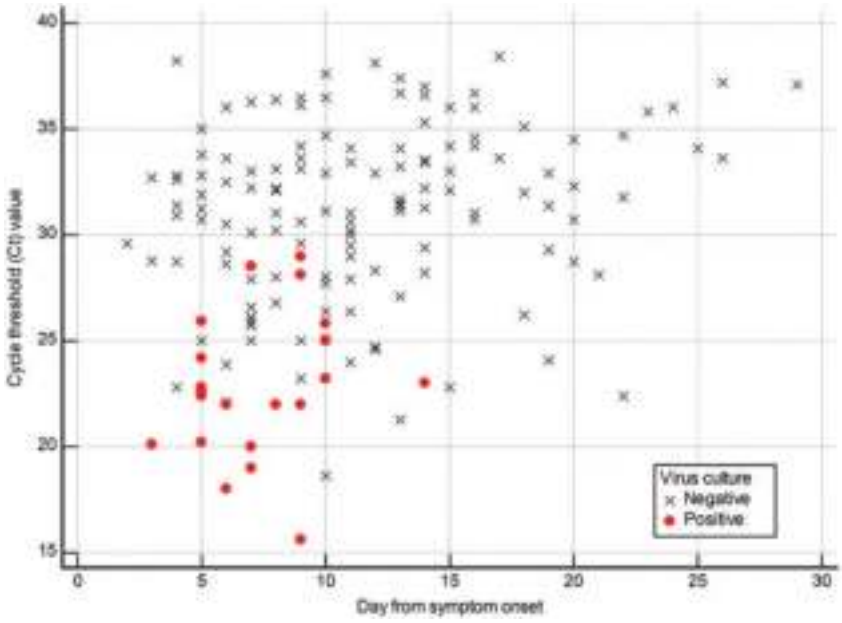

Figure 2. Scatterplot of viral culture results by day from symptom onset and PCR Ct value. Analysis includes 152 samples from 74 patients in whom virus was detectable by SARS-CoV-2 PCR. Virus was cultured from 21 (14%) samples from 19 patients. Abbreviations: PCR, polymerase chain reaction; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2.

factors vascular endothelial growth factor A (VEGF-A) and 2 B subunits of platelet-derived growth factor (PDGF-BB); and anti-inflammatory cytokine IL-1RA were associated with severity. Levels were significantly elevated between patients with pneumonia without hypoxia and patients with hypoxia compared with patients without pneumonia, except for MCP-1, which was only significantly higher in patients with hypoxia (Figure 4B and 4C; Supplementary Tables 2 and 3).

Further network analyses showed an association between the aforementioned immune mediators and clinical parameters (pneumonia, hypoxia, and ICU admission). The intertwined relationship of the cytokines is shown in Figure 5A. In addition, Ingenuity Pathway Analysis (IPA) revealed canonical pathways associated with these immune mediators and severity, with the top 10 canonical pathways involved in inflammatory diseases and cell signalling (Figure 5B). The top canonical pathway highlights the common immune mediators between influenza and SARS-CoV-2 infection, including MCP-1, IL-1RA, IP-10, and IL-6 (Figure 5C). In addition to IPA, STRING prediction of protein–protein interactions identified IL-6 as a direct interacting partner with other severity-associated immune mediators (Figure 5D).

A longitudinal comparison of these immune mediators associated with severity in 12 ICU patients was performed to explore their role as prognostic markers for severe COVID-19 (Supplementary Figure 6). Four of these 12 patients (CT009, CT032, CT037, and CT057) recovered and were discharged at the time of study. Interestingly, HGF and VEGF-A were distinctly separated into 2 levels, with the 4 discharged patients having lower HGF and VEGF-A levels, and HGF approaching healthy baseline levels during convalescence, which further indicates that high levels of these cytokines were associated with poor prognosis in ICU patients. Similarly, these patients had lower levels of MCP-1 and IL-6 compared with other ICU patients despite having a less distinct separation. Longitudinal comparison of other immune mediators, including IP-10, IL-18, PDGF-BB, and IL-1RA, revealed decreasing levels with days post–ICU admission and approaching healthy baseline levels during the latter period after ICU admission (Supplementary Figure 6).

DISCUSSION

This study of 100 patients in the first few months of the COVID-19 pandemic in Singapore provides a detailed overview of clinical presentation, progress, and outcomes. Case detection and contact tracing in Singapore are rigorous, with the main gap possibly in missing asymptomatic cases [22]. From the cohort, 43% of patients never developed pneumonia, 37% developed pneumonia without hypoxia, and 20% developed pneumonia with hypoxia. We found no relationship between illness severity and duration of viral shedding or PCR Ct values. The central role of the immune response to SARS-CoV-2 in COVID-19 was evident from the strong correlation between disease severity and levels of IgG/IgM and inflammatory immune mediators in our cohort.

Viral shedding of SARS-CoV-2 from the respiratory tract has been observed to persist for several weeks and potentially up

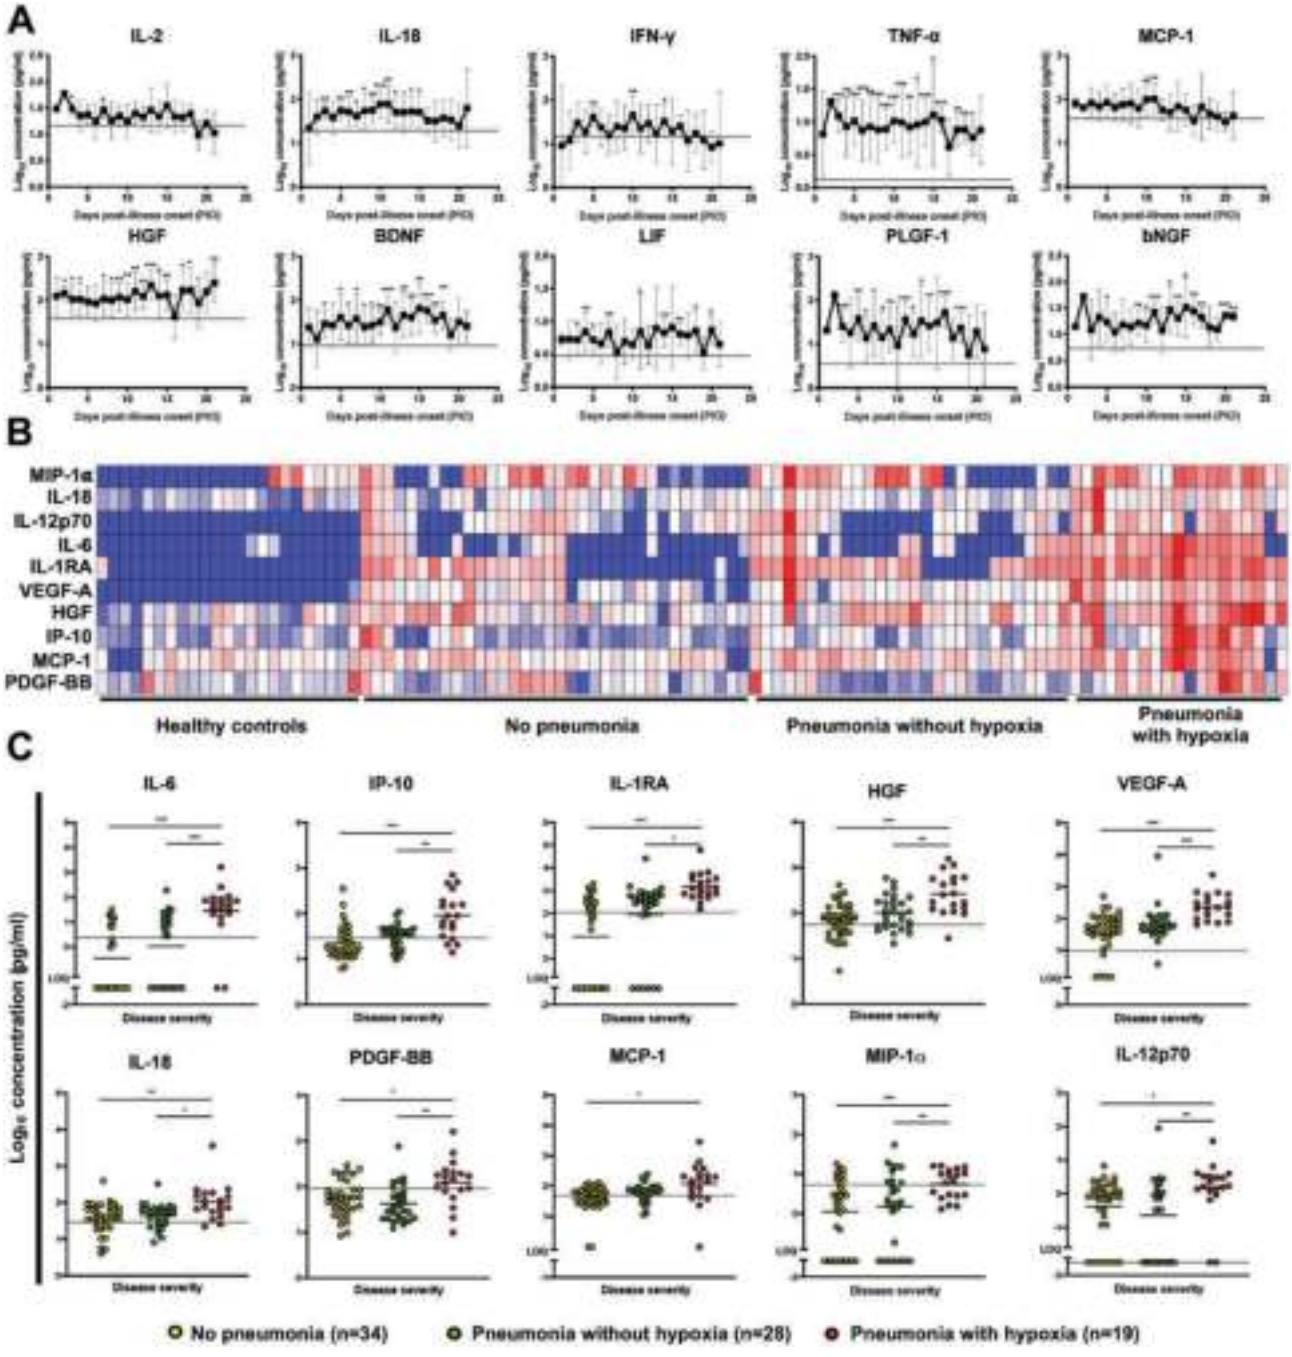

Figure 4. Immune signatures of patients with COVID-19 reveal cytokines associated with disease severity. Plasma fractions were isolated from the blood of patients with COVID-19 (n = 81) at different time points. Time points closest to event onset, including mild (no pneumonia), pneumonia without hypoxia, or pneumonia with hypoxia, were chosen to identify cytokines that were associated with disease severity. Concentrations of 45 immune mediators were quantified using a 45-plex microbead-based immunoassay. *A*, Longitudinal profile of detectable cytokines in patients with COVID-19 during the acute phase of disease. Statistical analyses were performed using unpaired *t* test against the healthy baseline (* = $P < .05$, ** = $P < .01$, *** = $P < .001$). Cytokine level for healthy controls (n = 23) is indicated by the dotted line. *B*, Heatmap of severity-associated cytokine levels in patients with different disease outcomes (healthy controls, n = 23; no pneumonia, n = 34; pneumonia without hypoxia, n = 28; pneumonia with hypoxia, n = 19). Each color represents the relative concentration of a particular analyte. Blue and red indicate low and high concentrations, respectively. *C*, Profiles of significant immune mediators are illustrated as scatterplots. One-way ANOVAs were conducted on the logarithmically transformed concentration with post hoc *t* tests corrected using the method of Bonferroni. ANOVA results were corrected for multiple testing using the method of Benjamini and Hochberg (* = $P < .05$, ** = $P < .01$, *** = $P < .001$). Cytokine level for healthy controls (n = 23) is indicated by the dotted line. Patient samples that are not detectable are assigned the value of logarithm transformation of LOQ. Abbreviations: ANOVA, analysis of variance; BDNF, brain-derived neurotrophic factor; bNGF, beta-nerve growth factor; COVID-19, coronavirus disease 2019; HGF, hepatocyte growth factor; IFN-γ, interferon-γ; IL, interleukin; IL-1RA, interleukin-1 receptor antagonist; IP-10, IFN-γ inducible protein; LIF, leukemia inhibitory factor; LOQ, limit of quantification; MCP-1, monocyte chemoattractant protein-1; PDGF-BB, 2 B subunits of platelet-derived growth factor; PLGF-1, placenta growth factor-1; TNF-α, tumor necrosis factor α; VEGF-A, vascular endothelial growth factor A.

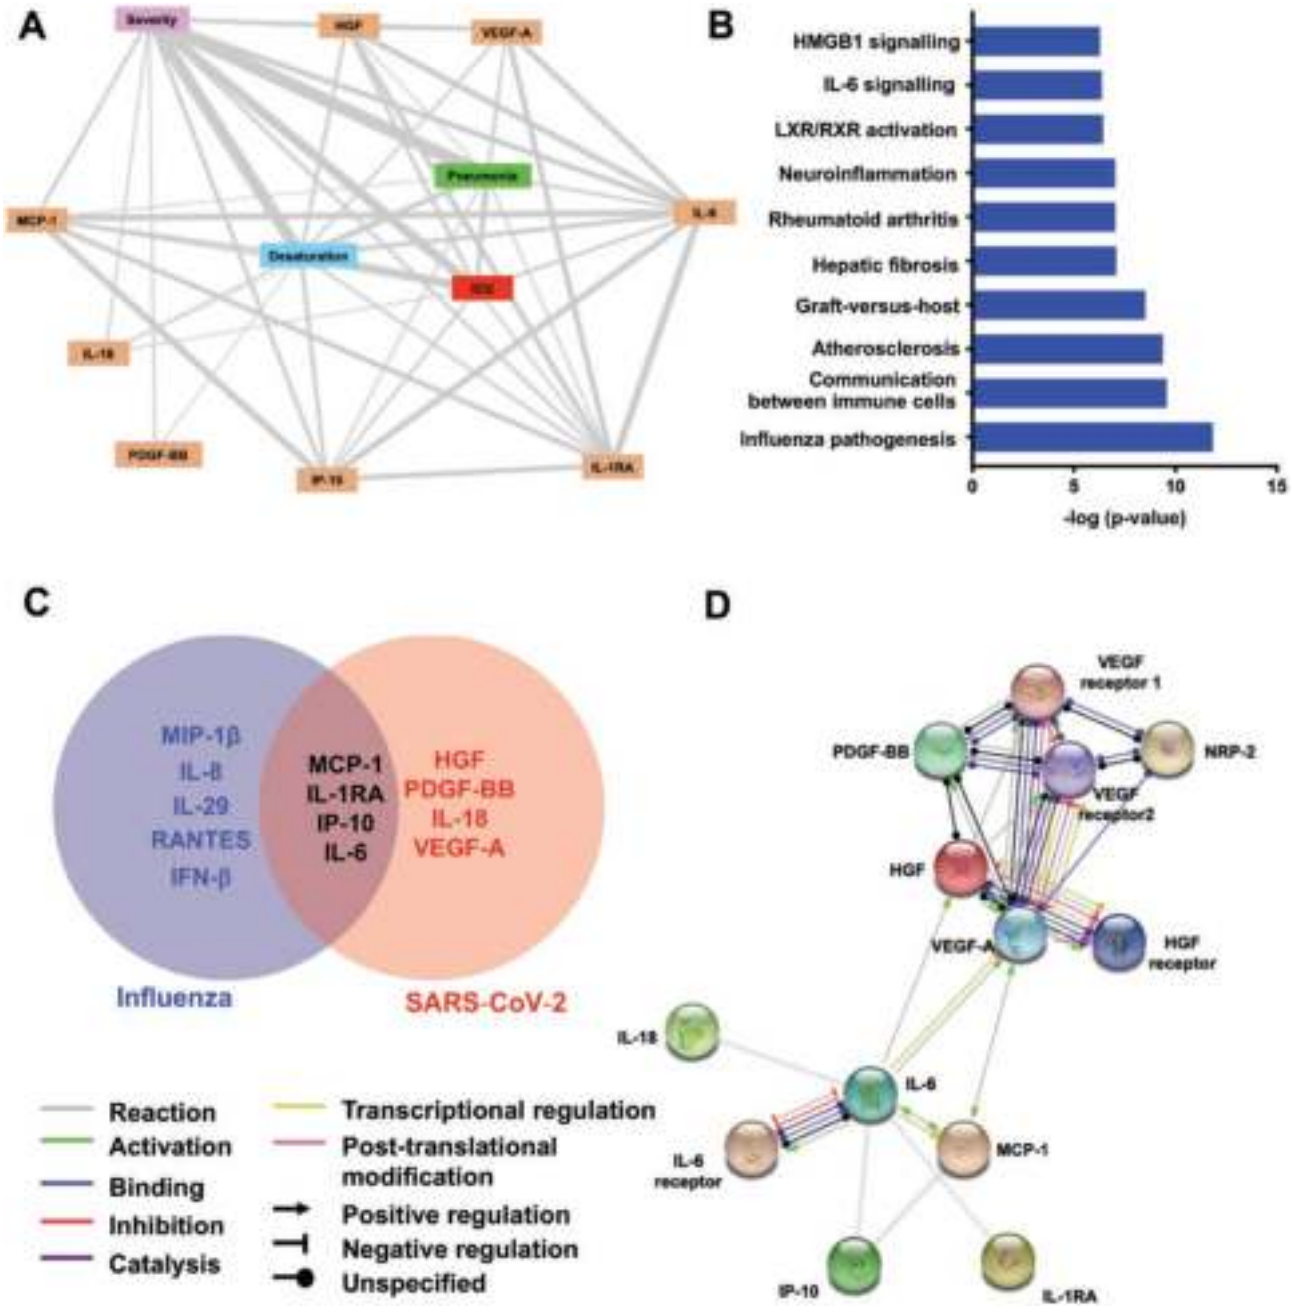

Figure 5. Network analysis of immune mediators associated with disease severity in patients with COVID-19. *A*, Interactomic analysis by IPA software. The network is displayed graphically as nodes and edges. Each node represents either severity-associated cytokine or disease condition. Thickness of edges represents the magnitude of biological relationship between connected nodes. Edges are thicker when the association between parameters is stronger. *B*, IPA analysis of the 8 significant immune mediators associated with disease severity in patients with COVID-19. The chart represents the top 10 significantly associated canonical pathways with the immune mediators. *C*, Venn diagrams show common immune mediators between influenza virus infection and SARS-CoV-2 virus infection. *D*, Interactive relationships between the immune mediators were determined by STRING analysis, with a confidence threshold of 0.8. Abbreviations: COVID-19, coronavirus disease 2019; HGF, hepatocyte growth factor; ICU, intensive care unit; IFN, interferon; IL, interleukin; IL-1RA, interleukin-1 receptor antagonist; IPA, Ingenuity Pathway Analysis; IP-10, IFN-γ inducible protein; MCP-1, monocyte chemoattractant protein-1; NRP-2, neuropilin 2; PDGF-BB, 2 B subunits of platelet-derived growth factor; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2; STRING, Search Tool for the Retrieval of Interacting Genes/Proteins database; VEGF-A, vascular endothelial growth factor A.

to months [18, 23–25]. Whether the virus remains infectious throughout this prolonged viral shedding is an important question to resolve. Smaller studies have found that viable virus was readily isolated from immunocompetent individuals during the first week of illness but were unable to successfully isolate viruses in culture from day 8 onward despite detectable viral loads by PCR [8, 25, 26]. However, a case report from Taiwan showed that it was possible to culture the virus up until day 18 [27],

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciaa1280/5898476 by guest on 20 March 2021

while positive cultures up to day 20 have been reported from a study of patients with severe infection [15]. We found that successful viral culture was associated with PCR Ct values of 30 or less. Virus was isolated up to day 14 post–symptom onset, although the majority were cultured at day 10 or earlier. Using the PCR Ct value to guide decision making on de-isolation may be an alternative to using day of illness and to provide an additional level of reassurance. However, this requires further validation.

We observed seroconversion of IgM at a median of 12.5 days and IgG at 15.0 days. Similar to a Hong Kong study of 16 patients, there were no significant differences in IgM and IgG titers by age or comorbidities [10]. We found IgM and IgG titers to be correlated with disease severity, which was similarly found in 2 Chinese studies of 173 [7] and 285 [28] patients, respectively.

We found a lower seroconversion rate of 87.1% in 62 patients from day 14 or later. A Chinese study of 173 patients reported that 94.3% of patients were IgM positive by days 15–39 and 79.8% were IgG positive by days 15–39 [7]. A Hong Kong study reported IgM positivity of 94% after day 14 and IgG positivity of 100% after day 14 in a smaller number of 16 patients [10]. The largest study from China of 285 patients reported IgM positivity of 94% by days 20–22 and IgG positivity of 100% by days 17–19 [28]. Different sample sizes and antibody assays may account for differing seroconversion rates, which merits further investigation in a large cohort over a longer period.

Serological testing is vital for determining the prevalence of infection in sero-surveys and as part of epidemiological investigations to understand transmission of clusters [29]. The timing of seroconversion may guide the timing of plasmapheresis for convalescent plasma [30, 31]. The role of antibodies in long-term immunity after infection needs further investigation.

Consistent with severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS), SARS-CoV-2 infection triggers a cytokine storm in a subset of patients with markedly increased levels of proinflammatory cytokines, chemokines, and growth factors [32, 33]. Notably, higher levels of IL-6, MCP-1, IP-10, IL-18, IL-1RA, PDGF-BB, HGF, VEGF-A, IL-12p70, and MIP-1α were associated with severe disease in our study. This robust induction of proinflammatory mediators indicates that innate immune cell responses and antiviral T-cell responses are responsible for SARS-CoV-2 pathogenesis in patients with COVID-19 [34]. In addition, elevation in growth factors, including HGF [35], PLGF-1 [36], and LIF [37], illuminates the repair mechanisms following acute lung injury during SARS-CoV-2 infection. Previous studies showed that ICU patients had more significant cytokine activation compared with non-ICU patients [1]. Our longitudinal cytokine profiling in ICU patients further evaluated prognostic values of specific cytokines. We observed better prognosis in critically ill patients with lower levels of acute lung injury–associated growth factors HGF and VEGF-A at the time of admission to the ICU. Our data suggest that the differences in degree of lung injury could reflect recovery rate of patients in the ICU. HGF and VEGF-A may serve as early indicators of poor prognosis and may provide guidance to make pre-emptive clinical decisions in critically ill patients.

A central role for IL-6 in lung injury has been postulated, with higher levels associated with mortality in 2 separate studies and severe immune-mediated injury in lung tissues of patients who died of COVID-19 [38, 39]. Similarly, the IL-1 pathway has been highlighted to contribute towards SARS-CoV-2 pathogenesis [40]. Importantly, our study highlighted the upregulation of IL-1 pathway mediators IL-18, MCP-1, and VEGF-A in critically ill patients, providing further evidence that dysregulation in the IL-1 pathway could contribute to the hyperinflammatory state, especially in fatal cases.

STRING analysis revealed potential protein-to-protein interactions in severe COVID-19 infection, in which IL-6 is the direct interacting partner of other cytokines associated with disease severity. Thus, several approved IL-6 receptor antagonists could be repurposed to treat severe SARS-CoV-2 infection. Given the elevated level of VEGF-A, Janus kinase (JAK) inhibitors should also be investigated as a potential therapeutic option [41, 42]. However, the serial data presented here indicate that the therapeutic window for intervention is narrow. Immune modulators will need to be active before the inflammatory cascade causing acute lung injury develops.

Our study has several limitations. Active case finding through contact tracing is likely to have identified the majority of symptomatic infections in Singapore over this time period. However, atypical or subclinical infections may have been missed. No infections were detected in children (<18 years) or residents of long-term-care facilities. Individuals were enrolled as soon as possible following admission, but while biological samples were collected serially, they were not all acquired at the same time point after symptom onset. Additionally, some laboratory data were incomplete, and clinical data such as date of symptom onset are subject to recall bias. We also did not investigate the effect of different SARS-CoV-2 lineages or mutations on study outcomes [43]. Finally, samples were processed consistently, but numerous factors determine the success of viral cultures and the correlation between culturability and infectiousness is unclear.

In conclusion, we found that virus viability was associated with lower PCR Ct values in early illness. This merits further investigation in terms of infectivity and infection control. SARS-CoV-2 IgM and IgG did not appear until days 15–21 of illness, with implications for the role of rapid diagnostic antibody assay and the timing of plasmapheresis for convalescent plasma. A stronger antibody response was associated with disease severity, suggesting a role in immune pathogenesis. Finally, the overactive proinflammatory immune signatures offer targets

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciaa1280/5898476 by guest on 20 March 2021

for host-directed immunotherapy, which should be evaluated in randomized controlled trials.

(See the Editorial Commentary by Binnicker on pages 2667–8.)

Background. Reverse-transcription polymerase chain reaction (RT-PCR) has become the primary method to diagnose viral diseases, including severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). RT-PCR detects RNA, not infectious virus; thus, its ability to determine duration of infectivity of patients is limited. Infectivity is a critical determinant in informing public health guidelines/interventions. Our goal was to determine the relationship between E gene SARS-CoV-2 RT-PCR cycle threshold (Ct) values from respiratory samples, symptom onset to test (STT), and infectivity in cell culture.

Methods. In this retrospective cross-sectional study, we took SARS-CoV-2 RT-PCR–confirmed positive samples and determined their ability to infect Vero cell lines.

Results. Ninety RT-PCR SARS-CoV-2–positive samples were incubated on Vero cells. Twenty-six samples (28.9%) demonstrated viral growth. Median tissue culture infectious dose/mL was 1780 (interquartile range, 282–8511). There was no growth in samples with a Ct > 24 or STT > 8 days. Multivariate logistic regression using positive viral culture as a binary predictor variable, STT, and Ct demonstrated an odds ratio (OR) for positive viral culture of 0.64 (95% confidence interval [CI], .49–.84; $P < .001$) for every 1-unit increase in Ct. Area under the receiver operating characteristic curve for Ct vs positive culture was OR, 0.91 (95% CI, .85–.97; $P < .001$), with 97% specificity obtained at a Ct of > 24.

Conclusions. SARS-CoV-2 Vero cell infectivity was only observed for RT-PCR Ct < 24 and STT < 8 days. Infectivity of patients with Ct > 24 and duration of symptoms > 8 days may be low. This information can inform public health policy and guide clinical, infection control, and occupational health decisions. Further studies of larger size are needed.

Keywords. SARS-CoV-2; COVID-19; RT-PCR; infectivity; public health.

The emergence of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the causative agent of coronavirus disease 2019 (COVID-19), represents a public health emergency of historic proportion. The global containment efforts have had broad societal and economic impacts. Policy decisions to relax public health measures will require a better understanding of duration of infectivity. This information will also impact infection control practices and occupational health.

To date, the diagnosis of COVID-19 has relied on the detection of SARS-CoV-2 through molecular detection. While this method is both rapid and highly sensitive, there are important limitations. Several studies describe the persistence of SARS-CoV-2 RNA within different body sites [1, 2]. It is known from other viruses that viral RNA can persist beyond infectivity [3, 4]. As a result, demonstration of in vitro infectiousness on cell lines is a more informative surrogate of viral transmission. The ability of viral culture to inform infectivity is an important aspect of diagnostics, but its use is hampered by its difficult and labor-intensive nature. This is further complicated by the need for Biosafety Level 3 facilities in the case of SARS-CoV-2. In a recent cohort study of 9 patients, no virus could be recovered beyond 7 days after symptom onset [1]. This important study is limited by the small number of patients examined and the fact that all 9 cases are linked; therefore, the data may represent a unique viral subpopulation. Here we add to the existing body of literature by presenting viral culture results on a larger cross-sectional group of patients, compared to polymerase chain reaction (PCR) data and time of symptom onset.

MATERIALS AND METHODS

SARS-CoV-2 Reverse-Transcription PCR Cycle Threshold Values and Symptom Onset to Test

All samples in this study were obtained to support routine care and surveillance of the public health response in the province of Manitoba, Canada. All suspected COVID-19 cases had

SARS-CoV-2 reverse-transcription PCR (RT-PCR) performed on nasopharyngeal (NP) or endotracheal (ETT) samples at Cadham Provincial Laboratory (CPL), the public health laboratory.

The NP swabs and ETT specimens in viral transport media were stored at 4°C for 24–72 hours until they were tested for the presence of SARS-CoV-2 RNA using real-time RT-PCR targeting a 122-nt portion of the Sarbecovirus envelope gene (E gene) [5]. Fifty-five microliters of RNA was extracted from 200 µL of a respiratory specimen using the Ambion AM1836 RNA kit (Thermo Fisher) paired with the Kingfisher Flex instrument (Thermo Fisher). The 20 µL reactions, comprised of TaqMan Fast Virus One-step master mix and 5 µL of RNA, were cycled for 5 minutes at 50°C, 20 seconds at 95°C followed by 40 cycles of 5 seconds at 95°C and 30 seconds at 58°C on a Bio-Rad CFX96 thermal cycler. RT-PCR results were analyzed with the CFX manager software (version 3.1).

Through public health and epidemiology/surveillance and laboratory records, date of symptom onset was determined. Time from symptom onset to RT-PCR, or symptoms to test (STT), was calculated based on laboratory records. For all positive samples, the cycle threshold (Ct) was obtained. The study was performed in accordance with protocol HS23906 (H2020:211), approved by the University of Manitoba Research Ethics Board.

Median Tissue Culture Infectious Dose Assay

Samples were stored at −80°C for between 2 and 4 weeks before being processed for culture. Viral titers of patient samples were determined through median tissue culture infectious dose ($TCID_{50}$) assays inside a Biosafety Level 4 laboratory. In brief, Vero cells (ATCC: CCL-81), maintained in modified Eagle's medium (MEM) supplemented with 5% fetal bovine serum (FBS), 1% penicillin/streptomycin, 0.5 µg/mL amphotericin B, and 1% L-glutamine, were seeded into 96-well plates (Thermo Scientific, 167008) at 70% confluency. Using dilution blocks, patient samples were serially diluted 10-fold from 10^{-1} to 10^{-8} in MEM supplemented with 2% FBS, 1% penicillin/streptomycin, 0.5 µg/mL amphotericin B, and 1% L-glutamine. Dilutions were placed onto the Vero cells in triplicate and incubated at 37°C with 5% carbon dioxide for 96 hours. Following incubation of 4 days, cytopathic effect was evaluated under a microscope and recorded. $TCID_{50}$ and $TCID_{50}$/mL were calculated using the Reed and Muench method previously described [6]

Statistical Methods

Data are presented as mean ± standard deviation for normally distributed data and as median with interquartile range (IQR) for nonnormally distributed data. *P* values are reported as 2-tailed. All statistical analysis was performed with Stata version 14.2 (StataCorp, College Station, Texas). Between-group comparisons were performed using a Student *t* test or Mann-Whitney test. Normality was assessed using the Kolmogorov-Smirnov test, and logistic regression was performed with robust standard errors.

RESULTS

A total of 90 samples were analyzed. Median age of the patients sampled was 45 (IQR, 30–59) years. Almost half (49%) of our samples were from males. SARS-CoV-2 was successfully cultivated from 26 (28.9%) of the samples. The samples included in this study included those positive for SARS-CoV-2 by RT-PCR from day of symptom onset (day 0) up to 21 days after symptom onset. Within this range of samples, positive cultures were only observed up to day 8 after symptom onset (Figure 1). Median Ct count of all samples was 23 (IQR, 17–32). The median $TCID_{50}$/mL was 1780 (IQR, 282–8511). Positive culture samples had a significantly lower Ct compared with culture-negative samples (17 [IQR, 16–18] vs 27 [IQR, 22–33]; $P < .001$; Figure 2). Symptom to test time was also significantly lower in culture-positive vs culture-negative samples (3 [IQR, 2–4] days vs 7 [IQR, 4–11] days; $P < .001$; Figure 2).

Multivariate logistic regression using positive culture as a predictor variable (binary result) and STT, age, and sex as independent variables showed Ct as being significant (odds ratio [OR], 0.64 [95% confidence interval {CI}, .49–.84]; $P < .001$). This implies that for every 1-unit increase in Ct, the odds of a positive culture decreased by 32%. Increasing symptom to test time was also significantly associated with a negative culture (OR, 0.63 [95% CI, .42–.94]; $P = .025$). For every 1-day increase in STT, the odds ratio of being culture positive was decreased by 37%. Receiver operating characteristic curves constructed using Ct vs positive culture showed an area of 0.91 (95% CI, .85–.97; $P < .001$) with 97% specificity obtained at a Ct of > 24. Similarly, STT vs positive culture showed an area of 0.81 (95% CI .73–.90; $P < .001$), with 96% specificity at > 8 days. The probability of successfully cultivating SARS-CoV-2 on Vero cell culture compared to STT is demonstrated in Figure 3. The probability of

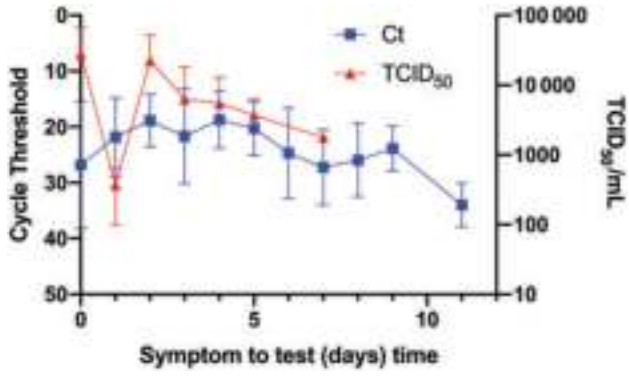

Figure 1. Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) viral dynamics as expressed by E gene reverse-transcription polymerase chain reaction cycle threshold (Ct) value and cell culture median tissue culture infectious dose ($TCID_{50}$)/mL, over time (days).

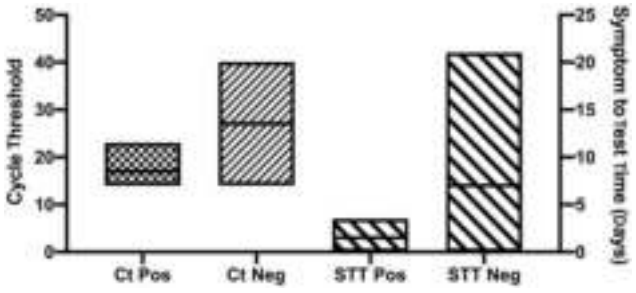

Figure 2. Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) E gene reverse-transcription polymerase chain reaction cycle threshold (Ct) values and symptom to test time (STT) in samples that were culture positive or negative. Positive SARS-CoV-2 culture samples had a significantly lower Ct compared with culture-negative samples (17 [interquartile range {IQR}, 16–18] vs 27 [IQR, 22–33]; $P < .001$). STT was also significantly lower in culture-positive vs culture-negative samples (3 [IQR, 2–4] days vs 7 [IQR, 4–11] days; $P < .001$).

obtaining a positive viral culture peaked on day 3 and decreased from that point.

DISCUSSION

PCR and other nucleic amplification (NA) strategies have surpassed viral culture as the gold standard viral diagnostic, because of their wider application, higher sensitivity, rapid performance, and ability for field deployment. A major drawback to PCR and other diagnostic approaches (including other NA, serology, and antigen detection) is that they all fail to determine virus infectivity; PCR sensitivity is excellent but specificity for detecting replicative virus is poor [7]. Our study utilized a cross-sectional approach to correlate COVID-19 symptom onset to specimen collection with SARS-CoV-2 E gene RT-PCR and virus viability as determined by cell culture.

These results demonstrate that infectivity (as defined by growth in cell culture) is significantly reduced when RT-PCR Ct values are > 24. For every 1-unit increase in Ct, the odds ratio for infectivity decreased by 32%. The high specificity of Ct and STT suggests that Ct values > 24, along with duration of symptoms > 8 days, may be used in combination to determine duration of infectivity in patients. Positive cell culture results in our study were most likely between days 1 and 5. This finding is consistent with existing literature [1, 2].

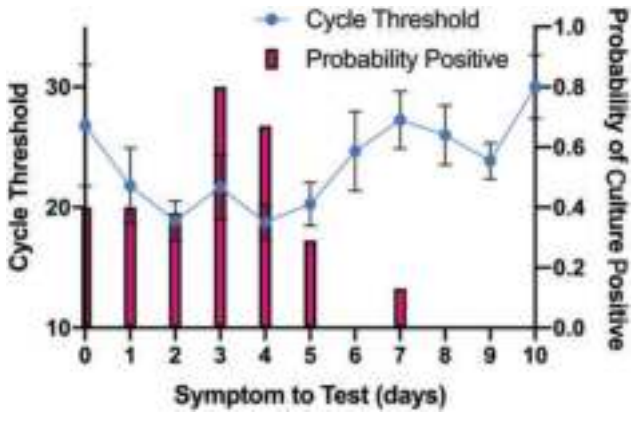

Figure 3. Comparison of symptom onset to test (days) to the probability of successful cultivation on Vero cells (Probability Positive) and severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) E gene reverse-transcription polymerase chain reaction cycle threshold (Ct) value.

