TABLE OF CONTENTS

TAB	DESCRIPTION	PAGES
	Affidavits of the Appellants	
1.	Affidavit of Pastor Jacob Reaume, Trinity Bible Chapel, sworn June 4, 2021	10
A.	Exhibit "**A**" — Letter from Trinity Bible Chapel to Authorities dated April 23, 2020	31
B.	Exhibit "**B**" — Letter from Reopening Ontario Churches to Premier dated May 11, 2020	37
C.	Exhibit "**C**" — News release from Waterloo Regional Police dated June 2, 2020	46
D.	Exhibit "**D**" — CTV article regarding BLM march dated June 3, 2020	49
E.	Exhibit "**E**" — Trinity Bible Chapel Risk Mitigation Strategy	56
F.	Exhibit "**F**" — Letter from Trinity Bible Chapel to MPP Harris dated September 18, 2020	59
G.	Exhibit "**G**" — Open Letter dated December 3, 2020	62
H.	Exhibit "**H**" — Ontario news release dated December 21, 2020	68
I.	Exhibit "**I**" — Letter from Trinity Bible Chapel to Chief Larkin dated December 23, 2020	73
J.	Exhibit "**J**" — Letter from Region of Waterloo to Trinity Bible Chapel dated February 16, 2021	76
K.	Exhibit "**K**" — Public Health Ontario Epidemiologic Summary for February 16, 2020 to December 26, 2020 dated January 11, 2021	79
L.	Exhibit "**L**" — Ontario news release dated February 12, 2021	110
M.	Exhibit "**M**" — Ontario news release dated March 12, 2021	114
N.	Exhibit "**N**" — CTV News article dated December 31, 2021	117
O.	Exhibit "**O**" — 680News article dated January 5, 2021	124
P.	Exhibit "**P**" — CTV News article dated January 18, 2021	129
Q.	Exhibit "**Q**" — Photo of Farmers' Market	132
R.	Exhibit "**R**" — CTV News article dated May 8, 2021	134
S.	Exhibit "**S**" — Series of photos from Farmers' Market	138

T.	Exhibit "**T**" — Photo of Conservation Area	145
U.	Exhibit "**U**" — Kitchener Today article dated June 4, 2021	147
V.	Exhibit "**V**" — Open Letter from Trinity Bible Chapel dated January 22, 2021	153
W.	Exhibit "**W**" — Constitution of Trinity Bible Chapel	157
X.	Exhibit "**X**" — Blog post dated February 25, 2021	166
2.	Affidavit of Craig Williams sworn June 4, 2021	172
3.	Affidavit of Pastor Henry Hildebrandt sworn June 4, 2021	177
A.	Exhibit "**A**" — Public Statement of Aylmer Police Chief Horvat dated April 24, 2020	190
B.	Exhibit "**B**" — Church of God website printout dated May 8, 2020	192
C.	Exhibit "**C**" — Justice Centre for Constitutional Freedoms news release dated May 19, 2020	199
D.	Exhibit "**D**" — Letter from Justice Centre for Constitutional Freedoms to Premier dated September 28, 2020	202
E.	Exhibit "**E**" — Ontario news release dated December 21, 2020	206
F.	Exhibit "**F**" — Photos of posters taken by Herbert Hildebrandt	211
G.	Exhibit "**G**" — CBC News article dated April 23, 2021	214
H.	Exhibit "**H**" — Tweet by Prime Minister Trudeau dated May 16, 2021	219
I.	Exhibit "**I**" — London Free Press article dated March 15, 2021	221
4.	Affidavit of K. Bergen sworn June 4, 2021	229
Affidavits of Experts for the Appellants		
5.	Affidavit of Dr. T. Warren sworn May 25, 2021	233
A.	Exhibit "**A**" — CV of Dr. Thomas Warren	263
6.	Book of Sources referred to in Affidavit of Dr. T. Warren	272
7.	Affidavit of Dr. R. Schabas sworn May 29, 2021	3023
A.	Exhibit "**A**" — CV of Dr. Richard Schabas dated May 7, 2021	3037

COURT FILE NO: CV-21-95-0000

ONTARIO SUPERIOR COURT OF JUSTICE

BETWEEN

THE ATTORNEY GENERAL OF ONTARIO

Applicant (Responding Party)

-and-

TRINITY BIBLE CHAPEL, JACOB REAUME, WILL SCHUURMAN, DEAN WANDERS, RANDY FREY, HARVEY FREY, AND DANIEL GORDON

Respondents (Moving Parties)

AFFIDAVIT OF REV. JACOB REAUME
(Constitutional Challenge)
(Sworn June 4, 2021)

I, JACOB REAUME, of the [redacted] in the Province of Ontario, MAKE OATH AND SAY:

1. I am one of the Respondents (Moving Parties) herein, and as such have personal knowledge of the matters hereinafter deposed to, except where they are based on information and belief, in which case I verily believe them to be true.

2. I am the senior pastor of the Respondent, Trinity Bible Chapel ("**TBC**") and have been pastoring there since 2009. I achieved a baccalaureate degree in Religious Education in 2003 and have a Master of Divinity from the Southern Baptist Theological Seminary in Louisville, Kentucky. I was ordained as a Minister on November 20, 2005, and served in churches across Ontario and the United States before becoming a lead Pastor at TBC. In 2020, I helped found and became Chancellor of King Alfred Academy, a private Christian school which operates out of the TBC campus. I was

born and raised in Guelph, have been happily married for 20 years, and I have 5 children with another on the way.

3. The other personal Respondents are elders and associate pastors of TBC and form the leadership team of the church.

4. Trinity Bible Chapel has been in existence for 20 years. Prior to the first lockdown in March of 2020, we often had between 600-700 people in attendance for services each week, usually including between 100-150 university students. Our facility can safely house over 900 people based on fire code regulations, including the sanctuary and a large gymnasium.

Initial Response to Covid-19 and Government Restrictions

5. In the early months of the first lockdown, commencing in March 2020, the TBC facility was shut down for in-person services, provided online productions, and our staff members called each regularly attending household to provide pastoral guidance. At that time, we were banned from any gathering of more than five people and drive-in services were not permitted. In the very earliest stages of the declared public health emergency, we did not know what we were dealing with and were prepared to give the government the benefit of the doubt for a short period of time.

6. On April 23, 2020, we submitted an open letter to governing officials requesting that they work with us to reopen. In it we included our proposed course of action to mitigate the spread of Covid-19. We received no substantive reply. Attached hereto and marked as **Exhibit "A"** to this my Affidavit is a copy of the said letter and risk management addendum.

7. After the first lockdown had continued for some weeks, we became involved with a group of pastors who started a website called Reopen Ontario Churches. The group wrote a letter to our authorities in May of 2020, providing recommendations and seeking a safe re-opening of our churches. Our pleas and lobbying were ignored. Attached hereto and marked as **Exhibit "B"** to this my Affidavit is a copy of the letter.

8. We, and other church leaders in our group, expressed eagerness to get back to public gatherings in some capacity, as we were by that point several months into the first lockdown and were growing increasingly concerned about the well-being of our parishioners and the broader community.

9. After drive-in services were permitted, our church conducted one service in this fashion on June 7, 2020. However, drive-in services are a poor substitute for in-person gatherings, as people are not able to partake of the Lord's Supper or participate in other important practices and ceremonies, such as baptism, and cannot meaningfully interact with one another.

10. On June 2, 2020, while severe gathering restrictions were still in effect, including the prohibition on groups of more than five (5) congregating outdoors, the Waterloo Chief of Police, Bryan Larkin, issued a news release concerning planned Black Lives Matter protests in the region. Attached hereto and marked as **Exhibit "C"** to this my Affidavit is a true copy of the press release, downloaded from the Waterloo Regional Police Service website. The police chief expressed full support for the protest and advised that its officers would be in attendance to provide protection and to stand in solidarity with those in attendance. Local media reported that the crowd "may have been between 12,000 and 20,000 strong". Attached hereto and marked as **Exhibit "D"** to this my Affidavit is a copy of a CTV Kitchener article covering the event.

11. In the News Release, Chief Larkin wrote, "We realize that this event is being held during a health crisis. But, we also realize that you are hurting. You are grieving. And you are justifiably angry. We realize that this is a time for us all to come together in an attempt to heal, to show support, and to pave the way for a better future for all."

12. To the best of my knowledge and information, no charges were laid despite the fact thousands of people breached the gatherings restrictions in force at that time. My perspective on the arbitrariness of the gathering restrictions, and the hypocrisy of their selective enforcement, was impacted by these actions.

13. Shortly thereafter, the Ontario Government announced that houses of worship would be permitted to open to 30% capacity, effective June 12, 2020.

14. Following that announcement, our church switched back to in-person services, which was a great and profound relief. We initially maintained 30% building capacity limits, set up a massive overflow section in our gymnasium to space people out further, provided access to hand sanitizers and face masks, and developed a comprehensive policy to mitigate the spread of COVID-19. For example, when serving the Lord's Supper all elders wore masks. We implemented public health protocols, in accordance with the document dated June 25, 2020, attached hereto as **Exhibit "E"** to this Affidavit.

15. It was a wonderful blessing to our community to meet in person over the summer months. However, as the fall approached the Government began making public comments about potential further restrictions. In early autumn, we wrote a letter to our local MPP asking for churches to remain open and continue to operate safely. Attached hereto and marked as **Exhibit "F"** to this my Affidavit is a true copy of the said letter, dated September 18, 2020, to which we did not receive a response.

16. On or about November 3, 2020, the Ontario Government abandoned its Stage 1, 2 and 3 approach, and introduced a colour-coded system and some apparently objective benchmarks for imposing further restrictions. For each of the stages, including "red", houses of worship were to remain at 30% capacity.

17. It was not long before the Government changed gears again, and introduced a more restrictive "grey zone", modelled on the earlier Stage 1 restrictions. Toronto and Peel were the first areas to go back into the grey zone, which permitted houses of worship to only have ten (10) persons in attendance, regardless of building capacity.