This study is the first to report a large enough data set that demonstrates a link between in vitro viral growth, Ct value, and STT. These results have implications for clinical care, infection prevention and control, and public health. These data can be used to efficiently target case finding efforts by better defining the period of maximal transmission risk. This will be of particular importance in the maintenance phase of the response, where case finding efforts to rapidly interrupt chains of transmission will be essential. Isolation of COVID-19 cases in the community is typically recommended for at least 10 days after symptom onset. Our data supports this approach. Jurisdictions across Canada and the United States are recommending a variety of strategies to discontinue isolation of hospitalized COVID-19 cases [8–13]. Clinical criteria including 14 days from symptom onset or 72 hours symptom free (whichever is longer) are being used in some, while other jurisdictions are using 2 negative NP RT-PCR results 48 hours apart after 14 days of symptoms. Our data support the former approach since RT-PCR positivity persists significantly beyond infectivity; the alternative approach may lead to unnecessary isolation, and use of personal protective equipment and testing resources. The qualitative reporting of results of SARS-CoV-2 RT-PCR as positive or negative is sufficient for diagnosis but may be supplemented by Ct, a semiquantitative value, as well as time of symptom onset to guide infection control, public health, and occupational health decisions.

Our study has important limitations. First, our study utilized a single SARS-CoV-2 gene target (E gene). Though other gene targets may offer greater specificity, the SARS-CoV-2 E gene is more consistently used in both laboratory-developed tests and commercial assays. The testing criteria in Manitoba had sufficient pretest probability to make the likelihood of a false-positive remote. In addition, the first 71 of 90 samples were confirmed using the described protocol with the Centers for Disease Control and Prevention N1 gene target [14]. Second target confirmation was discontinued at that time based on being satisfied with testing criteria and assay sensitivity to accurately identify true COVID-19 cases. Reagent supply also played a role. Second, the recall bias of symptom onset is possible, but this likely would have been equally distributed between those who were culture positive and negative. Third, the infectivity of certain individual cases and the accuracy of our culture assay may have unique variations. Though some individuals in our cross-sectional study would be considered immunocompromised, patients with these conditions could have prolonged shedding of infective SARS-CoV-2 and may not be

Downloaded from https://academic.oup.com/cid/article/71/10/2663/5842165 by guest on 20 March 2021

fully represented here. Few children have been diagnosed with COVID-19 in our province (median age of positive PCR, 45 [IQR, 30–59] years). With other respiratory viruses, children may have prolonged shedding. Finally, our patient numbers remain small and larger studies are needed to establish Ct criteria that reliably correlate with loss of infectivity and that utilize additional SARS-CoV-2 gene targets.

In conclusion, the SARS-CoV-2/COVID-19 pandemic represents a dynamic situation where decisions and policy must be guided by evidence. Our study showed no positive viral cultures with a Ct > 24 or STT > 8 days. The odds of a positive culture were decreased by 32% for each unit increase in Ct. These data, if confirmed, may help guide isolation, contact tracing, and testing guidelines.

Notes

Acknowledgments. This work was supported by the collaborative efforts in the public health response to the current pandemic by Manitoba Health and Cadham Provincial Laboratory (CPL), and the Public Health Agency of Canada and the National Microbiology Laboratory. A special acknowledgment goes to the medical laboratory technologists in the Virus Detection Section of CPL. We would be blind without you.

EDITORIAL COMMENTARY

Can the Severe Acute Respiratory Syndrome Coronavirus 2 Polymerase Chain Reaction Cycle Threshold Value and Time From Symptom Onset to Testing Predict Infectivity?

Matthew J. Binnicker

Division of Clinical Microbiology, Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, Minnesota, USA

(See the Major Article by Bullard et al on pages 2663–6.)

Keywords. SARS-CoV-2; PCR; cycle threshold; infectivity; COVID-19.

To curb the spread of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), a 3-pronged strategy is recommended, which consists of testing, isolating those who are infected, followed by contact tracing. To date, the vast majority of testing for SARS-CoV-2 has been performed using real-time polymerase chain reaction (PCR). This diagnostic tool is inherently sensitive, but positive results may be due to the presence of active, replicating virus or residual viral nucleic acid (ie, noninfectious virus). Despite this important limitation, real-time PCR is commonly being used as a "test of cure" following a diagnosis of coronavirus disease 2019 (COVID-19). For symptomatic patients, the US Centers for Disease Control and Prevention recommends either a symptom- or test-based strategy to guide decisions regarding the discontinuation of transmission-based precautions (ie, isolation). When following a test-based strategy, the criteria for discontinuing isolation requires negative results for SARS-CoV-2 RNA from at least 2 consecutive respiratory samples collected ≥24 hours apart [1]. Although this is a conservative approach, it has been justified during the early stages of the COVID-19 pandemic due to the lack of data on the period of infectivity of SARS-CoV-2, as well as the significant repercussions associated with discontinuing transmission-based precautions prior to confirming that an individual is no longer infectious. However, this strategy has increased the use of limited resources (eg, tests, swabs, transport media), has led to some patients testing positive for weeks following their initial diagnosis [2, 3] and, therefore, has significantly extended the period of isolation and/or quarantine for many individuals.

In this issue of *Clinical Infectious Diseases*, Bullard et al [4] assessed the correlation of the real-time PCR cycle threshold (Ct) value, as well as the time from symptom onset to testing, with growth of SARS-CoV-2 in cell culture. The study included 90 samples (nasopharyngeal swabs and endotracheal specimens in viral transport media) that were positive for SARS-CoV-2 RNA by a real-time PCR assay targeting the Sarbecovirus envelope (E) gene [5]. Among the 90 samples that were inoculated into a Vero cell culture line, a cytopathic effect consistent with SARS-CoV-2 was observed in 26 (28.9%) cases. Notably, positive cultures were not observed in samples collected from patients with >8 days of symptoms, and a PCR Ct value >24 showed a strong correlation with reduced recovery of SARS-CoV-2 in cell culture. If confirmed, these results add to our growing understanding of the period of SARS-CoV-2 infectivity and have important implications on isolation, quarantine, and return-to-work decisions. However, there are several significant limitations that should be carefully considered when interpreting the results.

First, Bullard et al tested for SARS-CoV-2 RNA using a single real-time PCR assay targeting the E gene of the virus. The data suggest that SARS-CoV-2 infectivity was reduced when the Ct value was >24, and that for every single unit increase in the Ct, the odds ratio for recovering the virus in cell culture decreased by 32%. Although real-time PCR Ct values can be used to estimate the relative concentration of target nucleic acid in clinical samples, Ct values are not interchangeable between assays. The PCR Ct value can be impacted by the assay's gene target(s) and by factors affecting the efficiency of the PCR reaction, including the nucleic acid extraction system and PCR amplification chemistry. Prior studies have demonstrated that Ct values may vary by up to 5 cycles when the same samples are tested by different assays [6, 7]. Interestingly, a recent report by La Scola et al [8] assessed the correlation of SARS-CoV-2 isolation in cell culture with real-time PCR Ct values. In this study, inoculation of 183 respiratory samples

(nasopharyngeal swabs [n = 174], sputum [n = 9]) into a Vero E6 cell line yielded detectable cytopathic effect in 129 (70.5%) cases. As expected, culture positivity declined with increasing PCR Ct values, and SARS-CoV-2 was not isolated in culture from any sample that had a PCR Ct value ≥ 34. These data highlight that despite the same PCR gene target being used, the Ct value threshold correlating with SARS-CoV-2 culture positivity may vary significantly between tests. Therefore, Ct value criteria must be established by each healthcare institution.

A second key consideration when interpreting the results from Bullard et al is that samples were stored at −80°C for up to 4 weeks prior to being inoculated in cell culture. Although storage of clinical samples at temperatures ≤ −70°C has been shown to maintain infectivity of other human coronaviruses [9], it is important to emphasize that we do not yet fully appreciate all of the factors that may influence the recovery of SARS-CoV-2 in cell culture. Furthermore, we do not yet know what percentage of COVID-19 patients are culture positive, since the overall number of patients with confirmed disease who have had viral culture performed is exceedingly small. Due to its low sensitivity for recovery of other respiratory viruses (eg, influenza), cell culture has been discontinued in most clinical laboratories and replaced by molecular testing. Therefore, we should be hesitant to conclude that a negative viral culture equates to a lack of SARS-CoV-2 infectivity. In the study by La Scola et al [8], growth of SARS-CoV-2 in 5 cases was only accomplished following blind subculture, suggesting there was a low amount of replicating virus in these samples, which may have been missed if blind passage had not been performed. Due to these challenges, future studies incorporating viral culture should be designed to optimize the recovery of SARS-CoV-2 by inoculating cell lines as soon as possible following collection. If prolonged specimen storage is required, positive controls containing low viral titers (ie, SARS-CoV-2 whole virus spiked into representative specimen matrices) should be included and stored under the same conditions as clinical samples prior to culture. This will help control for the potential impact of prolonged storage on the recovery of SARS-CoV-2.

Despite these limitations, the study by Bullard et al provides informative data on the period of infectivity of SARS-CoV-2, and helps to confirm that PCR positivity is likely not a reliable surrogate marker for determining the infectious status of COVID-19 patients. Along with recent data emerging from South Korea [10] and Singapore [11], these results suggest that the period of SARS-CoV-2 infectivity is likely highest during the first week of illness, and subsequently declines between days 8 and 11 after onset of symptoms. Together, these data should help inform testing guidelines and isolation policies. Future studies are needed to confirm these observations, and should include a combination of testing by multiple real-time PCR assays, carefully controlled viral culture studies, and contact tracing to define which factors can be used to reliably predict the infectious status of patients with COVID-19.

Summary

The reliability of RT-qPCR for assessing infectious potential of Covid-19 positives is defined by testing reference and culture specimens and their relation to patient characteristics (date and severity of symptoms, medical history) and test factors (cycle threshold).

ABSTRACT:

Objective to review the evidence from studies relating SARS-CoV-2 culture with the results of reverse transcriptase polymerase chain reaction (RT-PCR) and other variables which may influence the interpretation of the test, such as time from symptom onset

Methods We searched LitCovid, medRxiv, Google Scholar and the WHO Covid-19 database for Covid-19 to 10 September 2020. We included studies attempting to culture or observe SARS-CoV-2 in specimens with RT-PCR positivity. Studies were dual extracted and the data summarised narratively by specimen type. Where necessary we contacted corresponding authors of included papers for additional information. We assessed quality using a modified QUADAS 2 risk of bias tool.

Results We included 29 studies reporting attempts at culturing, or observing tissue infection by, SARS-CoV-2 in sputum, nasopharyngeal or oropharyngeal, urine, stool, blood and environmental specimens. The quality of the studies was moderate with lack of standardised reporting. The data suggest a relationship between the time from onset of symptom to the timing of the specimen test, cycle threshold (Ct) and symptom severity. Twelve studies reported that Ct values were significantly lower and log copies higher in specimens producing live virus culture. Two studies reported the odds of live virus culture reduced by approximately 33% for every one unit increase in Ct. Six of eight studies reported detectable RNA for longer than 14 days but infectious potential declined after day 8 even among cases with ongoing high viral loads. Four studies reported viral culture from stool specimens.

Conclusion

Complete live viruses are necessary for transmission, not the fragments identified by PCR. Prospective routine testing of reference and culture specimens and their relationship to symptoms, signs and patient co-factors should be used to define the reliability of PCR for assessing infectious potential. Those with high cycle threshold are unlikely to have infectious potential.

Keywords: Covid-19; mode of transmission, viral culture; symptom onset to test date; polymerase chain reaction; SARS-CoV-2; infectious potential.

Introduction

Effective prevention and management of SARS-CoV-2 infections relies on our capacity to identify those who are infected or potentially infectious. In the absence of predictive clinical signs or symptoms, the major means of detection is testing using Reverse Transcriptase quantitative Polymerase Chain Reaction (RT-qPCR) [1, 2, 3]

The test amplifies genomic sequences identified in specimens, and is highly sensitive, being capable of generating observable signals from specimens containing minute amounts of matching genomic sequence. Amplification of genomic sequence is measured in cycle thresholds (Ct), each cycle being a cut off for positive detection. There may be a correlation between Ct values from respiratory specimens, symptom onset to test (STT) date and positive viral culture. Evidence suggests the lower the Ct value and the shorter the STT, the higher the infectious potential. [4] If this is so, we should be able to identify those with the highest infectious potential.

Identification of a whole virion (as opposed to fragments) and proof that the isolate is capable of replicating its progeny in culture cells is the closest we are likely to get to a gold standard. [5] RT-qPCR cannot distinguish between the shedding of live virus or of viral fragments with no infectious potential, and it cannot measure the quantity of live virus present in a person's excreta. Although viral culture is difficult, time consuming and requires specialised facilities it potentially represents the best indicator of infection and infectious potential. We, therefore, set out to review those studies attempting viral culture, regardless of specimen type tested. We investigated the probability of successful culture with time from symptom onset to test and cycle threshold. We also examined the relationship between specimen cycle threshold and infectious potential.

Methods

We searched four databases: LitCovid, medRxiv, Google Scholar and the WHO Covid-19 database, using the terms 'viral culture' or 'viral replication' and associated synonyms on 10 September 2020. For relevant articles, citation matching was undertaken and relevant results identified.

We included studies reporting attempts to culture SARS-CoV-2 and those which also estimated the potential infectivity of the isolates or observed tissue infection by SARS CoV-2 and related them to other clinical variables such as date of symptom onset to test and patient characteristics.

Isothermal methods of detection are not included in our review, as they do not provide a Ct value

One reviewer extracted data for each study and a second reviewer checked the extraction. Heterogeneity and lack of detail of some of the reported data in the included studies prevented pooling. We tabulated data and summarised it descriptively by specimen: fecal, respiratory,

Accepted Manuscript

environment or mixed. Where possible, we also reported the duration of detectable RNA and the relationship of PCR cycle threshold and log 10 copies to positive viral culture.

Where necessary we contacted corresponding authors of the cited papers for additional information. We assessed quality using the QUADAS 2 risk of bias tool, simplified because the included studies were not designed as primary diagnostic accuracy studies. [6] Our methods are more fully described in our protocol (published on the 4th of July and updated on 5th of October 2020). [7]

Results

We identified 145 possible articles for inclusion and after screening, 29 full texts were read and included (see PRISMA [8] flow chart - Figure 1)**.** One unpublished study was not included as no permission was given by the authors. The included studies were published in 30 articles (see web appendix references w1-w29), four of which were in pre-print servers. The characteristics of each study are shown in Table 1. All included studies were case series of **moderate quality** (Table 2. Quality of included studies). We could not identify a protocol for any of the studies. All had been made public in 2020. We received five author responses regarding clarifying information (see Acknowledgments).

Studies using fecal specimens

Nine studies assessed viral viability from fecal specimens positive for SARS-CoV-2 based on RT-PCR result [W10, W11, W13, W17, W22, W23, W25-W27] One study reported infecting ferrets with stool supernatant; [w10] two reported visual growth in tissue [w19, w22[and four reported achieving viral replication [w13, w23, w24, w26]. In one further study, methods were unclear.[W28]

Studies using respiratory specimens

Seventeen studies reported attempting viral isolation and culture from respiratory specimens [W3, W4, W6-10, W13-16, W18, W21-23, W26, W27] One study successfully cultured 26/90 nasopharyngeal specimens: positive cultures were observed only up to day eight post-symptom onset; [w7] another study obtained cultures from 31/46 nasopharyngeal and oropharyngeal specimens. [w3] The largest study came from the La Scola group publications [w15] with positive cultures of 1,941 from 3,790 specimens. Another study of UK health care workers during a period of low viral circulation isolated SARS Cov-2 from 1/19 specimens. [w5]

Two more studies reported a clear correlation between symptoms onset, date of sampling, Ct and likelihood of viral culture. [w18, w21]

Accepted Manuscript

One study [w14] of nasopharyngeal specimens from 638 patients aged <16 years reported achieving culture from 12 (52%) of the 23 who tested positive for SARS CoV-2 with a Ct of around 28. Gniazdowski [w8] assessed RNA and infectious virus detection in 161 nasopharyngeal specimens from hospitalised Covid-19 patients. Positive culture was associated with Ct values of 18.8 ± 3.4 (median 18.7); negative culture was associated with mean Ct values 27.1 ± 5.7 (median 27.5). Over 90% of the virus isolates were obtained from specimens with a Ct value below 23

Basile [w4] reported 24% culture positivity, with specimens significantly more likely to be positive from ICU. A report by the Korean Centres for Disease Control failed to grow live viruses from 108 respiratory specimens from "re-positives" i.e. people who had tested positive after previously testing negative.[w12]

Ladhani [w16] and colleagues reported a successful culture rate of 87/158 RT-PCR positive naso-pharyngeal specimens from six nursing homes in London.

Studies using environmental specimens

Two possible (the text is unclear) positive cultures were obtained from 95 environmental specimens in one study that assessed aerosol and surface transmission potential of SARS-CoV-2 [w20]. No viruses could be grown from specimens from seven areas of a large London hospital from specimens with a cut-off RT-PCR Ct > 30. [w29]

Ahn and colleagues [w1] failed to grow live virus from an unspecified number of air specimens from isolation rooms of patients with severe Covid-19, but were able to grow virus from swabs of handrails, and the external surfaces of intubation cannulae.

Mixed sources

Some studies labelled as mixed source specimens are also reported by indvidual specimen in this text.

Eight studies reported viral culture from mixed sources: 12 oropharyngeal, nine nasopharyngeal and two sputum specimens [w9], one stool specimen and an unreported number of other specimens[w10], from saliva, nasal swabs, urine, blood and stool collected from nine Covid-19 and a possible

Accepted Manuscript

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciaa1764/6018217 by guest on 14 March 2021

specimen stool culture [[w23], nine nasopharyngeal, oropharyngeal, stool, serum and urine specimens [w13], seven sputum specimens, three stool specimens and one nasopharyngeal specimen of 11 patients. [w26] . In this study all specimens had been taken within 5 days of symptom onset and there was a relationship between copy thresholds and cytopathic effect observed in infected culture cells.

Kim and colleagues reported no viral growth from an unclear number of serum, urine and stool specimens, despite these specimens being collected soon after admission [w11] . Lu and colleagues also reported no viral growth, however their specimens were from 87 cases tested "re-positive". [w17]

One study [w27] reported 21 positive cultures from from naso-pharyngeal specimens of 19 hospitalised patients in Singapore but no growth from specimens with a Ct value >30, or collected >14 days after symptoms onset. No culture was achieved from the urine or stool specimens.

Blood cultures

In one study by Andersson [w2] et al 20 RT-PCR positive serum specimens from 12 individual patients were selected at random from a Covid-19 specimen bank at 3 to 20 days following onset of symptoms. None of the 20 serum specimens produced a viral culture.

Post mortem study

One study on alveolar specimens from 68 elderly deceased reported postmortem studies on lung tissues from six cases were available for viral isolation. The evaluation showed viable SARS-CoV-2 in all six cases - in one case on day 26 from symptom onset. [w6]

Duration of RNA viral detection

Table 3 shows that nine studies report on the duration of viral RNA detection as assessed by PCR for SARS-CoV-2 RNA. [w7, w8, w10, w12, w13, w21, w24, w25, w27] All nine studies reported RNA detection for longer than 7 days. Young et al [w27] reported that SARS-CoV-2 was detectable from nasopharyngeal swabs by PCR up to 48 days after symptom onset.

Live viral culture window

The live viral culture time window was much shorter than for viral RNA identification, ranging from less than 8 days from symptom onset to test [w23] and Ct < 24 [w7]. Median duration of viral RNA identification in culture was 4 days (InterQuartile Range: 1 to 8) [w21].

Accepted Manuscript

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciaa1764/6018217 by guest on 14 March 2021

The relationship between RT-PCR results and viral culture of SARS-CoV-2

Table 4 shows that ten studies analysed the relationship between Ct values and the possibility of culturing live virus [w4, w5, w7, w8, w9 w15, w16, w21, w23, w27] and three quantified the mean log copies of detected virus and live culture [w9, w14, w18]. All reported that Ct were significantly lower and log copies were significantly higher in those with live virus culture. Five studies reported no growth in specimens based on a Ct cut-off value [w5, w7, w9, w16, w27] ranging from CT > 24 [w7] to 35 [w15].

The estimated probability of recovery of virus from specimens with Ct > 35 was 8.3% (95% CI: 2.8% to 18.4%)[w21]. All donors above the Ct threshold of 35 (n=5) producing live culture were symptomatic.

In six London nursing homes there was no correlation between Ct values and symptoms in either residents or staff, [w16] although nearly 50% of both categories were asymptomatic.

One study [w9] reported different cut-off thresholds depending on the gene fragment analysed[34]. No growth was found for the NSP 12 fragment at Ct > 31.5, whereas the value was higher for the N gene fragment (>35.2).

The odds for culturing live virus decreased by 0.64 for every one unit increase in Ct (95%CI 0.49 to 0.84, p<0.001) [w7]; another study[w21] reported similar results in line with empirical evidence of an increased Ct of 0.58 per day since symptoms started. [9]

Discussion

The studies in this review attempted, and some successfully achieved, culture of SARS-CoV-2 in the laboratory, using a range of different specimens. There is evidence of a positive relationship between lower cycle count threshold, likelihood of positive viral culture and date of symptom onset. [10] This is seen clearly in the two studies assessing the infectious potential of "re-positives", i.e. COVID-19 cases who had been discharged from hospital after testing negative repeatedly and who then tested positive again after discharge: Lu 2020 [w17] , Korean CDC [w12].

Lu and colleagues considered four hypotheses for the origin of "re-positives" [w17]. On the basis of their evidence they discarded re-infection and latency as explanations, and concluded that the most plausible explanations were either contamination of the specimen by extraneous material or

Accepted Manuscript

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciaa1764/6018217 by guest on 14 March 2021

identification in the specimen of minute and irrelevant particles of dead SARS-CoV-2 representing virus long neutralised by the immune system.

Rapid expansion in testing capability requires training protocols and precautions to avoid poor laboratory practice which may not be possible in the time pressure of a pandemic. The evidence in this review shows that those with high cycle threshold are unlikely to have infectious potential.

Interpreting the results of RT-PCR requires consideration of patient characteristics such as symptoms and their severity, contacts history, presence of pre-existing morbidities and drug history, the cycle threshold value, the number of days from symptom onset to test and the specimen donor's age.[11 12]

Several of our included studies assessed the relationship of these variables and there appears to be a time window during which RNA detection is at its highest with low cycle threshold and higher possibility of culturing a live virus, with viral load and probability of growing live virus of SARS-CoV2 peaking much sooner than that of SARS CoV-1 or MERS-CoV.[11] We propose that further work should be done on this with the aim of constructing an algorithm for integrating the results of PCR with other variables, to increase the effectiveness of detecting infectious patients.

PCR should be continuously calibrated against a reference culture in Vero E6 cells in which cytopathic effect has been observed [w6]. Confirmation of visual identification using methods, such as an immunofluorescence assay may also be needed to aid diagnosis. [13] Henderson and colleagues have called for a multicentre study of all currently manufactured SARS-CoV-2 nucleic acid amplification tests to correlate the cycle threshold values on each platform for patients who have positive and negative viral cultures. Calibration of assays could then be done to estimate virus viability from the cycle threshold with some certainty. [14]

Ascertainment of infectious potential is all the more important as there is good evidence of viral RNA persistence across a whole range of different viral diseases with little or no infectious potential in the post infectious phase of MERS,[15] measles,[16] other coronoviridae, HCV and a variety of animal RNA viruses.[17]

In one COVID-19 (former) case, viral RNA was detectable until day 78 from symptoms onset with a very high Ct [18] but no culture growth, implying a lack of infectious potential.

SARS CoV-2 methods of cell culture vary and to our knowledge have not been standardised. Methods vary depending upon the selection of the cell lines; the collection, transport, and handling of and the maintenance of viable and healthy inoculated cells. [19] We therefore urgently recommend the development of standard culture methods and external quality assessment schemes for laboratories offering testing for SARS CoV2. [20 21] If identification of viral infectious potential relies on

Accepted Manuscript

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciaa1764/6018217 by guest on 14 March 2021

visual inspection of cytopathogenic effect, then a reference culture of cells must also be developed to test recognition against infected cells. Viral culture may not be appropriate for routine daily results, but specialized laboratories should use viruses as controls, perform complete investigations when needed, and store representative clinical strains whenever possible. [22] Current evidence is too limited to establish the feasibility of generating a universal cycle threshold value as this may change with circumstances (e.g. hospital, community, cluster and symptom level), laboratory methods, so more information is urgently needed [23].

We suggest the WHO produce a protocol to standardise the use and interpretation of PCR and routine use of culture or animal model to continuously calibrate PCR testing, coordinated by designated Biosafety Level III laboratory facilities with inward directional airflow.[24] Further studies with standardised methods [25] and reporting are needed to establish the magnitude and reliability of this association.

The results of our review agree with the scoping review by Byrne and colleagues on infectious potential periods [26] and those of the living review by Cevick and colleagues[11]. The authors reviewed 79 studies on the dynamics, load and RNA detection for SARS CoV-1, MERS and SARS CoV-2 from symptoms onset. They concluded that although SARS-CoV-2 RNA identification in respiratory (up to 83 days) and stool (35 days) can be prolonged, duration of viable virus is relatively short-lived (up to a maximum of 8 days from symptoms onset). Those results are consistent with Bullard et al who found no growth in specimens with a cycle threshold greater than 24 [w7] or when symptom onset was greater than 8 days, and Wölfel et al [w23] who reported that virus could not be isolated from specimens taken after day 8 even among cases with ongoing high viral loads. The review by Rhee and colleagues reaches conclusion similar to ours.[10]

The importance of symptom onset and reported PCR threshold is shown in a study that collected test data during a prospective household transmission study. The authors found that Ct values were lowest soon after symptom onset and correlated with time elapsed since symptom onset (within 7 days after symptom onset, the median Ct value was 26.5 compared with a median of 35.0 21 days after onset). Ct values were significantly higher among those participants reporting no symptoms, and lower in those reporting upper respiratory symptoms at the time of specimen collection.[28]

The evidence is increasingly pointing to the probability of culturing live virus being related to the amount of viral RNA in the specimen and, therefore, inversely related to the cycle threshold. Thus, detection of viral RNA *per se* cannot be used to infer infectiousness. Duration of excretion may also be linked to age, male gender and possibly use of steroids and severity of illness.

Accepted Manuscript

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciaa1764/6018217 by guest on 14 March 2021

Our review is limited by the lack of standardised reporting and lack of standard testing methods amongst the included studies[20]. Ct threshold reporting was inconsistent, preventing pooling or further in-depth analysis of the data, and insufficient clinical details were reported to define the possible role of asymptomatics or pre-symptomatics in transmission. The included studies were case reports or case series with a mixture of laboratory and clinical data, and variable in reporting the relation between donor characteristics and PCR results.

We may have missed some studies or new studies as they are published and we aim to update this review with emerging evidence.

Conclusion

The evidence gathered in this review points to a relationship between the time from collection of a specimen to test, cycle threshold, and symptom severity. We recommend that a uniform international standard for reporting of comparative SARS-CoV-2 culture with index test studies be produced. Particular attention should be paid to the relationship between the results of testing, clinical conditions and the characteristics of the source patients, description of flow of specimens and testing methods. Defining cut off levels predictive of infectious potential [27]should be feasible and is necessary for diagnosing viral respiratory infections using molecular tests.

Accepted Manuscript

Table 1 Characteristic of Included Studies

Study [ref id]	Specimens (source)	Specimens (n) [SST]	Culture methods	Culture Positive	Additional notes
Ahn 2020 [W1]	Air and surfaces of isolation room of 3 patients with severe Covid 19	48 [not reported]	Only positive samples (Ct value ≤35 for the RdRp and E genes) were cultured in Vero E6 cells 10-fold dilutions of the SARS-CoV-2 supernatants from the environmental specimens was used. The inoculated cultures were grown in a humidified 37°C incubator with 5% CO2. After 72 hours, areas of cell clearance with crystal violet staining were used to demonstrate the cytopathic effect. In the presence of cytopathic effect was observed, detection of nucleic acid of SARS-CoV-2 by rRT-PCR in the supernatant was performed to confirm a successful culture.	External surfaces of intubation cannulae and surfaces in the room of patient not intubated	No air specimens grew virus Ct values of specimens who grew virus were uniformly low below 30 except in one case.
Andersson 2020 [W2]	20 RT-PCR positive serum specimens, selected at random from a Covid-19	20 serum specimens from 12 hospitalised	Specimens VC01-20 were provided blinded for viral culture experiments. 50 µL aliquots of specimens VC1-VC20 were separately added to 2.4 x 105 Vero E6 cells in 24-well plates.	0 / 20 these serum specimens produced positive viral culture	Serum specimens.

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciaa1764/6018217 by guest on 14 March 2021

	specimen bank, representing specimens from 12 individual patients (four individuals were represented at two timepoints), collected at 3 to 20 days following onset of symptoms.	Covid-19 patients	Cells were propagated in DMEM supplemented with 10% FBS. Virus growth assays were done in DMEM supplemented with 1% FBS, glutamine and penicillin/streptomycin, according to published methods. In parallel, wells of the same number of cells were cultured in triplicate without virus challenge but with 50 µL control serum (VC21), or in duplicate with a stock of Victoria/01/2020 SARS-CoV-2 passage 4 (Oxford) at calculated ten-fold serial dilutions per well of 78, 7.8, 0.78 and 0.078 plaque forming units (pfu) in 50 µL of control serum (VC21). Wells were observed daily for cytopathic effects (CPE), and 50 L specimens were taken for vRNA extraction on day 3 post-challenge. On day 4, 50 L aliquots of supernatants from cells challenged with VC01-20 were “blind passaged” to fresh cells, and the remaining supernatants were harvested and stored separately at -80C for future analysis. After a further 3 days, CPE was recorded, if any, for second passage cultures.		
Arons 2020 [W3]	nasopharyngeal and oropharyngeal swabs	48 rRT-PCR–positive specimens [For asymptomatic median 4 days, Ct 23.1]	All rRT-PCR positive specimens shipped to USA CDC for viral culture using Vero-CCL-81 cells. Cells showing cytopathic effects were used for SARS-CoV-2 rRT-PCR to confirm isolation and viral growth in culture.	31 [no relation to symptoms presence. Culturable virus isolated from 6 days before to 9 days after symptom onset]

Basile 2020 [W4]	234 specimens, 228 (97%) from the upper respiratory tract (sputum, naso pharyngeal swabs, bronchial lavage from 195 individuals with Covid-19.	Specimens from routine laboratory tests or from patients admitted to ICU or from a physician request [mean 4.5 days, 0-18, only one day to day 18]	Probes targets for PCR included E, RdRp, N, M, and ORF1ab for specimens from ICU patients and 1 to 4 E, RdRp, N and Orf1ab for all other specimens. After stabilization at 4 degrees centigrade specimens were inoculated into Vero E6 cells and incubated at 370C in 5% CO2 for 5 days (day 0 to 4). Cultures were observed daily for cytopathic effect (CPE). CPE when it occurred took place between days 2 and 4. Day 4 was chosen for terminal sampling.	Culture positivity rate was 56 (24%) and significantly more likely positive in ICU patients compared with other inpatients or outpatients and significantly more likely positive in specimens from inpatients	The highest Ct value with a successful culture was 32 (N gene target). A Ct cut-off of ≥37 was not indicative of viable virus
Borczuk 2020 [W5]	Post mortem lung tissue from 68 elderly deaths (median age 73)	Six	When a cytopathic effect was seen, the Vero cell culture supernatant was passed to a fresh Vero cell culture tube to ensure reproducibility. SARS-CoV-2 in the supernatant was further confirmed by RT-PCR	6	No ct reported. In one case virus grew on day 26 from symptoms kick off
Brown 2020 [W6]	Combined viral throat and nose swab from each participant n=1,152	Health care workers in six UK hospitals	Specimens were sent on the same day for detection of SARS-CoV-2 RNA by RT-PCR to the PHE national reference laboratory (five hospitals) or one hospital laboratory. The PHE laboratory used an Applied Biosystems 7500 FAST system targeting a conserved region of the SARS-CoV-2 open reading frame (ORF1ab) gene. The hospital laboratory used a different CE-IVD kit, targeting 3 SARS-CoV-2 genes (RdRp, E, and N). Both PCRs had	SARS-CoV-2 virus was isolated from only one (5%) of nineteen cultured specimens. It had a Ct value of 26.2.	Symptoms in the past month were associated with threefold increased odds of testing positive (aOR 3.46, 95%CI 1.38 to 8.67; p = 0.008). 23 of 1,152 participants

Accepted Manuscript

			internal controls. Viral culture of PHE laboratory positives was attempted in Vero E6 cells with virus detection confirmed by cytopathic effect up to 14 days post- inoculation.		tested positive (2.0%) with a median Ct of 35.70 (IQR:32.42 to 37.57).
Bullard 2020 [W7]	Nasopharyngeal (NP) or endotracheal (ETT) from COVID-19 patients (mean age 45 years)	90 [0 to 7 days]	NP swabs and ETT specimens in viral transport media were stored at 4°C for 24-72 hours until they were tested for the presence of SARS-CoV-2 RNA using real-time RT-PCR targeting a 122nt portion of the envelope gene (E gene). Dilutions were placed onto the Vero cells in triplicate and incubated at 37°C with 5% CO2 for 96 hours. Following incubation of 4 days, cytopathic effect was evaluated under a microscope and recorded.	26	The range of symptoms onset to negative PCT was 21 days. Within this period, positive cultures were only observed up to day 8 post symptom onset
Gniazdowski 2020 [W8]	161 probably nasopharyngeal specimens	161 cases with positive PCR [not reported]	Ct values were calculated of only one gene target per assay: the Spike (S) gene for the RealStar® SARS-CoV-2 and the nonstructural protein 101 (Nsp) 2 gene for the NeuMoDx™ SARS-CoV-2 assays. Genome sequencing was carried out. Incubation of the inoculum in VeroE6 cells cultured at 37°C was observed for 4 days for cytopathic effect and immunofluorescence used to identify viral presence	Unclear possibly 47 isolates	Positive culture was associated with Ct values of 18.8 ± 3.4. Infectious viral shedding occurred in specimens collected up to 20 days after the first positive result in symptomatics. Mean and 184 median Ct values associated with recoverable virus were 18.8 ± 3.4 and 18.17 respectively, which

Accepted Manuscript

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciaa1764/6018217 by guest on 14 March 2021

					was significantly lower than the mean and median Ct values that did not correlate with infectious virus recovery: 27.1 ± 5.7 and 27.5 respectively. PCR results should be interpreted alongside symptoms
Huang 2020 [W9]	Oropharyngeal (OP) or nasopharyngeal (NP) swabs, or sputum (SP)	60 specimens from 50 cases [3,4 days mean but see table 1 for freeze thaw cycles delays]	SARS-CoV-2 cDNA was prepared using RNA extracted from the specimens of the first patient with confirmed COVID-19. RT was performed using the MMLV Reverse transcription kit. All procedures for viral culture were conducted in a biosafety level-3 facility. Vero-E6 and MK-2 (ATCC) cells were maintained in a virus culture medium and the cells were maintained in a 37°C incubator with daily observations of the cytopathic effect.	Obtained 23 isolates from different specimen types (12 from OP, nine from NP, and two from SP).	Specimens with high copy numbers of the viral genome, indicative of higher viral load, were more likely to be culturable.
Jeong 2020 [W10]	Naso/oropharyngeal swabs, saliva, urine, and stool	5 patients	Specimens positive by qPCR were subjected to virus isolation in Vero cells. Urine and stool specimens were inoculated intranasally in ferrets and they evaluated the virus titers in nasal washes on 2, 4, 6, and 8 days post-infection (dpi). Immunofluorescence antibody assays were also done.	Naso/ oropharyngeal saliva, urine and stool Specimens were collected between days 8 to 30 of the clinical course. Viable SARS-CoV-2 was isolated from 1 naso / oropharyngeal swab. Ferrets inoculated with patient urine or stool were	Viral loads in urine, saliva, and stool specimens were almost equal to or higher than those in naso / oropharyngeal swabs. After symptom resolution, patients shed viable virus in their saliva and urine up to day 15 of illness.