Church Response to Threats of Second Lockdown

18. On December 3, 2020, fearing that the restrictions would spread to other parts of the province, I wrote an open letter advising that TBC would practice peaceful civil disobedience in the event of a second lockdown. At that time, Waterloo Region was

still open at 30% capacity for churches. Attached hereto and marked as **Exhibit "G"** to this my Affidavit is a true copy of this letter. I posted it publicly on our website and forwarded it to multiple provincial and federal representatives, as well as the mayor and other officials at the Region of Waterloo, who provided no substantive replies.

19. Indeed, the Premier announced on December 21, 2020, that the entire province, regardless of case counts or the presence or absence of any crisis regionally, would begin a four-week lockdown on Boxing Day. Attached hereto and marked as **Exhibit "H"** to this my Affidavit is a copy of the province's news release.

20. The effect of these restrictions was a gross and substantial interference in the practice of our faith, individually and collectively.

21. We made the decision as a leadership team to continue to exercise our fundamental freedoms guaranteed under the *Charter of Rights and Freedoms* and to assemble in person for worship services with the risk mitigation protocols in place. We continued to make online services available for those who chose, for health or other reasons, not to attend in person. At that point, nine months into Covid-19, the lockdown harms I was observing and counselling my parishioners about were mounting. I wanted to provide hope and comfort to our congregation and our community through the continuation of our religious practices in association with other members of our faith community.

22. On December 23 I sent a letter to the Chief of Police and copied the mayor of Woolwich Township, inviting him to support our constitutional rights, just as he had supported the Black Lives Matter marches in June, which were also held during gathering restrictions. Attached hereto and marked as **Exhibit "I"** to this my Affidavit is a true copy of the letter. The Mayor replied with a brief email saying they would like compliance and that the police would be in touch with me.

23. On December 24, I received a visit from two police officers at the church. They advised that a second lockdown would be going into effect on December 26 across the entire province. I informed the officers that I could not, in keeping with my conscience and religious convictions, agree to a further shutdown of our church and that, while I had

not had occasion to bury anyone dying of Covid-19, our church community was impacted by other lockdown harms which I believe were imposing far more damage to the vast majority of the population than Covid-19, including suicides.

24. On or about December 26, 2020, Ontario placed the entire province under a "shutdown", which severely restricted many of the activities of Ontarians, including their attendance at places of worship which were limited to a hard cap of 10 persons indoors, regardless of capacity.

25. On December 27, 2020, and January 3, 2021, our church opened at approximately 30% capacity, as usual, and we were blessed to be in fellowship with one another and participate in corporate worship and prayer.

26. Although we initially adhered quite closely to public health protocols, as the Region of Waterloo's treatment of our church became more punitive, their approach had the opposite effect. In accordance with provincial and local public health guidance, we do not enquire into the reasons for an attendee's decision not to wear a mask. We assume that they, as adults, are capable of making their own health decisions. We did ask that anyone who is feeling unwell stay away from in-person services.

27. I believe that Trinity Bible Chapel is being observed very closely, however public health has never contacted us about an outbreak. In fact, in response to a Freedom of Information request to the Regional Municipality of Waterloo for any references in their documents to "Jacob Reaume", "Randy Frey", "Trinity Bible Chapel", or "King Alfred Academy", we received a letter indicating that they had approximately 6000 emails and 144 documents on file for the period between March 1, 2020, and January 14, 2021. Attached hereto and marked as **Exhibit "J"** to this affidavit is a true copy of the letter from the Regional Municipality of Waterloo, dated February 16, 2021.

28. Furthermore, the government's own published data shows that places of worship in general are not responsible for community spread of Covid-19, even though many have been open during the reporting period to at least some degree (30%, more or less). Attached hereto and marked as **Exhibit "K"** to this affidavit is a copy of a document

published by Public Health Ontario, entitled "*COVID-19 Outbreaks and Cases in Ontario, by Setting: February 16, 2020 to December 26, 2020*." The government has had this information since at least January 11, 2021, according to the report date.

29. The document includes various tables, which note the following data for the entire Province of Ontario:

> Table 1: Fewer than 1% (0.55%) of all outbreaks (23 / 4151) are due to places of worship.
>
> Table 2: Fewer than 1% (0.56%) of all outbreak cases (221 / 39774) are due to places of worship.
>
> Table 3: Places of worship account for 0.1% (5 / 3460) of all outbreak associated hospitalizations.
>
> Table 3: Places of worship account for 0% (0 / 3681) of all outbreaks associated deaths.

30. My observation and belief is that these times of isolation, due to the government's restrictive actions, have harmed people and society by perpetuating loneliness, hopelessness, fear, poverty, division, anger, the deterioration of relationships, and a plethora of other evils which will become more evident with time. These observations do not surprise me because the restrictive actions of the government have wrongfully reduced human beings to biological units with little purpose to existence other than to avoid contracting and spreading a virus.

31. Scripture teaches us that people are much more than biological units. We are created in the image of God with dignity and worth to live free, love one another, worship together, grow families, eat with each other, laugh and cry together, embrace one another, exchange goods and services, and build things. Central to the Christian life is the ministry of the church, and TBC asserts that the church must remain open.

The Government's Response – Charges and Contempt

32. On December 30, 2020, I, along with five other church leaders, Will Schuurman, Dean Wanders, Randy Frey, Harvey Frey and Daniel Gordon, were issued summonses to attend court on the charge of "being an owner/occupier of the said premises did host

or organize at prescribed premises being a place of worship and the number of people in attendance exceeded the number permitted contrary to s. 10.1 of the *Reopening Ontario Act* Ontario Regulation 82/20 Schedule 4 s. 1(d)" ("the *Act*").

33. On January 6, 2021, Pastor Will Schuurman and I were issued two summonses each for a service held on January 3, 2021, on charges of "attended gathering of more than 10 people for the purposes of a religious service, rite or ceremony contrary to the *Act*," and "host a gathering at a prescribed premises where the number of people in attendance exceeded the number permitted under a continued s. 7.0.2. contrary to the *Act*, section 10.1(1)."

34. Four other church elders, Dean Wanders, Randy Frey, Harvey Frey and Daniel Gordon, as well as Trinity Bible Chapel, also received summonses to attend court on the charge of "Host a gathering at a prescribed premises where the number of people in attendance exceeded the number permitted under a continued s. 7.0.2. contrary to the *Act*, section 10.1(1)." These charges also related to the service on January 3, 2021.

35. On January 7, 2021, we received a letter from counsel to the Attorney General of Ontario (the "**AG**"), threatening to bring a Section 9 Application under the *Act* to restrain TBC and anyone acting on its behalf from contravening Regulation 82/20 unless we provided an undertaking that there would be no further gatherings in excess of ten people at TBC.

36. Despite serious reservations and acting against our consciences, we undertook not to have any further gatherings at TBC in excess of ten people until January 23, 2021, which was the end of the scheduled second lockdown date. We abided by that undertaking.

37. Unfortunately, the goalposts moved again. On January 14, 2021, Premier Doug Ford issued a "stay-at-home order", following a declaration of a "state of emergency", extending the second lockdown to at least February 11, 2021.

38. On January 15, 2021, we received a second letter from the AG, once again threatening to bring enforcement proceedings unless we provided a second undertaking that there

would be no further gathering in excess of ten people at TBC until at least February 11, 2021.

39. After much deliberation among our church elders, we decided that we were no longer able to provide undertakings not to have in-person services because to do so deeply violates our sincerely held Christian beliefs and would sear our consciences. Furthermore, as indicated above, the gross interference with our essential communal religious practices was harmful to our parishioners on many levels. On January 21, 2021, we informed counsel to the AG through our lawyer that we would not be signing any further undertakings.

40. A motion was brought by the AG with a return date of the following day, January 22, 2021, at which time the Order of the Honourable Mr. Justice P.R. Sweeny was made, restraining TBC and those associated with it from violating Ontario Reg. 82/20 by holding gatherings of more than 10 persons in conjunction with the operations of the church.

41. We subsequently held two in-person services on January 24, 2021. Although some in the media have been critical of our decision, I have received many dozens of heart-felt emails and letters from people who either attended, or wished they could have attended, or who aren't even Christian but expressed a renewed bond with the church. We did what we set out to do – we shared hope and love with an oppressed and psychologically-ravaged community.

42. Following those services, Pastor Schuurman and I each received two more summonses to court, and the other elders and TBC each received one.

43. The AG brought an immediate motion for contempt, which was heard on January 27, 2021. We were found in contempt by Justice Sweeny of his order. Pending sentencing, scheduled for February 11, and feeling pressured by the weight of the state against us, we expressed a willingness through our lawyer to refrain from opening our facility for in-person services temporarily, and did in fact hold drive-in services only on January 31 and February 7, 2021.

44. On February 11 we attended a sentencing hearing via Zoom on the contempt matter, and later learned when we received the court's endorsement that we were to be fined $83,000, inclusive of costs. This has now been paid.

45. Immediately thereafter, the province returned to the colour-coded framework, and Waterloo Region was placed into the "Red Zone", which meant religious gatherings were limited to 30% of room capacity. Attached hereto and marked as **Exhibit "L"** is a copy of Ontario's news release to this effect, dated February 12, 2021.

46. While the Waterloo Region was in the Red Zone, we continued to hold services and enjoyed a brief reprieve from heavy-handed enforcement to conduct our religious worship in relative peace. We did not turn anyone away who wished to worship with us.

47. Effective on or about March 15, 2021, Ontario amended Regulation 89/20 to remove the 10-person cap and replace it with a 15% capacity limit for regions in the "Grey Zone" or "Shutdown Zone". Attached hereto and marked as **Exhibit "M"** is a copy of Ontario's news release, dated March 12, 2021.

48. On or about April 3, 2021, Waterloo Region was moved into the "Grey Zone" and church services were then required to be limited to 15% of building capacity. On or about April 7, 2021, Ontario declared a third state of emergency across the entire province.