Accepted Manuscript

				infected. SARS-CoV-2 was isolated from the nasal washes of the 2 urine-treated ferrets and one stool-treated ferret	
Kim 2020 [W11]	Unclear. Possibly 323 serum 247 urine and 129 stool specimens	74 COVID-19 hospital patients	RT-PCR was performed on the target genes were E and RdRp. Cell culture was performed in a Level III facility by inoculum into CaCo-2 cell line after stabilisation at 4C and harvested after 5 days and the supernatant after centrifugation was re-inoculated for another 5 days and assessed with RT-PCR.	No viral growth was detected in any specimen despite a positive RT-PCR very soon after admission	
Korean CDC 2020 [W12]	Respiratory swab specimens for individuals testing positive after having previously tested positive, then negative.	108 specimens	Methods not reported	0 / 108 respiratory specimens	This report does not report the laboratory methods used.
Kujawski 2020 (for The COVID-19 Investigation Team) [W13]	Nasopharyngeal (NP), oropharyngeal (OP), stool, serum and urine specimens	12 patients had initial respiratory specimens collecte	SARS-CoV-2 real-time PCR with reverse transcription (rRT–PCR) cycle threshold (Ct) values of virus isolated from the first tissue culture passage were 12.3 to 35.7 and for one patient, virus isolated from tissue culture passage 3 had a titer of 7.75 × 106 median tissue culture infectious dose per ml; these data were likely more reflective of growth in tissue culture than patient viral load.	Viral culture was attempted on initial respiratory specimens from 9 patients and was successful in all 9, including 2 patients who not hospitalized	Viable SARS-CoV-2 was cultured at day 9 of illness (patient 10), but was not attempted on later specimens. SARS-CoV-2 rRT–PCR Ct values of virus isolated from the first tissue culture passage were 12.3 to 35.7.

Accepted Manuscript

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciaa1764/6018217 by guest on 14 March 2021

					Mean Ct values in positive specimens were 17.0 to 39.0 for NP, 22.3 to 39.7 for OP and 24.1 to 39.4 for stool. All blood and urine isolates were negative. Ct values of upper respiratory tract specimens were lower in the first week of illness than the second in most patients.
L'Huillier 2020 [W14]	Nasopharyngeal swabs in 638 patients aged less than 16 years in Geneva Hospital	23 (3.6%) tested positive for SARS CoV-2 - median age of 12 years (range 7 days to 14.9 years) [1-4]	Observation of cytopathic effect on days 2,4, and 6 of inoculum in Vero cells in two passages.	12 (52% of PCR positive)	Ct was around 28 for the children whose specimens grew viable viruses
La Scola 2020 [W15]	Naso pharyngeal swabs or sputum specimens Only Naso pharyngeal specimens from the	183 (4384 specimens from 3466 patients) [not reported]	From 1,049 specimens, 611 SARS-CoV-2 isolates were cultured. 183 specimens testing positive by RT-PCR (9 sputum specimens and 174 nasopharyngeal swabs) from 155 patients, were inoculated in cell cultures. SARS-CoV-2. RNA rtPCR targeted the E gene. Nasopharyngeal swab fluid or sputum specimen were filtered and then inoculated in Vero E6 Cells. All specimens were inoculated	Of the 183 specimens inoculated in the studied period of time, 129 led to virus isolation. Of these 124 specimens had detectable cytopathic effect	There was a significant relationship between Ct value and culture positivity rate: specimens with Ct values of 13–17 all had positive culture. Culture positivity rate decreased progressively according to Ct values to 12% at 33 Ct.

	subsequent Jaafar et al letter.		between 4 and 10 h after sampling and kept at + 4 °C before processing. After centrifugation they were incubated at 37 °C. They were observed daily for evidence of cytopathogenic effect. Two subcultures were performed weekly and scanned by electron microscope and then confirmed by specific RT-PCR targeting E gene.	between 24 and 96 h The letter by Jaafar et al adds that 1941 SARS-Cov-2 30 isolate cultures were positive out 3 790 inoculated specimens. These could be seen after the first inoculation or up to 2 blind subcultures. At at Ct of > 34 2.6% of specimens yielded a positive culture.	No culture was obtained from specimens with Ct > 34. The 5 additional isolates obtained after blind subcultures had Ct between 27 and 34, thus consistent with low viable virus load.
Ladhani 2020 [W16]	Naso pharyngeal swabs	87 [Residents post, pre and symptomatic, 5 (6 to 3) 4 (2 to 11) 7 (10 to 4). Staff post, pre and symptomatic 7 (9 to 4) 3 (2-5) 5 (9 to _3)]	All SARS-CoV-2 positive specimens with a Ct value of <35 were incubated on Vero E6 mammalian cells and virus detection was confirmed by cytopathic effect (CPE) up to 14 days post-inoculation. Whole genome sequencing (WGS) was carried out on all RT-PCR positive specimens	87	Ct values < 35 Higher Ct values (lower virus load) specimens were associated with decreasing ability to recover infectious virus from 100% (2/2) with Ct <20.00 to 17.0% (9/53) with Ct 30.00_34.99 (x2 for trend, P<0.001)
Lu 2020 [W17]	87 cases testing “re-positive” at RT-PCR	619 hospital discharges of which tested positive after	137 swabs and 59 serum specimens from 70 “re-positive” cases to assess the immunological and virologic characteristics of the SARS-CoV-2 “re-positive” cases. From 23 January, hospital	No cultures were positive	“Re-positive” cases are unlikely to be infectious as no intact RNA single helix was detected or viral

Accepted Manuscript

	137 swabs (51 nasopharyngeal, 18 throat and 68 anal)	discharge	dischargees followed a strict isolation protocol living (for example) in single dedicated hotel rooms and went home only when nucleic acid tests were negative on both respiratory tract and digestive tract specimens. Specimens (nasopharyngeal, throat and anal swabs), were collected for RT-PCR diagnosis at 7 and 14 days after discharge. Culture was carried out by inoculating Vero E6 cells with patient specimen. CPE were observed daily at 7 days with a second round of passage. RT-PCR diagnosis was carried out on RNA using three RT-PCR kits to conduct nucleic acid testing, in an attempt to avoid false negatives. Ct varied from 29 to 39 depending on gene and kit		isolated grew. Prolonged detection of viral RNA is a challenge for public health interventions targeted at isolating infectious cases. “Re-positive” discharged cases are caused by intermittent shedding of cells containing remnant RNA.
Perera 2020 [W18]	68 specimens: nasopharyngeal aspirates combined with throat swab (n=49), nasopharyngeal aspirate (n=2), nasopharyngeal swab combined with throat swab (n=3), nasopharyngeal swab (n=2), sputum (n=11) and saliva	35 patients, 32 with mild disease [1 to 67 days]	Specimens were tested for sgRNA with ≥5 log10 N gene copies per ml. The complementary DNA obtained was subjected to PCR (40 cycles). Vero E6 cells were seeded and incubated for 24 hours in a CO2 incubator. The culture medium was removed and 125 µL of the clinical specimen in virus transport medium diluted and was inoculated into 2 wells. After 2 hours incubation in a CO2 incubator at 37°C, the plates were incubated at 37°C in a CO2 incubator. A specimen (100 µL) of supernatant was specimend for a quantitative real-time RT-PCR at 0 and 72 hours post inoculation. At 72 hours, cells were scraped into	Virus was isolated from 16 specimens for 16 patients out of a total of 35 specimens	Culturable SARS CoV-2 and sub-genomic RNA (good indicator of replication) was rarely detectable beyond 8 days after onset of illness although virus RNA by RT-PCR remained for up to 70 days.

	(n=1).		the supernatant and transferred onto fresh cells in 24-well plates and monitored for an additional 72 hours. A final quota of cells was collected for quantitative real-time RT-PCR. Cells were observed for cytopathic effect daily and harvested for testing if 25%–50% of cells showed a cytopathic effect.		
Qian 2020 [W19]	Rectal tissue obtained from a surgical procedure was available.	1 [1 to 3 days post op]	Ultrathin sections of tissue fixed in epoxy resin on formvar-coated copper grids were observed under electron microscope under 200kV. Immunohistochemical staining was used to establish expression and distribution of SARS-CoV-2 antigen.	1	No culture performed. Visualisation of virions in rectal tissue and detection of SARS-CoV-2 antigen in the rectal tissue.
Santarpia 2020 ([W20]	Windowsill and air, mean 7.3 specimens per room. The percentage of PCR positive specimens from each room was 40% -100%	13 patients [days 5 to 9 and day 18 of isolation in a quarantine unit]	Vero E6 cells were used to culture virus from environmental specimens. The cells were cultured in Dulbeccos's minimal essential medium (DMEM) supplemented with heat inactivated fetal bovine serum (10%), Penicillin/Streptomycin (10,000 IU/mL &10,000 µg/mL) and Amphotericin B (25 µg/mL).	Possibly 2 with weak cyotopathic effect	Isolates were from days 5 and 8 of occupancy of hospital/isolation rooms
Singanayagam 2020 [W21]	324 specimens: nose, throat, combined nose-and throat and nasopharyngeal swabs and aspirates	253 positive case [-10 to 60 days]	Vero E6 cells were inoculated with clinical specimens and incubated at 37 °C, 5% CO2. Cells were inspected for cytopathic effect daily up to 14 days. Presence of SARS-CoV-2 was confirmed by SARSCoV-2 nucleoprotein staining by enzyme immunoassay on infected	133 (41%) specimens (from 111 cases)	RT-PCR cycle threshold values correlate strongly with cultivable virus i.e. likelihood of infectiousness. Median Ct of all 324 specimens was 31.15. Probability of culturing virus

			cells.		declines to 8% in specimens with Ct > 35 and to 6% 10 days after onset and was similar in asymptomatic and symptomatic persons. Asymptomatic persons represent a source of transmissible virus but there is no difference in Ct values and culturability by age group.
Wang 2020 [W22]	Bronchoalveolar fluid, sputum, feces, blood, and urine specimens from hospital in-patients with COVID-19	1,070 specimens collected from 205 patients with COVID-19	rRT-PCR targeting the open reading frame 1ab gene of SARS-CoV-2; cycle threshold values of rRT-PCR were used as indicators of the copy number of SARS-CoV-2 RNA in specimens with lower cycle threshold values corresponding to higher viral copy numbers. A cycle threshold value less than 40 was interpreted as positive for SARS-CoV-2 RNA.	Live SARS-CoV-2 was observed in the stool specimen from 2 patients who did not have diarrhea.	The details of how the specimens were cultured were not reported.
Wölfel 2020 [W23]	Saliva, nasal swabs, urine, blood and stool	9 patients [2 to 4 days]	The average virus RNA load was 6.76 × 105 copies per the whole swab until day 5, and the maximum load was 7.11 × 108 copies per swab. The last swab specimen that tested positive was taken on day 28 after the onset of symptoms.	Yes in respiratory specimens, and indicative in stool

Xiao F SJ 2020 [W24]	Esophageal, gastric, duodenal, and rectal tissues were obtained from 1 COVID-19 patients by endoscopy.	1 plus an unknown additional number of fecal specimens from RNA-positive patients.	Histological staining (H&E) as well as viral receptor ACE2 and viral nucleocapsid staining were performed.	1/1 RNA-positive patient. Positive staining of viral nucleocapsid protein was visualized in the cytoplasm of gastric, duodenal, and rectum glandular epithelial cell, but not in esophageal epithelium of the 1 patient providing these tissues. Additionally, positive staining of ACE2 and SARS-CoV-2 was also observed in gastrointestinal epithelium from other patients who tested positive for SARS-CoV-2 RNA in feces, results not shown.	Total specimen numbers are not reported.
Xiao F 2020 [W25]	Serial feces specimens collected from 28 hospitalised COVID-19 patients: 3 specimens from 3 RNA-positive patients were tested for possible viral culture.	3, one patient admitted day 7 post onset	Inoculation of Vero 6 cells. Cycle threshold values for the fecal specimen were 23.34 for the open reading frame 1lab gene and 20.82 for the nucleoprotein gene. A cytopathic effect was visible in Vero E cells 2 days after a second-round passage. The researchers negatively stained culture supernatant and visualized by transmission electron microscopy. Viral particles that were visible were spherical and had distinct surface spike protein projections, consistent with a previously published SARS-CoV2 image.	Infectious virus was present in faeces from two cases)	Selection of specimens is not entirely clear.

Yao 2020 [W26]	Sputum (n=7), stool (n=3) and one nasopharyngeal specimen	11 patients admitted to hospital: 9 classified as serious or critical, 1 moderate, 1 mild symptoms [0 to 16 days]	The specimens of the 11 patients involved in this study were collected during the early phase of the Covid-19 break out in China, dates ranging from 2nd of January to the 2nd of April 2020. All except one of the patients had moderate or worse symptoms. Three patients had co-morbidities and one patient needed ICU treatment. Seven patients had sputum specimens, one nasopharyngeal and three had stool specimens The specimens were pre-processed by mixing with appropriate volume of MEM medium with 2% FBS, Amphotericin B, Penicillin G, Streptomycin and TPCK-trypsin. The supernatant was collected after centrifugation at 3000 rpm at room 434 temperature. Before infecting Vero-E6 cells, all collected supernatant was filtered using a 435 0.45 μm filter to remove cell debris etc. Vero-E6 cells were infected with 11 viral isolates and quantitatively assessed their viral load at 1, 2, 4, 8, 24, and 48 hours post-infection (PI) and their viral cytopathic effects (CPE) at 48 and 72 hours PI and examined whether the viral isolates could successfully bind to Vero-E6 243 cells as expected. Super-deep sequencing of the 11 viral isolates on the Novaseq 6000 platform was performed.	11 specimens taken up to 16 days from admission to hospital.	Cultured viruses were inoculated in Vero cells. At 8 hours post-infection there was a significant decrease in Ct value (increases in viral load) for five isolates. At 24 hours significant decreases in the Ct values for all of the viral isolates were observed. Mutations of the viruses are also reported

Young 2020 [W27]	Naso pharyngeal swabs, stool, fresh urine	152 of 74 patients	Material from nasopharyngeal swabs was inoculated in Vero-E6 cells in a Level 3 laboratory. Urine and stool specimens were collected and transported fresh for virus culture but stools were filtered before inoculation. Cells were cultured at 37C for seven days or less if cytopathic effect (CPE) was observed by day 4 and confirmed by PCR.	21 naso pharyngeal specimens from 19 (14%) patients	No virus was isolated when the PCR cycle threshold (Ct) value was >30 or >14 days from symptom onset. Urine and stool specimens at admission did not grow virus
Zhang 2020 [W28]	Stool	Unknown [not reported]	Vero cells were used for viral isolation from stool specimens of Covid-19 patients. A 2019-nCoV strain was isolated from a stool specimen of a laboratory-confirmed COVID-19 severe pneumonia case, who experienced onset on January 16, 2020 and was specimend on February 1, 2020. The interval between sampling and onset was 15 days. The full-length genome sequence indicated that the virus had high-nucleotide similarity (99.98%) to that of the first isolated novel coronavirus isolated from Wuhan, China. In the Vero cells, viral particles with typical morphology of a coronavirus could be observed under the electron microscope.	1	We do not know what influenced successful virus culture e.g. methods optimal, or concentration of virus optimal. More information needed.
Zhou 2020 [W29]	218 surface specimens 31 air specimens	7 areas of large London hospital	RT-PCR with primers and probes for the envelope (E) gene. Duplicate PCR was carried out and specimens were considered positive if both duplicates had Ct< 40.4, or suspect if one of the two have Ct<40.4 (equivalent to one genome copy. For culture Vero E6 and Caco2 cells were used from air and environmental	No cultures were positive	The pre-defined cycle threshold cut off was too high

Table 3. Duration of **detectable SARS-CoV-2 RNA** in the included studies.

Study	**Duration of detectable SARS-CoV-2 RNA as assessed by PCR**	**Comments on the clinical course**
Bullard [w7]	Specimens included in this study included those positive for SARS-CoV-2 by RT-PCR from day of symptom onset (Day 0) up to 21 days post symptom onset.	SARS-CoV-2 Vero cell infectivity of respiratory specimens from SARS-CoV-2 positive individuals was only observed for RT-PCR Ct < 24 and symptom onset to test of < 8 days.
Gniazdowski [w8]	Patients that received repeated testing with longitudinal positive results were tested within a time frame that ranged from less than one day to more than 45 days	Four patients had infectious virus recovered from specimens collected in up to 22 days after the first positive result. Many patients who tested negative for SARS-COV-2 showed a subsequent positive result
Jeong [w10]	Five positive-PCR patients, day 8 to day 30 after symptom onset.	Viable SARS-CoV-2 was demonstrated in saliva, urine and stool specimens from COVID-19 patients up to days 11-15 of the clinical course.

Accepted Manuscript

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciaa1764/6018217 by guest on 14 March 2021

Korean CDC [w12]	On average, it took 45 days (range: 8 to 82 days) from the initial symptom onset date to testing re positive after discharge. (Based on 226 cases symptomatic at the time of initial confirmation)	This may indicate duration of viral RNA detection over a long period of time and inconsistently. These data may not be comparable with information from studies specifically observing the duration of viral RNA detection as an outcome. Time to retesting positive via PCR is reported, among this specific group of individuals who retested positive by PCR.
Kujawski (for The COVID-19 Investigation Team) [w13]	Duration of SARS-CoV-2 detection by RT-PCR was 7 to 22 days	First 12 identified patients in the US. Respiratory specimens collected between illness days 1 to 9 (median, day 4) All patients had SARS-CoV-2 RNA detected in respiratory specimens, typically for 2 to 3 weeks after illness onset. Mean duration of fever was 9 days. Two patients received a short course of corticosteroids.
Singanayagam [w21]	SARS-CoV-2 viral load identified that the level of SARS-CoV-2 RNA in the URT was greatest around symptom onset, steadily decreased during the first 10 days after illness onset and then plateaued up to day 21	Probability of culturing virus declined to 8% in specimens with Ct > 35 and to 6% 10 days after onset;
Xiao F SJ [w24]	The viral load was higher in feces than in respiratory specimens collected at multiple time points (17–28 days after symptom onset)	Isolation of virus from feces specimens collected at later time points was not successful, although results for virus RNA remained positive, indicating only RNA fragments, not infectious virus, in feces of this patient collected at later time points of disease onset.
Xiao F w25	The duration time of positive stool results ranged from 1 to 12 days.	17 (23%) patients continued to have positive results in stool after showing negative results in respiratory specimens.

Accepted Manuscript

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciaa1764/6018217 by guest on 14 March 2021

Young w27	SARS-CoV-2 RNA was detectable from nasopharyngeal swabs by PCR up to 48 days after symptom onset.	Mean duration of viral RNA detection by PCR was 16.7 days (95% CI 15.2-18.3). C Cessation of viral RNA detection by PCR occurred in 4% by day 7, 30% by day 14, 78% by day 21 and 91% by day 28. There were no differences by disease severity No virus was isolated when the PCR cycle threshold (Ct) value was >30 or >14 days after symptom onset.

Accepted Manuscript

Criteria for releasing COVID-19 patients from isolation

Scientific brief

17 June 2020

World Health Organization

Background

On 27 May 2020, WHO published updated interim guidance on the clinical management of COVID-19,[1,2] and provided updated recommendations on the criteria for discharging patients from isolation. The updated criteria reflect recent findings that patients whose symptoms have resolved may still test positive for the COVID-19 virus (SARS-CoV-2) by RT-PCR for many weeks. Despite this positive test result, these patients are not likely to be infectious and therefore are unlikely to be able to transmit the virus to another person.

This scientific brief provides the rationale for the changes made to the clinical management of COVID-19 guidance, based on recent scientific evidence. WHO will update these criteria as more information becomes available. For more information about clinical care of COVID-19 patients, see WHO's full guidance.[1]

Previous recommendation

Initial recommendation (published on 12 January 2020)

WHO's first technical package of guidance for the clinical management of the novel coronavirus, now known as COVID-19, was published in early January 2020, shortly after a cluster of atypical pneumonia cases was first reported in Wuhan, People's Republic of China,[3] and included recommendations on when a patient with COVID-19 is no longer considered infectious.

The initial recommendation to confirm clearance of the virus, and thus allow discharge from isolation, required a patient to be clinically recovered and to have two negative RT-PCR results on sequential samples taken at least 24 hours apart.[4] This recommendation was based on our knowledge and experience with similar coronaviruses, including those that cause SARS and MERS.[5]

Updated recommendation

New recommendation (published on 27 May 2020 as part of more comprehensive clinical care guidance[1])

Within the Clinical Management of COVID-19 interim guidance published on 27 May 2020,[1] WHO updated the criteria for discharge from isolation as part of the clinical care pathway of a COVID-19 patient. These criteria apply to all COVID-19 cases regardless of isolation location or disease severity.

Criteria for discharging patients from isolation (i.e., discontinuing transmission-based precautions) without requiring retesting[i]:

- For symptomatic patients: 10 days after symptom onset, plus at least 3 additional days without symptoms (including without fever[ii] and without respiratory symptoms)[iii]
- For asymptomatic cases[iv]: 10 days after positive test for SARS-CoV-2

For example, if a patient had symptoms for two days, then the patient could be released from isolation after 10 days + 3 = 13 days from date of symptom onset; for a patient with symptoms for 14 days, the patient can be discharged (14 days + 3 days =) 17 days after date of symptom onset; for a patient with symptoms for 30 days, the patient can be discharged (30+3=) 33 days after symptom onset).

**Countries may choose to continue to use testing as part of the release criteria. If so, the initial recommendation of two negative PCR tests at least 24 hours apart can be used.*

What is the reason for the change?

In consultations with global expert networks and Member States, WHO has received feedback that applying the initial recommendation of two negative RT-PCR tests at least 24 hours apart, in light of limited laboratory supplies, equipment, and personnel in areas with intense transmission, has been extremely difficult, especially outside hospital settings.

With widespread community transmission, these initial criteria for SARS-CoV-2 posed several challenges:

[i] Countries can choose to continue to use a laboratory testing algorithm as part of the release criteria in (a subset of) infected individuals if their risk assessment gives reason to do so.
[ii] Without the use of any antipyretics.
[iii] Some patients may experience symptoms (such as post viral cough) beyond the period of infectivity. Further research is needed. For more information about clinical care of COVID-19 patients, see our Clinical Management Guidance.[1]
[iv] An asymptomatic case is an individual who has a laboratory confirmed positive test and who has no symptoms during the complete course of infection.

- Long periods of isolation for individuals with prolonged viral RNA detection after resolution of symptoms, affecting individual well-being, society ,and access to healthcare.[13]
- Insufficient testing capacity to comply with initial discharge criteria in many parts of the world.
- Prolonged viral shedding around the limit of detection, having negative results followed by positive results, which unnecessarily challenges trust in the laboratory system.[23-28]

These challenges and newly available data on the risk of viral transmission over the course of the COVID-19 illness provided the framework for updating WHO's position on the timing of discharging recovered patients from isolation in and outside health care facilities. WHO continuously reviews scientific literature on COVID-19 through its Science Division and its COVID-19 technical teams. All aspects of clinical management of COVID-19 patients and laboratory testing strategies are discussed within WHO and with Member States and WHO's global expert networks of public health professionals, clinicians, and academics around the world. These expert networks and the Strategic and Technical Advisory Group for Infectious Hazards (STAG-IH)[7] considered the challenges and reviewed the available data in the decision process to change the initial recommendation.

The updated criteria for discharge from isolation balances risks and benefits; however, no criteria that can be practically implemented are without risk. There is a minimal residual risk that transmission could occur with these non–test-based criteria. There can be situations in which a minimal residual risk is unacceptable, for example, in individuals at high risk of transmitting the virus to vulnerable groups or those in high-risk situations or environments. In these situations, and in patients who are symptomatic for prolonged periods of time, a laboratory-based approach can still be useful.

WHO encourages the scientific community to compile additional evidence to further improve isolation discharge criteria and establish the conditions under which isolation can be abbreviated or where the possible risks of the current discharge criteria require further adaptation. Better understanding of transmission risk among individuals with different clinical presentations or comorbidities and in different settings will aid further refinement of these criteria. For situations that might still require a laboratory-based approach, we encourage the further optimization of such a laboratory algorithm. WHO encourages countries to continue testing patients, if they have the capacity to do so, for systematic data collection that will enhance understanding and better guide decisions about infection prevention and control measures, especially among patients with prolonged illness or those who are immunocompromised.

Current understanding of transmission risk

Infection with the virus causing COVID-19 (SARS-CoV-2) is confirmed by the presence of viral RNA detected by molecular testing, usually RT-PCR. Detection of viral RNA does not necessarily mean that a person is infectious and able to transmit the virus to another person. Factors that determine transmission risk include whether a virus is still replication-competent, whether the patient has symptoms, such as a cough, which can spread infectious droplets, and the behavior and environmental factors associated with the infected individual. Usually 5-10 days after infection with SARS-CoV-2, the infected individual starts to gradually produce neutralizing antibodies. Binding of these neutralizing antibodies to the virus is expected to reduce the risk of virus transmission.[10,11,29,35]

SARS-CoV-2 RNA has been detected in patients 1-3 days before symptom onset, and viral load in the upper respiratory tract peaks within the first week of infection, followed by a gradual decline over time.[10,12,15,19,21,22,36-39] In the feces and lower respiratory tract, this viral load seems to peak in the second week of illness.[19] Viral RNA has been detected in upper respiratory tract (URT) and lower respiratory tract (LRT) and feces, regardless of severity of disease.[19] There seems to be a trend in longer detection of viral RNA in more severely ill patients.[10,14,15,18,19,41-43] Studies of viral RNA detection in immunocompromised patients are limited, but one study suggested prolonged detection of viral RNA in renal transplant patients.[33] Some studies analyzed the risk of transmission related to symptom of onset, and the estimated risk of transmission was highest at or around the time of symptom onset and in the first 5 days of illness.[13,15]

The ability of the virus to replicate in cultured cells serves as a surrogate marker of infectivity but requires special laboratory capabilities and may not be as sensitive as PCR.[10,20] Animal models can aid understanding of transmission risk. In a study by Sia, et al., hamsters infected with SARS-CoV-2 were housed with healthy hamsters on either day 1 or day 6 after infection. Transmission to healthy hamsters occurred in the day 1 group, but not in those exposed 6 days after inoculation. In this model, the timing of transmission correlated with the detection of virus using cell culture, but not with detection of viral RNA in donor nasal washes.[31]

Studies using viral culture of patient samples to assess the presence of infectious SARS-CoV-2 are limited.[8-10,21,29,30,34] Viable virus has been isolated from an asymptomatic case.[9] A study of 9 COVID-19 patients with mild to moderate disease found no SARS-CoV-2 virus able to be cultured from respiratory samples after day 8 of symptom onset.[10] Three studies of patients with undisclosed or variable degree of illness showed an inability to culture virus after days 7-9 of symptom onset.[8,29,30] Patients who were RT-PCR positive on retesting after an initial negative RT-PCR on discharge from isolation were also studied, and none of these patients yielded positive viral cultures.[29] One possible outlier is a case report of a patient with mild COVID-19 who remained PCR-positive for 63 days after symptom onset. In this patient, viral cultures were positive from upper respiratory tract specimens only on the day of symptom onset, but were culture-positive from sputum samples until day 18.[22] It is unclear whether this posed a transmission risk as the patient had no respiratory symptoms. In a hospital-based study of 129 patients severely or critically ill with COVID-19, 23 patients yielded at least one positive viral culture. This study included 30 patients who were immunocompromised. The median duration of viral shedding as measured by culture was 8 days post onset, the interquartile range was 5-11, and the range was 0-20 days.[11] The probability of detecting virus in culture dropped below 5% after 15.2 days after of symptoms. In this study, patients testing positive by viral culture were still experiencing symptoms at the time of sample collection.[11] This and other studies have described the correlation between reduced infectivity with the decrease in viral loads[10,11,29,34] and a rise in neutralizing

antibodies.[10,11,29] Although viral RNA can be detected by PCR even after the resolution of symptoms, the amount of detected viral RNA is substantially reduced over time and generally below the threshold where replication competent virus can be isolated. Therefore, the combination of time after onset of symptoms and the clearance of symptoms seems to be a generally safe approach based on current data.

Conclusion

Based on evidence showing the rarity of virus that can be cultured in respiratory samples after 9 days after symptom onset, especially in patients with mild disease, usually accompanied by rising levels of neutralizing antibodies and a resolution of symptoms, it appears safe to release patients from isolation based on clinical criteria that require a minimum time in isolation of 13 days, rather than strictly on repeated PCR results. It is important to note that the clinical criteria require that patients' symptoms have been resolved for at least three days before release from isolation, with a minimum time in isolation of 13 days since symptom onset.

These modifications to the criteria for discharge from isolation (in a health facility or elsewhere) balance the understanding of infectious risk and the practicality of requiring repeated negative PCR testing, especially in settings of intense transmission or limited testing supplies. Although the risk of transmission after symptom resolution is likely to be minimal based on what is currently known, it cannot be completely ruled out. However, there is no zero-risk approach, and strict reliance on PCR confirmation of viral RNA clearance creates other risks (e.g. straining resources and limiting access to health care for new patients with acute disease). In patients with severe disease who are symptomatic for prolonged periods of time, a laboratory-based approach might also aid decision-making on the need for prolonged isolation. Such a laboratory-based approach can include measuring viral load and neutralizing antibody (or proven equivalent antibody) levels.[10,11,29] More research is needed to further validate such an approach.

WHO will update these criteria as more information becomes available. For more information about clinical care of COVID-19 patients, see WHO's full guidance.[1]

Foreword and summary

The *Strategic preparedness and response plan* outlines the World Health Organization (WHO) strategic objectives to end the COVID-19 pandemic and assists national stakeholders with developing a structured approach to their response. The WHO's main objectives for COVID-19 are to:

1) supress transmission;
2) provide optimized care for all patients; and save lives
3) minimize the impact of the epidemic on health systems, social services and economic activity.

To achieve these objectives, the WHO *Operational considerations for case management of COVID-19 in health facility and community* describes key actions that should be taken in different scenarios: no cases; sporadic cases; clusters of cases; and community transmission, in order to enable delivery of clinical and public health services in a timely fashion.

The guidance in this document is based on the above strategic priorities, and is intended for clinicians involved in the care of patients with suspected or confirmed COVID-19. It is not meant to replace clinical judgment or specialist consultation but rather to strengthen frontline clinical management and the public health response. Considerations for special and vulnerable populations, such as paediatric patients, older people and pregnant women, are highlighted throughout the text.

In this document we refer to the **COVID-19 care pathway (Annex 1).** This describes a coordinated and multidisciplinary care pathway that a patient enters after s/he is **screened for COVID-19 and becomes a suspect COVID-19 case,** and follows the continuum of their care until release from the pathway. The objective is to ensure delivery of safe and quality care while stopping onwards viral transmission. All others enter the health system in the non-COVID-19 pathway. For the most up-to-date technical guidance related to the COVID-19 response, visit WHO Country & Technical Guidance *(1).*

Basic psychosocial support skills are at the core of any clinical intervention for COVID-19. Such skills are indispensable for all involved in the COVID-19 clinical response, whether they identify as mental health and psychosocial providers or not. Basic psychosocial skills are essential for supporting the emotional well-being of people who have COVID-19, those who have lost someone to COVID-19, or are family members and carers who are caring for someone with COVID-19 or have recovered from COVID-19.

Summary: what is this living guidance?

Clinical questions: What is the clinical management of patients with COVID-19?

Target audience: The target audience is clinicians and health care decision-makers.

Current practice: Current practice to treat COVID-19 is variable reflecting large-scale uncertainty. Numerous clinical trials are underway looking at various interventions that will inform clinical practice. Providing trustworthy guidance that is comprehensive and holistic for the optimal care of COVID-19 patients, throughout their entire illness, is necessary. The previous version of the *Clinical management of COVID-19* provided recommendations that can be applied when caring for patients during the COVID-19 care pathway. This guideline now also includes information on caring for COVID-19 patients after their acute illness.

Updates to this guidance: The panel made the following new recommendations:

- A conditional recommendation to use clinical judgment, including consideration of patients' values and preferences and local and national policy if available, to guide management decisions including admission to hospital and to the intensive care unit (ICU), rather than currently available prediction models for prognosis when caring for patients with COVID-19 of any severity assessed in a clinic or hospital (very low certainty).

- A conditional recommendation for use of pulse oximetry monitoring at home as part of a package of care, including patient and provider education and appropriate follow-up, in symptomatic patients with COVID-19 and risk factors for progression to severe disease who are not hospitalized (very low certainty).
- A conditional recommendation for the use of awake prone positioning in patients with severe COVID-19 that are hospitalized requiring supplemental oxygen or non-invasive ventilation (low certainty).
- A conditional recommendation to use thromboprophylaxis dosing of anticoagulation rather than intermediate or therapeutic dosing in patients hospitalized with COVID-19, without an established indication for higher dose of anticoagulation (very low certainty).
- A conditional recommendation for the use of existing care bundles (defined as three or more evidence-informed practices delivered together and consistently to improve care) chosen locally by hospital or ICU and adapted as necessary for local circumstances in patients with critical COVID-19 (very low certainty).
- Best practice statement: patients who have had suspected or confirmed COVID-19 (of any disease severity) who have persistent, new or changing symptoms should have access to follow-up care (see the new Chapter 24. Care of COVID-19 patients after acute illness).

For chapters without new recommendations, each responsible technical unit (member of steering committee) reviewed the chapter and provided narrative updates to reflect new literature searches. Two technical units used expert panel reviews to review and update their chapters (neurological and mental manifestations [Chapter 17] and rehabilitation [Chapter 19]).

How this guideline was created: This living guideline is an innovation from WHO, driven by the urgent need for global collaboration to provide trustworthy and evolving COVID-19 guidance informing policy and practice worldwide. An international Guideline Development Group (GDG) of content experts, clinicians, patients, ethicists and methodologists produced recommendations following standards for trustworthy guideline development using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach. No conflict of interest was identified for any panel member. WHO has partnered with the non-profit MAGIC (Making GRADE the Irresistible Choice) Evidence Ecosystem Foundation for support through their publication platform that facilitates continued updating.

The latest evidence: The evidence included in this guidance update includes six rapid reviews on specific topics that can be found in Annex 3. No conflict of interest was identified for any external contributors.

Understanding the recommendations: When moving from evidence to recommendations, the panel made five conditional recommendations based primarily on low to very low certainty evidence.

- For suggested use of clinical judgment rather than available prediction models, the panel considered the evidence in favour of prognostic models in patients with COVID-19 to be of very low certainty, lack validation studies, and lack evidence of the impact of using models on decision-making and patient outcomes.
- For suggested use of pulse oximetry monitoring at home, the panel felt the potential benefits would outweigh the potential harms, especially if used in patients that were symptomatic and at risk for severe disease; but only as part of a larger package of care including education and follow-up.
- For suggested use of awake prone positioning in hospitalized patients with severe COVID-19, the panel emphasized the low certainty evidence of reduction in mortality, downgraded from higher certainty evidence for mechanically ventilated critically ill patients with acute respiratory distress syndrome (ARDS) and the limited harm with the experience thus far from different resource settings.
- For suggested use of existing care bundles, the panel emphasized the low to very low certainty evidence of reduction in mortality and possible administrative burdens for implementation; but if the hospital or ICU selected among existing care bundles and adapted them to local circumstances that would take into account contextual factors of resource considerations and increase feasibility.

For these four recommendations the panel did not expect much variation in values and preferences.

- For suggested use of thromboprophylaxis dosing rather than intermediate or therapeutic dosing, the panel emphasized the very low certainty evidence of reduction in mortality or pulmonary embolism with higher anticoagulant dosing but also an increased risk of major bleeding; the possible harm indicated by studies of therapeutic anticoagulation rather than intermediate dosing.

For this last recommendation, some panellists anticipated variability in patient values and preferences.

Update 1.4 Clinical Management of COVID-19: Living Guidance

This updated version of the *Clinical management of COVID-19* guidance includes five new recommendations and a new chapter on care for patients after acute illness with COVID-19, adding to the interim guidance published 27 May 2020. Please view section text for a summary of these new recommendations, also available within each section of the guidelines, labelled as new. Other recommendations remain unchanged although underlying content and references have been updated in this version. Concerning therapeutics for COVID-19, please see the linked WHO living guidelines also published as BMJ Rapid Recommendations, which replace the initial guidance (e.g. for corticosteroids).

As described in Methods (Chapter 2), the first interim guidance applied a simplified approach to produce rapid guidance. In this 4th updated version the GDG applied GRADE and standards for trustworthy guidelines. To reflect these two different approaches, the recommendations are therefore marked with different labels and colour codings.

This is a living guidance, so the recommendations included here will be updated, and new recommendations will be added as evidence emerges. The guideline is therefore written, disseminated and updated in MAGICapp, with a format and structure aiming to make it user friendly and easy to navigate while accommodating for dynamically updated evidence and recommendations, focusing on what is new while keeping existing recommendations within the guideline.

1. Background

Coronavirus disease 2019 (COVID-19) is caused by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), a newly emergent coronavirus, that was first recognized in Wuhan, Hubei province, China, in December 2019. SARS-CoV-2 is a positive-sense single-stranded RNA virus that is contagious in humans. It is the successor to SARS-CoV-1, the strain that caused the 2002–2004 SARS outbreak.