49. On Thursday, April 8, one of Waterloo Region's by-law officers visited our church to hand deliver two new summonses to appear in court. One summons was for Trinity Bible Chapel, and the other summons was for me. This pertained to the offence of worshipping the risen Christ together on Resurrection Sunday (Easter), on April 4.

50. On April 11, 2021, we noticed Region of Waterloo by-law officers observing our parishioners through binoculars from across the street. We felt uncomfortable and violated by this invasion of our privacy and by our women and children being peered at by officers as we gathered for worship.

51. On April 14, 2021, we were served through our lawyer with a second Motion for Contempt by the AG, for the services held on April 4 and 11.

52. On April 15, 2021, Waterloo Region by-law officers visited our church to hand deliver two new summonses to appear in court. One summons was for Trinity Bible Chapel, and the other summons was for me. This was the church's fourth summons. Each summons to the church carries a maximum penalty of $10 million. This was my seventh summons. Each summons to me carries a maximum penalty of $100,000 and one year in jail.

53. On April 15 and 16, 2021, our staff packed up our church offices because we faced a hearing on April 16 to have us locked out of our facility. The anticipation and the result of this action created stress to our staff and hindered our ability to provide pastoral care to our congregation.

54. The AG's motion was set for April 16, 2021, at which time the contempt hearing was adjourned and the AG's interim injunction request to lock the doors was denied, since there was a lack of clarity over whether the original order (limiting us to 10 persons) was still in effect.

55. After Justice P.R. Sweeny's oral ruling on April 16, while we were still in Zoom court, the AG brought a motion without notice for a new enforcement order. Justice Sweeny made a further Order pursuant to s. 9 of the *ROA*, mandating, in essence, that TBC and those connected with the church be restrained from contravening the maximum size of gathering as permitted from time to time under various regulations for the purpose of a religious service, rite or ceremony.

56. Subsequently, the entire province was placed again under a "shutdown" order, and as of April 19, 2021, and continuing to date, places of worship are again restricted to a maximum of ten persons inside the building, regardless of capacity limits.

57. Our congregation continued meeting but were impeded by the presence of police and/or by-law enforcers near our property. On April 25, several members of our congregation were charged for attending church. We have been under constant threat

of more summonses, more fines for contempt, potential jail time, and being locked out of our church indefinitely. The stress on our leaders, parishioners and volunteers, as law-abiding citizens, cannot be overstated.

58. On April 30, 2021, a new contempt motion was brought to court, based on the order of April 16. An interim injunction was granted to lock the church doors, even though we did not have an opportunity to file responding materials or cross-examine the AG's witnesses.

59. The following day, on May 1, the church doors were locked by the Sheriff. I went to the parking lot that afternoon, with a small informal group of people (about 30), and we prayed and sang outdoors. I received two new charges for organizing and hosting an illegal gathering. A number of our parishioners were also charged. There were so many cruisers and unmarked vehicles observing I could not easily count them all.

60. On May 6, 2021, that injunction was continued by Justice Krawchenko, pending a return to at least 30% capacity for religious gatherings. Further sentencing for contempt has been scheduled for July, 2021.

61. We now have more than 30 charges before the courts, and we are facing maximum penalties of over $40 million with jail time, plus a further contempt penalty. We were continually monitored by bylaw officials and/or police, who attended many Sundays and parked near our church to count heads and intimidate worshipers. Police have driven by my home (at the end of a dead-end street), which is something I have not previously observed. I believe that this is to intimidate my family and me.

62. To say that our Charter-guaranteed freedoms to worship, assemble, associate, and express ourselves have been infringed is an understatement.

63. Additionally, we have been targeted relentlessly in the media, faced threats from members of the public, and even our lender has frozen our line of credit and has reminded us that they can call our loan anytime. When we took out our loan, we agreed to abide by the law of the land as part of our lending agreement. We are a church, and

we are a church in what claims to be a free country. We did not foresee the day when the consequences of inviting the community to church in Canada would be illegal.

64. The inconsistencies and hypocrisy of our leaders and health officials over the last months only reinforced our perspective. While the church could not meet, leaders such as Finance Minister Rod Phillips and Health Table advisor and hospital executive, Dr. Tom Stewart, to name just two, travelled to sunnier climates by air for vacation time. Attached hereto and marked as **Exhibits "N"** and **"O"** are two news articles containing those stories.

65. While the church could not meet, big-box stores like the Walmart located within 2.3 km of our church, have remained open throughout, with hundreds of people able to congregate there. LCBO stores, and others the government has deemed "essential" remain open.

66. While the church could not meet, a movie was filmed in Kitchener. Attached hereto and marked as **Exhibit "P"** to this Affidavit is a CTV article detailing this story.

67. While we were being charged for meeting with 30 people outdoors in our parking lot and praying, only a week later on May 8, the nearby Farmer's Market parking lot was packed. Attached hereto and marked as **Exhibit "Q"** to this Affidavit is a photograph taken by Al Vandergaag, one of TBC's members, and emailed to me.

68. Also on May 8, a nearby rally against "White Lives Matter" attracted 50 people. No charges were reportedly laid. Attached hereto and marked as **Exhibit "R"** to this Affidavit is a copy of the CTV news article detailing that event.

69. On May 9, I spoke at a rally organized by MPP Randy Hillier in Waterloo. A bylaw officer attended at my home to deliver a summons, charging me for that attendance. Police accompanied the officer. My wife was home and answered the door. She advises me, and I verily believe, that she asked the officer why police were accompanying bylaw, and the officer replied, "You might have a handgun."

70. On May 15, 2021, while the church was not permitted to gather outdoors in numbers greater than 10, the nearby Farmer's Market (1.2 km away) was again packed. Attached hereto and marked as **Exhibit "S"** to this Affidavit is a series of 6 photographs taken that day by a member of TBC's congregation and emailed to me.

71. On May 24, 2021, while the church was not permitted to gather outdoors, many people enjoyed nearby Shade's Mills Conservation Authority. Attached hereto and marked as **Exhibit "T"** to this Affidavit is a photo of the park that day, sent to me by an attendee of my congregation.

72. On June 3, 2021, a vigil was scheduled for Waterloo Park to commemorate the lives of children lost to the Residential School in Kelowna BC. According to the article in Kitchener Today, attached hereto and marked as **Exhibit "U"**, police advised that they would not be monitoring the event.

Offering Hope to the Community

73. We (being myself and the leadership at TBC) believe that a person's overall well-being must take into account much more than merely their physical health. Mental and spiritual health are critical as well. The seemingly endless lockdowns and stay-at-home orders, never before imposed on the entire population, are exclusively concerned with a single virus. This seems outrageous and unjustifiable to us.

74. People in Trinity Bible Chapel's congregation make their own informed decisions where they are comfortable going, whether it be the grocery store or to worship services. These are personal choices that TBC leaves to each individual's consideration and conscience.

75. Online video productions cannot replace the peaceful assembly and association of our members. For a week or two during a crisis it might be reasonable, but for a protracted period of time it is untenable. Church is not a show or spectacle on our screens – it is a participatory experience. It involves communal prayer, song, and fundamental rituals such as communion and baptism. Physical gathering is essential to us, to our well-being, to our faith, and to civil society.

76. In my open letter to the community, dated January 22, 2021, attached hereto and marked as **Exhibit "V"**, I noted: "People are lonely, afraid, despairing of life itself, and facing financial ruin, among many other deprivations and tribulations. This is all during the darkest and coldest season of the year. If ever our fellow Ontarians needed hope, it is now. Out of neighbourly love, I am personally openly inviting anyone and everyone to experience the hope of the Gospel and the warmth of Christian worship at Trinity Bible Chapel this Sunday during our two Lord's Day services at 9:00 AM and 11:15 AM."

77. I noted that this was done in love for God and neighbour and stated: "Risking reputation and financial viability to offer eternal hope and warm Christian fellowship to a world in despair is an act of love that I am certain Jesus smiles on."

78. Therefore, up until May 1 and the locks being put on our church, we continued to open our doors to members of the public and regular congregants at TBC, allowing them to attend or not at their own discretion. Many returned to gather and worship. We have observed these past many months that those attending TBC were healthy people and were very happy when they attended.

79. Personally, I have never experienced a more palpable manifest presence of God's Holy Spirit during public worship than I did on that Sunday, January 24 (for which we were first found in contempt). On Sunday, February 21, we baptized 13 individuals, some of whom traced their conversion to those weeks in January, especially January 24.

Freedom of Religion, Conscience and Expression, and the Scriptural Foundation

80. We are bound by our faith to gather for corporate worship, and to engage in communal prayer, preaching, singing, and partaking of the Lord's Supper and other important rites. The government's restrictions have prohibited, limited, and punished us for worshiping as our faith and consciences require.

81. Since its creation, TBC has served our Lord and community by preaching the Good News of the Gospel of Jesus Christ. We do this primarily through our in-person worship

services. In addition to those services, we provide many other supports and services to the benefit of not only our congregation, but the community as a whole. These include, but are not limited to sponsoring foreign missionaries, contributing to local pregnancy centres through, for example, baby bottle drives (fundraising for struggling new mothers), assisting those in need, offering hope to those in despair, comforting the bereaved, providing pastoral care for families and singles, counselling broken marriages toward restoration, visiting the sick and lonely, sponsoring refugees and helping immigrants integrate into our community. In other words, we have been doing some of what the church does best and what the community needs most.

82. When we opened TBC, we chose the word “chapel” to identify with the Dissenting churches of seventeenth century England. During that century, the state church required all congregations to conform to a set form of liturgy and teaching. Bound by conscience as conscience was bound by Scripture, thousands dissented from that imposition. They were Dissenters or Nonconformists. Being forced to separate from the state church many were jailed and persecuted. Their spiritual descendants were economically disadvantaged for generations. Being excluded from the official state church, they formed chapels.

83. In our day, we desire to uphold their convictional example. We ourselves being bound by conscience as conscience is bound by Scripture dissent from the popular non-Scriptural beliefs of our own day. By God’s grace, we will not conform to any standard that opposes Scripture, whether that standard comes from government, another religious body, or a combination of both. In that respect, we are Nonconformists. We are Dissenters. To communicate that commitment, we have chosen to call ourselves a “chapel.”

84. I sincerely believe that Scripture commands us to meet for worship in person, that the definition of “church” requires us to gather in person, and that the Law of God demands we gather at least weekly. This has been articulated in our church doctrinal statement and each of our members has taken a solemn oath and covenant before God to meet regularly for worship, prayer, and to partake together of the Lord’s Supper. This is

found at page 6 of TBC's Constitution, which is attached hereto and marked as **Exhibit "W"** to this my affidavit:

> We will not forsake the assembling of ourselves together, nor neglect to pray for ourselves and others. We will regularly participate together in the ordinance of the Lord's Supper.

85. Being bound by Scripture to be with each other, members of Trinity Bible Chapel therefore have solemnly covenanted before God to worship together and be with each other regularly. To not be together is to violate God's commands and our own solemn oath and covenant. Scripture, which is God's Word to us, commands Christians to gather in person for church (Hebrews 10:24-25). Regularly meeting in person was the pattern established by Christ's apostles: "And they devoted themselves to the apostles' teaching and the fellowship, to the breaking of bread and the prayers" (Acts 2:42).

86. According to our doctrinal statement, located on page 3 of our Constitution, "The Scriptures command believers to gather locally in order to devote themselves to worship, prayer, teaching of the Word, fellowship, the ordinances of baptism and communion, service to the local body through the development and use of talents and spiritual gifts, and outreach to the world to make disciples. Wherever God's people meet regularly in obedience to this command, there is the local expression of the Church under the watchful care of a plurality of elders."

87. Christian meetings include fellowship, which entails togetherness, sharing of goods and food, showing hospitality and presence of person, much like a family unit (Acts 4:32-37). The New Testament upholds the church as a spiritual family, so much that the bonds within the church are stronger than blood relations (Matthew 10:37;13:53-58; Luke 14:26). For this reason, Christians often refer to each other as "brother" and "sister." To operate as a church, Christians are expected to experience fellowship regularly with one another like a family that lives under the same roof.

88. Embedded in the definition of church is gathering together. The New Testament word for church is the Greek word, *ekklesia*. Etymologically, *ekklesia* is the combination of two words that together mean "called out," as in a group of people called out to gather.

The definition of the word demands that a church not be reduced to less than a physical, in-person gathering of people. The lexical range of *ekklesia* includes "assembly," "gathering," "a specific Christian group assembly, gathering ordinarily involving worship and discussion of matters of concern to the community," and "the totality of Christians living and meeting in a particular locality." Where there is no physical gathering, there is no church. For the church to exist, it must gather.

89. The pattern since God created the world has been for those who believe in Him to meet officially for worship at least once weekly. The Ten Commandments were written in stone by the finger of God, thus signifying the abiding authority of God's Law. The fourth commandment reads, "Remember the Sabbath day, to keep it holy. Six days you shall labor, and do all your work, but the seventh day is a Sabbath to the LORD your God" (Exodus 20:8-11). The Old Testament Israelite community set aside the seventh day for rest and public congregational worship: to do otherwise was a transgression of the Law. Christ was raised from the dead on the first day of the week, and since then Christian churches have regularly met on the first day, Sunday, for worship, prayer, preaching, and the ordinances (Acts 20:7; 1 Corinthians 16:1-2).

90. To cease meeting together for worship at least weekly is to be a disobedient Christian. Scripture describes the church as a body with many parts. As a human body cannot exist without all its parts fastened together so the church cannot exist without all its people together. Saint Paul wrote, "Now you are the body of Christ and individually members of it" (1 Corinthians 12:27). Each individual is a valuable part of the church, and the church as a whole needs each individual. A church that does not gather is like a body with its parts scattered across a city. A body exists as parts together, and the church exists as Christians together.

91. The church must be together to fulfill its mission because its mission depends on in-person togetherness and physical presence. The Scriptures command the church to partake of the Lord's Supper together (1 Corinthians 11:17-34), to baptize new converts (Matthew 28:19), to anoint the sick with oil (James 5:14), and to ordain elders and pastors with the laying on of hands (1 Timothy 5:22). None of these actions are

possible while separate or isolated. Each must be done in person because the New Testament presupposes that the church will be together.

92. Jesus epitomized Christian togetherness by incarnating as a man in the flesh. “And the Word became flesh and dwelt among us” (John 1:14). Some have expected church services to be held online, but that betrays the Scriptural notion of an unmediated ministry. Had God conceived of something other than the normalcy of an in-person ministry, he might have sent a picture or a hologram or a pixelated representation of Himself on a computer screen. Instead, God incarnated in the person of Christ by being born of a virgin, living and eating among men, performing miracles, being crucified, and rising bodily from the dead. Christians still wait expectantly for the bodily return of Jesus Christ to earth. Because of Christ’s example to us, I believe that we must be physically present with each other.

Extent of Christian Obedience to Governing Authorities

93. While obedience to Federal, Provincial, and Municipal regulations is typically easily given, such as is the case with fire safety codes, municipal drainage requirements, and following federal, provincial and municipal law to the letter, a lockdown order to cease meeting as a church body for fellowship and worship contradicts the commandments of God, and in such a case we are compelled to listen to God instead of the government. We serve our Lord and God above all others. Further, while I respect the power and scope of various legislative and executive bodies in Canada to regulate public matters, the matters of a church are to be governed by the elders of a church (Acts 20:28; 1 Timothy 5:17; Titus 1:7).

94. Scripture commands Christians to be subject to governing authorities. “Let every person be subject to the governing authorities. For there is no authority except from God, and those that exist have been instituted by God” (Romans 13:1). The command, however, is not ultimate. In such cases when government edicts contradict God’s commands, Christians must obey God over government.

95. Confronted with governing authorities that required them to disobey God, Saint Peter and the other apostles once said, “We must obey God rather than men” (Acts 5:29). Faced with a temporary, 30-day prohibition on praying to anyone except the King, Daniel continued to pray to his God (Daniel chapter 6). Charged by Pharaoh with killing the newborn Hebrew boys, the Hebrew midwives “feared God, and did not do as the king of Egypt had commanded them” (Exodus 1: 15-17). Commanded by the king of Babylon to bow to a golden statue, three Jewish men refused, because of their belief in and devotion to God, even though the king threatened them with death (Daniel chapter 3).

96. To be absolutely clear, the Bible teaches us to honour all those in authority, and we do. But we believe that the state’s authority comes from above. “Let every person be subject to the governing authorities. For there is no authority except from God, and those that exist have been instituted by God” (Romans 13:1). God has designed all authorities, courts included, as delegated powers. He has given them power, and that power must be held in high regard by all men.

97. As noted in my blog post, dated February 25, 2021, attached hereto and marked as **Exhibit “X”**, Christians throughout history have often found themselves conflicted when earthly rulers order them to do what God forbids or forbids them from doing what God commands. In such instances, we must obey God over government. We believe that the church must meet. We further believe that Christ, not the government, has crown rights over the church and His worship.

98. The laws prohibiting us from worshiping together violate our consciences because our consciences are held captive by Jesus. We acted on our consciences and held an $83,000 act of worship, with potentially many more thousands or millions to be paid for other such acts of worship.

99. I and the church have received hundreds of messages of support from not only those who attended our services, but from across the province and beyond. Many share their personal struggles through these lockdowns, and express gratitude that our stand has provided them hope and encouragement in their faith.

100. I swear this affidavit *bona fide*, in support of our motion, and for no other or improper purpose.

SWORN REMOTELY by videoconference by Jacob Reaume at the [redacted], before me at the City of London, in the County of Middlesex, this 4th day of June, 2021 in accordance with O.Reg. 431/20 Administering Oath or Declaration Remotely

A Commissioner, etc.

RE: Worship Services and COVID-19

Attention:

Prime Minister of Canada - Hon. Justin Trudeau and local MPs
Premier of Ontario - Hon. Doug Ford and local MPPs
Chief Public Health Officer of Canada - Dr. Theresa Tam
Chief Medical Health Officer of Ontario - Dr. David Williams
Local Mayors of Waterloo, Kitchener, Cambridge, Guelph & Woolwich
Region of Waterloo Public Medical Health Officer Dr. Hsiu-Li Wang
Region of Waterloo Health Managers

Dear Governing Authorities:

Please be assured that you have our sincere thanks, support and prayers during this unprecedented time of isolation due to COVID-19. You are indeed well aware of the huge social and financial implications that this crisis has on Canadian individuals and institutions.

As countries around the world are gradually lifting some of the more restrictive measures that have been put in place, we want to express to you how eager we are to work with you so that we, too, can gather in face to face worship services.

Experts agree, a quarantine can help to keep people from getting the virus. It can, however, also be detrimental to a person's physical and mental health. Cabin fever and depression can become the unintended consequences of isolation. Solitary confinement, for example, is now deemed cruel and unusual by the federal government and medical professionals. We desperately need the company of others to sustain our well-being.

We concur with scientists who warn of a potential "echo-pandemic." Social ills could be rising soon, such as: substance abuse, domestic violence, suicide and general despair.

We do not need to belabour these points. You are also keenly aware, that matters of personal faith are cherished and shared in community. Online communication helps but it is not a satisfactory substitute. This past Easter season was particularly difficult, as you can imagine. Furthermore, we have not been able to practice ordinances like baptism and partake in the Lord's Supper/Communion.

Today, all informed people agree with our Lord's words when He quoted a passage (Deuteronomy 8:3) which was about 1,500 years before He lived on earth: "Man shall not live by bread alone …" (Matthew 4:4).

We have observed how other essential services, such as grocery stores, have been operating during this time. They practice social-distancing, which we can also practice, and much more. We have a team of enthusiastic volunteers motivated by a high calling to serve and protect our congregation. Please see the attached addendum that outlines potential COVID-19 protocols for a worship service. We will gladly receive further guidelines and instructions from our local health authorities.

If grocery stores can remain open with certain protocols, worship services can do the same.