Epidemiology and virologic studies suggest that transmission mainly occurs from both symptomatic and asymptomatic people to others by close contact through respiratory droplets or by direct contact with infected persons, or by contact with contaminated objects and surfaces *(2,3,4,5,6)*, or by aerosols, i.e. in enclosed spaces indoors, crowded and inadequately ventilated spaces, where infected persons spend long periods of time with others, which may include restaurants, choir practices, fitness classes, nightclubs, offices and places of worship *(7)*, or during aerosol-generating procedures. Clinical and virologic studies that have collected repeated biological samples from confirmed patients demonstrate that shedding of SARS-CoV-2 is highest in the upper respiratory tract (URT) (nose and throat) early in the course of the disease *(8,9,10)*, within the first 3 days from onset of symptoms *(10,11,12,13)*. A study of 77 infector-infectee transmission pairs observed the highest viral load in throat swabs at the time of symptom onset, suggesting infectiousness peak on or before symptom onset with an estimated 44% (95% confidence interval, 30–57%) of onward infections happening during the pre-symptomatic phase of the index case *(14)*. The incubation period for COVID-19, which is the time between exposure to the virus (becoming infected) and symptom onset, is, on average, 5–7 days, but can be up to 14 days. During this period, also known as the “presymptomatic” period, some infected persons can be contagious, from 1–3 days before symptom onset *(12)*. It is important to recognize that presymptomatic transmission still requires the virus to be spread via infectious droplets or by direct or indirect contact with bodily fluids from an infected person. An asymptomatic case is a person infected with SARS-CoV-2 who does not develop symptoms *(15,16)*. Among symptomatic patients, the duration of infectious virus shedding has been estimated at 8 days from the onset of any symptoms *(17,18,19)*.

The proportion of persons who become infected with SARS-CoV-2 and remain asymptomatic remains to be better understood, recent meta-analysis reported an overall estimate of 31%, from seven studies with predefined screened populations, prediction interval ranging between 26–37% *(20)*. One systematic review of 79 studies found that 20% (17–25%) of people remained asymptomatic throughout the course of infection *(20)*. Another systematic review, which included 13 studies considered to be at low risk of bias, estimated that 17% of cases remain asymptomatic (14–20%) *(21)*. A further meta-analysis included 28 studies. There was wide variance between two general population studies with the proportion of asymptomatic infections at the time of testing being 20% and 75% respectively, in contacts the proportion was 8.2–50% and 59% (49–68%) of obstetric patients remained asymptomatic throughout whilst 54% (42%-65%) of nursing home residents were asymptomatic at testing of which 28% (13–50%) remained asymptomatic through follow-up *(22)*. Whole cohort testing such as in the Diamond Princess cruise ship found an asymptomatic proportion (among all infected cases) of 17.9% (95% CI: 15.5–20.2%) *(23)* and in a cohort of 356 dialysis patients, 52 (40.3%) had asymptomatic disease or disease which was not detected using RT-PCR when serological testing for antibodies were done *(24)*. In those patients that do become symptomatic, most people with COVID-19 develop only mild (40%) or moderate (40%) disease (see Table 6.3), approximately 15% develop severe disease that requires oxygen support, and 5% have critical disease with complications such as respiratory failure, acute respiratory distress syndrome (ARDS), sepsis and septic shock, thromboembolism, and/or multiorgan failure, including acute kidney injury and cardiac injury *(25)*. Older age, smoking *(26,27)* and underlying noncommunicable diseases (NCDs), such as diabetes, hypertension, cardiac disease, chronic lung disease and cancer, have been reported as risk factors for severe disease and death, and multivariable analyses have confirmed older age, higher sequential organ failure assessment (SOFA) score and D-dimer > 1 µg/L on admission were associated with higher mortality *(28,29)* (see Table 6.3). This study also observed a median duration of viral RNA detection of 20.0 days (IQR 17–24 days) in survivors, but COVID-19 viral RNA was detectable until death in non-survivors. In a study of 20 immunocompromised haemoncology patients viral RNA was detected for up to 78 days after the onset of symptoms (IQR 24–64 days). Viable virus was detected up to 61 days after the onset of symptoms *(30)*.

COVID-19 is associated with mental and neurological manifestations, including anxiety, depression, sleep problems, headache, dizziness, impaired sense of smell or taste *(31)*, myalgias, delirium/encephalopathy, agitation, stroke, hypoxic ischaemic brain injury, seizures, coma, meningo-encephalitis and Guillain-Barré syndrome *(32,33,34,35)*. Anxiety and depression appear to be common amongst people hospitalized for COVID-19, with one hospitalized cohort from Wuhan, China, revealing over 34% of people experiencing symptoms of anxiety and 28% experiencing symptoms of depression *(36)*. Preliminary findings from retrospective cohort studies of over 60 000 COVID-19 cases in the United States of America indicate an 18.1% incidence of psychiatric diagnoses (including anxiety disorders and insomnia) in the first 2 weeks to 3 months after COVID-19 diagnosis, 5.8% of which were new diagnoses *(37)*.

In many cases, neurological manifestations have been reported even without respiratory symptoms. Over 80% of COVID-19 patients in a hospitalized United States' cohort experienced neurological symptoms during the course of their illness and these manifestations were associated with a four-fold higher risk of severe COVID-19 in this cohort *(38)*. An observational case series from France found that 65% of people with COVID-19 in ICUs showed signs of confusion (or delirium) and 69% experienced agitation *(39)*. Delirium, in particular, has been associated with increased mortality risk in the context of COVID-19 *(40)*. Moreover COVID-19 has been associated with acute cerebrovascular disease (including ischaemic and haemorrhagic stroke) with reports from multiple case series and/or cohort series from China, France, the Netherlands, the United Kingdom and the United States of America *(36,39,41,42,43)*. Case reports of Guillain-Barré syndrome and meningo-encephalitis among people with COVID-19 have also been reported *(44,45,46)*.

Clinical manifestations of COVID-19 are generally milder in children compared with adults *(47,48,49)*. Relatively few cases of infants confirmed with COVID-19 have been reported; infants also experience mild illness *(49,50)*. However, an acute presentation with a hyperinflammatory syndrome leading to multiorgan failure and shock has been reported *(51,52)*, described as multisystem inflammatory syndrome temporally associated with COVID-19 in children and adolescents. Underlying conditions with severe illness in children appear to be similar to adults. Among 655 children with laboratory-confirmed COVID-19 and complete information about underlying conditions, 23% had an underlying condition, with obesity, chronic lung disease (including asthma), cardiovascular disease and immunosuppression most commonly reported *(52)*.

The results of a living systematic review (as of 6 October 2020) show that pregnant and recently pregnant women with COVID-19 appear to be less likely to be symptomatic (0.28, 95% CI 0.13–0.62; 4 studies; 462 051 women), or manifest common symptoms such as fever, dyspnoea and myalgia, compared with non-pregnant women of reproductive age *(53)*. These findings are largely influenced by studies of pregnant women who were managed in hospitals for any reason, with limited data on women during early pregnancy or postpartum. Pregnant or recently pregnant women with severe COVID-19 are at higher risk of requiring admission to an ICU (OR=2.13, 95% CI 1.53–2.95; 7 studies, 601 108 women), invasive ventilation (OR=2.59, 95% CI 2.28–2.94; 6 studies, 601 044 women) or extra corporeal membrane oxygenation (ECMO) (OR=2.02, 95% CI 1.22–3.34; 2 studies, 461 936 women). Older maternal age, high body mass index (BMI), non-white ethnicity, pre-existing comorbidities, chronic hypertension, pre-existing diabetes, are risk factors for developing severe COVID-19. Complications related to COVID-19 did not seem to be increased in women presenting in the third trimester compared with earlier trimester of pregnancy or in multiparous compared with primiparous women, but the existing sample sizes for these comparisons are not large.

The understanding of the mid- and long-term sequelae of COVID-19 is emerging. This new condition which has been described as post-COVID syndrome or long COVID *(54)* still lacks a consensus worldwide on terminology and clinical definition. The post-intensive care syndrome (PICS) has been well described in other critically ill patients and it seems is also being observed in COVID-19 patients. However, non-hospitalized patients (or those with mild and moderate COVID-19) and children are also reporting persisting clustering of symptoms and mid- and long-term sequalae, and children. Recent data (in press at *The Lancet* by Bin Cao et al.) on the long-term consequences of COVID-19 for patients in Wuhan, warned that dysfunctions and complications could persist in some discharged patients for at least 6 months *(55)*.

2. Methods

The original version (v1.1) of this document was developed in consultation with the International Forum for Acute Care Trialists (InFACT), the International Severe Acute Respiratory and Emerging Infection Consortium (ISARIC) and the Surviving Sepsis Campaign. This is the fourth edition of this document, which was originally adapted from *Clinical management of severe acute respiratory infection when Middle East respiratory syndrome coronavirus (MERS-CoV) infection is suspected* (WHO, 2019).

For the development of the third version (v1.3) of the COVID-19 clinical guidance, a formal Guideline Development Group (GDG) comprising individuals with broad expertise spanning multiple specialties and all regions was convened. Confidentiality and declarations of interest were collected and reviewed and no conflict of interest was identified (see Acknowledgements). Because of the accelerated timeline and very broad scope of the third version of the guideline, it was not feasible to undertake a formal GRADE process (PICO questions; systematic reviews; formal documentation of values and preferences and incorporation of considerations of costs, resources, and feasibility). The topics for consideration originated in the WHO interim guidance for MERS, but for COVID-19 were greatly expanded to reflect the full spectrum of illness, from screening to rehabilitation. Published evidence was synthesized under the coordination of the Science Division in rapid systematic reviews, which were pre-circulated to the GDG. The WHO Steering Committee initially drafted the recommendations about interventions based on these reviews and input from expert clinicians participating in twice-weekly clinical network teleconferences. The GDG held four virtual meetings via teleconference (total of 12 hours) to discuss all previous and new recommendations. Suggested revisions were incorporated into the guidance. Consensus was achieved for all recommendations presented in the final version. The direction and strength of recommendations are presented using symbols rather than formal GRADE terminology (strong and conditional recommendations with grading of certainty of evidence, or best practice statements).

The GREEN symbol denotes a strong recommendation or a best practice statement in favour of an intervention.

The RED symbol denotes a recommendation or a best practice statement against an intervention.

The YELLOW symbol denotes a conditional recommendation in favour of an intervention, or a recommendation where special care is required in implementation.

For this fourth version (v1.4) of the guidance, new recommendations have been developed according to standards and methods for trustworthy guidelines, making use of an innovative process to achieve efficiency in dynamic updating of recommendations. The methods are aligned with the *WHO Handbook for guideline development (56)*.

Related guidelines

This living WHO guidance for the clinical management of COVID-19 is related to the Living Guideline for therapeutics and COVID-19, also published in the BMJ and available in MAGICapp.

Timing

This guidance aims to be trustworthy and living; dynamically updated and globally disseminated once new evidence warrants a change in recommendations for COVID-19. We aim for an ambitious timeframe from trials that trigger guideline development process to WHO publication, within 1 month, while maintaining standards and methods for trustworthy guidelines (*WHO Handbook of guideline development*) *(56)*.

Stepwise approach

Here we outline the stepwise approach we take to improve efficiency and timeliness of the living, trustworthy guidance, in the development and dissemination of the recommendations. To do so, various processes occurred simultaneously.

Step 1: Evidence monitoring and mapping and triggering of evidence synthesis

Regular monitoring of evidence around key topics occurs with support from the WHO rapid review team and their network of collaborators. In September 2020, the WHO Steering Committee triggered this guidance update process, including PICO development. The trigger for producing or updating specific recommendations is based on the following:

- likelihood to change practice;
- relevance to a global audience.

Step 2: Convening the GDG

The pre-selected expert panel (see Acknowledgments) convened on four occasions. At each meeting, a review of the GRADE methodology was done, including how to make best practice statements.

The first meeting, held on 1 December 2020 reviewed the basics of GRADE methodology; including formulating PICO questions and subgroups of interests, assessment of certainty of evidence, incorporating patients' values and preferences, and prioritization of patient-important outcomes. Important questions in the clinical management of patients with COVID-19 focused on the prevention of complications by the use anticoagulation for thromboprophylaxis and the use of care bundles in ICU. The second meeting on 4 December 2020 addressed the use of pulse oximetry at home and awake prone positioning as well as further clarification around the use of care bundles in ICU. The third meeting on 11 December 2020 addressed the longer-term effects of COVID-19 and additional clarification around the use of care bundles in ICU. The fourth meeting on 11 December 2020 addressed risk factors as well as prognostic/prediction models in COVID-19 and completed recommendations for the use of care bundles in ICU.

Step 3: Evidence synthesis

The WHO Steering Committee requested the WHO methods support team to conduct rapid systematic reviews on the six PICOs. Two of the PICOs were conducted by the WHO rapid review team made up of systematic review experts, clinical experts and a librarian. The other four PICOs were addressed by collaborators, that were already engaged in conducting systematic reviews on these topics. This includes: National Institute of Health and Care Excellence (NICE, United Kingdom), the American Society of Haematology guideline/McMaster University GRADE Centre systematic review, COVIDPRECISE; and the Cochrane Library (see Acknowledgements).

Step 4: Final recommendations

The GDG panel members are responsible for the following critical activities:

- To advise on the priority questions and scope of guidance.
- To advise on the choice of important outcomes for decision-making.
- To comment on the evidence used to inform the guideline.
- To advise on the interpretation of the evidence, with explicit consideration of overall balance or risks and benefits.
- To formulate recommendations, taking into account diverse values and preferences according to GRADE.

The GRADE approach provided the framework for establishing evidence certainty and generating both the direction and strength of recommendations *(57,58)*. Good practice statements can be made in addition to, or instead of a recommendation when a large body of indirect evidence, made up of linked evidence including several indirect comparisons, strongly supports the net benefit of the recommended action, if deemed that it will be an onerous and unproductive exercise to collect the linked evidence supporting the recommendations. However, it still requires transparency and explicitness, with a clear rationale for the approach. Although a priori voting procedures were established at the outset, in case consensus was not reached, these procedures were not necessary for this recommendation which reached consensus amongst the panel.

The following key factors were used to formulate transparent and trustworthy recommendations:

- absolute benefits and harms for all patient-important outcomes through structured evidence summaries (e.g. GRADE summary of findings tables);
- quality/certainty of the evidence *(57,59)*;
- values and preferences of patients *(60)*;
- resources and other considerations (including considerations of feasibility, applicability, equity) *(60)*;
- each outcome will have an effect estimate and confidence interval, with a measure of certainty in the evidence, as presented in summary of findings tables. If such data are not available narrative summaries will be provided;

- recommendations will be rated as either conditional or strong, as defined by GRADE. If the panel members disagree regarding the evidence assessment or strength of recommendations, WHO will apply voting according to established methods.

Step 5: External and internal review
The WHO guideline was then reviewed by pre-specified external reviewers (see Acknowledgements) and then approved by the WHO Publication Review Committee.

3. The latest evidence

Based on information needs from the GDG, six rapid reviews informed development of recommendations in this update. Whereas evidence summaries are provided for each updated recommendation, details about the literature search, identified studies and references can be found in the Annex 3 of this document.

Table 3.1 Panel outcome rating from a patient perspective

Outcome	Mean	SD	Range
Death at 28 days	9.0	0.0	9-9
Need for invasive mechanical ventilation	8.4	0.8	7-9
Duration of invasive mechanical ventilation	7.7	1.0	5-9
Time to clinical improvement	7.2	1.5	4-9
Serious adverse effect leading to drug discontinuation	7.1	1.4	4-9
Time to symptom resolution	6.6	1.5	3-9
Duration of oxygen support	6.6	1.3	5-9
Duration of hospitalization	6.4	1.3	3-8
Hepatitis (increased liver enzymes)	5.3	1.8	2-9
Duration of viral shedding	4.9	2.4	2-9
Nausea/vomiting	4.5	1.7	2-9
Diarrhea	4.3	1.5	2-8

Note: 1: not important, 9: critically important.

Values and preferences
There were insufficient published data to provide the GDG with an informative systematic review of studies describing patients' experiences or values and preferences on treatment decisions for COVID-19 drug treatments. The GDG therefore relied on their own judgments of what well-informed patients would value after carefully balancing the benefits, harms and burdens of treatment and their subsequent treatment preferences. The GDG included four patient-representatives who had lived experience with COVID-19. The WHO is currently conducting a survey of patients to expand the values and preferences statements for the next version update of the guidance.

The GDG agreed that the following values and preferences would be representative of those of typical well-informed patients:

- Mortality would be the outcome most important to patients, followed by need and duration of mechanical ventilation, time to clinical improvement, and serious intervention-related adverse events.
- Most patients would be reluctant to use a medication for which the evidence left high uncertainty regarding effects on the outcomes listed above. This was particularly so when evidence suggested treatment effects, if they do exist, are small, and the possibility of important harm remains.
- In an alternative situation with larger benefits and less uncertainty regarding both benefits and harms, more patients would be inclined to choose the intervention.

The GDG acknowledged, however, that values and preferences are likely to vary. There will be patients inclined to use a treatment in which evidence has not excluded important benefit, particularly when the underlying condition is potentially fatal. On the other hand, there will be those who have a high threshold of likely benefit before they will choose the intervention. Although the GDG focused on an individual patient perspective, they also considered a population perspective in which feasibility, acceptability, equity and cost are important considerations.

4. Who the recommendations apply to

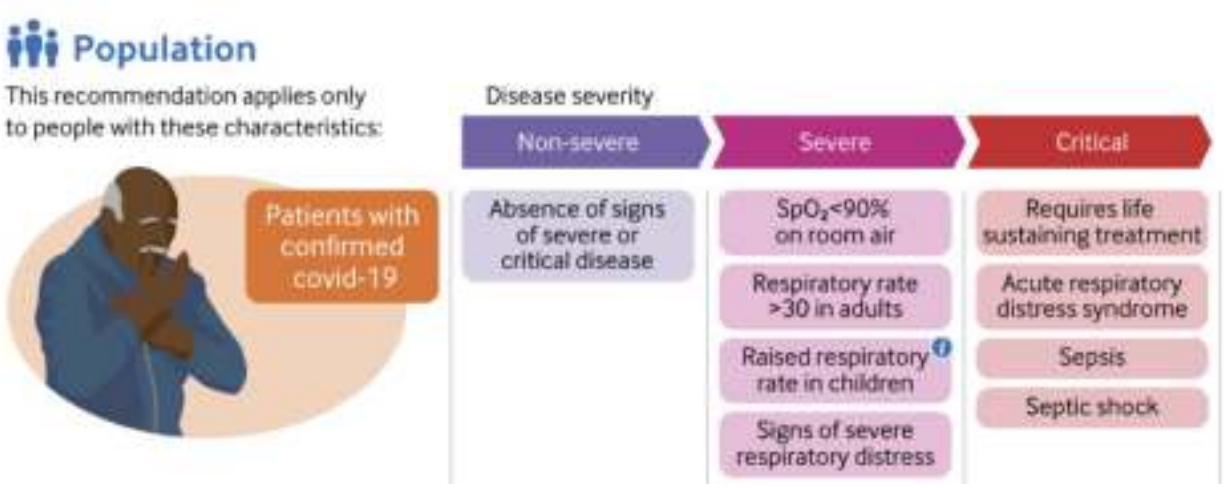
The GDG elected to use the WHO severity definitions based on clinical indicators, adapted from WHO COVID-19 disease severity categorization (see Table 6.3). These definitions avoid reliance on access to health care to define patient subgroups.

WHO Severity definitions

- Critical COVID-19: Defined by the criteria for acute respiratory distress syndrome (ARDS), sepsis, septic shock, or other conditions that would normally require the provision of life-sustaining therapies such as mechanical ventilation (invasive or non-invasive) or vasopressor therapy.
- Severe COVID-19: Defined by any of:
  - Oxygen saturation < 90% on room air.
  - Respiratory rate > 30 breaths/min in adults and children > 5 years old; ≥ 60 breaths/min in children < 2 months old; ≥ 50 in children 2–11 months old; and ≥ 40 in children 1–5 years old.
  - Signs of severe respiratory distress (accessory muscle use, inability to complete full sentences, and, in children, very severe chest wall indrawing, grunting, central cyanosis, or presence of any other general danger signs).
- Non-severe COVID-19: Defined as absence of any criteria for severe or critical COVID-19.

Caution: The panel noted that the oxygen saturation threshold of 90% to define severe COVID-19 was arbitrary and should be interpreted cautiously. For example, clinicians must use their judgment to determine whether a low oxygen saturation is a sign of severity or is normal for a given patient with chronic lung disease. Similarly, a saturation > 90–94% on room air is abnormal (in patient with normal lungs) and can be an early sign of severe disease, if patient is on a downward trend. Generally, if there is any doubt, the panel suggested erring on the side of considering the illness as severe.

The infographic illustrates these three disease severity groups and key characteristics to apply in practice, for a recommendation within this guideline.



Infographic co-produced by BMJ and MAGIC; designer Will Stahl-Timmins (see BMJ Rapid Recommendations).

5. COVID-19 care pathway (see Annex 1)

We recommend that COVID-19 care pathways be established at local, regional and national levels. COVID-19 care pathways are for persons with suspected or confirmed COVID-19.

Remarks:

1. A person enters the COVID-19 care pathway after s/he is *screened*, based on a standardized case definition, including assessment of symptoms, and meets criteria for a suspect case.
   - Suspect cases may be referred to as "persons or patients under investigation" (PUIs) in some contexts.
   - Probable cases are suspect cases for whom testing for SARS-CoV-2 is inconclusive or not available.
   - Confirmed cases are persons with laboratory confirmation of infection with SARS-CoV-2.
2. All persons with suspected, probable or confirmed infection with SARS-CoV-2 should be immediately isolated to contain virus transmission. Refer to Chapter on IPC considerations in cohorting suspect, probable and confirmed cases separately.
3. Considerations for co-infections (i.e. influenza, malaria, TB) and/or chronic diseases must be made within the COVID-19 care pathway. Ensuring that these other conditions can management according to national or local protocols.
4. All suspect cases should be tested to determine if they are a ***confirmed*** case. Until proven negative, all suspected cases should remain in the COVID-19 care pathway. If testing is not available, the person becomes a probable case (based on clinical suspicions) and should be cared for in the COVID-19 pathway.

Discontinue transmission-based precautions (including isolation) and release from COVID-19 care pathway as follows.

Remarks:

1. Criteria for discharging patients from isolation (i.e. discontinuing transmission-based precautions) without requiring retesting:
   - For symptomatic patients: 10 days after symptom onset, plus at least 3 additional days without symptoms (including without fever and without respiratory symptoms).
   - For asymptomatic cases: 10 days after positive test for SARS-CoV-2.
2. For example, if patient had symptoms for 2 days, then the patient could be released from isolation after 10 days + 3 = 13 days from date of symptom onset; for a patient with symptoms for 14 days, then the patient can be discharged 14 days + 3 days = 17 days from date of symptom onset; for a patient with symptoms for 30 days, the patient can be discharged 30 days + 3 days = 33 days after symptom onset.
3. Countries may choose to continue to use testing as part of the release criteria. If so, the initial recommendation of two negative PCR tests at least 24 hours apart can be used.
4. Some patients may experience symptoms beyond the period of infectivity. See Chapter 24. Care of COVID-19 patients after acute illness.
5. Please note that the clinical pathway needs to be clearly outlined by countries to follow each patient until outcome, including full recovery. Discharge criteria from clinical care need to take into account the patient's condition, disease experience and other factors.
6. Release from the COVID-19 care pathway is not the same as clinical discharge from a facility or from one ward to another. For example, some patients may still require ongoing rehabilitation, or other aspects of care, beyond release from the COVID-19 care pathway, based on clinical needs in the COVID-19 care pathway. If release from the COVID-19 care pathway coincides with clinical discharge, then several clinical considerations, such as medication reconciliation, plan for follow up with clinical provider in place, review of routine immunization status, among others, should be taken into account.
7. See scientific brief *Criteria for releasing COVID-19 patients from isolation* for more details *(13)*.

6. Screening, triage and clinical assessment: early recognition of patients with COVID-19

The primary objective of the COVID-19 global response is to slow and stop transmission, find, isolate and test every suspect case, and provide timely appropriate care of patients with COVID-19. The recommended location of care will depend on the epidemiologic scenario and be either at a designated COVID-19 health facility, community facility or, where not possible, at home. Refer to the WHO *Operational considerations for case management of COVID-19 in health facility and community (61).*

Please find new recommendation on methods for clinical decision-making in COVID-19 as the third recommendation.

We recommend screening all persons at the first point of contact with the health system in order to identify individuals that have suspected or confirmed COVID-19.

Remarks:

1. Screening can be performed in areas such as the emergency unit, outpatient department/primary care clinic, in the community by a community health worker or by telemedicine. In the context of this outbreak, this should be done at a distance (> 1 m). Use a simple set of questions based on the WHO case definition (see Table 6.1). This is best done by establishing screening protocols at all health access points and during contact tracing activities. Older people and those immunosuppressed may present with atypical symptoms such as fatigue, reduced alertness, reduced mobility, diarrhoea, loss of appetite, delirium and absence of fever *(62,63,64)*. Thus, screening questions may need to be adjusted for certain settings and guided by epidemiologic considerations.
2. Persons with symptoms (see Table 6.1) that meet the case definition for suspected COVID-19 enter into the COVID-19 care pathway and should immediately be given a medical mask and directed to a single room. If a single room is not possible, then group patients with similar clinical diagnosis and based on epidemiological risk factors, with a spatial separation (at least 1 m between patients). Suspected cases should not be cohorted together with confirmed cases (see Chapter 7 on infection prevention and control (IPC)).
3. In areas with other endemic infections that cause fever, such as malaria, dengue, tuberculosis (TB) etc., as part of screening, febrile patients should be tested as per routine protocols *(65,66,67,68,69)*, irrespective of the presence of respiratory signs and symptoms. Coinfection with COVID-19 may coexist.
4. When influenza virus is known or suspected to be circulating, ensure that is also considered as part of screening of patients with fever and influenza-like-illness; and that testing is per local routine protocols. Coinfection with COVID-19 may exist.
5. Large outbreaks have been observed in long-term care facilities (LTCFs) *(63)*. The COVID-19 care pathway should be activated for all residents of LTCFs who are contacts of a confirmed case in that LTCF, including immediate isolation, testing and treatment as needed. The priority focus in these settings should be to ensure the well-being of residents and protect health workers, and implementation of clinical management and IPC that considers the individual's condition and prognosis (such as screening visitors for COVID-19) *(70)*.

In community settings, community health workers should continue to follow usual protocols for recognition and treatment of other common illnesses and danger signs while activating the COVID-19 care pathway (including for referral as needed) for suspect cases. Refer to WHO/IFRC/UNICEF guidance on community-based health care, including outreach and campaigns, in the context of the COVID-19 pandemic *(71)*.

At a health facility, after screening and isolation, triage patients with suspected COVID-19 using a standardized triage tool (such as the WHO/IFRC Interagency Integrated Triage Tool); and evaluate the patient to determine disease severity (see Table 6.3).

- **Initiate timely care for the acutely ill using a systematic approach, as described in WHO/ICRC Basic emergency care *(72,73)*.**
- **After initial assessment, management and stabilization, refer patient to appropriate COVID-19 care destination: within the health facility (critical care unit or ward); to a different health facility; community facility; or home, according to patient medical needs and established COVID-19 care pathways.**

Remarks:

1. Patients with mild and moderate illness may not require emergency interventions or hospitalization; however, isolation is necessary for all suspect or confirmed cases to contain virus transmission. The decision to monitor a suspect case in a health facility, community facility or home should be made on a case-by-case basis. This decision will depend on the clinical presentation, requirement for supportive care, potential risk factors for severe disease (see Table 6.2), and conditions at home, including the presence of vulnerable persons in the household. In situations where TB may co-exist, specific measures may be necessary in addition to the above *(67)*.
2. Early identification of patients at risk for and with severe disease allows for rapid initiation of optimized supportive care treatments and safe, rapid referral to a designated destination in the COVID-19 care pathway (with access to oxygen and respiratory support).
3. Known risk factors for rapid deterioration, severe disease, and/or increased mortality are: older age (> 60 years) and NCDs such as cardiovascular disease, diabetes mellitus, chronic lung disease, cancer and cerebrovascular disease *(28)* (see Table 6.2). Patients with one or more of these risk factors should be monitored closely for deterioration, preferably in a health facility. As described above, the decision to monitor in a health facility, community facility or home should be made on a case-by-case basis. This decision will depend on the clinical presentation, requirement for supportive care, risk factors and conditions at home, including the presence of additional vulnerable persons in the household. Risk factors for severe disease in pregnancy include increasing maternal age, high BMI, non-white ethnicity, pre-existing comorbidities and pregnancy-specific conditions such as gestational diabetes and pre-eclampsia *(53)*.
4. Some patients develop severe pneumonia and require oxygen therapy, and a minority progress to critical disease with complications such as respiratory failure or septic shock (see Table 6.3) *(74,75)*.
5. COVID-19 confirmation needs to be made prior to determining severity; particularly in children, for whom the differential diagnosis for respiratory distress is particularly important.
6. Children with suspected or confirmed COVID-19 infection should be kept together with caregivers wherever possible (if caregivers also have suspected or confirmed COVID-19 infection), and cared for in child-friendly spaces, taking into account specific medical, nursing, nutritional, and mental health and psychosocial support needs of children.

Methods for clinical decision-making in COVID-19

Conditional recommendation for

For patients COVID-19 of any severity assessed in a clinic or hospital, we suggest clinical judgment, including consideration of patients' values and preferences and local and national policy if available, to guide management decisions including admission to hospital and to the ICU, rather than currently available prediction models for prognosis (conditional recommendation, very low certainty).

Evidence to decision

Benefits and harms Important harms

Clinical judgment and policy developed locally or nationally are typically used to make decisions regarding admission of patients with COVID-19 to hospital and to the ICU. Judgment and policy may include ethical considerations regarding allocation of resources. Over the course of the pandemic, many models have been developed for patients with COVID-19 to predict hospital admission, ICU admission, need for

mechanical ventilation, mortality, or other outcomes. All existing models are at unclear or high risk of bias using the multiple domain PROBAST assessment tool *(76)*, and there are as yet no studies of whether the use and implementation of these models improves (shared) decision-making and subsequent patient outcomes. With respect to their effects on patient outcomes, the certainty of evidence for any of these prognostic models is very low.

Certainty of the evidence — Very low

The GDG considered the evidence in favour of prognostic models in patients with COVID-19 to be of very low certainty, due to risk of bias, insufficient predictive accuracy with many models (range of C-statistics for prognosis models 0.54 to 0.99), lack of validation studies, and lack of evidence of the impact of using models on decision-making and patient outcomes. A review and assessment of existing models on their applicability and risks of bias is available (https://www.covprecise.org/living-review/). These prediction models for patient prognosis are distinct from triage models that have been developed to decide which patients are offered admission (typically to an ICU); triage models were not reviewed.

The GDG acknowledged that ongoing model development and validation, along with studies of predictive accuracy and impact on decision-making and patient outcomes of those selected models with sufficient predictive accuracy, may change the certainty of evidence in the future.

Values and preferences — Substantial variability is expected or uncertain

Applying the agreed values and preferences, the GDG inferred that the majority of well-informed physicians and patients would not want care decisions to be based on existing prognostic models, due to the very low certainty of evidence for benefit on patient outcomes. Given the lack of evidence of harm, some patients may choose to have their care informed by the use of such models.

Resources and other considerations — Important considerations

Commonly included predictors in these prognostic models include age, sex, comorbidities, vital signs (e.g. temperature, heart rate, respiratory rate, oxygen saturation, blood pressure), imaging features, lymphocyte count, and C reactive protein (https://www.covprecise.org/living-review/). Some laboratory tests and imaging modalities may not be available in resource-constrained settings, and existing models have not been validated such settings.

Justification

The GDG emphasized the very low certainty evidence supporting the use of prognostic models to enhance clinical-decision making and patient outcomes, and recognized the lack of studies and uncertain feasibility in resource-constrained settings and potential negative impact on health equity, depending on how prognostic models are used to inform clinical decisions. Accordingly, the GDG made a conditional recommendation in favour of usual practice to guide decision-making, consisting of clinical judgment, patients' values and preferences, and local and national policy, if available.

Subgroup analyses

The GDG did not find any evidence bearing on subgroup effects across patients with different levels of COVID-19 disease severity or between children and adults. In other words, the conditional recommendation is applicable across all these subgroups.

Applicability

Special populations

There is insufficient information on the performance and impact of prognostic models in pregnant women. Therefore, the GDG concluded that the recommendation applies to pregnant women.

Practical info

Existing prognostic models are reviewed in a living systematic review, available at https://www.covprecise.org/living-review/.

Uncertainties

Available prognostic models need to be validated in other populations.

Table 6.1 Symptoms associated with COVID-19

Presenting signs and symptoms of COVID-19 vary.

Most persons experience fever (83–99%), cough (59–82%), fatigue (44–70%), anorexia (40–84%), shortness of breath (31–40%), myalgias (11–35%). Other non-specific symptoms, such as sore throat, nasal congestion, headache, diarrhoea, nausea and vomiting, have also been reported *(28,77,78,79)*. Loss of smell (anosmia) or loss of taste (ageusia) preceding the onset of respiratory symptoms has also been reported *(31,80,81)*.

Additional neurological manifestations reported include dizziness, agitation, weakness, seizures, or findings suggestive of stroke including trouble with speech or vision, sensory loss, or problems with balance in standing or walking *(32,33)*.

Older people and immunosuppressed patients in particular may present with atypical symptoms such as fatigue, reduced alertness, reduced mobility, diarrhoea, loss of appetite, confusion, and absence of fever *(62,63,64)*.

Symptoms such as dyspnoea, fever, gastrointestinal (GI) symptoms or fatigue due to physiologic adaptations in pregnant women, adverse pregnancy events, or other diseases such as malaria, may overlap with symptoms of COVID-19 *(82)*.

Children might not have reported fever or cough as frequently as adults *(83)*.

Table 6.2 Risk factors associated with severe disease

Age more than 60 years (increasing with age).

Underlying noncommunicable diseases (NCDs): diabetes, hypertension, cardiac disease, chronic lung disease, cerebrovascular disease, dementia, mental disorders, chronic kidney disease, immunosuppression, obesity and cancer have been associated with higher mortality *(84,85)*.

In pregnancy, increasing maternal age, high BMI, non-white ethnicity, chronic conditions and pregnancy specific conditions such as gestational diabetes and pre-eclampsia *(53)*.

Smoking.

Table 6.3 COVID-19 disease severity

Mild disease		Symptomatic patients (Table 6.1) meeting the case definition for COVID-19 without evidence of viral pneumonia or hypoxia. See the WHO website for most up-to-date case definitions *(1)*.
Moderate disease	**Pneumonia**	**Adolescent or adult** with clinical signs of pneumonia (fever, cough, dyspnoea, fast breathing) but no signs of severe pneumonia, including SpO_2 ≥ 90% on room air *(86)*. **Child** with clinical signs of non-severe pneumonia (cough or difficulty breathing + fast breathing and/or chest indrawing) and no signs of severe pneumonia. Fast breathing (in breaths/min): < 2 months: ≥ 60; 2–11 months: ≥ 50; 1–5 years: ≥ 40 *(87)*. While the diagnosis can be made on clinical grounds; chest imaging (radiograph, CT scan, ultrasound) may assist in diagnosis and identify or exclude pulmonary complications. **Caution:** The oxygen saturation threshold of 90% to define severe COVID-19 was arbitrary and should be interpreted cautiously. For example, clinicians must use their judgment to determine whether a low oxygen

		saturation is a sign of severity or is normal for a given patient with chronic lung disease. Similarly, a saturation >90–94% on room air is abnormal (in patient with normal lungs) and can be an early sign of severe disease, if patient is on a downward trend. Generally, if there is any doubt, the panel suggested erring on the side of considering the illness as severe.
Severe disease	**Severe pneumonia**	**Adolescent or adult** with clinical signs of pneumonia (fever, cough, dyspnoea, fast breathing) plus one of the following: respiratory rate > 30 breaths/min; severe respiratory distress; or SpO_2 < 90% on room air *(86,88)*. **Child** with clinical signs of pneumonia (cough or difficulty in breathing) + at least one of the following: • Central cyanosis or SpO_2 < 90%; severe respiratory distress (e.g. fast breathing, grunting, very severe chest indrawing); general danger sign: inability to breastfeed or drink, lethargy or unconsciousness, or convulsions *(87)*. • Fast breathing (in breaths/min): < 2 months: ≥ 60; 2–11 months: ≥ 50; 1–5 years: ≥ 40 *(87)*. While the diagnosis can be made on clinical grounds; chest imaging (radiograph, CT scan, ultrasound) may assist in diagnosis and identify or exclude pulmonary complications.
Critical disease	**Acute respiratory distress syndrome (ARDS)** *(89,90,91)*	**Onset:** within 1 week of a known clinical insult (i.e. pneumonia) or new or worsening respiratory symptoms. **Chest imaging:** (radiograph, CT scan, or lung ultrasound): bilateral opacities, not fully explained by volume overload, lobar or lung collapse, or nodules. **Origin of pulmonary infiltrates:** respiratory failure not fully explained by cardiac failure or fluid overload. Need objective assessment (e.g. echocardiography) to exclude hydrostatic cause of infiltrates/oedema if no risk factor present. **Oxygenation impairment in adults** *(89,91)*: • Mild ARDS: 200 mmHg < PaO2/FiO2a ≤ 300 mmHg (with PEEP or CPAP ≥ 5 cmH2O).b • Moderate ARDS: 100 mmHg < PaO2/FiO2 ≤ 200 mmHg (with PEEP ≥ 5 cmH2O).b • Severe ARDS: PaO_2/FiO_2 ≤ 100 mmHg (with PEEP ≥ 5 cmH_2O).[b] **Oxygenation impairment in children:** note OI and OSI.[c] Use OI when available. If PaO_2 not available, wean FiO_2 to maintain SpO^2 ≤ 97% to calculate OSI or SpO_2/FiO_2 ratio: • Bilevel (NIV or CPAP) ≥ 5 cmH2O via full face mask: PaO2/FiO2 ≤ 300 mmHg or SpO2/FiO2 ≤ 264. • Mild ARDS (invasively ventilated): 4 ≤ OI < 8 or 5 ≤ OSI < 7.5. • Moderate ARDS (invasively ventilated): 8 ≤ OI < 16 or 7.5 ≤ OSI < 12.3. • Severe ARDS (invasively ventilated): OI ≥ 16 or OSI ≥ 12.3.
	Sepsis *(92,93)*	**Adults:** acute life-threatening organ dysfunction caused by a dysregulated host response to suspected or proven infection. Signs of organ dysfunction include: altered mental status (delirium), difficult or fast breathing, low oxygen saturation, reduced urine output *(92)*, fast heart rate, weak pulse, cold extremities or low blood pressure, skin mottling, laboratory evidence of coagulopathy, thrombocytopenia, acidosis, high lactate, or hyperbilirubinemia. **Children:** suspected or proven infection and ≥ 2 age-based systemic inflammatory response syndrome (SIRS) criteria,[d] of which one must be abnormal temperature or white blood cell count.
	Septic shock *(92,93)*	**Adults:** persistent hypotension despite volume resuscitation, requiring vasopressors to maintain MAP ≥ 65 mmHg and serum lactate level > 2 mmol/L. **Children:** any hypotension (SBP < 5th centile or > 2 SD below normal for age) or two or three of the following: altered mental status; bradycardia or tachycardia (HR < 90 bpm or > 160 bpm in infants and heart rate < 70 bpm or > 150 bpm in children); prolonged capillary refill (> 2 sec) or weak pulse;

		fast breathing; mottled or cool skin or petechial or purpuric rash; high lactate; reduced urine output; hyperthermia or hypothermia *(94)*.
	Acute thrombosis	Acute venous thromboembolism (i.e. pulmonary embolism), acute coronary syndrome, acute stroke.
	MIS-C	**Preliminary case definition:** children and adolescents 0–19 years of age with fever ≥ 3 days **AND** two of the following: rash or bilateral non-purulent conjunctivitis or muco-cutaneous inflammation signs (oral, hands or feet); hypotension or shock; features of myocardial dysfunction, pericarditis, valvulitis, or coronary abnormalities (including ECHO findings or elevated troponin/NT-proBNP); evidence of coagulopathy (by PT, PTT, elevated D-dimers), acute gastrointestinal problems (diarrhoea, vomiting, or abdominal pain); **AND** elevated markers of inflammation such as ESR, C-reactive protein, or procalcitonin. **AND** no other obvious microbial cause of inflammation, including bacterial sepsis, staphylococcal or streptococcal shock syndromes. **AND e**vidence of COVID-19 **(**RT-PCR, antigen test or serology positive), or likely contact with patients with COVID-19. See scientific brief, 15 May 2020 WHO: Multisystemic inflammatory syndrome in children and adolescents temporally related to COVID-19

[a] If altitude is higher than 1000 m, then the correction factor should be calculated as follows: PaO_2/FiO_2 x barometric pressure/760.
[b] When PaO_2 is not available, $SpO_2/FiO_2 \leq 315$ suggests ARDS (including in non-ventilated patients).
[c] Oxygenation Index (OI) is an invasive measurement of the severity of hypoxaemic respiratory failure and may be used to predict outcomes in paediatric patients. It is calculated as follows: percentage of fraction of inhaled oxygen multiplied by the mean airway pressure (in mmHg), divided by the partial pressure of arterial oxygen (in mmHg). Oxygen Saturation Index (OSI) is a non-invasive measurement and has been shown to be a reliable surrogate marker of OI in children and adults with respiratory failure. OSI replaces PaO_2 with oxygen saturation as measured by pulse oximetry (SpO_2) in the OI equation.
[d] SIRS criteria: abnormal temperature (> 38.5 °C or < 36 °C); tachycardia for age or bradycardia for age if < 1 year; tachypnoea for age or need for mechanical ventilation; abnormal white blood cell count for age or > 10% bands.
Abbreviations: BP blood pressure; bpm beats per minute; CPAP continuous positive airway pressure; CT computed tomography; FiO_2 fraction of inspired oxygen; MAP mean arterial pressure; NIV non-invasive ventilation; OI Oxygenation Index; OSI Oxygenation Index using SpO_2; PaO_2 partial pressure arterial oxygen; PEEP positive end-expiratory pressure; SBP systolic blood pressure; SD standard deviation; SIRS systemic inflammatory response syndrome; SOFA sequential organ failure assessment; SpO_2 oxygen saturation.

7. Immediate implementation of appropriate infection prevention and control measures

Infection prevention and control (IPC) is a critical and integral part of clinical management of patients, health workers' safety and hospital-acquired infections. In addition to screening, triage, and rapid source control, WHO guidance emphasizes the importance of administrative, environmental and engineering controls in health care settings *(95)*. Universal masking in health facilities (wearing a mask at all times except when eating or drinking) is required for all persons (staff, patients, visitors, service providers and others) in areas of known or suspected community or cluster SARS-CoV-2 transmission *(96)*, as well as rational and appropriate use of all personal protective equipment (PPE) *(101)*.

For the most up-to-date, comprehensive WHO guidance see *Infection prevention and control during health care when coronavirus disease (COVID-19) is suspected or confirmed (95)* and *Transmission of SARS-CoV- 2: implications for infection prevention precautions*, 9 July 2020 *(102)*.

How to implement IPC measures for patients with suspected or confirmed ***(95)***

Screening and triage for early recognition of suspected COVID-19 patients and rapid implementation of source control measures. Screen all persons at first point of contact in health facility to allow for early recognition followed by their immediate isolation/separation.

Remarks:
Ask the suspected or confirmed COVID-19 patient to wear a medical mask and direct the patient to a separate, well-ventilated area, ideally an isolation room/area if available. Keep at least 1 m distance between patients. Instruct all patients to cover nose and mouth during coughing or sneezing with tissue or flexed elbow, dispose of tissues safely immediately after use in a closed bin and perform hand hygiene

after contact with respiratory secretions. In areas with COVID-19 community transmission, restrict visitors to those that are essential such as the parents of paediatric patients and caregivers and ask them to wear a mask.

Apply standard precautions for all patients.

Remarks:
Apply standard precautions according to risk assessment for all patients, at all times, when providing any diagnostic and care services. Standard precautions include but are not limited to, hand and respiratory hygiene and the appropriate use of PPE; universal masking is required for all persons in areas of known or suspected community or cluster SARS-CoV-2 transmission *(96)*. Standard precautions also include appropriate patient placement; environmental cleaning; prevention of needle-stick or sharps injury and safe waste management.

Carefully practise hand hygiene using an alcohol-based hand rub if hands are not visibly dirty or soap and water and disposable towels, before PPE use and after PPE removal, and when indicated while providing care, according to the WHO Five Moments for hand hygiene *(97)*.

If possible, use either disposable or dedicated equipment (e.g. stethoscopes, blood pressure cuffs, pulse oximeters and thermometers). If equipment needs to be shared among patients, clean and disinfect between each patient use. Ensure that health care workers avoid contaminating environmental surfaces that are not directly related to patient care (e.g. door handles and light switches) and refrain from touching their eyes, nose and mouth with potentially contaminated gloved or ungloved hands. All surfaces should be routinely cleaned and disinfected, especially high touch surfaces, those surfaces touched by patients and whenever visibly soiled or if contaminated with blood and body fluids.

Best practices for safely managing health care waste, including waste related to surgeries and obstetric care, should be followed.

Apply contact and droplet precautions for suspected or confirmed COVID-19 patients.

Remarks:
For suspected and confirmed COVID-19 patients, contact and droplet or airborne precautions should be applied depending on activity to be undertaken. Where possible, designate a team of health workers to care for patients with suspected or confirmed COVID-19 and restrict their contact with COVID-19 patients.

Place all cases in well-ventilated single rooms if feasible. When single rooms are not available or bed occupancy rate is anticipated to be 100% or more, suspected, probable or confirmed COVID-19 patients should be grouped together (cohorted) in adequately ventilated areas with bed space at least 1 m apart.

Limit patient movement within the institution and ensure that patients wear medical masks when outside of their care area (e.g. when being transported).

Health workers should use gloves, a clean, long sleeved gown, medical mask and eye protection (goggles or face shield). Remove PPE when leaving the patient care area, following instructions how to remove PPE safely *(98)*.

Apply airborne precautions when performing aerosol-generating procedures.

Remarks:
Perform procedure in adequately ventilated rooms.

When performing aerosol-generating procedures (tracheal intubation, non-invasive ventilation [CPAP and BiPAP], tracheotomy, cardiopulmonary resuscitation, manual ventilation before intubation, bronchoscopy and sputum induction induced by using nebulized hypertonic saline) or in settings where aerosol-generating procedures are performed, airborne in combination with contact precautions should be used. Use the appropriate PPE, including fit-tested particulate respirators (N95 or equivalent, or higher level of protection), gloves, long-sleeved gowns, eye protection (goggles or face shield). In areas of community transmission, in ICUs where aerosol-generating procedures are frequently performed, the health worker may choose to wear a particulate respirator throughout their shift. There is insufficient evidence to classify

high-flow nasal oxygen (HFNO) and nebulizer therapy as an aerosol-generating procedure that is associated with transmission of COVID-19; thus airborne in combination with contact precautions should be used.

Note: In situations where TB may co-exist, specific measures may be necessary in addition to the above *(67)*.

8. Laboratory diagnosis

For more details, we refer to published WHO guidance *Diagnostic testing for SARS-CoV-2* regarding specimen collection, processing and laboratory testing and the diagnostic algorithm *(99)*.

We recommend, for all suspect COVID-19 cases, at minimum the collection of respiratory specimens for nucleic acid amplification testing (NAAT), for example reverse transcription polymerase chain reaction (RT-PCR). Repetitive testing of upper respiratory tract (URT) and/or lower respiratory tract (LRT) might be needed to establish a diagnosis *(100)*. Additional samples that might aid the diagnosis of COVID-19 can be faecal specimens (if appropriately validated by the receiving laboratory). If deceased consider the collection of postmortem specimens *(99)*. In addition, testing for other respiratory viruses and bacteria should be considered when clinically indicated according to local guidelines.

SARS-CoV-2 antibody tests are not recommended for diagnosis of current infection with COVID-19.

Remarks:

1. Use appropriate PPE for specimen collection (droplet and contact precautions for URT specimens; airborne precautions for LRT specimens). See IPC guidelines for the most up-to-date guidance *(101,102)*.
2. In the first week of symptom onset relatively high viral loads are generally observed in the upper respiratory tract (URT) specimens. For the collection of URT samples, we recommend the collection of nasopharyngeal and oropharyngeal specimens. When collecting URT samples, use viral swabs (sterile Dacron or rayon, not cotton), for nasopharyngeal swabbing use a swab with a long flexible shaft designed for nasopharyngeal sampling. For instructions on appropriate URT sampling see *Clinical care for severe acute respiratory infection toolkit: COVID-19 adaptation (73)*. Unless specified differently by the receiving laboratory, transport sample in viral transport media.
3. LRT (vs URT) samples are more likely to be positive after the first week of illness. Thus if URT are negative and clinical suspicion remains, also collect specimens from the LRT when readily available (expectorated sputum, or endotracheal aspirate/bronchoalveolar lavage in ventilated patient). Clinicians may elect to collect only LRT samples when these are readily available (for example, in mechanically ventilated patients). Sputum induction should be avoided owing to increased risk of aerosol transmission. In a patient with suspected COVID-19, especially with pneumonia or severe illness, a single negative URT sample does not exclude the diagnosis, and additional URT and LRT samples are recommended *(99)*. In hospitalized patients with confirmed COVID-19, repeated URT and LRT samples can be collected, as clinically indicated, but are no longer indicated for release from COVID-19 precautions *(13)*.
4. NAAT testing is the recommended for the diagnosis of COVID-19. However in cases where NAAT is unavailable or where prolonged turnaround times preclude clinical utility, antigen testing can be included in the diagnostic algorithm under the right circumstances. For details on appropriate utilization of antigen testing see interim guidance *Antigen-detection in the diagnosis of SARS-CoV-2 infection using rapid immunoassays (103)*. If antigen testing is used, assure that sample collection and testing is performed according to the instructions for use of the antigen tests, staff are appropriately trained and testing quality is embedded in a diagnostic quality system and assessed regularly.
5. If repetitive negative NAAT/RT-PCR results are obtained from a patient in whom COVID-19 is strongly suspected, a paired serum specimen could be collected. One specimen taken in the acute phase and one in the convalescent phase 2–4 weeks later. This is only useful if validated (semi) quantitative

serology assays and trained staff for the interpretations are available in the receiving laboratory. With these paired samples it can be retrospectively evaluated whether there is seroconversion or a rise in antibody titres, further supporting the suspicion that this individual indeed had recent COVID-19 despite negative NAATs.

Depending on the local epidemiology and clinical symptoms, test for other potential etiologies (e.g. influenza, malaria, dengue fever, typhoid fever) as appropriate.

Remarks:

1. Patients should also be tested for other respiratory pathogens, as recommended in local clinical management guidelines. Examples, but not excluding others as this depends on epidemiological or clinical parameters, are the viral respiratory pathogens influenza A and B (including zoonotic influenza A), respiratory syncytial virus, parainfluenza viruses, rhinoviruses, adenoviruses, enteroviruses (e.g. EVD68), human metapneumovirus and endemic human coronaviruses (i.e. HKU1, OC43, NL63, and 229E). Examples of bacterial pathogens include *Streptococcus pneumoniae, Haemophilus influenzae*, atypical respiratory pathogens (e.g. *Legionella pneumophila, Coxiella burnetii, Chlamydia psittaci or pneumoniae, Mycoplasma pneumoniae*). URT and LRT specimens are generally suitable for viral respiratory pathogens. For bacterial culture sputum or other LRT specimens are required.
2. Dual infections with other respiratory infections (viral, bacterial and fungal) have been found in COVID-19 patients *(104)*. As a result, a positive test for a non-COVID-19 pathogen does not rule out COVID-19, or vice versa. Some microbes found in respiratory culture can be either be a pathogen or be part of normal mouth/respiratory flora, thus evaluation on whether a found micro-organism is a coinfection or part of the normal flora needs to be weighted for each individual patient.
3. In malaria-endemic areas, patients with fever should be tested for the presence of malaria or other co-infections with validated rapid diagnostic tests (RDTs) or thick and thin blood films and treated as appropriate *(105)*. In endemic settings, arbovirus infection (dengue/chikungunya) should also be considered in the differential diagnosis of undifferentiated febrile illness, particularly when thrombocytopenia is present *(65)*. Coinfection with COVID-19 virus may also occur and a positive diagnostic test for dengue (e.g. dengue RDTs) does not exclude the testing for COVID-19 *(106)*. If TB is also suspected, collect sputum with specific instructions (e.g. to be done in open area outside the home and away from others) or in an open, well-ventilated space – preferably outside of the health facility *(67)*. Staff should not stand near the patient during sample collection.
4. When influenza virus is known or suspected to be circulating, test patients with severe or complicated disease and those with risk factors for severe influenza (note, this includes younger children and pregnant women up to two weeks postpartum) for influenza virus with a rapid molecular testing when results can be made available within 24 hours preferably. The longer the time lag between sampling and test results, the less the test will benefit clinical management (see policy brief) *(107)*. Empiric treatment, when indicated, should not be delayed while waiting for results (see Chapter 16. Treatment of other acute and chronic infections in patients with COVID-19).

For COVID-19 patients with severe or critical disease, also collect blood cultures, ideally prior to initiation of antimicrobial therapy *(92)*.

Remark:

If blood cultures cannot be taken timely before the administration of antimicrobial therapies, indicate the details of administered antibiotics on the laboratory request.

9. Management of mild COVID-19: symptomatic treatment

Patients with mild disease may present to an emergency unit, primary care/outpatient department, or be encountered during community outreach activities, such as home visits or by telemedicine.

Please find new recommendation on the use of pulse oximetry at home in Chapter 10 (Management of moderate COVID-19: pneumonia treatment).

We recommend that patients with suspected or confirmed mild COVID-19 be isolated to contain virus transmission according to the established COVID-19 care pathway. This can be done at a designated COVID-19 health facility, community facility or at home (self-isolation).

Remarks:

1. In areas with other endemic infections that cause fever (such as malaria, dengue, etc.), febrile patients should be tested and treated for those endemic infections per routine protocols *(65,66,69)* irrespective of the presence of respiratory signs and symptoms. Coinfection with COVID-19 may occur.
2. The decision to monitor a suspect case with mild COVID-19 in a health facility, community facility or home should be made on a case-by-case basis based on the local COVID-19 care pathway. Additionally, this decision may depend on the clinical presentation, requirement for supportive care, potential risk factors for severe disease, and conditions at home, including the presence of vulnerable persons in the household.
3. If managed at home in self-isolation, refer to WHO guidance on home care for patients with COVID-19 presenting with mild symptoms and management of their contacts *(108)*.

We recommend patients with mild COVID-19 be given symptomatic treatment such as antipyretics for fever and pain, adequate nutrition and appropriate rehydration.

Remark:
At present, there is no evidence to indicate that there are severe adverse events in patients with COVID-19 as a result of the use of non-steroidal anti-inflammatory drugs *(109)*.

Counsel patients with mild COVID-19 about signs and symptoms of complications that should prompt urgent care.

Remark:
Patients with risk factors for severe illness should be monitored closely, given the possible risk of deterioration. If they develop any worsening symptoms (such as light headedness, difficulty breathing, chest pain, dehydration, etc.), they should seek urgent care through the established COVID-19 care pathway. Caregivers of children with mild COVID-19 should monitor for signs and symptoms of clinical deterioration requiring urgent re-evaluation. These include difficulty breathing/fast or shallow breathing (for infants: grunting, inability to breastfeed), blue lips or face, chest pain or pressure, new confusion, inability to awaken/not interacting when awake, inability to drink or keep down any liquids. Consider alternative delivery platforms such as home-based, phone, telemedicine or community outreach teams to assist with monitoring *(110)*. See new recommendation in Chapter 10 on use of home pulse oximetry.

We recommend that antibiotic therapy or prophylaxis should not be used in patients with mild COVID-19.

Remark:
Widespread use of antibiotics should be discouraged, as their use may lead to higher bacterial resistance rates, which will impact the burden of disease and deaths in a population during the COVID-19 pandemic and beyond *(111,112,113)*.

10. Management of moderate COVID-19: pneumonia treatment

Patients with moderate disease may present to an emergency unit or primary care/outpatient department, or be encountered during community outreach activities, such as home visits or by telemedicine. See Table 6.3 for definition of non-severe pneumonia.

Please find new recommendation on the use of pulse oximetry at home in this chapter as the second recommendation.

We recommend that patients with suspected or confirmed moderate COVID-19 (pneumonia) be isolated to contain virus transmission. Patients with moderate illness may not require emergency interventions or hospitalization; however, isolation is necessary for all suspect or confirmed cases.

- **The location of isolation will depend on the established COVID-19 care pathway and can be done at a health facility, community facility or at home.**
- **The decision on location should be made on a case-by-case basis and will depend on the clinical presentation, requirement for supportive care, potential risk factors for severe disease, and conditions at home, including the presence of vulnerable persons in the household.**
- **For patients at high risk for deterioration (see Table 6.2), isolation in hospital is preferred.**

Remark:
In areas with other endemic infections that cause fever (such as malaria, dengue, etc.), febrile patients should be tested and treated for those endemic infections per routine protocols *(65,66,105)*, irrespective of the presence of respiratory signs and symptoms. Coinfection with COVID-19 may occur.

Conditional recommendation for

For symptomatic patients with COVID-19 and risk factors for progression to severe disease who are not hospitalized, we suggest the use of pulse oximetry monitoring at home as part of a package of care, including patient and provider education and appropriate follow-up (conditional recommendation, very low certainty evidence).

Evidence to decision

Benefits and harms — Uncertain benefits or harms

Possible theoretical benefits of home oximetry monitoring include earlier detection of and intervention for severe disease (such as more intense monitoring for deterioration or starting corticosteroid therapy), patient reassurance in case of normal values, limiting hospital strain due to prevented admission of patients who may not need acute care, and increased opportunities for patient-provider educational conversations (very low certainty).

Possible harms of home oximetry monitoring include the possibility of increased patient anxiety and stress, the possibility of increased hospital visits for patients who would otherwise not seek out hospital care, and the possibility of false reassurance with misinterpretation of the data. Low quality or inaccurate pulse oximeters, particularly with pulse oximeters not validated in different skin colours, may provide false reassurance or false alarms (very low certainty).

The GDG suggested that the possible benefits would outweigh the possible harms, and this may be most likely in specific subgroups of patients, i.e. those with symptoms and those with risk factors for severe disease. The GDG also suggested that the intervention would only have benefit in symptomatic patients with COVID-19, and that asymptomatic patients would have no benefit.

Certainty of the evidence	Very low

For key outcomes of hospitalization, mortality, mechanical ventilation, and ICU admission the panel considered the evidence to be of very low certainty.

Values and preferences	No substantial variability expected

Applying the agreed values and preferences, the GDG inferred that well-informed patients would consider the minimal possible harms associated with home oximetry monitoring to not outweigh the possible, theoretical benefits on the outcomes of hospitalization and patient satisfaction. Patient members of the panel agreed with this standard.

Resources and other considerations	Important considerations

Home oximetry monitoring is not accessible to many patients, due to lack of available equipment, lack of relevant personnel to monitor it, lack of ability to interpret the results at home, or lack of knowledge about implementation. Home pulse oximetry may be useful in certain settings, including low-resource settings, particularly when hospitals are strained and where it may be necessary to effectively monitor patients in a home-based setting. However, home oximetry monitoring will only be of value if the users are adequately informed on how to interpret the readings and have ready access to providers who can advise on the response to readings. Considerations for education and training of patients and providers, as well as adequate staffing, to implement care pathways with available access to acute care, will need to be integrated.

Justification

When moving from evidence to the conditional recommendation for the use of home pulse oximetry monitoring for patients with COVID-19, the panel emphasized the lack of evidence in either direction and the need for high-quality clinical trials examining both patient symptoms of stress, as well as other clinical outcomes listed above. The panel also emphasized contextual factors, such as resource considerations, accessibility, feasibility, and impact on health equity as important considerations. Ultimately, the panel thought that the theoretical benefit targeted to symptomatic and high-risk populations was notable only as part of a larger package of care including education and follow-up. Important caveats raised by the panel included the importance of integrating any intervention with education between providers and patients about the meaning of relevant output from the pulse oximeter and ability to act on results.

Subgroup analyses

There were insufficient data based on the presented data to perform any subgroup analyses.

Applicability

Special populations

There is no evidence for home pulse oximetry monitoring for patients with COVID-19 in special populations. Considerations for implementation and applicability centred around focusing on higher-risk populations, where benefits would be most notable. Please see Table 6.2 for information on definitions of who would be considered high risk for this implementation.

Practical info

The GDG made a conditional recommendation for the use of home pulse oximetry monitoring. This recommendation is predicated on the availability and accessibility of high-quality and reliable pulse oximeters for home use; the integration of home pulse oximetry into a health system, from a training and human resources perspective; and targeting the intervention to patients who would likely get the most benefit, namely those at high risk and those who are symptomatic. Also, no recommendation was made on the frequency or duration of pulse oximetry monitoring. *Note:* training on appropriate IPC (cleaning and disinfection) should be included.

Uncertainties

The panel encourage further research to clarify uncertainties, especially in low-resource settings. Research gaps remain as to ensuring standards of quality across pulse oximeter devices.

PICO (12.1)
Population: Patients treated at home with confirmed or suspected COVID-19 disease
Intervention: SpO_2 < 92% (Pulse oximetry use at home)
Comparator: SpO_2 ≥ 92% (Pulse oximetry use at home)

Outcome Timeframe	**Study results and measurements**	**Absolute effect estimates** SpO_2 ≥ 92% (Pulse oximetry use at home)	 SpO_2 < 92% (Pulse oximetry use at home)	**Certainty of the evidence** (Quality of evidence)	**Plain text summary**
Hospitalization	Relative risk: 7.0 (CI 95% 3.4–14.5) Based on data from 77 patients in 1 study	**103** per 1000	**840** per 1000 Difference: **737 more per 1000** (CI 95% 453 more – 1597 more)	**Very low** Due to serious risk of bias. Due to serious imprecision[a]	SpO_2 < 92% possibly increases need for hospitalization.
ICU admission	Relative risk: 9.8 (CI 95% 2.2–44.6) Based on data from 77 patients in 1 study	per 1000	per 1000 Difference: **fewer per 1000**	**Very low** Due to serious risk of bias. Due to serious imprecision[b]	SpO_2 < 92% possibly increases need for ICU admission.
ARDS	Relative risk: 8.2 (CI 95% 1.7–38.7) Based on data from 77 patients in 1 study	per 1000	per 1000 Difference: **fewer per 1000**	**Very low** Due to serious risk of bias. Due to serious imprecision[c]	SpO_2 < 92% possibly increases the risk of ARDS.
Septic shock	Relative risk: 6.6 (CI 95% 1.3–32.9) Based on data from 77 patients in 1 study	per 1000	per 1000 Difference: **fewer per 1000**	**Very low** Due to serious risk of bias. Due to serious imprecision[d]	SpO_2 < 92% possibly increases the risk of septic shock.
Hospitalization	Based on data from patients in 2 studies	Two small single arm (no comparator group) studies that offered home monitoring to patients discharged from emergency department. 3/20 (150 per 1000) and 6/52 (115 per 1000) of patients using home SpO_2 monitors required hospitalization.		**Very low** Due to serious risk of bias. Due to serious imprecision[e]	No data re whether home SpO_2 monitoring vs no monitoring affects hospitalization rates.

[a] **Risk of bias: serious. Imprecision: serious.**
[b] **Risk of bias: serious. Imprecision: serious.**
[c] **Risk of bias: serious. Imprecision: serious.**
[d] **Risk of bias: serious. Imprecision: serious.**
[e] **Risk of bias: serious. Imprecision: serious.**

We recommend for patients with suspected or confirmed moderate COVID-19, that antibiotics should not be prescribed unless there is clinical suspicion of a bacterial infection.

Remarks:

1. Few patients with COVID-19 experience a secondary bacterial infection. A recent systematic review of patients hospitalized with COVID-19 reported only 8% were reported as experiencing bacterial/fungal co-infection during hospital admission *(104)*.
2. Consider in older people, particularly those in LTCFs, and children < 5 years of age, to provide empiric antibiotic treatment for possible pneumonia *(111,112)*. As these patients are not hospitalized, treatment with Access antibiotics (such as co-amoxicillin) is adequate, instead of broad-spectrum antibiotics (Watch and Reserve antibiotics) *(113)*.

We recommend close monitoring of patients with moderate COVID-19 for signs or symptoms of disease progression. Provision of mechanisms for close follow up in case of need of escalation of medical care should be available.

Remarks:

1. For patients being treated at home, counselling regarding signs and symptoms of complications (such as difficulty breathing, chest pain, etc.) should be provided to patients and their caregivers. If they develop any of these symptoms, they should seek urgent care through the established COVID-19 care pathway. Consider alternative delivery platforms such as home-based, phone, telemedicine or community outreach teams to assist with monitoring.
2. For hospitalized patients, regularly monitor vital signs (including pulse oximetry) and, where possible, utilize medical early warning scores (e.g. NEWS2, PEWS) that facilitate early recognition and escalation of treatment of the deteriorating patient *(114)*.

11. Management of severe COVID-19: severe pneumonia treatment

Please find new recommendation on awake prone positioning in this chapter as the fourth recommendation.

All areas where severe patients may be cared for should be equipped with pulse oximeters, functioning oxygen systems and disposable, single-use, oxygen-delivering interfaces (nasal cannula, Venturi mask and mask with reservoir bag).

Remark:
This includes areas in any part of health facilities, including emergency units, critical care units, primary care/outpatient clinics, as well as pre-hospital settings and ad hoc community facilities that may receive patients with severe COVID-19. See WHO *Oxygen sources and distribution for COVID-19 treatment centres (115)*.

We recommend immediate administration of supplemental oxygen therapy to any patient with emergency signs during resuscitation to target SpO_2 ≥ 94% and to any patient without emergency signs and hypoxaemia (i.e. stable hypoxaemic patient) to target SpO_2 > 90% or ≥ 92–95% in pregnant women.

Remarks for adults:

1. Adults with emergency signs (obstructed or absent breathing, severe respiratory distress, central cyanosis, shock, coma and/or convulsions) should receive emergency airway management and oxygen therapy during resuscitation to target SpO_2 ≥ 94% *(72,116)*.
2. Once the patient is stable, target > 90% SpO_2 in non-pregnant adults and ≥ 92–95% in pregnant women.
3. Deliver oxygen flow rates using appropriate delivery devices (e.g. use nasal cannula for rates up to 5 L/min; Venturi mask for flow rates 6–10 L/min; and face mask with reservoir bag for flow rates 10–15 L/min). For more details about oxygen titration, refer to the WHO *Clinical care for severe acute respiratory infection toolkit: COVID-19 adaptation (73)*.
4. In adults, techniques such as positioning, e.g. high supported sitting, may help to optimize oxygenation, ease breathlessness and reduce energy expenditure *(117)*.
5. In adult patients with evidence of increased secretion production, secretion retention, and/or weak cough, airway clearance management may assist with secretion clearance. Techniques include gravity-assisted drainage and active cycle of breathing technique. Devices including mechanical insufflation-exsufflation and inspiratory positive pressure breathing should be avoided where possible. Implementation of techniques should be tailored to the individual patient and follow available guidelines *(117)*.

Remarks for children:

1. Children with emergency signs (obstructed or absent breathing, severe respiratory distress, central cyanosis, shock, coma or convulsions) should receive emergency airway management and oxygen therapy during resuscitation to target SpO_2 ≥ 94% *(72,116,118)*.
2. Once patient is stable, the target is > 90% SpO_2 *(118)*.
3. Use of nasal prongs or nasal cannula is preferred in young children, as they may be better tolerated.

Closely monitor patients for signs of clinical deterioration, such as rapidly progressive respiratory failure and shock and respond immediately with supportive care interventions.

Remarks:

1. Patients hospitalized with COVID-19 require regular monitoring of vital signs (including pulse oximetry) and, where possible, utilization of medical early warning scores (e.g. NEWS2, PEWS) that facilitate early recognition and escalation of treatment of the deteriorating patient *(114)*.
2. Haematology and biochemistry laboratory testing and electrocardiogram and chest imaging should be performed at admission and as clinically indicated to monitor for complications, such as ARDS and acute liver injury, acute kidney injury, acute cardiac injury, disseminated intravascular coagulation (DIC) and/or shock. Application of timely, effective and safe supportive therapies is the cornerstone of therapy for patients who develop severe manifestations of COVID-19.
3. Monitor patients with COVID-19 for signs or symptoms suggestive of venous or arterial thromboembolism, such as stroke, deep venous thrombosis, pulmonary embolism or acute coronary syndrome, and proceed according to hospital protocols for diagnosis (such as laboratory tests and/or imaging) and further management.
4. After resuscitation and stabilization of the pregnant woman, fetal well-being should be monitored. The frequency of fetal heart rate observations should be individualized based on gestational age, maternal clinical status (e.g. hypoxia) and fetal conditions.

Conditional recommendation for

We suggest awake prone positioning of severely ill patients hospitalized with COVID-19 requiring supplemental oxygen (includes high-flow nasal oxygen) or non-invasive ventilation (conditional, low certainty evidence).

Evidence to decision

Benefits and harms — Uncertain benefits or harms

There have been no randomized controlled trials (RCTs) completed for awake prone positioning for patients with COVID-19 requiring supplemental oxygen or non-invasive ventilation. Observational studies of awake prone position in patients with COVID-19 suggest benefits on patient-important outcomes of mortality and the need for intubation COVID-19 (very low certainty). Evidence from RCTs of prone positioning for intubated, critically ill patients with ARDS (non-COVID-19) have demonstrated benefits in mortality. The effect on less important outcomes is uncertain.
The harms of awake prone positioning are possibly patient discomfort and pain (very low certainty). The indirect evidence on harms of prone positioning from the randomized evidence on sedated, intubated patients are pressure sores, nerve injury, and haemodynamic instability, which were not considered relevant for this less severely ill population.

Certainty of the evidence — Low

For patient-important outcomes of mortality and the need for mechanical ventilation, the panel considered the direct evidence to be of very low certainty. For the patient-important outcomes of mortality, indirect evidence from intubated, sedated patients with ARDS was downgraded for indirectness, from high to low, with key considerations including the different physiology of critical disease, data from a non-COVID-19 period, and the different sedation strategies employed.

Values and preferences — No substantial variability expected

Applying the agreed values and preferences, the GDG inferred that almost all well-informed patients would want to undergo prone positioning if awake, requiring oxygen or non-invasive respiratory support, given the lack of harm from the observational studies and panel experience. The panel did not expect there would be much variation in values and preferences between patients when it came to this intervention. Patient discomfort for prone position could limit time spent in individual circumstances.

Resources and other considerations — Important considerations

Patients who are able to follow instructions can self-prone, without assistance from health care workers. Proning patients who require assistance is associated with human resource requirements regarding training, particularly with monitoring of respiratory status. The panel felt that that this intervention should be feasible in all settings, but implementation requires dedicated training and monitoring.

Justification

When moving from evidence to the conditional recommendation for the use of awake prone positioning in severely ill hospitalized patients with COVID-19, the panel emphasized the low certainty evidence of reduction in mortality, downgraded from higher certainty evidence in critically ill patients with ARDS. It also noted the limited harm with the experience thus far with awake prone positioning across different resource settings.

Subgroup analyses

The panel commented on the need for data in specific populations, namely paediatrics, older people, and pregnant women in the first two trimesters.

Practical info

The GDG made a conditional recommendation for awake prone positioning in severely ill patients with COVID-19 requiring supplemental oxygen (including HFNO) or non-invasive ventilation.

In light of the uncertain benefits of awake prone positioning, a high level of vigilance should be maintained, and patients should be monitored closely for signs of clinical deterioration.

Monitoring of patients and training of providers in caring for patients who are awake and prone is an important part of implementation, as part of multi-faceted training for acute care management, which includes medical device training.

As for duration, some suggest regimens that target being in awake prone position for 8–12 hours/day, broken into shorter periods over the day.

Uncertainties

Further RCTs are recommended to better define benefits and harms, as well as specific populations of interest.

PICO (13.1)

Population: Patients hospitalized with severe COVID-19 infection
Intervention: Awake prone positioning + usual care
Comparator: Usual care

Outcome Timeframe	**Study results and measurements**	**Absolute effect estimates** Usual care	Awake prone positioning + usual care	**Certainty of the evidence** (Quality of evidence)	**Plain text summary**
Mortality	Based on data from 334 patients in 17 studies	17 single arm (no comparator group) studies that enrolled a total of 334 participants. 37/334 (110 per 1000) patients positioned prone while receiving oxygen supplementation or NIV dead.		**Very low** Due to serious risk of bias. Due to very serious imprecision[a]	There are no comparative data assessing the effect of awake proning in COVID-19 patients with regards to mortality.

Intubation	Based on data from 450 patients in 25 studies	25 single arm (no comparator group) studies that enrolled a total of 450 participants. 130/450 (289 per 1000) patients positioned prone while receiving oxygen supplementation or NIV required intubation.	**Very low** Due to serious risk of bias. Due to very serious imprecision[b]	There are no comparative data assessing the effect of awake proning in COVID-19 patients with regards to intubation rates.
Adverse effect (pain or discomfort)	Based on data from 151 patients in 6 studies	6 single arm (no comparator group) studies that enrolled a total of 151 participants. 29/151 (192 per 1000) patients positioned prone while receiving oxygen supplementation or NIV reported pain or discomfort.	**Very low** Due to serious risk of bias. Due to very serious imprecision[c]	There are no comparative data assessing the effect of awake proning in COVID-19 patients with regards to adverse events.

[a] **Risk of bias: serious. Imprecision: very serious.**
[b] **Risk of bias: serious. Imprecision: very serious.**
[c] **Risk of bias: serious. Imprecision: very serious.**

Use cautious fluid management in patients with COVID-19 without tissue hypoperfusion and fluid responsiveness.