We continue to respect your important leadership role. Our operations remain compliant with your instructions, keeping ourselves, fellow citizens and neighbours safe. It is our desire that you can similarly respect our roles as leaders within our faith community, trusting us to practice physical distancing when being together for a worship service.

Please let us know at your earliest convenience if the measures in the addendum are sufficient to conduct our next worship service.

We continue to pray to the Creator, our Heavenly Father, being thankful for your commitment to protect us all and that He will give you wisdom and protect you in the days ahead.

Yours sincerely,

ADDENDUM

Potential Safety Protocol during COVID-19 outbreak

When gatherings are limited to 5 persons

Attendance at Sunday church worship is cancelled – all communication is conducted online. There will be no smaller mid-week meetings until further notice.

When gatherings are limited to 15 persons

Worship services will continue online.

Attendance at mid-week Home Church (Small Groups) can begin with the following stipulations:

No refreshments are served, physical contact is to be avoided (no hugs or handshakes) and hand sanitizer is applied upon entering the home. Each person shall cover their nose and mouth with a scarf, handkerchief or mask. People from different households shall try to sit separately, as much as possible.

The following people will not attend a Home Meeting:

- Anyone who has travelled outside of Canada within 14 days
- Anyone who has a compromised pre-existing health condition
- Anyone who is not feeling completely healthy
- Anyone who has had contact with an unhealthy person within 14 days
- Anyone who does not have a free conscience to attend
- All those 70 years old and above

When gatherings are limited to 250 people

Mid-week Small Group meeting will continue with the same protocols as before.

Attendance at the Sunday worship service can begin with the following stipulations:

Parking lot attendants are to direct a two-metre social-distance line-up as people enter the building.

Upon entering the building each person shall apply hand sanitizer that will be made available.

Each person shall have their nose and mouth covered with a scarf, handkerchief or mask, except those on the main stage when speaking or singing.

All doors to enter and inside the building are to remain open, reducing the touching of surfaces.

There will be no drinks made or brought into the building.

Each washroom will be assigned a person who will wipe with sanitizer anything that is touched by hands three times every 15 minutes before the worship service and three times every 15 minutes after the worship service.

There will be no separate gatherings for children, they will remain under the supervision of their parents.

Ushers will escort all people to their seats – ensuring households will sit together and there will be a separation of at least two seats between each household.

There will be no collection-plate or bag passed through the aisle, rather a box for donations will be placed near the sound-technician's desk.

The total attendance will not exceed 60% of the building's seating capacity.

The following people will not attend the worship service:

- Anyone who has travelled outside of Canada within 14 days
- Anyone who has a compromised pre-existing health condition
- Anyone who is not feeling completely healthy
- Anyone who has had contact with an unhealthy person within 14 days
- Anyone who does not have a free conscience to attend
- All those 70 years old and above

After the service, people will remain seated waiting to be escorted by the ushers in single-file to their vehicles, again maintaining two metre social-distancing.

There is to be no loitering or socializing in the parking lot.

If there is another service scheduled within three hours, the ushers will swipe and sanitize the arm-rest of each seat.

When gatherings are unlimited

Our worship service will be conducted as we have done previously – still being mindful to practice good hygiene.

RE: REOPENING ONTARIO CHURCHES

Dear Premier Ford:

Thank you for your continued service to our communities and province and for the tireless effort you have made on all our behalf during the COVID-19 related crisis. We recognize that your role is not easy, and we commend you for your diligent work. We have prayed for you and are grateful for the news that COVID-19 related deaths remain well below what was feared and that the curve has been flattened in many of our communities.

As you may be aware, the Bible and centuries of tradition oblige Christians to gather weekly for worship and witness around the Word of God and sacraments – we need one another to flourish in our service to Christ (Ex. 20:9-11; 1 Cor. 16:1-2; Heb. 10:24-25; Acts 2:42, 20:7). Neither confessional Christian faith nor the Church institute can faithfully exist without a Lord's Day gathering. This divine obligation and hard-won historic freedom is so important for Christians, that it supersedes all human legislation and regulation. The church is not comparable to a sports or dance club and cannot be dismissed as non-essential by an expert in any field. We would respectfully remind the civil government that the church does not exist by permission of the state, for its establishment and rule is found in Jesus Christ himself. Please remember, the existence and freedom of the church institute long predates the founding of the Christian Dominion of Canada (our Coat of Arms citing Psalm 72:8), so we cannot stress enough how troubling and perplexing these times have been for us. Nonetheless, we are thankful to live in a nation shaped by and indebted to the Christian faith, constitutionally recognizing the supremacy of God in our Charter, and we are grateful for a government that affirms religious freedom. Thank you for continuing to champion religious liberty in Ontario.

Over the past two months, church government has cooperated with civil government by suspending our worship services and mercy ministries, leaving us with the following dilemma: (1) to love our neighbour, as Jesus taught us, by suspending our services to potentially help slow the spread of the virus, or (2) to obey the Word of God which obliges us to meet for worship, sacraments and spiritual ministry to both the healthy and the sick. In weighing this dilemma, whilst seeking to respect civil authority in light of God's ultimate authority, we rightly chose to voluntarily and temporarily cease meeting. We did so to demonstrate love to our fellow citizens during a time of great uncertainty as well as difficulty for civil authorities working with limited information. As Christians, we do not fear death because of the resurrection hope that is ours through Christ, but we deeply desire to show love to all people.

That said, never in 1500 years of Western history has the Church of Jesus Christ not met for Easter or missed months of worship and ministry – even in times of war or plague far more devastating than COVID-19. Never before has the church been denied the opportunity to be with the sick in the hour of their death. Never before has the church ceased to celebrate the sacraments, pray together, offer counsel to the afflicted, visit the prisoner, officiate weddings and funerals, or fellowship together. The inhumanity of abandoning people in their deepest hour of grief or need is gut-wrenching for followers of Christ.

The consequences of the lockdown on people's lives are far-reaching. We know as pastors that addictions are resurfacing and that isolation, unemployment and economic ruin are taking their toll on family relationships and physical and mental health. Our service to the poor and disadvantaged in the community has been curbed, with serious implications for the most vulnerable. To save lives are we actually sacrificing lives? In short, we implore you that we must start meeting very soon because of our obligations to God and because our people need us. We cannot delay.

We are committed, faithful and reasonable citizens and desire to be collaborative rather than be perceived as unreasonable people. Many of our members hold prominent positions in society in law, medicine, politics, education and business. As churches, we have researched, read, listened to and discussed all the relevant issues. As such, we would like the provincial government to support the reopening of churches and ministries by early June, pending any unforeseen circumstances. Given the access people have to other services like grocery stores and the recent announcement to open access to retail stores in malls, to garden centres and to other areas of public gathering, this seems like more than a reasonable course of action.

Here is our reasonable plan:

1. To communicate and enforce health protocols in our churches based on the provincial government guidelines.

2. To initially limit access to our services and ministries to approximately 40% of our building capacities to permit physical distancing, expanding that number as circumstances permit. This will allow for plenty of room between persons well beyond two metres in most facilities and acknowledges that not all church facilities have equal capacity.

3. To provide a clean facility including hand sanitizers and wiping down of common surfaces between services.

4. To continue offering online messages as we are able, so that those who are not comfortable or cannot meet in person due to age or health challenges can at least watch from home.

5. To require attendees to explicitly affirm that they have no symptoms, have not travelled out of the country within the last fourteen days and have not been in contact with anyone with the virus in order to attend.

We would humbly request a response from you by May 29th and are very willing to meet with you or consider any further advice you have to offer us. We would also request that the Premier appoint an additional person to the Ontario Jobs and Recovery Committee who can be an ongoing voice for faith groups. We are anticipating a positive response and continued good relationship with civil authorities as we seek to honour our Creator and Saviour in the nation.

You are greatly appreciated and honoured amongst us.

Pro Rege,

WRPS Supports Solidarity March for Black Lives Matter - "We Stand United With You."

Show More

Posted on June 02, 2020

On June 3, 2020, our community will come together to walk through downtown Kitchener as part of a peaceful Solidarity March for Black Lives Matter.

If you are taking part, please know that you have the full support of your Police Service.

As your Chief of Police, I want you to know that our members will be there to not only ensure your safety and the safety of the public, but to show that we stand united with you.

They will ensure you have the support needed to practice your democratic right and have your voice heard.

Because that voice is needed.

The fight against racism isn't just an American issue. It isn't just a Canadian issue. It's an issue throughout the entire world, including right here in Waterloo Region.

As your Chief of Police, I can assure you that the members of the Waterloo Regional Police Service stand together with you in your anger over the events that have unfolded recently. We are appalled, disheartened, and deeply saddened. Many of our members are grieving alongside the rest of the world and are questioning the actions of the officers in Minneapolis. They are frustrated that their hard work to build bridges and trust within the community has been set back by actions that simply can't be understood nor accepted.

As police officers, we have an obligation to preserve life, to keep people safe, and to keep our community safe. Every day our members do this job and do it very well. But, we are not perfect. We know there is work to do and we are committed to working with you and our community partners to ensure everyone feels safe and included. Our Equity, Inclusion, and Diversity Unit is committed to ensuring all tools, training, and education is provided to our members to ensure we continue to build and maintain your trust.

It's my promise to you, on behalf of our Service, that we will do whatever it takes to be better.

We realize this event is being held during a health crisis. But, we also realize that you are hurting. You are grieving. And you are justifiably angry. We realize that this is a time for us all to come together in an attempt to heal, to show support, and to pave the way for a better future for all.

We want to thank the organizers of this event for taking health precautions, including mandatory face coverings, available hand sanitizer, and requests for physical distancing. The event is also being shared virtually on Facebook as an option for those who do not wish to jeopardize their health or the health of others.

We encourage you all to practice the proper health precautions and to make this peaceful march one that sends a message to our entire community – that we all have a role to play in confronting and ending systemic racism.

On behalf of the Waterloo Regional Police Service, thank you for sharing your voice and for demanding change that will make our community, our country, and our world a stronger, safer and more inclusive place to live.