Remark:

Patients with COVID-19 should be treated cautiously with intravenous fluids; aggressive fluid resuscitation may worsen oxygenation, especially in settings where there is limited availability of mechanical ventilation *(119)*. This applies to both children and adults.

12. Management of critical COVID-19: acute respiratory distress syndrome (ARDS)

The mortality in hospitalized and critically ill patients has varied substantially in different case series throughout the pandemic. The following recommendations are aligned with current international standards for management of all cause ARDS *(92)*.

Please find new recommendation on the use of existing care bundles in Chapter 14 (Prevention of complications in hospitalized and critically ill patients with COVID-19).

The following recommendations pertain to adult and paediatric patients with mild ARDS who are treated with non-invasive or HFNO systems.

In selected patients with COVID-19 and mild ARDS, a trial of HFNO, non-invasive ventilation – continuous positive airway pressure (CPAP), bilevel positive airway pressure (BiPAP) may be used. Refer to Table 6.3 for definitions of mild, moderate and severe ARDS.

Remarks:

1. Patients with hypoxaemic respiratory failure and haemodynamic instability, multiorgan failure or abnormal mental status should not receive HFNO or NIV in place of other options such as invasive ventilation.
2. Patients receiving a trial of HFNO or NIV should be in a monitored setting and cared for by personnel experienced with HFNO and/or NIV and capable of performing endotracheal intubation in case the patient acutely deteriorates or does not improve after a short trial (about 1 hour). Intubation should not be delayed if the patient acutely deteriorates or does not improve after a short trial.
3. Adult HFNO systems can deliver 60 L/min of gas flow and FiO_2 up to 1.0. Paediatric circuits generally only handle up to 25 L/min, and many children will require an adult circuit to deliver adequate flow. When considering delivering HFNO or NIV outside the usual care settings, evaluating oxygen capacity is important to ensure the higher flow rates required for these devices can be maintained. See WHO *Oxygen sources and distribution for COVID-19 treatment centres (115)*.

4. Because of uncertainty around the potential for aerosolization, HFNO, NIV, including bubble CPAP, should be used with airborne precautions until further evaluation of safety can be completed. If these interventions are performed outside of private rooms in ICUs with appropriate ventilation systems installed, then cohorting of patients requiring these interventions in designated wards will facilitate the implementation of airborne precautions, ensuring all staff entering wear appropriate PPE and adequate environmental ventilation is ensured.
5. Compared with standard oxygen therapy, HFNO may reduce the need for intubation *(121)*. Patients with hypercapnia (exacerbation of obstructive lung disease, cardiogenic pulmonary oedema), haemodynamic instability, multiorgan failure or abnormal mental status should generally not receive HFNO, although emerging data suggest that HFNO may be safe in patients with mild-moderate and non-worsening hypercapnia *(121)*. Evidence-based guidelines on HFNO do not exist, and reports on HFNO in patients infected with other coronaviruses are limited *(122,123)*.
6. NIV guidelines make no recommendation on use in hypoxaemic respiratory failure (apart from cardiogenic pulmonary oedema, postoperative respiratory failure and early NIV for immunocompromised patients) or pandemic viral illness (referring to studies of SARS and pandemic influenza) *(120)*. Risks include delayed intubation, large tidal volumes, and injurious transpulmonary pressures. Limited data suggest a high failure rate in patients with other viral infections such as MERS-CoV who receive NIV *(123)*.
7. In situations where mechanical ventilation might not be available, bubble nasal CPAP may be a more readily available alternative for newborns and children with severe hypoxaemia *(124)*.

The following recommendations pertain to adult and paediatric patients with ARDS who need intubation and invasive mechanical ventilation.

We recommend prompt recognition of progressive acute hypoxaemic respiratory failure when a patient with respiratory distress is failing to respond to standard oxygen therapy and adequate preparation to provide advanced oxygen/ventilatory support.

Remark:

Patients may continue to have increased work of breathing or hypoxaemia even when oxygen is delivered via a face mask with reservoir bag (flow rates of 10–15 L/min, which is typically the minimum flow required to maintain bag inflation; FiO_2 0.60–0.95). Hypoxaemic respiratory failure in ARDS commonly results from intrapulmonary ventilation-perfusion mismatch or shunt and usually requires mechanical ventilation *(92)*.

We recommend that endotracheal intubation be performed by a trained and experienced provider using airborne precautions.

Remark:

Patients with ARDS, especially young children or those who are obese or pregnant, may desaturate quickly during intubation. Pre-oxygenation with 100% FiO_2 for 5 minutes, and use of a face mask with reservoir bag is preferred. When possible, avoid bag-valve mask ventilation to reduce exposure to aerosols. Rapid-sequence intubation is appropriate after an airway assessment that identifies no signs of difficult intubation *(125,126,127)*.

The following recommendations pertain to mechanically ventilated adult and paediatric patients with ARDS *(92,128)*.

We recommend implementation of mechanical ventilation using lower tidal volumes (4–8 mL/kg predicted body weight [PBW]) and lower inspiratory pressures (plateau pressure < 30 cmH_2O).

Remark for adults:
The implementation of mechanical ventilation using lower tidal volumes and lower inspiratory pressures is a strong recommendation from a clinical guideline for patients with ARDS *(92)*, and is also suggested for patients with sepsis-induced respiratory failure who do not meet ARDS criteria *(92)*. The initial target tidal

volume is 6 mL/kg PBW; tidal volume up to 8 mL/kg PBW is allowed if undesirable side-effects occur (e.g. dyssynchrony, pH < 7.15). Permissive hypercapnia is permitted. Ventilator protocols are available *(129)*. The use of deep sedation may be required to control respiratory drive and achieve tidal volume targets.

Remarks for children:
In children, a lower level of plateau pressure (< 28 cmH_2O) is targeted, and a lower target of pH is permitted (7.15–7.30). Tidal volumes should be adapted to disease severity: 3–6 mL/kg PBW in the case of poor respiratory system compliance, and 5–8 mL/kg PBW with better preserved compliance *(128)*.

In adult patients with severe ARDS (PaO_2/FiO_2 < 150) prone ventilation for 12–16 hours per day is recommended.

Remarks:
Application of prone ventilation is recommended for adult patients, preferably for 16 hours per day, and may be considered for paediatric patients with severe ARDS but requires sufficient human resources and expertise to be performed safely; protocols (including videos) are available *(130,131)*.
There is little evidence on prone positioning in pregnant women with ARDS; this could be considered in early pregnancy. Pregnant women in the third trimester may benefit from being placed in the lateral decubitus position.

Use a conservative fluid management strategy for ARDS patients without tissue hypoperfusion and fluid responsiveness.

Remarks for adults and children:
This has also been recommended in another international guideline *(92)*. The main effect is to shorten the duration of ventilation. A sample protocol for implementation of this recommendation is available *(132)*.

In patients with moderate or severe ARDS, a trial of higher positive end-expiratory pressure (PEEP) instead of lower PEEP is suggested and requires consideration of benefits versus risks. In COVID-19, we suggest the individualization of PEEP where during titration the patient is monitored for effects (beneficial or harmful) and driving pressure.

Remarks:
PEEP titration requires consideration of benefits (reducing atelectrauma and improving alveolar recruitment) vs risks (end-inspiratory overdistension leading to lung injury and higher pulmonary vascular resistance). Tables are available to guide PEEP titration based on the FiO_2 required to maintain SpO_2 *(133)*. In younger children, maximal PEEP pressures are 15 cmH_2O. Although high driving pressure (plateau pressure − PEEP) may more accurately predict increased mortality in ARDS compared with high tidal volume or plateau pressure *(134)*; data from RCTs of ventilation strategies that target driving pressure are not currently available.
A related intervention of recruitment manoeuvres (RMs) is delivered as episodic periods of high CPAP (30–40 cmH_2O), progressive incremental increases in PEEP with constant driving pressure, or high driving pressure; considerations of benefits vs risks are similar. Higher PEEP and RMs were both conditionally recommended in a clinical practice guideline. For PEEP, the guideline considered an individual patient data meta-analysis *(135)* of three RCTs. However, a subsequent RCT of high PEEP and prolonged high-pressure RMs showed harm, suggesting that the protocol in this RCT should be avoided *(136)*. Monitoring of patients to identify those who respond to the initial application of higher PEEP or a different RM protocol and stopping these interventions in non-responders are suggested *(137)*.

In patients with moderate-severe ARDS (PaO_2/FiO_2 < 150), neuromuscular blockade by continuous infusion should not be routinely used.

Remark:
A trial found that this strategy improved survival in adult patients with moderate-severe ARDS (PaO_2/FiO_2 < 150) without causing significant weakness *(138)*, but results of a recent larger trial found that use of neuromuscular blockade with high PEEP strategy was not associated with a survival benefit when

compared with a light sedation strategy without neuromuscular blockade *(139)*. Intermittent or continuous neuromuscular blockade may still be considered in patients with ARDS, both adults and children, in certain situations: ventilator dyssynchrony despite sedation, such that tidal volume limitation cannot be reliably achieved; or refractory hypoxaemia or hypercapnia.

Avoid disconnecting the patient from the ventilator, which results in loss of PEEP, atelectasis and increased risk of infection of health care workers.

Remarks:

Use in-line catheters for airway suctioning and clamp endotracheal tube when disconnection is required (for example, transfer to a transport ventilator).
Manual hyperinflation should be avoided and ventilator hyperinflation used instead, if indicated *(117)*.

In patients with excessive secretions, or difficulty clearing secretions, consider application of airway clearance techniques. These should be performed only if deemed medically appropriate *(117)* and appropriate IPC measures are in place.

Remarks:

Active cycle of breathing techniques and positioning techniques can be used to optimize oxygenation *(140,141)*. Techniques for airway clearance and secretion management include positioning with gravity-assisted drainage, active cycle of breathing techniques, positive expiratory pressure therapy, and assisted or stimulated cough manoeuvres *(141)*. These techniques are only indicated for patients with mucous hypersecretion and difficulties clearing secretions, and for patients with co-existing respiratory or neuromuscular comorbidities *(141)*.
All interventions inducing cough for airway clearance are potentially aerosol-generating procedures, and airborne precautions should be in place (see Chapter 7 on IPC) *(95)*; and single-patient-use disposable options are recommended (such as positive expiratory pressure device).
Consider use respiratory muscle training in patients recovering from critical illness with suspected respiratory muscle weakness *(141)*.
Especially for critically ill patients, the early involvement of the multidisciplinary rehabilitation team is paramount to improve short- and long-term outcomes. This may include physiotherapists, occupational therapists, speech and language therapists, mental health and psychosocial providers, dieticians and in complex cases, physical and rehabilitation medicine doctors. However, rehabilitation workforce composition may vary by context and availability in different parts of the world.

The following recommendations pertain to adult and paediatric patients with ARDS in whom lung protective ventilation strategy fails to achieve adequate oxygenation and ventilation.

In settings with access to expertise in ECMO, consider referral of patients who have refractory hypoxaemia (e.g. including a ratio of partial pressure of arterial oxygen [PaO_2] to the fraction of inspired oxygen [FiO_2] of < 50 mmHg for 3 hours, a PaO_2:FiO_2 of < 80 mmHg for > 6 hours) despite lung protective ventilation.

Remarks for adults:
An RCT of ECMO for adult patients with ARDS was stopped early and found no statistically significant difference in the primary outcome of 60-day mortality between ECMO and standard medical management (including prone positioning and neuromuscular blockade) *(142)*. However, ECMO was associated with a reduced risk of the composite outcome that consisted of mortality and crossover to ECMO treatment *(142)*, and a post-hoc Bayesian analysis of this RCT showed that ECMO is very likely to reduce mortality across a range of prior assumptions *(143)*. In patients with MERS, ECMO vs conventional treatment was associated with reduced mortality in a cohort study *(123)*. ECMO is a resource-intensive therapy and should be offered only in expert centres with a sufficient case volume to maintain expertise and staff volume and capacity to apply the IPC measures required *(144,145)*. In children, ECMO can also be considered in those with severe ARDS, although high-quality evidence for benefit is lacking *(128)*.

13. Management of critical COVID-19: septic shock

The mortality in hospitalized and critically ill patients has varied substantially in different case series throughout the pandemic. The following recommendations are aligned with current international standards for management of all-cause sepsis *(92)*.

Please find new recommendation on the use of existing care bundles in Chapter 14 (Prevention of complications in hospitalized and critically ill patients with COVID-19).

Recognize septic shock in adults when infection is suspected or confirmed AND vasopressors are needed to maintain mean arterial pressure (MAP) ≥ 65 mmHg AND lactate is ≥ 2 mmol/L, in the absence of hypovolaemia (see Table 6.3).

Recognize septic shock in children with any hypotension (SBP < 5th centile or > 2 SD below normal for age) or two or more of the following: altered mental status; bradycardia or tachycardia (HR < 90 bpm or > 160 bpm in infants and HR < 70 bpm or > 150 bpm in children); prolonged capillary refill (> 2 sec) or feeble pulses; tachypnoea; mottled or cold skin or petechial or purpuric rash; increased lactate; oliguria; hyperthermia or hypothermia (see Table 6.3).

Remarks:

1. In the absence of a lactate measurement, use blood pressure (i.e. MAP) and clinical signs of perfusion to define shock.
2. Standard care includes early recognition and the following treatments to be done immediately, within 1 hour of recognition: antimicrobial therapy, and initiation of fluid bolus and vasopressors for hypotension *(92)*. The use of central venous and arterial catheters should be based on resource availability and individual patient needs. Detailed guidelines from the Surviving Sepsis Campaign and WHO are available for the management of septic shock in adults *(92)* and children *(87,93)*. Alternate fluid regimens are suggested when caring for adults and children in resource-limited settings *(146,147)*.

The following recommendations pertain to resuscitation strategies for adult and paediatric patients with septic shock.

In resuscitation for septic shock in adults, give 250–500 mL crystalloid fluid as rapid bolus in first 15–30 minutes.

In resuscitation for septic shock in children, give 10–20 mL/kg crystalloid fluid as a bolus in the first 30–60 minutes.

Fluid resuscitation may lead to volume overload, including respiratory failure, particularly with ARDS. If there is no response to fluid loading or signs of volume overload appear (e.g. jugular venous distension, crackles on lung auscultation, pulmonary oedema on imaging, or hepatomegaly), then reduce or discontinue fluid administration. This step is particularly important in patients with hypoxaemic respiratory failure.

Remarks:

1. Crystalloids include normal saline and Ringer's lactate.
2. Determine the need for additional fluid boluses (250–500 mL in adults; 10–20 mL/kg in children) based on clinical response and improvement of perfusion targets and reassess for signs of fluid overload after each bolus. Perfusion targets include MAP (> 65 mmHg or age-appropriate targets in children), urine output (> 0.5 mL/kg/hr in adults; 1 mL/kg/hr in children), and improvement of skin mottling and extremity perfusion, capillary refill, heart rate, level of consciousness, and lactate.
3. Consider dynamic indices of volume responsiveness to guide volume administration beyond initial resuscitation based on local resources and experience *(92)*. These indices include passive leg raises, fluid challenges with serial stroke volume measurements, or variations in systolic pressure, pulse

pressure, inferior vena cava size, or stroke volume in response to changes in intrathoracic pressure during mechanical ventilation.

4. In pregnant women, compression of the inferior vena cava can cause a decrease in venous return and cardiac preload and may result in hypotension. For this reason, pregnant women with sepsis and or septic shock may need to be placed in the lateral decubitus position to off-load the inferior vena cava *(148)*.
5. Clinical trials conducted in resource-limited settings comparing aggressive versus conservative fluid regimens suggest higher mortality in patients treated with aggressive fluid regimens *(146,147)*. Refer to the WHO-ICRC *Basic emergency care* (Shock module) for an initial approach and management of shock in resource-limited settings *(72)*.

Do not use hypotonic crystalloids, starches or gelatins for resuscitation.

Remark:

Starches are associated with an increased risk of death and acute kidney injury compared with crystalloids. The effects of gelatins are less clear, but they are more expensive than crystalloids *(92,149)*. Hypotonic (vs isotonic) solutions are less effective at increasing intravascular volume. Surviving Sepsis guidelines also suggest albumin for resuscitation when patients require substantial amounts of crystalloids, but this conditional recommendation is based on low-quality evidence *(92)*.

In adults, administer vasopressors when shock persists during or after fluid resuscitation. The initial blood pressure target is MAP ≥ 65 mmHg in adults and improvement of markers of perfusion.

In children, administer vasopressors if signs of fluid overload are apparent or the following persist after two fluid bolus:

- **signs of shock such as altered mental state;**
- **bradycardia or tachycardia (HR < 90 bpm or > 160 bpm in infants and HR < 70 bpm or > 150 bpm in children);**
- **prolonged capillary refill (> 2 seconds) or feeble pulses;**
- **tachypnoea; mottled or cool skin or petechial or purpuric rash; increased lactate; oliguria persists after two repeat boluses;**
- **or age-appropriate blood pressure targets are not achieved *(93)*.**

Remarks:

1. Vasopressors (i.e. norepinephrine, epinephrine, vasopressin and dopamine) are most safely given through a central venous catheter at a strictly controlled rate, but it is also possible to safely administer them via peripheral vein *(150)* and intraosseous needle. Monitor blood pressure frequently and titrate the vasopressor to the minimum dose necessary to maintain perfusion and prevent side-effects. A recent study suggests that in adults 65 years or older a MAP 60–65 mmHg target is equivalent to ≥ 65 mmHg *(151)*.
2. Norepinephrine is considered the first-line treatment in adult patients; epinephrine or vasopressin can be added to achieve the MAP target. Because of the risk of tachyarrhythmia, reserve dopamine for selected patients with low risk of tachyarrhythmia or those with bradycardia.
3. In children, epinephrine is considered the first-line treatment, while norepinephrine can be added if shock persists despite optimal dose of epinephrine *(93)*.

If central venous catheters are not available, vasopressors can be given through a peripheral IV, but use a large vein and closely monitor for signs of extravasation and local tissue necrosis. If extravasation occurs, stop infusion. Vasopressors can also be administered through intraosseous needles.

If signs of poor perfusion and cardiac dysfunction persist despite achieving MAP target with fluids and vasopressors, consider an inotrope such as dobutamine.

Remark:
No RCTs have compared dobutamine with placebo for clinical outcomes.

14. Prevention of complications in hospitalized and critically ill patients with COVID-19

Please find new recommendation on the use of existing care bundles in this chapter as the first recommendation, and new recommendation on anticoagulation for thromboprophylaxis in this chapter as the third recommendation.

Conditional recommendation for

For patients with COVID-19 who are critically ill, with or without invasive mechanical ventilation, we suggest the use of existing care bundles (defined as three or more evidence informed practices delivered together and consistently to improve care; (see Evidence to decision for examples), chosen locally by the hospital or ICU and adapted as necessary for local circumstances (conditional recommendation, very low certainty).

Evidence to decision

Benefits and harms — Some benefits

Indirect evidence in patients without COVID-19 suggest that some care bundles may improve patient-important outcomes, such as mortality, but the effects vary depending on the specific bundle, and the population targeted. The certainty of evidence is generally low to very low. Examples of care bundles in the critically ill include those for reducing delirium and improving cognition and sleep (reviewed in *(152)*; other information available at https://www.icudelirium.org/medical-professionals/overview), preventing VAP *(153)*, treating sepsis (reviewed in http://links.lww.com/CCM/C326), preventing central venous catheter infection *(154)*, and preventing pressure ulcers (https://www.nice.org.uk/guidance/cg179). Details of selected other bundles reviewed by the Cochrane Collaboration in their review of the literature are in Annex 3. The effect on other outcomes is uncertain.

Potential harms of bundles include the administrative burden of initial implementation, ongoing training, and monitoring of performance (very low certainty).

Certainty of the evidence — Very low

The evidence review consisted of a rapid review by the Cochrane Collaboration, supplemented by references provided by GDG members. The Cochrane review found very low certainty evidence in support of a mortality reduction with implementation of care bundles in critically ill patients. Supplementary references provided low to very low certainty evidence for important effects on mortality with bundles to reduce delirium *(152)*, prevent VAP *(153)*, treat sepsis (http://links.lww.com/CCM/C326), and prevent central venous catheter infection *(154)* and pressure ulcers (https://www.nice.org.uk/guidance/cg179). All evidence reviewed was indirect, from non-COVID-19 populations.

Values and preferences	No substantial variability expected

Applying the agreed values and preferences, the GDG inferred that the majority of well-informed patients would want to receive care bundles, locally adapted as necessary and applicable to their situation, given the low to very low certainty evidence suggesting a reduction in mortality and very low certainty of harm.

Resources and other considerations	Important considerations

Care bundles may contain practices that require adaptation to implement in all settings, depending on their contents. For example, early mobilization and rehabilitation as part of a care bundle to reduce delirium may require additional training, and central line insertion may require multiple sterile towels or a sterile gown placed on the patient, if large sterile drapes are not available.

Justification

When moving from evidence to the conditional recommendation in favour of care bundles for critically ill patients with COVID-19, the panel emphasized the low to very low certainty evidence of reduction in mortality and possible administrative burdens for implementation. The GDG recognized that hospital or ICUs may select among existing care bundles and adapt them to local circumstances as required, based on contextual factors of resource considerations and feasibility. The GDG judged that considerations of accessibility and impact on health equity would not alter the recommendation. The GDG was not aware of ongoing studies of care bundles in the critically ill COVID-19 population.

Subgroup analyses

The panel did not find any evidence bearing on the question of subgroup effects across patients with different levels of disease severity or between children and adults. In other words, the conditional recommendation is applicable across all these subgroups.

Applicability

Special populations

None of the reviewed studies of care bundles enrolled children, and therefore the applicability of this recommendation to children is uncertain. However, the panel thought that the implementation of relevant care bundles for children with COVID-19 would have similar effects to care bundles in adults. Similarly, the panel concluded that the recommendation applies to pregnant women.

Practical info

The GDG made a conditional recommendation in favour of care bundles for critically ill patients with COVID-19. Existing care bundles for critically ill patients include those for reducing delirium and improving cognition and sleep (reviewed in *(152)*; other information available at https://www.icudelirium.org/medical-professionals/overview), preventing VAP *(153)*, treating sepsis (reviewed in http://links.lww.com/CCM/C326), preventing central venous catheter infection *(154)*, and preventing pressure ulcers (https://www.nice.org.uk/guidance/cg179). For some bundles, observational data have shown variable association between the bundle components and patient important outcomes *(155)*. Even in currently accepted care bundles, the components may change as the evidence base evolves. Hospitals and ICUs should choose bundles for which adherence is likely to be high.

Uncertainties

Monitor multiple RCTs in process in patients with COVID-19.

PICO (16.2)

Population: Patients with COVID-19 and ARDS or viral pneumonia who are critically ill in ICU, with or without invasive ventilation. Populations of children (defined <18 years) and adult patients (≥18 years)
Intervention: Existing validated care bundles*, chosen locally by the hospital or ICU, adapted to local circumstances, and felt to be appropriate for patients with COVID-19 as specified above. *A care bundle is defined as three or more evidence informed practices delivered together and consistently to improve care.
Comparator: Not using existing care bundles

Outcome Timeframe	**Study results and measurements**	**Absolute effect estimates** No care bundles	Care bundles	**Certainty of the evidence** (Quality of evidence)	**Plain text summary**
Mortality (randomized trials) at 6 months	Relative risk: 0.75 (CI 95% 0.53–1.06) Based on data from 180 patients in 1 study	**489** per 1000	**367** per 1000 Difference: **122 fewer per 1000** (CI 95% 259 fewer – 29 more)	**Very low** Due to very serious indirectness. Due to very serious imprecision[a]	ICU care bundles possibly reduce mortality.
Mortality (observational studies) 28 days or to hospital discharge	Relative risk: 0.75 (CI 95% 0.65–0.86) Based on data from 1258 patients in 7 studies	**359** per 1000	**269** per 1000 Difference: **90 fewer per 1000** (CI 95% 126 fewer – 50 fewer)	**Very low** Due to very serious indirectness. Due to very serious imprecision[b]	ICU care bundles possibly reduce mortality.
Administrative burden	Based on data from 0 patients in 0 studies			**Very low**	Care bundles may be associated with an appreciable administrative burden.
Impingement on physician autonomy	Based on data from 0 patients in 0 studies			**Very low**	Care bundles may be associated with an impingement of physician autonomy.

[a] **Indirectness: very serious. Imprecision: very serious.**
[b] **Indirectness: very serious. Imprecision: very serious.**

Thromboembolism

Coagulopathy is common in patients with severe COVID-19, and both venous and arterial thromboembolism have been reported *(41,42,156,157,158)*.

Monitor patients with COVID-19, for signs or symptoms suggestive of thromboembolism, such as stroke, deep venous thrombosis, pulmonary embolism or acute coronary syndrome. If these are clinically suspected, proceed immediately with appropriate diagnostic and management pathways.

Thromboprophylaxis

Conditional recommendation for

In hospitalized patients with COVID-19, without an established indication for higher dose anticoagulation, we suggest administering standard thromboprophylaxis dosing of anticoagulation rather than therapeutic or intermediate dosing (conditional recommendation, very low certainty).

Evidence to decision

Benefits and harms Important harms

Therapeutic or intermediate dosing of anticoagulation, compared with prophylactic dosing of anticoagulation, possibly reduces mortality (very low certainty) and pulmonary embolism and probably increases the risk of major bleeding (moderate certainty for therapeutic anticoagulation; low certainty for intermediate dosing of anticoagulation). The effects on other outcomes are uncertain.

The absolute reductions in risks of mortality and pulmonary embolism, and the absolute increase in risk of major bleeding, are likely to be higher in patients with severe or critical illness due to COVID-19, who may have a higher baseline risk of these outcomes compared with patients with mild or moderate illness.

Certainty of the evidence Very low

For reduction in mortality and pulmonary embolism, the panel considered the evidence in favour of therapeutic or intermediate dosing of anticoagulation to be of very low certainty, due to serious imprecision (confidence intervals included both important benefit and important harm) and risk of bias (confounding in observational studies; no randomized trials).

For avoidance of major bleeding, the panel considered the evidence in favour of standard thromboprohylaxis dosing, compared with therapeutic anticoagulation, to be of moderate certainty. This judgment was based on low-certainty evidence in observational studies in COVID-19 that was upgraded to moderate certainty based on a large body of supportive indirect evidence at low risk of bias (randomized trials of therapeutic anticoagulation for other indications).

For the comparison of standard thromboprophylaxis dosing compared with intermediate dosing of anticoagulation, the evidence for avoidance of major bleeding was rated as low certainty.

The panel acknowledged that reporting of ongoing randomized trials of therapeutic and intermediate dosing of anticoagulation, compared with standard thromboprophylaxis dosing, over the next several months were highly likely to upgrade the certainty of evidence and may lead to changes in recommendations.

Values and preferences Substantial variability is expected or uncertain

The majority of GDG members inferred that most well-informed patients would not want to receive therapeutic or intermediate dosing of anticoagulation given the very low certainty evidence suggesting a possible reduction in mortality and pulmonary embolism and the low certainty (for intermediate dosing of anticoagulation) or moderate certainty (for therapeutic anticoagulation) of increased risk of major bleeding. A minority of GDG members believed that some well-informed patients would choose to receive intermediate dosing of anticoagulation, given the very low certainty evidence suggesting a possible reduction in mortality and pulmonary embolism and the low certainty of increased risk of major bleeding.

Resources and other considerations Important considerations

Unfractionated heparin sodium and low molecular weight heparins such as enoxaparin are relatively inexpensive and are listed on the WHO Model List of Essential Medicines; but availability is variable. Shortages may reduce the availability of low molecular weight heparins in some settings. In low-resource settings, management of bleeding complications in patients receiving anticoagulant dosing higher than that used for standard thromboprophylaxis may be challenging due to limited coagulation testing and transfusion capacity.

Justification

When moving from evidence to the conditional recommendation in favour of standard thromboprophylaxis anticoagulation for patients with moderate, severe, and critical COVID-19, the panel emphasized the very low certainty evidence of reduction in mortality or pulmonary embolism with higher anticoagulant dosing. The panel recognized that the evidence supporting an increased risk of major bleeding was dominated by studies of therapeutic anticoagulation rather than intermediate dosing. The GDG panellists anticipated variability in patient values and preferences, and judged that other contextual factors, such as resource considerations, accessibility, feasibility and impact on health equity would not alter the recommendation. The panel acknowledged that ongoing randomized trials are expected to add substantially to the evidence base over the next several months.

Subgroup analyses

The panel did not find any evidence bearing on the question of subgroup effects across patients with different levels of disease severity, between children and adults, by different anticoagulant regimens (including agent, dose and duration), and therefore did not make any subgroup recommendations. In other words, the conditional recommendation is applicable across all these subgroups.

Applicability

Special populations

None of the studies enrolled children, and therefore the applicability of this recommendation to children is uncertain. However, the panel did not think that children with COVID-19 would respond any differently to therapeutic or intermediate intensity anticoagulation. One observational study enrolled pregnant women, with very low certainty evidence in this population for a possible reduction in mortality. The panel thought that pregnant women would have a similar risk of increased bleeding as non-pregnant individuals. Therefore, the panel concluded that the recommendation applies to pregnant women. Safe anticoagulants for the fetus in pregnancy include unfractionated heparin and low molecular weight heparin, which do not cross the placental barrier.

Practical info

Therapeutic dosing of anticoagulation refers to the dose used for treatment of acute venous thromboembolism; intermediate dosing is commonly interpreted as twice the standard thromboprophylaxis dose. The GDG made a conditional recommendation in favour of standard thromboprophylaxis dosing of anticoagulation in patients with COVID-19 who do not have an established indication for higher dose anticoagulation.

Patients on standard thromboprophylaxis dosing of anticoagulation do not require monitoring, except for platelet count monitoring after 5–7 days if unfractionated heparin is used. Dosing should be adjusted according to body weight/BMI and renal function according to local protocols. For example, if renal failure is present, patient should receive unfractionated heparin or reduced dose of low molecular weight heparin.

Suggested dosing of standard thromboprophylaxis is as follows:

Enoxaparin 40 mg by subcutaneous injection every 24h:
- Prophylactic dosages (non-weight adjusted) in low body weight (women < 45 kg, men < 57 kg) may lead to a higher risk of bleeding. Careful clinical observation is advised.
- If BMI > 40 kg/m^2 or weight > 120 kg: enoxaparin 40 mg by subcutaneous injection every 12h.

Unfractionated heparin (UFH) 5000 units by subcutaneous injection every 8 or 12h:
- If BMI > 40 kg/m^2 or weight > 120 kg: 7500 units q12h or 5000 units every 8h.

Tinzaparin 4500 units/day if BMI < 40 kg/m^2 or weight < 120 kg; 9000 units/day if BMI > 40 kg/m^2 or weight > 120 kg.

Dalteparin 5000 units/day BMI < 40 kg/m^2 or weight < 120 kg; 5000 units every 12h if BMI > 40 kg/m^2 or weight > 120 kg.

Fondaparinux 2.5 mg by subcutaneous injection every 24h.

Exoxaparin and unfractionated heparin are both on the WHO Model List of Essential Medicines; enoxaparin has the advantage of daily dosing. The suggested duration of standard thromboprophylaxis is until hospital discharge.

If therapeutic dosing is prescribed, clinicians should be aware of the increased risk of bleeding, including major bleeding requiring transfusion (e.g. gastrointestinal) or clinically significant bleeding even if transfusion is not required (e.g. intracranial). These increased risks may also occur with intermediate dosing of anticoagulants, especially in the presence of other risk factors for bleeding. Heparin-induced thrombocytopenia associated with thrombosis is also a risk of unfractionated heparin and, less commonly, low molecular weight heparin.

Potential agents for therapeutic and intermediate intensity anticoagulation include low molecular weight heparin, unfractionated heparin, direct oral anticoagulants, or fondaparinux. Factors influencing the choice of agent include availability of laboratory monitoring (needed for unfractionated heparin), requirement for rapid reversibility (favours unfractionated heparin), presence of severe renal dysfunction (favours unfractionated heparin), interaction with other drugs used to treat COVID-19 (especially direct oral anticoagulants), convenience (least with unfractionated heparin, most with direct oral anticoagulants), and suspicion of heparin-induced thrombocytopenia (favours fondaparinux or direct oral anticoagulants).

For therapeutic or intermediate intensity anticoagulation, patients should have baseline creatinine, platelet count, prothrombin time or international normalized ratio, and partial thromboplastin time. Patients on therapeutic dosing of unfractionated heparin require monitoring of partial thromboplastin time or anti-factor Xa levels and ideally platelet count. Patients on warfarin require monitoring of international normalized ratio.

PICO (16.1)
Population: Hospitalized patients without an indication for therapeutic anticoagulation
Intervention: Anticoagulation at therapeutic or intermediate intensity
Comparator: Anticoagulation at prophylactic intensity

Outcome Timeframe	**Study results and measurements**	**Absolute effect estimates** Anticoagulation at prophylactic intensity	Anticoagulation at therapeutic or intermediate intensity	**Certainty of the evidence** (Quality of evidence)	**Plain text summary**
Mortality at 14 days	Hazard Ratio: 0.86 (CI 95% 0.73–1.07) Based on data from 2626 patients in 1 studies	Difference: **19.0 fewer** (CI 95% 38.0 fewer – 3.0 more)		**Very low** Due to very serious risk of bias. Due to very serious imprecision[a]	Therapeutic or intermediate intensity anticoagulation possibly reduces mortality.
Pulmonary embolism at 14–28 days	Odds Ratio: 0.09 (CI 95% 0.02–0.57) Based on data from 82 patients in 1 studies	Difference: **16.0 fewer** (CI 95% 15.0 fewer – 7.0 fewer)		**Very low** Due to very serious risk of bias. Due to very serious imprecision[b]	Therapeutic or intermediate intensity anticoagulation possibly reduces pulmonary embolism.
Major bleeding at 4–12 days		Effect estimates ranged from OR 1.42 (matched case control) to 3.89 (retrospective cohort). Risk differences ranged from: 7 fewer per 1000 to 46 more per 1000		**Moderate** Upgraded due to all plausible confounding would have reduced the effect[c]	Therapeutic or intermediate intensity anticoagulation probably increases major bleeding.

[a] **Risk of bias: very serious. Imprecision: very serious.**
[b] **Risk of bias: very serious. Imprecision: very serious.**
[c] **Upgrade: All plausible confounding would have reduced the effect.** Upgraded from low certainty evidence due to large body of relevant indirect evidence.

This summary of findings table was generated from a living systematic review (www.hematology.org/COVIDguidelines) based on data accessed on 1 December 2020.

Prevention of other complications

Table 14.1 shows interventions to prevent complications in hospitalized and critically ill patients with COVID-19. They are based on Surviving Sepsis *(92)* or other guidelines *(153,159,160,161)*, and are generally limited to feasible recommendations based on high-quality evidence. Recent publications have encouraged best practices to continue during the COVID-19 outbreak *(162)*. See the WHO *Clinical care for severe acute respiratory infection toolkit: COVID-19 adaptation* for practical tools to assist implementation *(73)*.

Table 14.1 Interventions to prevent complications in hospitalized and critically ill patients with COVID-19

Anticipated outcome	**Interventions**
Reduce days of invasive mechanical ventilation	• Use weaning protocols that include daily assessment for readiness to breathe spontaneously • Minimize continuous or intermittent sedation, targeting specific titration endpoints (light sedation unless contraindicated) or with daily interruption of continuous sedative infusions • Early mobilization • Implementation of the above as a bundle of care (may also reduce delirium); such as the **A**wakening and **B**reathing **C**oordination, **D**elirium assessment/management, and **E**arly mobility (ABCDE)
Reduce incidence of ventilator-associated pneumonia	• Oral intubation is preferable to nasal intubation in adolescents and adults • Keep patient in semi-recumbent position (head of bed elevation 30–45º) • Use a closed suctioning system; periodically drain and discard condensate in tubing • Use a new ventilator circuit for each patient; once patient is ventilated, change circuit if it is soiled or damaged, but not routinely

	• Change heat moisture exchanger when it malfunctions, when soiled, or every 5–7 days
Reduce incidence of catheter-related bloodstream infection	• Use a checklist with completion verified by a real-time observer as a reminder of each step needed for sterile insertion and as a daily reminder to remove catheter if no longer needed
Reduce incidence of pressure ulcers	• Turn patient every 2 hours
Reduce incidence of stress ulcers and GI bleeding	• Give early enteral nutrition (within 24–48 hours of admission) • Administer histamine-2 receptor blockers or proton-pump inhibitors in patients with risk factors for GI bleeding. Risk factors for GI bleeding include mechanical ventilation for ≥ 48 hours, coagulopathy, renal replacement therapy, liver disease, multiple comorbidities, and higher organ failure score
Reduce the development of antimicrobial resistance	• Utilize de-escalation protocols as soon as patient is clinically stable and there is no evidence of bacterial infection
Reduce the development of adverse drug effects	• Expose patient to empiric antimicrobial therapy for the shortest time possible, to prevent nephrotoxicity, cardiac and other side-effects from unnecessary antimicrobial use
Promote appropriate antimicrobial prescribing and use during the COVID-19 pandemic *(163)*	• Do not prescribe antibiotics to suspected or confirmed COVID-19 patients with low suspicion of a bacterial infection, to avoid more short-term side-effects of antibiotics in patients and negative long-term consequences of increased antimicrobial resistance

Adverse effects of medications

Careful consideration should be given to the numerous, clinically significant side-effects of medications that may be used in the context of COVID-19, as well as drug-drug interactions between medications, both of which may affect COVID-19 symptomatology (including effects on respiratory, cardiac, immune and mental and neurological function). Both pharmacokinetic and pharmacodynamic effects should be considered.

Remarks:

1. The risk of relevant side-effects and drug-drug interactions relating to COVID-19 symptomatology include sedation, cardiotoxicity via QTc-prolongation and respiratory suppression, and these may be dose-dependent (i.e. increase with escalating doses). For this reason, care should be taken that minimum effective doses of medications with dose-dependent negative effects are used and for the shortest durations possible.
2. Use medications that carry the least risk possible for drug-drug interactions with other medications the person may be receiving. Psychotropic medications with sedative proprieties, such as benzodiazepines, can worsen respiratory function. Some, psychotropic medications have QTc-prolonging activity (such as some antipsychotics and some antidepressants). Use medications that carry the least risk possible for side-effects that may worsen COVID-19 symptomatology, including sedation, respiratory or cardiac function, risk of fever or other immunological abnormalities, or coagulation abnormalities.

15. Therapeutics and COVID-19

For the most up to date clinical practice guideline on therapeutics and COVID-19 see WHO website and BMJ website and MAGICapp.

By 17 December 2020 this guideline contains the following recommendations:

- Strong recommendations against the use of hydroxychloroquine and lopinavir/ritonavir in patients with COVID-19, regardless of disease severity.
- A strong recommendation for systemic corticosteroids in patients with severe and critical COVID-19.
- A conditional recommendation against systemic corticosteroids in patients with non-severe COVID-19.
- A conditional recommendation against remdesivir in hospitalized patients with COVID-19.

We recommend that the use of unproven drugs not be administered as treatment or prophylaxis for COVID-19, outside of the context of clinical trials.

Remarks:

Outside of clinical trials, the following criteria should be met for access to investigational therapeutics: 1) no proven effective treatment exists; 2) it is not possible to initiate clinical studies immediately; 3) data providing preliminary support of the intervention's efficacy and safety are available, at least from laboratory or animal studies, and use of the intervention outside clinical trials has been suggested by an appropriately qualified scientific advisory committee on the basis of a favourable risk–benefit analysis; 4) the relevant country authorities, as well as an appropriately qualified ethics committee, have approved such use; 5) adequate resources are available to ensure that risks can be minimized; 6) the patient's informed consent is obtained; and 7) the emergency use of the intervention is monitored and the results are documented and shared in a timely manner with the wider medical and scientific community *(164)*.

16. Treatment of other acute and chronic infections in patients with COVID-19

The prevalence of acute coinfections or secondary infections coinciding with COVID-19 has not been adequately described but appears to be low *(104)*, and will be based on local factors and endemic or other emerging infections *(77,111,112,163)*. Antibiotic overuse increases the risk of emergence and transmission of multidrug-resistant bacteria. Infections with multidrug-resistant bacteria are more difficult to treat, and associated with increased morbidity and mortality.

Acute coinfections with bacteria

We recommend for patients with suspected or confirmed mild COVID-19, against the use of antibiotic therapy or prophylaxis.

We recommend for patients with suspected or confirmed moderate COVID-19, that antibiotics should not be prescribed unless there is clinical suspicion of a bacterial infection.

We recommend for patients with suspected or confirmed severe COVID-19, the use of empiric antimicrobials to treat all likely pathogens, based on clinical judgment, patient host factors and local epidemiology, and this should be done as soon as possible (within 1 hour of initial assessment if possible), ideally with blood cultures obtained first. Antimicrobial therapy should be assessed daily for de-escalation.

Remarks:

1. For patients with severe disease, early and appropriate empiric antimicrobial therapy *(92)* can be administered in the emergency unit and/or pre-hospital setting. Empiric antibiotic treatment should be based on the clinical diagnosis (community-acquired pneumonia, health care-associated pneumonia (if infection was acquired in health care setting) or sepsis), local epidemiology and susceptibility data, and national treatment guidelines. Choose antibiotics with the least ecologic impact based on data and guidance from your own institution, region or country (e.g. of the Access group of the AWaRe classification) *(113)*. The AWaRe classification categorizes antibiotics into three different groups (Access, Watch and Reserve) based on their indication for common infectious syndromes, their spectrum of activity, and their potential for increasing antibiotic resistance. The AWaRe classification is a tool for antibiotic stewardship at local, national and global levels with the aim of optimizing antibiotic use and reducing antibiotic resistance.
2. Empiric antibiotic therapy should be de-escalated on the basis of microbiology results and clinical judgment. Regularly review the possibility of switching of intravenous to oral route of administration and provide targeted treatment based on microbiologic results.
3. Duration of empiric antibiotic treatment should be as short as possible; generally 5–7 days.
4. An increase in antibiotic use during the pandemic may cause adverse reactions such as *Clostridioides difficile* infections, with clinical disease ranging from diarrhoea and fever to colitis *(165)*. Antibiotic stewardship programmes should be put into place or continue among COVID-19 patients.

Acute coinfections with other pathogens (not bacteria)

Treatment of other coinfections may be based on a laboratory-confirmed diagnosis or epidemiological and clinical criteria.

Remarks:

1. In malaria endemic areas, when a malaria RDT is also positive, antimalarials should be initiated as soon as possible as per local protocol *(66)*.
2. When there is ongoing suspected or confirmed local circulation of seasonal influenza, empiric therapy with a neuraminidase inhibitor (i.e. oseltamivir) should be considered for patients with severe disease or at risk for severe influenza, and given as soon as possible.
3. If TB coinfection is suspected or confirmed, then follow local TB treatment protocols *(69)*.

Chronic infections

It is currently unknown whether immunosuppression caused by chronic coinfections such as human immunodeficiency virus (HIV) puts persons at greater risk for severe COVID-19. However, people living with HIV with advanced disease have an increased risk of opportunistic infections (notably TB) *(166)* and related complications in general. Facility-based HIV testing services should continue and those newly diagnosed should start antiretroviral therapy as soon as possible. For people living with HIV already on treatment, continuity of antiretroviral therapy and prophylaxis for coinfections is essential, with multi-month prescribing.

17. Management of neurological and mental manifestations associated with COVID-19

People with COVID-19 are at increased risk for neurological, neuropsychiatric, and mental manifestations (see Chapter 1. Background). Neuropsychiatric manifestations such as delirium/encephalopathy and neurological manifestations such as stroke may be presenting features without respiratory symptoms (see Table 6.1). In addition to acute neurological manifestations, Guillain-Barré syndrome, acute disseminated encephalomyelitis, and acute haemorrhagic leukoencephalitis-like presentations may occur weeks after the acute stage of infection *(46)*. Moreover, there may be potential for longer term neurological consequences such as cognitive impairment *(167)* and/or post-intensive care syndrome (PICS). Further research is needed in order to fully characterize these complications.

Anxiety and depressive symptoms constitute common reactions for people in the context of COVID-19 diagnosis, especially for those who may be hospitalized, due to concerns for one's own health or the health of others, the need for physical isolation (which can lead to social isolation), potential risk of death, concerns over the risk of infecting others, and concerns over leaving family members alone who may need care. Stressors particular to COVID-19 include: fear of falling ill and dying, fear of being socially excluded/placed in quarantine, loss of livelihood and loss of loved ones, and feelings of helplessness, boredom and loneliness due to being isolated. These stressors may trigger new symptoms or exacerbate underlying mental or neurological conditions. Pre-existing mental, neurological or substance use disorders increase the risk of becoming severely ill or of death, or of having long-term complications due to COVID-19 *(84,85,168,169,170,171)*. People with COVID-19 are also at higher risk for sleep problems owing to acute stress responses, as well as additional reasons for those who are hospitalized such as environmental factors, invasive medical procedures (e.g. mechanical ventilation) and the frequent combination of multiple medications possibly disrupting sleep patterns *(172)*.

Delirium

We recommend, in patients with COVID-19, that measures to prevent delirium, an acute neuropsychiatric emergency, be implemented; and patients be evaluated using standardized protocols, for the development of delirium. If detected, then immediate evaluation by a clinician is recommended to address any underlying cause of delirium and treat appropriately.

Remarks:

1. Manage any underlying cause of delirium by monitoring oxygenation and fluid status, correcting metabolic or endocrine abnormalities, addressing coinfections, minimizing the use of medications that may cause or worsen delirium, treating withdrawal from substances, understanding and minimizing the effects of any harmful drug-drug interactions and maintaining normal sleep cycles as much as possible *(173)*.
2. In patients receiving invasive ventilation, minimize continuous or intermittent sedation, targeting specific titration endpoints (light sedation unless contraindicated) or with daily interruption of continuous sedative infusions, to reduce delirium *(173)*.
3. In patients experiencing agitation (defined as marked restlessness or excessive motor activity, often accompanied by anxiety), use calming communication strategies and attempt to reorient the person. Acute pain due to physical illness or air hunger should be considered as triggers for agitation and need to be addressed immediately. If the person continues to be agitated despite the strategies described above and is experiencing severe distress, it may be necessary to use psychotropic medications *(174)*.
4. When using antipsychotic medications for agitation, consider side-effects that may worsen symptomatology, including sedation, respiratory or cardiac function, risk of fever or other immunological abnormalities, or coagulation abnormalities and any potential drug-drug interactions between these and other medications. Use minimum effective doses of antipsychotic medications at the lowest frequency and for the shortest duration possible, with doses adjusted according to age, medical co-morbidities and degree of distress *(174)*. For severe agitation, low doses of haloperidol (administered orally or by intramuscular injection) can be considered, while carefully monitoring for adverse effects such as QT prolongation and extrapyramidal symptoms *(174)*.
5. If haloperidol is contraindicated due to the patient's clinical condition (e.g. prolonged QT interval, recent myocardial infarction, Parkinson's Disease, Lewy-Body dementia, etc.), other antipsychotic medications with safer cardiovascular profiles may be used after careful consideration of other risks (such as respiratory suppression or sedation) and drug-drug interactions *(175)*.
6. If the patient remains severely agitated despite the strategies described above, benzodiazepines can be added, with preference given to those with shorter half-lives and lower risk of drug-drug interactions (such as lorazepam); lowest doses should be used and for the shortest duration possible. The intravenous route should be avoided *(175)*.

Stroke

Patients presenting with rapidly developing neurological symptoms suggestive of stroke should be evaluated as soon as possible and standard stroke protocols should be followed including systemic thrombolysis and/or intra-arterial thrombectomy, if indicated. Signs and symptoms of stroke can include weakness of limbs or face, sensory loss, speech difficulties, impairment of vision, ataxia, confusion, or decreased consciousness. Standard IPC measures must be followed during the clinical evaluation, neuroimaging or procedures for patients with stroke.

Remark:

Strokes can be missed in severely sick or unresponsive ICU patients and a low threshold for further evaluation (including neuroimaging) is recommended for acute neurological worsening.

Mental health and psychosocial support

We recommend providing basic mental health and psychosocial support (MHPSS) for all persons with suspected or confirmed COVID-19 by asking them about their needs and concerns, and addressing them *(176)*.

Remarks:

1. Basic psychosocial support skills are essential for management of all patients and they represent an integral part of the care to be provided for different groups, including children, older adults, pregnant women and others affected by COVID-19 *(177)*.
2. This recommendation is consistent with the Inter-Agency Standing Committee briefing note about mental health and psychosocial aspects of COVID-19 *(176)*, and guidance on basic psychosocial skills for COVID-19 responders *(177)*, and WHO recommendations on providing access to support based on psychological first aid principles to people in acute distress exposed recently to a traumatic event *(178)*.
3. Ask people about their needs and concerns around diagnosis, prognosis, and other social, family or work-related issues. Listen carefully, try to understand what is most important to the person at this moment, and help them work out what their priorities are and link them with relevant resources and services.
4. Give accurate information on the person's condition and treatment plans in easily understood and non-technical language, as lack of information can be a major source of stress. Help people address urgent needs and concerns, and help with decision-making, as necessary. Help connect people with loved ones and social support, including through phone or internet as appropriate.
5. MHPSS and follow up should continue after the person is discharged from hospital to ensure their symptoms are not worsening and they are continuing to do well. This can be provided through telehealth, where available and appropriate.
6. Given the stress that COVID-19 may create at individual and family levels, the high prevalence of common mental health conditions among women in the antenatal and postpartum period, and the acceptability of programmes aimed at them, interventions for MHPSS targeted to mothers need to be more widely implemented. Prevention services should be available in addition to services that treat mental health conditions.
7. Parents and caregivers who may need to be separated from their children, and children who may need to be separated from their primary caregivers, should have access to appropriately trained health or non-health workers for MHPSS. MHPSS should be appropriately adapted for the needs of children, taking into consideration their social and emotional development, learning and behaviour *(176)*.

We recommend prompt identification and assessment for anxiety and depressive symptoms in the context of COVID-19 and to initiate psychosocial support strategies and first-line interventions, for the management of new anxiety and depressive symptoms.

Remarks:

1. For people who are experiencing symptoms of anxiety, basic psychological skills such as psychological first aid stress management, and brief psychological interventions based on the principles of cognitive behavioural therapy should be considered *(178,179)*.
2. For relieving anxiety causing severe distress that is not responsive to psychosocial support strategies, benzodiazepines can be considered, specifically in the hospital setting. Benzodiazepines should only be used with extreme caution with preference for those with shorter half-lives and lower risk of drug-drug interactions (such as lorazepam). Lowest doses should be used and for the shortest duration possible; high doses and longer term use should be avoided. Benzodiazepines carry the risks of confusion and respiratory suppression, may worsen traumatic stress reactions, can produce tolerance and dependence, and are known to be prescribed indiscriminately in many emergencies *(174)*.
3. For people who are experiencing symptoms of depression, brief psychological interventions based on the principles of cognitive behavioural therapy, problem-solving treatment and relaxation training can be considered *(180)*. Consider using remote mental health support (i.e. telephone therapy) when access to regular services is disrupted.

4. If a person's anxiety or depressive symptoms persist beyond recovery from COVID-19 and/or discharge from the hospital, then an underlying anxiety or depressive disorder may be suspected, and a mental health professional should be consulted and these conditions should be managed appropriately. Refer to the *mhGAP Intervention Guide for mental, neurological and substance use disorders in non-specialized health settings (181)*.
5. It is important to ask about thoughts or acts of self-harm, particularly during COVID-19, due to risk factors for self-harm and suicide such as sense of isolation, loss of a loved one, job, or financial loss and hopelessness. Remove possible means of self-harm, activate psychosocial support, follow up with the person, and consult a mental health professional as necessary. Refer to the *mhGAP Intervention Guide for mental, neurological and substance use disorders in non-specialized health settings (181)*.
6. To ensure comprehensive care and based on the initial assessment, following discharge, link the person to employment, education, social services (including housing) and other relevant sectors *(181)*.
7. Cognitive-behavioural therapy with a trauma focus, eye movement desensitization and reprocessing or stress management should be considered for adults with post-traumatic stress disorder (PTSD) *(182)*.

We recommend psychosocial support strategies as the first-line interventions for management of sleep problems in the context of acute stress.

Remarks:

1. Sleep hygiene advice (including avoiding the use of psychostimulants such as caffeine, nicotine or alcohol), and stress management (including relaxation techniques and mindfulness practices) are effective in reducing sleep problems and may be offered. Psychological interventions based on the principles of cognitive behavioural therapy may also be considered.
2. For people who are hospitalized for COVID-19, additional causes of insomnia may include environmental factors (e.g. excessive light and noise at night), anxiety, persistent cough, delirium, agitation, pain or air hunger. Identifying and promptly addressing underlying causes should be prioritized before using any pharmacological sleep aids.

18. Noncommunicable diseases and COVID-19

Pre-existing NCDs, including cardiovascular disease, diabetes, chronic respiratory disease, hypertension, obesity and cancer, have been identified as independent risk factors for death (see Table 6.1).

We recommend when caring for patients with suspected and confirmed COVID-19 that have underlying NCDs to continue or modify previous medical therapy according to the patient's clinical condition.

Antihypertensive drugs should not routinely be stopped in patients with COVID-19, but therapy may need to be adjusted based on general considerations for patients with acute illness, with particular reference to maintaining normal blood pressure and renal function.

Remark:

SARS-CoV-2 uses the ACE 2 receptor for entry into cells. It has been suggested that antihypertensive drugs that exert their effect by inhibiting ACE or blocking the ACE 2 receptor may either aggravate or ameliorate the clinical course of patients with COVID-19 *(183)*. To date, there are no studies that can substantiate this, and it is generally advised to continue these medications unless there are other reasons to stop these (e.g. hyperkalaemia, hypotension or acute deterioration in renal function) *(184)*.

19. Rehabilitation for patients with COVID-19

At the outset of the pandemic, the rehabilitation needs for patients recovering from COVID-19 were based on evidence from the critical care population and long-term sequelae in SARS-CoV-1 survivors *(185,186,187,188,189,190,191,192,193,194,195,196)*. Post-intensive care syndrome (PICS) refers to a range of impairments including physical deconditioning, and cognitive and mental health impairments. The COVID-19 patients who are at higher risk of ICU admission are also those at higher risk to develop PICS, i.e. older persons with underlying diseases such as diabetes, hypertension, increased frailty and other chronic disorders *(197)*. Intensive care unit-acquired weakness is ubiquitous in ARDS survivors, as it is in critically ill COVID-19 patients who required prolonged sedation *(198)*, and recovery may be incomplete at 5 years after ICU discharge *(199)*. Some studies suggest that cognitive impairment ranges from 70–100% at hospital discharge, 46–80% at 1 year, and 20% at 5 years. Mood disorders including depression and PTSD are also sustained and prevalent *(199)*. For ARDS survivors, a reduced exercise capacity persists in the context of relatively preserved pulmonary function at 1 year *(200)*. In SARS-CoV-1 survivors, pulmonary function at 1-year is reported to be normal in 63%, mildly reduced in 32% and moderately impaired in 5%, with abnormalities characterized by restrictive patterns and reduced carbon monoxide diffusing capacity *(201)*.

The following symptoms have been reported 4–8 weeks after discharge from the hospital in both ICU admitted COVID-19 patients and non-ICU admitted COVID-19 patients: new illness-related fatigue, breathlessness, PTSD symptoms, pain, voice change, cough, dysphagia, anxiety, depression, and problems with concentration, memory and continence. Patients admitted to ICU had greater prevalence of symptoms in almost all reported symptom domains than COVID-19 patients not admitted to ICU *(202)*. More than half of all COVID-19 patients who had been hospitalized, regardless of their clinical management, reported persistence of fatigue at 60 days since the onset of symptoms *(202,203)*.

With progression of the pandemic and the follow up of patients who have not been critically ill, new evidence is emerging about COVID-19 related persistent symptoms, which have parallels with other coronavirus diseases. Some patients with SARS-CoV-1 infection went on to develop a long-term illness with widespread pain, fatigue, depression and sleep disturbance *(204,205)*. PTSD has also been described after SARS-CoV- 1 infection *(205,205)*.

Early findings report, most commonly reported ongoing symptoms (regardless of hospitalization status) are fatigue, muscle ache, shortness of breath and headache at a follow up of 4 months *(205)*. Not returning to usual health within 2–3 weeks of testing was reported by approximately one third of symptomatic adults in an outpatient setting *(206)*. A study reported that at 3 months after the onset of symptoms, one third of non-hospitalized patients were to some degree dependent on others for personal care *(207)*.

In addition, several complications from COVID-19 have been reported in different clinical domains, resulting from a thrombotic event (such as ischaemic stroke and ischaemic heart disease), direct invasion (such as myocarditis, myositis, and meningitis) or an immune-mediated reaction (such as Guillain-Barré syndrome). While many of these complications are amenable for rehabilitation, they are not addressed in this chapter. Clinicians and rehabilitation professionals can refer to existing clinical practice guidelines for the appropriate management of these sequelae.

COVID-19 is a multisystem disease which, in certain cases, will require full multidisciplinary team rehabilitation to enable recovery *(208)*.

In hospitalized patients, during the acute phase of illness, rehabilitation professionals may provide interventions that relieve respiratory distress, prevent complications and support communication.

Remarks:

1. Decision on when to start rehabilitation should be determined by a multidisciplinary team taking into account the patient's medical status *(209)*. Ensure that appropriate IPC is available at designated rehabilitation areas caring for patients with COVID-19 that remain infectious. Make optimal use of digital and/or written information for the instruction of patients *(141)*. Telehealth may play a role in the acute and subacute phases, in which face-to-face rehabilitation is costly, risky, and impractical *(210)*. Consider strategies for communication with and engagement of families during physical distancing *(211)*.

2. Early mobilization is recommended for all patients with severe risk of functional limitations, resulting from frailty or ICU-acquired weakness *(117)*. In ICU, early mobilization should be part of a bundle of care (See Chapter 12 and 13 on management of critical COVID-19 for new recommendation on bundles), and appropriate levels of activity would be based on the Richmond Agitation-Sedation Scale *(141)*. Monitor oxygen saturation levels closely as desaturation may occur. To identify every next level of mobility the ICU mobility scale can be used.
3. See Chapter 12 (Management of critical COVID-19: ARDS) for examples of respiratory interventions that may be considered.
4. Communication challenges may result from voice and speech disorders that are often linked with intubation or a cognitive impairment. Augmented communication strategies may assist, and where available, refer for speech and language therapy.
5. COVID-19 patients with dysphagia are at risk of aspiration. Dysphagia is common post-extubation and the presumed aspiration prevalence for the general critical care population is 10–25% at ICU discharge *(185)*. Referral to an appropriately trained health professional such as a speech and language therapist, for additional breathing exercises, vocal exercises, and eating and drinking exercises where available *(212)*.
6. Patients with COVID-19 have demonstrated improved mobility at hospital discharge and higher probability of discharging home with increased frequency and longer mean duration of physical therapy visits *(213)*. Some reports have found that early aerobic exercises may not be well tolerated and result in rapid desaturation in COVID-19 inpatients. Exercise training may have to start with gradual functional exercises, using no or minimal equipment *(141)* including an active range of motion exercises, balance exercises, and walking with or without a walking aid. When (assisted) exercises are well tolerated while lying supine, the rehabilitation professional may proceed with exercises while sitting, and then standing *(141)*.

Prior to hospital discharge, COVID-19 patients should be screened for rehabilitation needs in order to facilitate onward referral.

Remarks:

1. Hospitalized COVID-19 patients may have ongoing rehabilitation needs which prevent safe discharge or require continued rehabilitation services. These needs can be based on physical deconditioning, and respiratory, swallow, cognitive and mental health impairments. Consider the context of the person's individual situation, including social support and home environment when making decisions about a course of intervention or support needs.
2. When indicated from screening, further assessment of rehabilitation needs can be based on a basic set of measures that cover potentially affected functioning domains. This includes, but is not limited to: respiratory function (such as respiratory rate and SpO_2), mobility (such as ICU mobility scale), muscle strength (such as Medical Research Council sumscore), balance (such as Berg balance scale), dysphagia (such as fluid and food trials), and activities of daily living (ADL) (such as Barthel index). Additional tests might be helpful based on a first screening for mental and cognitive impairment (such as Montreal Cognitive Assessment, Hospital Anxiety and Depression Scale, PTSD Checklist-5).
3. When the patient is ready for discharge, evaluate the need of an assistive device (such as a mobility aid) and oxygen requirements at rest and during exertion. Oxygen desaturation on exertion may happen during the recovery phase, even during physical exercise of moderate activity, and is unrelated to the oxygen saturation at rest and the degree of dyspnoea *(214)*. An example of a rapid exercise test to assess desaturation on exertion is the 1-minute sit-to-stand test *(215)*.
4. Where continued rehabilitation needs are identified, refer for inpatient, outpatient or community-based follow up as indicated and according to the type and severity of rehabilitation needs. When a patient does not require inpatient rehabilitation but would benefit from rehabilitation follow up post-discharge, refer to outpatient or community-based services according to local service availability. Consider which options have the least barriers to attendance/service utilization and, where available and appropriate, refer to services delivered through telehealth *(210)* particularly where IPC measures prevent in-person consultations.
5. Information, including documentation, should be communicated between hospitals and to other hospital-based or community rehabilitation services and primary care services *(209)*.
6. Ensure patients are provided with education and information resources for self-management management of COVID-19 symptoms, especially when barriers to accessing rehabilitation follow up are anticipated (patient leaflet https://www.who.int/publications/m/item/support-for-rehabilitation-self-management-after-covid-19-related-illness).

Patients with COVID-19, should be provided with education and support for the self-management of breathlessness and resumption of activities, both in a hospitalized and a non-hospitalized setting caring for COVID-19.

Remarks:

1. Education about control of breathing can support COVID-19 patients to those recovering from respiratory illness, especially those troubled by breathlessness. Patients may be advised to adopt positions, such as high side lying and forward lean sitting, and breathing techniques, such as pursed lip breathing and square box breathing, that help to manage breathlessness. Adequate walking pace regulation is recommended to reduce breathlessness and to prevent desaturation on exertion. Severe shortness of breath that is not relieved by positioning and breathing techniques requires medical investigation.
2. All rehabilitating patients should be educated about resuming everyday activities conservatively at an appropriate pace that is safe and manageable for energy levels within the limits of current symptoms and should not be pushed for post-exertional fatigue. A gradual increase in exercise should be based on symptoms.
3. For patients with COVID-19 that also have underlying cardiovascular or pulmonary conditions, resumption of exercise should be done after consultation with appropriate health professionals *(208,216,217)*. COVID-19 patients with confirmed cardiac involvement need a cardiac evaluation before resuming exercise.
4. Resuming sports gradually should also be guided by appropriate health professionals, an example is provided for return-to-play guideline for myocarditis *(208,216,217)*.

For patients who have been discharged from the hospital or patients who have been managed at home and experience persistent symptoms and/or limitations in functioning, screen for physical, cognitive and mental impairments, and manage accordingly.

Remarks:

1. Patients with COVID-19, regardless of the disease severity, might present with persistent symptoms and a functional decline which may not be obviously apparent (such as a cognitive impairment). Consult with family members or caregivers about health-related premorbid functional difficulties and compare with their current presentation.
2. Screening may include a full history, evaluation of pre-existing health conditions, observation of the patient performing functional tasks, and a symptom-based questionnaire or easily administered screening tool *(218)* (such as Timed Up and Go test for physical function, Whooley questions for depression, Generalized Anxiety Disorder 2-item for anxiety, and Mini-Cog for cognition). Rapid exercise tests for exertional desaturation should not be attempted outside a supervised care setting if resting oximeter reading is < 96% *(215)*.
3. When resources permit, define and clinically assess impairment types by functional domains, including respiratory function (such as spirometry, diffusing capacity of the lungs for carbon monoxide, Medical Research Council dyspnoea scale), cardiovascular function (such as 6 minutes walking distance), swallowing function (such as dysphagia severity scale), musculoskeletal function (such as hand grip strength, Medical Research Council sumscore), cognitive functioning (such as Montreal Cognitive Assessment, Mini-Mental State Examination), and mental functioning (such as Hospital Anxiety and Depression Scale, PTSD checklist-5, Impact of Event Scale-Revised). Additional tests may be indicated for pain, fatigue, and difficulties with ADL *(218)*.
4. Late deterioration of COVID-19 may still occur and late onset inflammatory, thromboembolic and autonomic complications including pulmonary embolism, heart attack, heart failure and stroke have been reported. Rehabilitation or health staff should be alerted and referred to specialist, as part of multidisciplinary, coordinated care pathway.

Provide individualized rehabilitation programmes from subacute to long term according to patient needs. The prescription and provision of rehabilitation programmes should be guided by persistent symptoms and functional limitations.

Remarks:

1. COVID-19 related impairments, such as fatigue, muscle weakness and cognitive impairment, might impact the performance of ADLs. As patients regain strength and fitness, autonomy in ADLs will improve, but some will need to accept additional support from a caregiver for a time. Provide ADL training and consider home modifications (such as grab bars in the shower and toilet, handrails along stairs) and the provision of an assistive product (such as a mobility aid, shower chair, over-toilet frame), as needed.
2. The training principles of comprehensive pulmonary rehabilitation programmess apply for COVID-19 patients with persistent fatigue, reduced exercise capacity and breathlessness *(140,214,219)*. COVID-19 population needs patient-tailored supervised programmes that are flexible to adapt for patients with gas exchange abnormalities *(140,214,219,220)* guided by baseline oxygen needs at rest and during exercise.
3. Patients with physical deconditioning and muscle weakness should start with exercises that support recovery in daily functioning. Start with active range of motion exercises, and when tolerated, proceed with progressive muscle strengthening, typically offered with resistance training. Return to physical exercise should always be guided by symptoms *(216)*.
4. For patients having difficulties with memory, concentration and problem solving, education should be provided, and advice on strategies to help establish expectations (including from family members) and to alleviate stress and anxiety. Cognitive restorative rehabilitation may support with cognitive exercises (such as memory exercises, puzzles, games, reading) and compensation tools such as prompts (e.g. lists and notes) and breaking down activities. Encourage participation in daily activities that are meaningful for the patient.
5. For patients with anxiety, depression and PTSD, basic mental health and psychosocial support by appropriately trained health or non-health workers should be provided. See Chapter 17 on neurologic and mental manifestations *(218,221,222)*.
6. For patients with persistent pain, a multidisciplinary approach is recommended in order to provide pain management according to the principles of the biopsychosocial model.

20. Caring for women with COVID-19 during and after pregnancy

The results of a living systematic review (as of 6 October 2020) show that pregnant and recently pregnant women with COVID-19 appear to be less likely to be symptomatic (0.28, 95% CI 0.13 –0.62; 4 studies; 462 051 women), or manifest common symptoms such as fever, dyspnoea and myalgia, compared with non-pregnant women of reproductive age *(53)*. These findings are largely influenced by studies of pregnant women who were managed in hospitals for any reason, with limited data on women during early pregnancy or postpartum.

Pregnant women with COVID-19 are more likely to experience any type of preterm birth (OR=1.47, 95% CI 1.14–1.90; 18 studies; 8549 women) compared with pregnant women without the disease. Overall rates of spontaneous preterm birth in pregnant women with COVID-19 is broadly similar to those observed during the pre-pandemic period. A third of all neonates born to mothers with COVID-19 were admitted to the neonatal intensive care unit (NICU) (33%) and were at increased risk of NICU admission for any indication (OR=4.89, 95% CI 1.87–12.81; 10 studies, 5873 neonates) compared with those born to mothers without COVID-19.

Transmission of SARS-CoV-2 may be possible in utero or intrapartum, but most neonatal infections reported so far seem to have occurred in the postnatal period *(53)*. However, available studies varied in the rigor of ascertaining mother-to-child transmission of SARS-CoV-2, limiting interpretation of these results.

This section builds on existing recommendations from WHO on pregnancy and infectious diseases and provides additional remarks for the management of pregnant and recently pregnant women.

We recommend all pregnant women with history of contact with a person with confirmed COVID-19 be carefully monitored considering asymptomatic transmission of COVID-19.

Pregnant or recently pregnant women with suspected or confirmed mild COVID-19 may not require acute care in hospital, unless there is concern for rapid deterioration or an inability to promptly return to hospital; but isolation to contain virus transmission is recommended, and can be done at a health facility, community facility or at home, according to established COVID-19 care pathways.

Pregnant or recently pregnant women with moderate or severe COVID-19 require acute care in the hospital, as there is concern for rapid deterioration that may warrant supportive care for severe respiratory morbidity; and/or interventions to improve maternal and fetal survival.

Remarks:

1. Counsel pregnant and recently pregnant women about maternal and newborn signs, including COVID-19 danger signs and maternal perception of decreased fetal movements, and advise them to seek urgent care if they develop any worsening of illness or other danger signs, such as danger signs of pregnancy (including: bleeding or leaking fluid from the vagina, blurry vision, severe headaches, weakness or dizziness, severe abdominal pain, swelling of face, fingers, feet, inability to tolerate foods or liquids, convulsions, difficulty in breathing, decrease in fetal movements). Update birth preparedness and complication readiness plans so they know when and where to seek care.
2. In pregnant and postnatal women that are being cared for at home in self-isolation, self-care interventions should be encouraged. Routine antenatal or postnatal health visits in health facilities should be postponed, and delivery of antenatal and postnatal counselling and care, should instead be conducted via alternative platforms such as home-based, phone or telemedicine *(223,224)*. If postponed, health visits should be rescheduled until after the period of self-isolation following national guidelines and advice, and in consultation with the health care provider. For women requiring abortion services, consider alternative modes of service delivery, including self-management of medical abortion up to 12 weeks' gestation, where women have access to accurate information and to a health care provider at any stage of the process. Postponing abortion care may lead to increased morbidity and mortality where individuals resort to unsafe abortion practices as abortion service delivery is time-bound by gestational limits prescribed by the law *(225).* See the *WHO Consolidated guideline on self-care interventions for health (226).*
3. Counsel women about healthy diet, mobility and exercise, intake of micronutrients for herself and her infant, tobacco use and second-hand smoke exposure, use of alcohol and other substances, as per WHO guidelines on antenatal and postnatal care. Clinical enquiry about the possibility of gender-based violence should be strongly considered, where there is the capacity to provide a supportive response (including referral where appropriate) and where the WHO minimum requirements are met. See resource *(227)*.
4. When caring for pregnant and recently pregnant women with underlying NCDs or pregnancy-induced conditions (e.g. gestational diabetes, pregnancy-induced hypertension) continue or modify previous medical therapy according to the woman's clinical condition.

Pregnant and recently pregnant women with suspected, probable or confirmed COVID-19, should have access to woman-centred, respectful skilled care, including midwifery, obstetric, fetal medicine and neonatal care, as well as mental health and psychosocial support, with readiness to care for maternal and neonatal complications.

Remarks:

1. Woman-centred, respectful, skilled care refers to care organized for and provided to all women in a manner that maintains their dignity, privacy and confidentiality, ensures freedom from harm and mistreatment, and enables informed choice. During labour and childbirth this includes a companion of choice, pain relief, mobility during labour and birth position of choice.
2. Screen birth companions using the standardized case definition. If the companion has suspected or confirmed COVID-19, arrange for an alternative, healthy birth companion in consultation with the woman. Emphasize to any and all companions the importance of IPC measures during labour, childbirth and the mother's and newborn's postnatal stay in the health facility, including appropriate training on and use of PPE and movement restriction in the health care facility.

Mode of birth should be individualized, based on obstetric indications and the woman's preferences. WHO recommends that induction of labour and caesarean section should only be undertaken when medically justified and based on maternal and fetal condition. COVID-19 positive status alone is not an indication for caesarean section. See *WHO recommendations for induction of labour (228)*

Remarks:

1. Emergency birth and pregnancy termination decisions are challenging and based on many factors such as gestational age, severity of maternal condition, and fetal viability and well-being.
2. Interventions to accelerate labour and childbirth (e.g. augmentation, episiotomy, operative vaginal birth) should only be undertaken if medically justified and based on maternal and fetal clinical condition. See *WHO recommendations: intrapartum care for a positive childbirth experience (229).*
3. Delayed umbilical cord clamping (not earlier than 1 minute after birth) is recommended for improved maternal and infant health and nutrition outcomes. The risk of transmission of COVID-19 through blood is likely to be minimal. There is no evidence that delaying cord clamping increases the possibility of viral transmission from the mother to the newborn. The proven benefits of a 1–3 minute delay, at least, in clamping the cord outweigh the theoretical, and unproven, harms.
4. Individualized decisions should be taken about postponing planned (elective) induction or caesarean section in pregnant women with suspected or confirmed mild COVID-19 *(227).*

Pregnant and recently pregnant women who have recovered from COVID-19 and been released from the COVID-19 care pathway, should be enabled and encouraged to receive routine antenatal, postpartum, or postabortion care, as appropriate. Additional care should be provided if there are any complications.

Remarks:

1. All pregnant women with or recovering from COVID-19 should be provided with counselling and information related to the potential risk of adverse pregnancy outcomes.
2. Women's choices and rights to sexual and reproductive health care should be respected regardless of COVID-19 status, including access to contraception and safe abortion to the full extent of the law *(225).*

21. Feeding and caring for infants and young children of mothers with COVID-19

Relatively few cases have been reported of infants confirmed with COVID-19; those that have been reported experienced mild illness. Of 115 mother-child pairs from 17 articles where the mother is confirmed to be infected with COVID-19, 13 children had COVID-19 (4 breastfed, 5 formula-fed, 2 mix-fed, 2 unreported feeding practice). Twenty mothers had breastmilk samples tested for the presence of SARS-CoV-2 RNA particles by RT-PCR; 7 of them had children with COVID-19 (2 breastfed,1 formula fed, 2 mix-fed, 2 unreported). Of the 20 with breastmilk tested, 18 had negative results and 2 had positive results. One of the two mothers whose breastmilk sample was positive for SARS-CoV-2, had a mix-fed child who was not infected with COVID-19; the other one had a child with COVID-19 (feeding practice was not reported) *(230,231,232,233,234,235,236,237,238,239,240)*.