KITCHENER -- Thousands turned out for a peaceful solidarity march in downtown Kitchener on Wednesday evening to protest anti-Black racism and police brutality.

The KW Solidarity March for Black Lives Matter was organized following a number of recent high-profile, police-involved deaths of black people in both Canada and the United States.

The event began around 5 p.m., but hundreds of people had arrived more than an hour before.

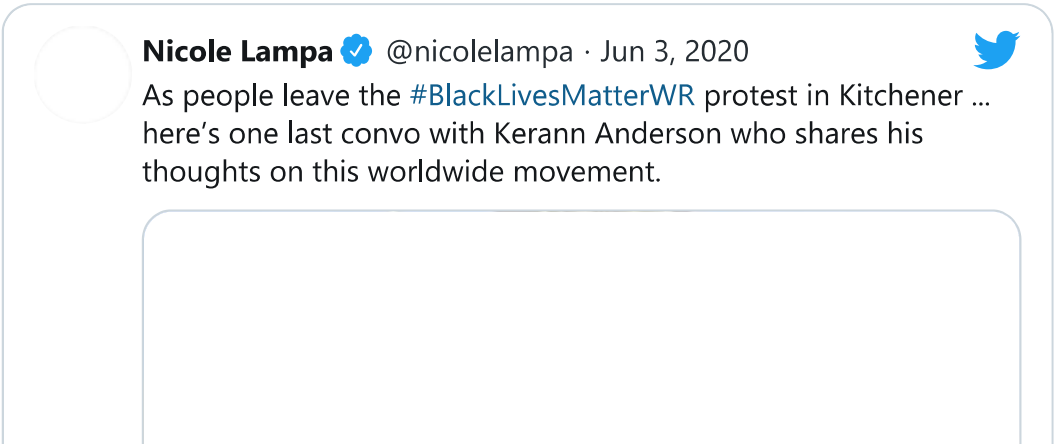
Several Black and Indigenous speakers addressed the crowd before the march set out from Gaukel and Joseph Streets, including MPP Laura Mae Lindo, who was wearing a mask and sunglasses.

"Behind the shades are tears, because I am looking down this street and I know that there is hope for my five-year-old son," she told the crowd, holding back tears.

Fellow protester Kerann Hutchinson echoed the sentiment, saying he was taking the risk during the pandemic so his kids can have a better life.

"It means a lot to me but it means more for my kids. I'm here mainly, I don't want my kids to grow up in the same environment, in the same fear that we have to grow up in," he said.

"I hope that people take the message and make a change. Make a change for all of us."



Lindo acknowledged the danger of thousands of people turning out during the pandemic, saying she felt that she didn't have a choice.

"I need you to recognize that anti-Black racism is a public health crisis," she told the crowd.

She also criticized Premier Doug Ford for suggesting that Canada did not have the same "systemic, deep roots" of racism as the U.S. Less than 24 hours later, he backpedaled those comments.

"Of course there's systemic racism in Ontario, there's systemic racism across the country," Ford said during a sitting at Queen's Park on Wednesday.

His answer came after he was asked by Opposition Leader Andrea Horwath about her call for the immediate collection of race-based data as it relates to COVID-19.

The speakers were joined by thousands of people in the march, which travelled down Charles Street to Frances Street before turning right down King and eventually looping back around to the terminal.

Organizers told CTV before the march began that they had received online threats, but by the end of the scheduled event at 7 p.m., the demonstration had remained peaceful.

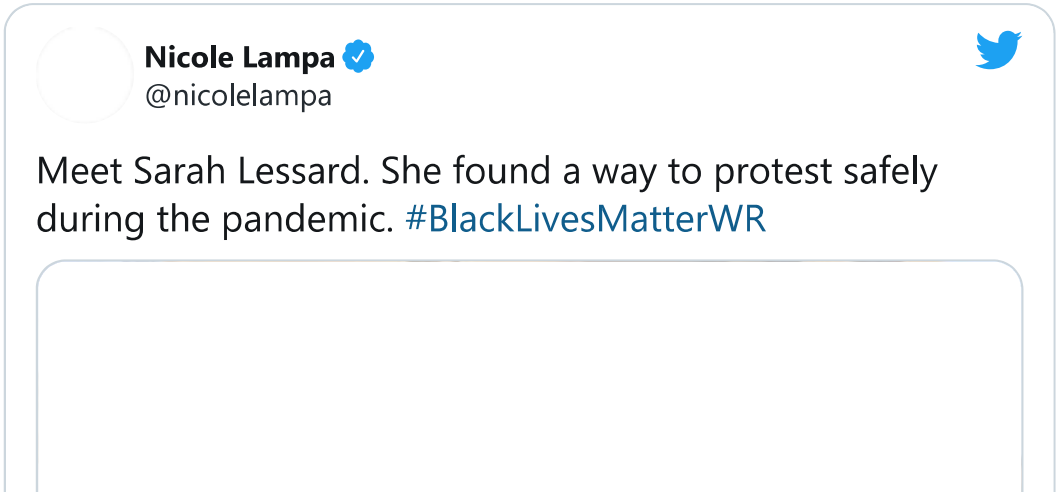
Police were on hand to help the flow of traffic and to keep people safe, but organizers stress that they were not there to walk with them.

"We asked police not, explicitly not to march with us, but let them know that this is an issue that could endanger other people," one organizer told CTV.

Most people who participated were wearing masks and other personal protective equipment, but with such a large crowd, six feet of space for physical distancing was hard to find.

Some people parked their cars along the march route, holding signs out their windows and honking.

"I just knew I had to be here and support in some way, but I wanted to be as safe as possible so I thought, 'get in there and figure it out,'" said Sarah Lessard.



6:36 PM · Jun 3, 2020

8 See the latest COVID-19 information on Twitter

Despite the crowd, as Regional Chair Karen Redman suggested on Tuesday, police officers were there to offer support, not issue tickets.

On Thursday morning, police confirmed that the protest was a peaceful one and that no charges were laid. They said they were not able to offer a crowd estimate, but others suggested that the crowd may have been between 12,000 and 20,000 strong.

The march ended with all attendees sitting on Charles Street next to the former bus terminal with fists raised. Shortly after, the crowd began dispersing.

Trinity Bible Chapel
Risk Mitigation Strategy for Sunday Services

1. Sign-ups will be needed for people to indicate which of the two services they would like to attend: 8:30am or 10:30am. If those services go over 160 people, then we will add a third service. Part of the Sign-up process will be to answer questions on a waiver. The waiver questions will be answered with yes or no to the following:
    a. I confirm that I will not attend the service if I have a fever of over 38C
    b. I confirm that I will not attend the service if I have a new cough or a worsening chronic cough.
    c. I confirm that I will not attend the service if I have a sore throat.
    d. I confirm that I will not attend the service if I have new or worsening shortness of breath.
    e. I confirm that I will not attend the service if I have any flu like symptoms including a runny nose.
    f. I confirm that I will not attend the service if I have nausea or vomiting.
    g. I confirm that I will not attend the service if I have recently tested positive for the novel coronavirus.
    h. I confirm that I will not attend the service if I am currently waiting for the results from a laboratory novel coronavirus test.
    i. I confirm that I will not attend the service if I have travelled outside of Canada in the last 14 days by car, air, train or bus.
    j. I confirm that I will not attend the service if I have been in contact with anyone who has tested positive for the novel coronavirus in the last 14 days.
    k. For those who are over the age of 65: I confirm that I understand that if I am over the age of 65 years old and have heart disease, lung disease, kidney disease or an auto-immune disease, I am at higher risk in contracting the virus if I choose to attend the service.
2. Two parking lot attendants will be present, one at each entrance to the parking lot to direct people to park in the back of the building and inform everyone that they must only enter the building through the back doors.
3. One greeter and two staff members will be stationed at the back doors to greet people. They will have a checklist of those that signed up. Anyone who didn't sign up will be directed to enjoy the service using the FM transmitter in parking lot. The greeter will open the door for people arriving. The inside sets of doors will be propped open, this provides for contactless entry to the building for those attending. The greeter will be instructed to NOT initiate physical contact with anyone arriving at the doors. The greeter (as well as a staff member) will also have a people counter clicker to use to track how many people are in the building as will the staff person at the door to double check numbers.
4. A hand sanitizing station will be present right inside the doors at the back of the building. Hand sanitizer will be recommended to all those who enter. There will also be a hand sanitizing station at the front doors used as the exit.
5. Two ushers will be present at the double set of wood doors into the worship center and they will be propped open. The usher will direct people to find a seat in any row that is not blocked off (every other row of seats will be blocked off which is 5' apart). The ushers will also assist people in spacing themselves out well from other families.
6. An offering box will be available on a table at the back of the auditorium for receiving cheques only from those that wish to give that way. But in announcements it will be encouraged to still continue giving online.
7. The connect folder will remain online and people will be directed to that in the announcements in the service.
8. The coffee bar will be closed and behind curtains so that no drinks or beverages are being offered.

9. In the washrooms, the doors into the washrooms will all be propped open (including the women's as there is no traffic going past that washroom at this time), there will be two containers of wipes in each washroom to allow people the option of wiping down surfaces before they touch them. Hand sanitizer will be available in the washrooms as well. We will have one container of wipes in the wheelchair washroom as well. The washrooms will be cleaned and sanitized between services.
10. There will be no children's ministry. And the doors to the construction area will be locked and signs posted that there is no access.
11. In order to move people out of the worship center, people are dismissed by the usher row by row, similar to at a funeral. And they are directed to head straight outside the building. Two staff members will be in the lobby to direct them to front doors. Have both sets of doors open. Exit only out the front doors (except those with physical limitations whose car might be in the back parking lot).
12. After the service, we have a team of volunteers wipe down the common touch areas in the worship center, all the chair arms at the ends of the open rows and the washrooms.
13. An attendee who becomes ill during the service is required to go home.

The legislation pertaining to numbers 14-17 is unclear. We are seeking legal counsel. For this Sunday we are being cautious by posting 14-17 within our risk mitigation strategy.