Breastfeeding protects against morbidity and death in the post-neonatal period and throughout infancy and childhood. The protective effect is particularly strong against infectious diseases that are prevented through both direct transfer of antibodies and other anti-infective factors and long-lasting transfer of immunological competence and memory. See WHO *Essential newborn care and breastfeeding (241).* Therefore, standard infant feeding guidelines should be followed with appropriate precautions for IPC.

Recommendations on the care and feeding of infants whose mothers have suspected or confirmed COVID-19 promote the health and well-being of the mother and infant. Such recommendations must consider not only the risks of infection of the infant with the COVID-19 virus, but also the risks of serious morbidity and mortality associated with not breastfeeding or the inappropriate use of breastmilk substitutes as well as the protective effects of skin-to-skin contact and kangaroo mother care. In light of the current

evidence, WHO has concluded that mothers with suspected or confirmed COVID-19 should not be separated from their infants. Mother-infant contact and holding enhances thermoregulation and other physiological outcomes, significantly reduces mortality and morbidity, and improves child and parental attachment. Overall, the recommendation to keep mothers and their children together is based on several important benefits that outweigh the potential (and likely mild) harms of COVID-19 transmission to the child.

We recommend that mothers with suspected or confirmed COVID-19 should be encouraged to initiate and continue breastfeeding. From the available evidence, mothers should be counselled that the benefits of breast-feeding substantially outweigh the potential risks of transmission.

Remarks:

1. WHO recognizes that the recommendation for an infected mother to be in close contact with her baby may appear to contradict other IPC measures that include isolation of persons infected with COVID-19 virus *(53)*. However, the balance of risks is significantly different for infants than for adults. In infants, the risk of COVID-19 infection is low, the infection is typically mild or asymptomatic, and the consequences of not breastfeeding or separation of mother and child can be significant. At this point it appears that COVID-19 in infants and children represents a much lower risk to survival and health than the other infections and conditions that breastfeeding is protective against. This protection is especially important when health and other community services are themselves under pressure. In contrast, the risks associated with COVID-19 in adults are much higher and more severe. Improved communication is needed to address the uncertainties and confusion among programme managers, health workers and communities on this issue.
2. See Table 21.1 below for recommendations when mother with COVID-19 is caring for infant.

Table 21.1. Summary of recommendations when mother with COVID-19 is caring for infant

	Interventions
Mother infant contact at birth	Mothers should not be separated from their infants unless the mother is too sick to care for her baby. If the mother is unable to care for the infant another competent family caregiver should be identified. Mother and infant should be enabled to remain together while rooming-in throughout the day and night and practise skin-to-skin contact, including kangaroo mother care, especially immediately after birth and during establishment of breastfeeding, whether they or their infants have suspected or confirmed COVID-19 virus infection. Neonates born to mothers with suspected or confirmed COVID-19 should be breastfed within 1 hour of birth. Mothers should apply appropriate IPC. Early and uninterrupted skin-to-skin contact between mothers and infants should be facilitated and encouraged as soon as possible after birth, while applying necessary measures for IPC. This applies also to infants who are born preterm or low birth weight. If the newborn or infant is ill and requires specialist care (such as neonatal unit), arrangements should be made to allow the mother free access to the unit, with appropriate IPC measures. Earlier initiation of breastfeeding results in greater benefits. This may be relevant to mothers who give birth by caesarean section, after an anaesthetic, or those who have medical instability that precludes initiation of breastfeeding within the first hour after birth.
During early childhood	Infants should be breastfed exclusively during the first 6 months after birth, as breastmilk provides all the nutrients and fluids they need. From 6 months of age, breastmilk should be complemented with a variety of adequate, safe and nutrient-dense foods. Breastfeeding should continue up to 2 years of age or beyond. Breastfeeding counselling, basic psychosocial support and practical feeding support should be provided to all pregnant women and mothers with infants and young children if they or their infants and young children have suspected or confirmed COVID-19 infection.

If feeding is interrupted	In situations when severe illness in a mother prevents her from caring for her infant or prevents her from continuing direct breastfeeding, mothers should be encouraged and supported to express milk, and the breastmilk provided safely to the infant, while applying appropriate IPC measures. In the event that the mother is too unwell to breastfeed or express breastmilk, explore the viability of feeding with donor human milk. If this is not possible, consider wet nursing (defined as another woman breastfeeds the child) or appropriate breastmilk substitutes, informed by feasibility, safety, sustainability, cultural context, acceptability to mother and service availability. Mothers who are not able to initiate breastfeeding during the first hour after delivery should still be supported to breastfeed as soon as they are able. Assistance should be provided after recovery for relactation to re-establish a milk supply and continue breastfeeding.
Practices the mother should perform during all infant and childcare	Perform frequent hand hygiene with soap and water or alcohol-based hand rub, especially before contact with her child. Perform respiratory hygiene: sneeze or cough into a tissue and immediately dispose of the tissue. Hands should immediately be washed with soap and water or alcohol-based hand rub. Clean and disinfect surfaces with which the mother has been in contact. Wear a medical mask until symptom resolution and criteria for release from isolation have been met. Additionally, breastfeeding mothers should be helped to clean her chest with soap and water if she has been coughing on it before breastfeeding. She does not need to wash her breasts prior to every breastfeed. While mothers are recommended to wear medical masks, if the mother does not have a medical mask, she should still be encouraged to continue breastfeeding as the benefits of breastfeeding outweigh the potential risks of transmission of the virus when breastfeeding while applying other IPC measures.
Best practices for breast-feeding	Health facilities providing maternity and newborn services should enable a mother to breastfeed for as often and for as long as she wishes. Minimizing disruption to breastfeeding will require health care practices that enable a mother to breastfeed. All mothers should receive practical support to enable them to initiate and establish breastfeeding and manage common breastfeeding difficulties. This support should be provided by appropriately trained health care professionals and community-based lay and peer breastfeeding counsellors. There should be no promotion of breastmilk substitutes, feeding bottles and teats, pacifiers or dummies in any part of facilities providing maternity and newborn services, or by any of the staff. Health facilities and their staff should not give feeding bottles and teats or other products that are within the scope of the International Code of Marketing of Breast-milk Substitutes and its subsequent related WHA resolutions, to infants. If the mother is too unwell to breastfeed or express breastmilk, explore the best alternatives to breastfeeding a newborn or young infant, in priority order, as follows: 1) donor human milk should be fed if available from a human milk bank; 2) if supplies are limited, prioritize donor human milk for preterm and low birth weight newborns; 3) wet nursing may be an option depending on acceptability to mothers and families, availability of wet nurses and services to support mothers and wet nurses. COVID-19 testing of a woman who is a potential wet nurse is not required. Prioritize wet nurses for the youngest infants. In settings where HIV is prevalent, prospective wet nurses should undergo HIV counselling and rapid testing where available. In the absence of testing, if feasible, undertake HIV risk assessment. If HIV risk assessment or counselling is not possible, facilitate and support wet nursing; 4) breastmilk substitutes may be used as a last resort.

22. Caring for older people with COVID-19

Older age has been reported as a risk factor for increased mortality in those affected by COVID-19. Other risk factors that have been reported are: smoking, diabetes, hypertension, cardiovascular, cancer, chronic lung disease, and functional decline *(242,243,244)*. Since older people are often affected by these conditions, they are potentially at the highest risk for fatality. Furthermore, the majority of long-term care service users are older people with multiple underlying conditions and weak immune systems, which make them more susceptible to severe COVID-19 and poor outcomes *(245)*. Refer to the WHO policy brief *Preventing and managing COVID-19 across long-term care services (245)* and WHO guidance *Integrated care for older people (ICOPE) (246)* for person-centred and coordinated model of care.

We recommend that older people be screened for COVID-19 at the first point of access to the health system, be recognized promptly if they are suspected to have COVID-19 and treated appropriately according to established COVID-19 care pathways. This should occur in all settings where older people may seek care; included but not limited to facility-based emergency units, primary care, prehospital care settings and LTCFs.

Remarks:

1. Older patients may present with atypical symptoms (including delirium) of COVID-19, especially those with cognitive decline and dementia *(247,248)* (see Table 6.1); health workers should take this into account during the screening process.
2. Provide accessible information to older people and their caregivers on clinical manifestation of COVID-19 including atypical symptoms, how to monitor symptoms, as well as when and how to seek care.

Identify if there is an advance care plan for patients with COVID-19 (such as desires for intensive care support) and respect their priorities and preferences. Tailor the care plan to be in line with patients' expressed wishes and provide the best care irrespective of treatment choice.

We recommend a review of medication prescriptions to reduce polypharmacy and prevent medicine interactions and adverse events for those being treated with COVID-19.

Remarks:

1. Older people are at greater risk of polypharmacy, as a result of newly prescribed medications, inadequate medication reconciliation, and a lack of coordination of care, all of which increases the risk of negative health consequences. If medications are prescribed for mental and neurological manifestations of COVID-19 in older people, this should be done with extreme caution given the increased susceptibility to drug side-effects and drug interactions with other prescribed medications.
2. Over 20% of adults over 60 years have pre-existing mental or neurological conditions for which they may already be taking medications before infection *(249)*. If a person has a previously diagnosed mental or neurological condition and is already on medications, consider how these medications (or withdrawal from them) may affect their COVID-19 symptoms. Stopping or adjusting the dosage of medications in people with COVID-19 are decisions that require careful risk-benefit analyses and when possible, consultation with a specialist is advised.

Ensure multidisciplinary collaboration among physicians, nurses, pharmacists, physiotherapists, occupational therapists, social workers, mental health and psychosocial providers, community workers and other health care professionals in the decision-making process to address multimorbidity and functional decline *(246,250,251)*.

Remarks:

1. Physiological changes with age lead to declines in physical and mental capacities such as malnutrition, cognitive decline, depressive symptoms, and those conditions interact at several levels. These interactions require an integrated approach to the screening, assessment and management of older people *(246)*.

2. Person-centred care including geriatric, psychosocial, and palliative care by a multidisciplinary team, with a careful evaluation of baseline conditions and functions, and disease severity, followed by frequent reassessments, ensures the provision of the appropriate level of care *(252,253)*.
3. Hearing loss and vision impairments become more prevalent among older people and may pose a communication barrier, especially when masks prevent lip reading and decrease vocal clarity. Cognitive decline may also need to be considered when communicating with older patients. Such impairments should be identified early so that health workers involved in their care can adjust their communication accordingly *(254)*.
4. Older people who experience COVID-19, including those admitted to ICU and/or treated with protracted oxygen therapy and bed rest, are more likely to experience pronounced functional decline and require coordinated rehabilitation care after acute hospitalization (see Chapter 19. Rehabilitation for patients with COVID-19).
5. Ensure that chronic infections are diagnosed and treated appropriately in older people. Other infections such as TB may mimic or co-exist with COVID-19 and therefore pass unrecognized, causing increased mortality *(67,68,69)*.

23. Palliative care and COVID-19

Palliative care is a multifaceted, integrated approach to improving the quality of life of adults and paediatric patients and their families facing the problems associated with life-threatening illness such as COVID-19. Palliative care focuses on prevention and relief of suffering by means of early identification, assessment and treatment of physical, psychosocial and spiritual stressors. Palliative care includes but is not limited to end-of-life care *(255)*. Palliative interventions should be integrated with curative treatment *(255)*. Basic palliative care, including relief of dyspnoea or other symptoms and social support, should be practised by all doctors, nurses, social workers and others caring for persons affected by COVID-19, adult or child *(255,256)*. Refer to the WHO guide *Integrating palliative care and symptom relief into responses to humanitarian emergencies and crises (255)*.

We recommend to identify, in all patients with COVID-19, if they have an advance care plan for COVID-19 (such as desires for intensive care support) and respect their priorities and preferences to tailor the care plan and provide the best care irrespective of treatment choice.

Palliative care interventions should be made accessible at each institution that provides care for persons with COVID-19.

Remarks:

1. Appropriate interventions should be accessible at each institution that provides care for persons with COVID-19. Efforts should be made to assure accessibility of interventions at home *(255)*.
2. Palliative care includes but is not limited to end-of-life care. Palliative interventions should be integrated with curative treatment. Basic palliative care, including relief of dyspnoea or other symptoms and social support, should be practised by all doctors, nurses, social workers and others caring for persons affected by COVID-19.
3. In hospitals, palliative care does not require a separate ward or department. Palliative care can be provided in any setting.
4. Consider non-pharmacologic and pharmacologic interventions (such as opioids) for relief of dyspnoea that is refractory to treatment of the underlying cause (i.e. oxygen therapy, escalation of respiratory support, corticosteroids) and/or as part of end-of-life care *(257)*. The narrow therapeutic margin of opioids in the management of dyspnoea requires that opioids are prescribed in accordance with evidence-based treatment protocols and that patients are closely monitored to prevent negative unintended effects due to inappropriate use of opioids. Where opioids are used, preference should be given for compounds less likely to cause delirium in medically ill patients. Providers should reference their institutional standards regarding the potential use of opioids for dyspnoea in patients with COVID-19.

5. Relieving spiritual and psychological suffering is an important aspect of palliative care. Visits from relatives and spiritual counsellors should be facilitated, especially for patients near to the end of life. This may include employing a range of techniques such as voice/video calls.
6. Palliative care is a person-centred approach; therefore all patients and families should be actively included in the decision-making processes about escalation of care. Medical decisions, where possible, should respect the priorities and preferences of patients, and should always be clearly explained to patients and relatives.

24. Care of COVID-19 patients after acute illness (new chapter)

New evidence is emerging about COVID-19 related persistent symptoms, which have parallels with other coronavirus diseases *(204)*.

The clinical characterization of mid- and long-term effect of COVID-19 remain to be clearly described and understood. In hospitalized patients, ICU and non-ICU, there are reports of new illness-related fatigue, breathlessness, PTSD symptoms, pain, voice change, cough, dysphagia, anxiety, depression, and problems with concentration, memory and continence. Patients admitted to ICU had greater prevalence of symptoms in almost all reported symptom domains than COVID-19 patients not admitted to ICU *(202)*. As well, more than half of all COVID-19 patients who had been hospitalized, regardless of their clinical management, reported persistence of fatigue at 60 days since the onset of symptoms *(202,203)*.

Early findings report, most common ongoing symptoms (regardless of hospitalization status) are fatigue, muscle ache, shortness of breath and headache at a follow up of 4 months *(205)*. Not returning to usual health within 2–3 weeks of testing was reported by approximately one third of symptomatic adults in an outpatient setting *(206)*. A study reported that at 3 months after the onset of symptoms, one third of non-hospitalized patients were to some degree dependent on others for personal care *(207)*.

Best Practice Statement

Patients who have had suspected or confirmed COVID-19 (of any disease severity) who have persistent, new, or changing symptoms should have access to follow-up care.

Remarks:

Recognition

- All patients (and their caregivers) with COVID-19 should be counselled to monitor for resolution of signs and symptoms. If any one or more of these persist, or patient develops new or changing symptom, then to seek medical care according to national (local) care pathways.
- This includes counselling about acute life-threatening complications, such as pulmonary embolism, myocardial infarction, dysrhythmias, myopericarditis and heart failure, stroke, seizures and encephalitis *(54,258)* for which they should seek emergency care.
- Patients with severe and critical COVID-19 may develop post-intensive care syndrome (PICS), with a range of impairment including (but not limited to) physical deconditioning, cognitive, and mental health symptoms. See Chapter 19. Rehabilitation for patients with COVID-19 for more details on PICS.

Management

- National (local), coordinated care pathways should be established that can include primary care providers (i.e. general practitioners), relevant specialists, multidisciplinary rehabilitation professionals, mental health and psychosocial providers, and social care services.
- Management should be tailored according to patient needs and be coordinated.
- Management interventions include addressing promptly life-threatening complications. For non-life-threatening complications, management may entail education, advice on self-management strategies (i.e. breathing techniques, pacing), caregiver support and education, peer-to-peer groups, stress management, stigma mitigation and home modification; prescription of rehabilitation programmes, and/or specialty management.
- See Chapter 19. Rehabilitation for patients with COVID-19 for recommendations regarding screening, assessment and rehabilitation interventions to facilitate onward referrals for inpatient, outpatient, or community-based follow up, to ensure continuity during transitions of care.

Evidence to decision

Values and preferences	No substantial variability expected

Applying the agreed values and preferences, the GDG inferred that well-informed patients would consider the possible harms associated with COVID-19 follow-up to be negligible, and that ensuring access to care is an important value to consider.

Resources and other considerations	Important considerations

National (local), coordinated care pathways should be established that can include primary care providers (i.e. general practitioners), relevant specialists, multidisciplinary rehabilitation professionals, mental health and psychosocial providers, and social care services. Alternative delivery platforms such as home-based phone, telemedicine, or community outreach teams may be used.

Justification
Applicability
Special populations
Considerations should be made when following up special populations such as older persons (see Chapter 22. Caring for older people with COVID-19), and children and their caregivers.

Practical info
Uncertainties
Further research on mid- and long-term sequelae of COVID-19 is a priority. Some items identified include:

- A consensus case definition to facilitate global surveillance, diagnosis, management and research to be convened by WHO.
- Detailed clinical characterization of mid- and long-term sequelae, using standardized tools for data collection (see Chapter 27. Clinical research during the COVID-19 pandemic).
- Multidisciplinary approach to research which involves patients and communities affected with COVID-19.
- Impact of therapeutics on longer term outcomes.

25. Ethical principles for optimum care during the COVID-19 pandemic

Ethics are central to the clinical care of COVID-19 patients in the same way that ethics pertain to all patients. Clinical care involves using clinical expertise to do what is best for patients within a relationship of care. This section provides a brief introduction to some of the ethical considerations that are important to remember in the context of COVID-19 *(259,260)*.

Ethical considerations that impact all persons affected by COVID-19

Equal moral respect: Every person is equally valuable. Treatment and care decisions should be based on medical need and not on irrelevant or discriminatory features such as **ethnicity, religion, sex, age, disability or political affiliation**. Patients with similar health problems or symptoms must receive equal treatment and care. Showing moral respect means involving patients and their caregivers in decision-making to the greatest extent possible, explaining options and limitations in treatment.

Duty of care: Every patient is owed the best possible care and treatment available in the circumstances. Even when resources need to be rationed during a crisis, health care professionals and frontline workers have a duty of care to promote their patients' welfare within available resources. Health care professionals and frontline workers are also owed a duty of care. In this regard, appropriate PPE for health care professionals and frontline workers should be provided to promote their safety and well-being. This is a benefit to them but also to the whole of society by ensuring that they are available to support the clinical response for as long as possible.

Non-abandonment: It follows from consideration of equal moral respect and duty of care, that no person in need of medical care should ever be neglected or abandoned. Care will extend to families and friends of patients and options to maintain communication with them should be explored. Palliative care must be accessible for all patients with respiratory failure for whom ventilatory support will be withheld or withdrawn.

Protection of the community: Appropriate IPC should be in place, respected and enforced. Such actions protect patients, health care professionals and the community. During a pandemic the focus should be on both clinical care for patients and the promotion of public health.

Confidentiality: All communications between patient and clinician must remain confidential except in the case of compelling public health concerns (e.g. contact tracing and surveillance etc.) or other accepted justifications for breach of confidentiality. Private individual information must be kept secure unless it is a justified breach.

We recommend that hospitals and health systems at local, regional, national and global level plan prepare and be ready to surge clinical care capacity (staff, structure, supplies and systems) in order to be able to provide appropriate care of all COVID-19 patients and maintain essential health services *(61,261)*.

Allocation of scarce resources: We recommend that each institution should establish a plan for what to do in situations of resource scarcity to cover the allocation or access to critical medical interventions (such as oxygen, intensive care beds and/or ventilators). Such a plan should establish a clear overall aim.

Decision-making regarding allocation: Part of planning for scarcity is ensuring that a fair system of decision-making for allocation is in place.

Remarks:

1. Personnel familiar with the medical triage criteria and allocation protocols, who are distinct from the clinical treating team are one option. Allocation decisions should be done according to the established plan and regularly reviewed. If necessary, there should be a reallocation of a resource that was previously allocated where it is not proving beneficial.
2. For example, the aim might be to ensure the best possible use of limited resources based upon chosen medical criteria. Triage criteria should seek to balance medical utility and equity, and ease of implementation. The same criteria should be applied for all patients with similar levels of need, regardless of COVID-19 status.

We recommend that it be clear when decision-making will move from routine allocation to pandemic allocation, so that institutions do not move too soon to restrict access in anticipation of possible future scarcity that might not arise.

Remarks:

1. It should be clear what the “tipping point” is to change to pandemic allocation (e.g. a declaration by a ministry of health, or hospitals reaching ICU bed and ventilator capacity). This should take into account maximizing surge clinical capacity.
2. Whatever method is chosen should be subject to a fair process, such as using the following procedural principles:
    - **Inclusiveness:** Input should be obtained from the most affected population(s).
    - **Transparency:** The mechanism should be easily accessible and understandable at an elementary school level and in all major languages in the institution’s catchment area.
    - **Accountability:** A mechanism should be available to review the application of an approved triage protocol, or requests to review a particular decision, in light of novel or updated clinical information or other concerns.
    - **Consistency:** Allocation principles should be applied consistently.

We recommend that caregivers should be:

- **Given access to adequate training in caregiving, including IPC.**
- **Given access to appropriate and adequate PPE.**
- **Exempted from travel restrictions that would preclude caring for the patient.**
- **Be given access to psychological, social and spiritual care, and also to respite and bereavement support as needed.**

Remark:
Caregivers are at risk for the same types of psychological, social and spiritual distress as patients. They are also at risk for becoming infected. Basic mental health and psychosocial support should be provided for all caregivers by asking them about their needs and concerns, and addressing them *(262)*.

26. Reporting and coding during the COVID-19 pandemic (mortality and morbidity)

All coding advice is available in the official WHO languages and can be found together with more detail for classification purposes at https://www.who.int/standards/classifications/classification-of-diseases/emergency-use-icd-codes-for-covid-19-disease-outbreak. See Table 26.1 and 26.2 for details.

Table 26.1 Morbidity and mortality coding for COVID-19 in ICD-10 and ICD-11

ICD**ICD**	**Description of codes**	
ICD -10	An emergency ICD-10 code of "U07.1 COVID-19, virus identified" is assigned to a disease diagnosis of COVID-19 confirmed by laboratory testing. An emergency ICD-10 code of "U07.2 COVID-19, virus not identified" is assigned to a clinical or epidemiological diagnosis of COVID-19 where laboratory confirmation is inconclusive or not available. Both U07.1 and U07.2 may be used for mortality coding and tabulation as cause of death.	
ICD-11	The code for the confirmed diagnosis of COVID-19 is RA01.0. The code for the clinical diagnosis (suspected or probable) of COVID-19 is RA01.1.	

A set of additional categories has been agreed to be able to document or flag conditions that occur in the context of COVID-19. Both, 3-character and 4-character codes have been defined to respond to the different levels of coding depth that is in place in different countries. The categories below will not be seen in primary tabulation of the single underlying cause of death. They may be used in multiple cause of death analysis and reporting.

Table 26.2 Coding for conditions occurring in context of COVID-19 in ICD-10 and ICD-111

ICD -10	1. U08 Personal history of COVID-19 U08.9 Personal history of COVID-19, unspecified Note: This optional code is used to record an earlier episode of COVID-19, confirmed or probable that influences the person's health status, and the person no longer suffers of COVID-19. This code should not be used for primary mortality tabulation. 2. U09 Post COVID-19 condition U09.9 Post COVID-19 condition, unspecified Note: This optional code serves to allow the establishment of a link with COVID-19. This code is not to be used in cases that still are presenting COVID-19. 3. U10 Multisystem inflammatory syndrome associated with COVID-19 U10.9 Multisystem inflammatory syndrome associated with COVID-19, unspecified
ICD-11	RA02 Post COVID-19 condition RA03 Multisystem inflammatory syndrome associated with COVID-19 QC42/RA01 Personal history of COVID-19

For mortality we recommend the use of emergency ICD codes as outlined in the *International guidance for certification and coding of COVID-19 as cause of death (263).*

Remarks:

1. The primary goal is to identify all deaths due to COVID-19. A death due to COVID-19 is defined for surveillance purposes as a death resulting from a clinically compatible illness, in a probable or confirmed COVID-19 case, unless there is a clear alternative cause of death that cannot be related to COVID-19 disease (e.g. trauma). There should be no period of complete recovery from COVID-19 between illness and death. A death due to COVID-19 may not be attributed to another disease (e.g. cancer) and should be counted independently of pre-existing conditions that are suspected of triggering a severe course of COVID-19.
2. Specification of the causal sequence leading to death in Part 1 of the certificate is important. For example, in cases when COVID-19 causes pneumonia, sepsis and acute respiratory distress; then pneumonia, sepsis and acute respiratory distress should be included, along with COVID-19, in Part 1. Certifiers should include as much detail as possible based on their knowledge of the case, from medical records, or about laboratory testing *(263).*
3. The use of official terminology, COVID-19, should be used for all certification of this cause of death. COVID-19 should be recorded on the medical certificate as cause of death for all decedents where the disease caused, or is assumed to have caused, or contributed to death. This helps to reduce uncertainty for the classification or coding and to correctly monitor these deaths.

27. Clinical research during the COVID-19 pandemic

A living mapping and systematic review of COVID-19 studies are available *(264)*. For more information about the WHO research roadmap see https://www.who.int/teams/blueprint/covid-19.

We recommend to collect standardized clinical data on all hospitalized patients to improve understanding of the natural history of the disease and contribute data to the WHO Global COVID-19 Clinical Data Platform (see website for details).

Remarks:

1. Member States are invited to contribute anonymized clinical data to the WHO Global COVID-19 Clinical Data Platform; contact: COVID_ClinPlatform@who.int to get log-in credentials. This will serve to inform the public health and clinical response.
2. Four case record forms (CRFs) are now available: These can be accessed on the WHO website *(265)*.
   - Rapid CRF
   - Pregnancy CRF
   - Multisystem inflammatory syndrome temporally associated with COVID-19 CRF
   - Follow up CRF.
3. Clinical characterization research protocols are also available *(266).*

The WHO Solidarity trial is a randomized clinical trial that is a currently enrolling. For more information see the WHO website *(267)*.

Remark:
Older age is reported to be a predictor of mortality in patients with COVID-19. The systematic exclusion of older adults from research activities or from accessing investigational therapeutic agents is not justified *(260).*

Acknowledgements

Acknowledgements for *Clinical management of COVID-19: interim guidance* 25 January 2021

Special thanks to experts who provided presentations to the GDG:
Pasi Penttinen (European Centre for Disease Prevention and Control): Risk factors for severe outcomes following COVID-19 infection – results of a systematic literature review.

Special thanks to the WHO Rapid Review team and WHO Library:
Thomas Allen (WHO Library); Haley Holmer (WHO Quality, Norms & Standards); Ajay Rangaraj (WHO UHC, Communicable and NCDs); Vanessa Veronese (WHO Research and Training in Tropical Diseases); for conducting the evidence search.

Special thanks to the external reviewers for their insights on the new recommendations:
Richard Kojan (Alliance for International Medical Action); Gabriel Alcoba, Francisco Bartolome, Edward Chu, Marcio da Fonseca, Amin Lamrous, James Lee, Bhargavi Rao, Saschveen Singh, Armand Sprecher (Médecins Sans Frontières).

Special thanks to the following reviewers of the updates on Chapter 17 (neurological and mental manifestations):
José Luis Ayuso-Mateos (Director, Department of Psychiatry, Universidad Autónoma de Madrid, CIBERSAM and WHO Collaborating Centre for Mental Health Services Research and Training, Spain); Corrado Barbui (WHO Collaborating Centre for Research and Training in Mental Health and Service Evaluation, University of Verona, Italy); Ettore Beghi (Professor of Neurology, Department of Neuroscience, Istituto di Ricerche Farmacologiche, Milano, Italy); Sherry H-Y Chou (Associate Professor of Critical Care Medicine, Neurology, and Neurosurgery, University of Pittsburgh School of Medicine, United States of America); Mario Maj (Director, Department of Psychiatry, University of Naples, Italy); Benedict Michael (Senior Clinician Scientist Fellow, Institute of Infection and Global Health, University of Liverpool, Liverpool, United Kingdom); Shubham Misra (Senior Research Fellow, Department of Neurology, All India Institute of Medical Sciences, New Delhi, India); Pratima Murthy (Professor and Head, Department of Psychiatry National Institute of Mental Health and Neuro-Sciences, Bangalore, India); Alessandro Padovani (Neurologist, Director, NeuroCOVID Unit, University of Brescia, Italy); Kameshwar Prasad (Professor of Neurology, All India Institute of Medical Sciences, New Delhi, India); Shekhar Saxena (Professor, Department of Global Health and Population, Harvard TH Chan School of Public Health, Boston, MA, United States of America); Kiran Thakur (Neurologist, Winifred Mercer Pitkin Assistant Professor of Neurology, Department of Neurology, Columbia University Irving Medical Center-New York Presbyterian Hospital, New York City, United States of America).

Special thanks to the following reviewers of the updates on Chapter 19 (rehabilitation):
Neelum Zehra Bukhari (Head, Department Occupational Therapy, Ziauddin College of Rehabilitation Sciences, Ziauddin University, Pakistan); Professor Trish Greenhalgh (Nuffield Department of Primary Care Health Sciences, University of Oxford, United Kingdom); Peter A Lim (Rehabilitation Medicine, Singapore General Hospital, Clinical Associate Professor, Duke-NUS Medical School, Singapore, and Clinical Professor, Physical Medicine and Rehabilitation, Baylor College of Medicine, Houston, TX, United States of America); Professor Sally Singh (Head of Pulmonary and Cardiac Rehabilitation, University Hospitals Leicester, United Kingdom); Dr Abena Tannor (Rehabilitation Medicine, Komfo Anokye Teaching Hospital, Accra, Ghana).

Special thanks also go to the WHO COVID-19 IPC Global Expert Panel:
April Baller (Infection Prevention and Control, WHE); Carole Fry (Infection Prevention and Control Hub and Task Force, Integrated Health Services, WHO).

Acknowledgements for *Clinical management of COVID-19: interim guidance* 27 May 2020

WHO Steering Committee: Janet V Diaz (Lead), Nazneen Anwar, Florence Baingana, April Baller, Anshu Banerjee, Silvia Bertagnolio, Mercedes Bonet, Andrea Bosman, Marie-Charlotte Bousseau, Andrea Bruni, Maurice Bucagu, Neerja Chowdhary, Jane Cunningham, Meg Doherty, Tarun Dua, Alexandra Fleischmann, Nathan Ford, Stéfanie Freel, Laurence Grummer-Strawn, Fahmy Hanna, Benedikt Huttner, Ernesto Jaramillo, Maria Van Kerkhove, Caron Kim, Kavitha Kolappa, Teresa Kortz, Ornella Lincetto, Aiysha Malik, Carmen Martinez, Alessandro Massazza, Jody-Ann Mills, Lorenzo Moja, Susan Norris, Olufemi Oladapo, Peter Olumese, Mark van Ommeren, Martina Penazzato, Anayda Portela, Andreas Reis, Pryanka Relan, Lisa Rogers, Nigel Rollins, Khalid Saeed, Katrin Seeher, Allison Schaefer, Nicoline Schiess, Ingrid Smith, Howard Sobel, Maria Pura Solon, Renato Souza, Yuka Sumi, Anna Thorson, Kavita Trivedi, Marco Vitoria, Prinzo Weise, Inka Weissbecker, Wilson Were, Matteo Zignol.

United Nations Children's Fund (UNICEF): Maya Arii.

Guideline Development Group members: Neill Adhikari (Sunnybrook Health Sciences Centre and University of Toronto); John Appiah (Senior Specialist, Paediatric Critical Care and Head of Paediatric Intensive Care Unit of the Komfo Anokye Teaching Hospital, Ghana); Abdullah Balkhair (Head of Infectious Diseases Unit and Infection Control Department, Sultan Qaboos University, Oman); Florence Baingana (Research Fellow, Makerere University, Kampala, Uganda); Corrado Barbui (WHO Collaborating Centre for

Research and Training in Mental Health and Service Evaluation, University of Verona, Italy); Lucille Blumberg (National Institute for Communicable Diseases, South Africa); Bin Cao (China-Japan Friendship Hospital, Capital Medical University, Beijing, China); Maurizio Cecconi (Head of Department Anesthesia and Intensive Care Units, Humanitas Research Hospital, Milan, Italy); Bronwen Connolly (Queen's University Belfast, United Kingdom of Great Britain and Northern Ireland); Vu Quoc Dat (Department of Infectious Diseases, Hanoi Medical University, Viet Nam); Jake Dunning (Head of Emerging Infections and Zoonoses, Public Health England, United Kingdom); Rob Fowler (University of Toronto, Canada); Heike Geduld (African Federation for Emergency Medicine, Cape Town, South Africa); Charles Gomersall (Chinese University of Hong Kong, Hong Kong SAR, China); Rumina Hasan (Professor, Department of Pathology and Laboratory Medicine, Aga Kahn University, Pakistan, and Honorary Professor, Department of Infectious and Tropical Diseases, London School of Hygiene and Tropical Medicine, United Kingdom); Manai Hela (Emergency Medical Service Tunis, Tunisia); David S Hui (Chairman of the Department of Medicine and Therapeutics, Chinese University of Hong Kong, Hong Kong SAR, China); Yae-Jean Kim (Sungkyunkwan University, Samsung Medical Center, Republic of Korea); Niranjan Kissoon (Professor in Critical Care, University of British Columbia and BC Children's Hospital, Vancouver, Canada); Arthur Kwizera (Department of Anaesthesia and Critical Care, Makerere University, Kampala, Uganda); Pisake Lumbiganon (Director WHO Collaborating Centre for Research Synthesis in Reproductive Health, Faculty of Medicine, Khon Kaen University, Thailand); Flavia Machado (Anesthesiology, Pain and Intensive Care Department, Federal University of São Paulo, Brazil); Srinivas Murthy (Associate Professor, University of British Columbia, Vancouver, Canada); Saniya Sabzwari (Aga Khan University Hospital, Karachi, Pakistan); Rohit Sarin (Director, National Center of Excellence Supranational TB Reference Laboratory, New Delhi, India); Yinzhong Shen (Shanghai Public Health Clinical Center, Fudan University, Shanghai, China); Maria Asuncion Silvestre (President, Kalusugan ng Mag-Ina (Health of Mother and Child), Quezon City, Philippines); João Paulo Souza (Professor of Public Health, Department of Social Medicine, Ribeirao Preto Medical School, University of São Paulo, Brazil).

External reviewer panel: Shekhar Saxena (Professor, Department of Global Health and Population, Harvard TH Chan School of Public Health, Boston, MA, United States of America); Francesco Castelli (Director, Department of Infectious and Tropical Diseases, University of Brescia and Brescia Civili General Hospital, Italy); Richard Kojan (President, Alliance for International Medical Action).

External review of Chapter 15 (neurological and mental manifestations): José Luis Ayuso-Mateos (Director, Department of Psychiatry, Universidad Autónoma de Madrid, CIBERSAM and WHO Collaborating Centre for Mental Health Services Research and Training, Spain); Corrado Barbui (WHO Collaborating Centre for Research and Training in Mental Health and Service Evaluation, University of Verona, Italy); Rabih El Chammay (Director, National Mental Health Programme, Beirut, Lebanon); Oye Gureje (Director, Institute of Neurosciences, University College Hospital, Ibadan, Nigeria); Mario Maj (Director, Department of Psychiatry, University of Naples, Italy); Farrah Mateen (Associate Professor of Neurology, Harvard Medical School, Boston, MA, United States of America); Pratima Murthy (Professor and Head, Department of Psychiatry National Institute of Mental Health and Neuro-Sciences, Bangalore, India); Giovanni Ostuzzi (Psychiatrist, University of Verona, Italy); Chuan Shi (Psychiatrist, University of Peking, Beijing, China); Felicia Smith (Psychiatrist, Massachusetts General Hospital, Harvard Medical School, Boston, MA, United States of America); Graham Thornicroft (Professor of Community Psychiatry, Institute of Psychiatry, Psychology and Neuroscience, and Health Service & Population Research Department, King's College London, United Kingdom); Peter Ventevogel (Senior Mental Health Advisor, United Nations High Commissioner for Refugees, Geneva, Switzerland).

Special thanks also go to the WHO COVID-19 IPC Global Expert Panel:
April Baller (Infection Prevention and Control, WHE); Fernanda Lessa (US CDC (WHO secondment)); Madison Moon (Infection Prevention and Control, WHE); Alice Simniceanu (Infection Prevention and Control, WHE); Benedetta Allegranzi (Infection Prevention and Control Hub and Task Force, Integrated Health Services, WHO).