14. The Province of Ontario requires us to abide by the Waterloo Region's recommendation that staff and volunteers should use a mask/face covering at all times while providing services. This includes greeters, ushers, and pastors administering baptisms.
15. The Province of Ontario requires us to abide by the Waterloo Region's recommendation that we encourage all attendees to bring their own non-medical masks/face coverings.
16. The Province of Ontario requires us to abide by the Waterloo Region's recommendation that we avoid physical contact and greet each other with a smile, wave or bow.
17. The Province of Ontario requires us to abide by the Waterloo Region's recommendation that there is no congregational singing, chanting, or choirs.

Suggested Signage:

1. No Entry signs posted on the metal screen at end of office hallway, on the construction door by the washrooms, and attached to the drapes hanging in front of the coffee bar area.
2. A Covid warning sign on the back doors (a copy of the one that is already there) warning people to not enter the building if they have any symptoms of coronavirus or been in contact with anyone who has or tested positive or been outside of Canada in the last 14 days.

A Commissioner for Oaths in and for Ontario

TRINITY
BIBLE CHAPEL

Mr. Mike Harris
MPP for Kitchener-Conestoga
[redacted]

September 19, 2020

Dear Mr. Harris,

We offer you warm greetings and assure you that our church continues to pray for governing officials on a regular basis. We hold you in high honour because Scripture teaches us that you, a governing official, are appointed by God as His servant to punish evil and reward good (Romans 13:1-6). We send this letter with grave concerns over the looming threat of another government lockdown this fall.

As elders of a fairly large church within your riding, we believe that flattening the curve and keeping our population healthy are good objectives and our church has taken measures to assist in reducing the contraction and transmission of COVID-19. However, the actions and mandates by the government have produced deleterious effects on the population worse than the avoidance of sickness. The loneliness of isolation, the psychological trauma, the postponing of medical treatments, the hindrance to the education of children, the closure of business, the deterioration of relationships within families, and the unprecedented increase of Ontario's debt are but a few of the effects we note. Our understanding is that since July 17 in our region, only one person has died of COVID-19 and not a single person is presently hospitalized with the virus. By way of comparison, as of today COVID-19 has killed 0.019% of Ontario's population while 0.11% of Ontarians die from tobacco related deaths each year. With countless businesses and families destroyed by the emergency orders, the sale of tobacco has continued throughout. This is not to protest the sale of tobacco but rather to point out a glaring

inconsistency in policy: The fearmongering and devastation associated with the COVID-19 lockdown are radically disproportionate to the actual risk when we consider the metrics. Jesus called this "straining a gnat while swallowing a camel." It is a fixation on the smaller things to the detriment of the greater things.

As Canadians, we are heirs of ancient liberties that have existed since time immemorial, and these liberties, as our Charter indicates, are rooted in the supremacy of God and the rule of law. Some of our ancestors came to Canada seeking freedom, and some also fought in wars against external threats to our freedom. With heartfelt sorrow we believe that our own government has now become a threat to our freedom by enforcing arbitrary laws without scientific or ethical substantiation to fight a virus that presents a fraction of a fractional risk to us. As Christians our primary allegiance is to God because He purchased us by the blood of His Son, and God commands us to gather on the Lord's Day for worship. We, with the data we have presently, cannot support any future lockdowns that interfere with Christian worship or the spiritual education of children.

The members of our congregation are among your most peaceful and productive constituents. Furthermore, we are reasonable and intelligent people who are willing to be influenced by objective data. But our patience has waned with the inordinate and oppressive policy founded on sensationalized reporting. Please do not attempt another lockdown, and please support an immediate end to these emergency measures.

Sincerely,

Harvey Frey,
Elder Chairman

Randy Frey,
Pastor/Elder

Jacob Reaume,
Sr. Pastor/Elder

Will Schuurman,
Elder Chairman

Dean Wanders,
Elder

HERE WE STAND: THE CHURCH MUST MEET

By Jacob Reaume | December 3, 2020 | Tagged: *church, covid-19, government*

This document has the full support of all pastors and elders of Trinity Bible Chapel.

To all who witness.

An open letter to the executive branches of Ontario and Canada, Municipal Regulatory Authorities, Judges, and all those who may be blessed by our commitment to obedience to our Lord and Saviour Jesus Christ who purchased us by His very own blood.

RE: Trinity Bible Chapel's position founded on the Word of God to remain open and meeting under Threat of Lockdown

This letter is intended to give notice and reasoning as to why Trinity Bible Chapel ("TBC"), located in Waterloo Region, Ontario will remain open in the event of a lockdown or similar order issued by the Province or Municipal government (a "lockdown").[1] TBC asserts that its religious belief, which freedom is protected under section 2(a) and 2(c) of the Constitution Act, 1982 (the "Charter"), requires it to meet regularly in person. Further TBC asserts that the Province has not demonstrated that the restrictions currently put in place with respect to COVID-19 or a lockdown would be effective, nor would they be considered the "least restrictive means" or a "minimal impairment", an essential branch of the seminal Oakes test, the proportionality test required to be satisfied whenever the Provincial/Federal government violates a person's (including a corporation's) constitutional rights.

In addition to the violation of religious freedom and a point that we wish not to belabour, a lockdown would represent an offence under section 176 of the Canada Criminal Code, obstructing or violence to or arrest of an officiating clergyman, since such a lockdown order would be an unconstitutional and unlawful restriction of religious freedom. An offence under section 176(1) of the Canada Criminal Code is an indictable offence carrying serious consequences. Despite the historic independence the church has enjoyed from the Federal and Provincial government, seen both in legal precedent and codified in the Canadian Constitution (British North America Act, 1867), Charter and the Canada Criminal Code, along with other

ABOUT THE AUTHOR

JACOB REAUME

Born and raised in Guelph, Jacob holds a Master of Divinity from The Southern Baptist Theological Seminary in Louisville, Kentucky. He became pastor of Trinity Bible Chapel in August, 2009. Jacob is married to his high school sweetheart, Joanna, and together they have five children.

ABOUT THE CHURCH

major acts of legislation (e.g. Income Tax Act, Corporations Act, Land Transfer Act, etc.), this independence has been seemingly abandoned by the rules set by the Province.

Biblical Requirement to Meet Regularly as a Church

TBC has, since its beginning, served our Lord and community by preaching the Gospel of Jesus Christ, sponsoring foreign missionaries, contributing to local pregnancy crisis centers, assisting those in need, offering hope to those in despair, comforting the bereaved, providing pastoral care for families and singles, counseling broken marriages towards restoration, visiting the sick and lonely, sponsoring refugees, helping immigrants integrate into our community, educating children, officiating at weddings and funerals, and performing a plethora of other good deeds which have positively contributed to the welfare of thousands of individuals. Our observation is that these times of isolation, due to the government's restrictive actions, have harmed people and society by perpetuating loneliness, hopelessness, fear, poverty, division, anger, the deterioration of relationships, and a plethora of other evils which will become more evident with time. These observations do not surprise us because the restrictive actions of the government have wrongfully reduced human beings to biological units with little purpose to existence other than to avoid contracting and spreading a virus.[2] Scripture teaches us that people are much more than biological units. We are created in the image of God with dignity and worth to live free, love one another, worship together, grow families, eat with each other, laugh and cry together, embrace one another, exchange goods and services, and build things. Central to the Christian life is the ministry of the church, and TBC asserts that the church must remain open.

TBC believes that Scripture commands us to meet for worship in person, that the definition of "church" requires us to gather in person, and that the Law of God demands we gather at least weekly. This has been articulated in our church doctrinal statement, and each of our members has taken a solemn oath and covenant before God to meet regularly for worship, prayer, and the Lord's Supper.

Scripture, which is God's Word to us, commands Christians to gather in person for church (Hebrews 10:24-25). Regularly meeting in person was the pattern established by Christ's apostles: "And they devoted themselves to the apostles' teaching and the fellowship, to the breaking of bread and the prayers" (Acts 2:42). Christian meetings include fellowship, which entails togetherness, sharing of goods and food, showing hospitality, and presence of person, much like a family unit (Acts 4:32-37). The New Testament upholds the church as a spiritual family, so much that the bonds within the church are stronger than blood relations (Matthew 10:37; 13:53-58; Luke 14:26). For this reason, Christians often refer to each other as "brother" and "sister." To operate as a church, Christians are expected to experience fellowship regularly with one another like a family that lives under the same roof.

Embedded in the definition of church is gathering together. The New Testament word for church is the Greek word, *ekklesia*. Etymologically, *ekklesia* is the combination of two words that together mean "called out," as in a group of people called out to gather. The definition of the word demands that a church not be reduced to less than a gathering of people. The lexical range of *ekklesia* includes "assembly," "gathering," "a specific Christian group assembly, gathering ordinarily involving worship and discussion of matters of concern to the community," and "the totality of Christians living and meeting in a particular locality."[3] Where there is no physical gathering there is no church. For the church to exist it must gather.

The pattern since creation has been for believers to meet officially for worship at least once weekly. The Ten Commandments were written in stone by the finger of God, thus signifying the abiding authority of God's Law. The fourth commandment reads, "Remember the Sabbath day, to keep it holy. Six days you shall labor, and do all your work, but the seventh day is a Sabbath to the LORD your God" (Exodus 20:8-11). The Old Testament community set aside the seventh day for rest and public congregational worship: to do otherwise was a transgression of the Law. Christ was raised from the dead on the first day of the week, and since then churches have regularly met on the first day, Sunday, for worship, prayer, preaching, and the ordinances (Acts 20:7; 1 Corinthians 16:1-2). To cease meeting together for worship at least weekly is to be a disobedient Christian.

THE FIRST EIGHT YEARS: A CELEBRATION OF ANSWERED PRAYER

Scripture describes the church as a body with many parts. As a human body cannot exist without all its parts fastened together so the church cannot exist without all its people together. Saint Paul presses this analogy,

> For the body does not consist of one member but of many. If the foot should say, "Because I am not a hand, I do not belong to the body," that would not make it any less a part of the body. And if the ear should say, "Because I am not an eye, I do not belong to the body," that would not make it any less a part of the body. If the whole body were an eye, where would be the sense of hearing? If the whole body were an ear, where would be the sense of smell? But as it is, God arranged the members of the body, each one of them, as he chose. If all were a single member, where would the body be? As it is, there are many parts, yet one body (1 Corinthians 12:14-20).

In essence, the church is a composition of members that function in harmony. It is a body, and as a body all the parts must be together. Saint Paul continues, "Now you are the body of Christ and individually members of it" (1 Corinthians 12:27). Each individual is a valuable part of the church, and the church as a whole needs each individual. A church that does not gather is like a body with its parts scattered across a city. A body exists as parts together, and the church exists as Christians together.

The church must be together to fulfill its mission because its mission depends on togetherness and physical presence. The Scriptures command the church to partake of the Lord's Supper together (1 Corinthians 11:17-34), to baptize new converts (Matthew 28:19), to anoint the sick with oil (James 5:14), to ordain elders and pastors with the laying on of hands (1 Timothy 5:22), and to greet each other with a holy kiss (1 Corinthians 16:20). None of these actions are possible while separate or isolated. Each must be done in person because the New Testament presupposes that the church will be together.

Jesus epitomized Christian togetherness by incarnating as a man in the flesh. "And the Word became flesh and dwelt among us" (John 1:14). Some have expected church services to be held online, but that betrays the Scriptural notion of an unmediated ministry. Had God conceived of something other than the normalcy of an in-person ministry, he might have sent a picture or a hologram or a pixelated representation of Himself on a computer screen. Instead, God incarnated in the person of Christ by being born of a virgin, living and eating among men, performing miracles, being crucified, and rising bodily from the dead. Christians still wait expectantly for the bodily return of Jesus Christ to earth. Because of Christ's example to us, TBC believes that we must be physically present with each other.

Ironically, politicians and medical bureaucrats are calling for people to self-isolate this Christmastime out of what they consider "love for neighbour" to "reduce the spread." Yet, Christmas is the season that celebrates God's act of love when He became a man and dwelt among men. The concept of healthy people self-isolating to love their neighbours is not only completely foreign to Scripture but is also condemned as foolish and selfish by Scripture: "Whoever isolates himself seeks his own desire; he breaks out against all sound judgment" (Proverbs 18:1). It is noteworthy that the indoor gathering of three wise men with Mary, Joseph, and Jesus would be an illegal gathering in a lockdown, as would Christ's miraculous feeding of the five thousand and His Last Supper with His twelve disciples. The call to isolate is a call that is contrary to Christ's example at Christmas when He became a man, and it is furthermore a contravention of God's demands on His people.

In accordance with the practice of the ancient church, TBC has taught since its inception that the church must meet. So fundamental to our existence is our gathering together that it is captured in TBC's doctrinal statement, a foundational document to the church, which all members agree to uphold:

> The Scriptures command believers to gather locally in order to devote themselves to worship, prayer, teaching of the Word, fellowship, the ordinances of baptism and communion, service to the local body through the development and use of talents and spiritual gifts, and outreach to the world to make disciples. Wherever God's people meet regularly in obedience to this command, there is the local expression of the Church under the watchful care of a plurality of elders.

Another foundational document to TBC is the church covenant. In accordance with that covenant, all members of TBC have taken a solemn oath and covenant to meet together for worship, prayer, and to partake together of the Lord's Supper:

> We will not forsake the assembling of ourselves together, nor neglect to pray for ourselves and others. We will regularly participate together in the ordinance of the Lord's Supper.

Being bound by Scripture to be with each other, members of TBC therefore have solemnly covenanted before God to worship together and be with each other regularly. To not be together is to violate God's commands and our own solemn oath and covenant.

Extent of Christian Obedience to Governing Authorities

Scripture also commands Christians to be subject to governing authorities. "Let every person be subject to the governing authorities. For there is no authority except from God, and those that exist have been instituted by God" (Romans 13:1). The command, however, is not ultimate. In such cases when government edicts contradict God's commands, Christians must obey God over government. Confronted with governing authorities that required them to disobey God, Saint Peter and the other apostles once said, "We must obey God rather than men" (Acts 5:29). The Lord Jesus predicted that governments would oppose His Law to the point of punishing His people through court systems (Matthew 10:16-25). Tradition and history recount that all of Christ's apostles, except one, were martyred for their obedience to God instead of man. History indicates that the one apostle who did die of natural causes, Saint John, was once imprisoned on the Isle of Patmos and also boiled in oil for his obedience to God instead of man. The apostles, along with the Lord Jesus and the earlier prophets, exhibited Christian faithfulness under the threat of government penalty. They "suffered mocking and flogging and even chains and imprisonment. They were stoned, they were sawn in two, they were killed with the sword" (Hebrews 11:36-37). When the government commands what God forbids or forbids what God commands, Christians must obey God over the government.

Typically obedience to Federal, Provincial, and Municipal regulations is easily given, such as is the case with fire safety codes, municipal drainage requirements, and other building codes. But a lockdown order to cease meeting as a church body for fellowship and worship would contradict the commandments of God, and in such a case TBC is compelled to listen to God instead of the government. Further, while TBC respects the power and scope of various legislative and executive bodies in Canada to regulate public matters, the matters of a church are to be governed by the elders of a church (Acts 20:28; 1 Timothy 5:17; Titus 1:7).

The Scriptures command the church to meet. The church must meet to be a church. God's Law teaches us to meet no less than once weekly. This is written in our church doctrinal statement, and every member of our church has taken a solemn oath and covenant before God to meet. Under threat of prosecution and public shaming, TBC will, with God's help, obey God over government.

Conclusion

While our desire is to work with the Province to care for the health of our community, TBC respectfully advises that it must practice civil disobedience in the event of a government lockdown. By God's grace, Canada was founded on Christian principles, as enumerated in the preamble of the Charter, namely the supremacy of God and the rule of law. While it is still our hope and prayer that another lockdown does not occur in our region, TBC will, with God's help and by His grace, continue to meet if any lockdown or similar order by the Province or Municipal government does occur and firmly states that the sincere belief and religious practice of regular Sunday meetings fall under the fundamental freedoms of religion and peaceful assembly found in sections 2(a) and 2(c) of the Charter.

To all those who read, we encourage you to prayerfully consider the biblical requirement of Christians to physically gather as a body and the blessing provided by this gift of fellowship.

SUPPLEMENTAL MATERIALS

Pastor Jacob Reaume and Trinity Bible Chapel hosted a webinar with constitutional litigator James Kitchen and Pastor Aaron Rock called "Conflicting Duties: Christian Worship and the Magistrate's Quarantine" on May 14, 2020. It can be accessed here.

Pastor Will Schuurman wrote several blogs on the Trinity Bible Chapel website in late May on related topics including "COVID-19 and Romans 13" on May 23, 2020 and "On Gathering, Assembly Bans, and Romans 13" on May 26, 2020. You can access them here and here.

Pastor Jacob Reaume and Trinity Bible Chapel were involved with the Reopen Ontario Churches Campaign in late May and early June, 2020. Several hundred churches petitioned the government to open the church, and the petition can be accessed here.

Pastor John Macarthur and Grace Community Church of Sun Valley, California wrote a blog called "Christ, not Caesar, Is Head of the Church" on July 24, 2020, in which they declared that their church will not abide by California lockdown orders. It can be accessed here.

Pastor Jacob Reaume and Trinity Bible Chapel were involved with and among the first signatories of the Niagara Declaration, drafted in September, 2020 in which many Canadian churches and politicians asserted the divine, historic, and legal independence of the church from the state. It can be accessed here.

Pastor Aaron Rock, senior pastor of Harvest Bible Church in Windsor, Ontario, authored a blog exhorting churches to obey God over the state, under threat of lockdown, called, "A Call to Divine Obedience, over Civil Obedience." It can be accessed here.

Pastor Jacob Reaume, senior pastor of Trinity Bible Chapel, was asked to pray at a worship protest, held November 29, 2020, at Queen's Park. The full video of the protest can be accessed here.

The Ezra Institute for Contemporary Christianity in Grimsby, Ontario, with Rev. Dr. Joe Boot, recently produced a series of podcasts responding to the threat of a second lockdown on the church. You can access them here, here, and here.

The Justice Centre for Constitutional Freedoms, on December 3, 2020 released a report that government data demonstrates that the lockdown is more deadly than COVID-19. The news release, which links to the report, is available here.

FOOTNOTES

1 The intent of this letter is to declare why TBC will remain open and ask its members and community to attend worship services. In declaring that, we are also declaring that under most circumstances Christians must be in church. Notwithstanding that declaration, we continue to teach that there are extenuating circumstances in which absence from church attendance is excusable and permitted. Thus, we will continue to offer a livestream option for those that would like to view our worship services from a distance. ↵

2 At the time of writing this, nine months into the pandemic, more than 99.967% of Canadians have not died from COVID-19. ↵

NEWS RELEASE

Ontario Announces Provincewide Shutdown to Stop Spread of COVID-19 and Save Lives

Government Providing Grants of up to $20,000 to Small Businesses Impacted by New Public Health Measures

December 21, 2020
Office of the Premier

TORONTO — As COVID-19 cases continue to rise at an alarming rate, the Ontario government, in consultation with the Chief Medical Officer of Health and other health experts, is imposing a Provincewide Shutdown. Additional restrictions will be put into place and reinforce that Ontarians should stay at home as much as possible to minimize transmission of the virus and prevent hospitals from becoming overwhelmed. The Provincewide Shutdown will go into effect as of Saturday, December 26, 2020, at 12:01 a.m.

Details were provided today by Premier Doug Ford, Christine Elliott, Deputy Premier and Minister of Health, Stephen Lecce, Minister of Education, Dr. David Williams, Chief Medical Officer of Health, and Dr. Naveed Mohammad, President and CEO, William Osler Health System.

"The number of daily cases continue to rise putting our hospitals and long-term care homes at risk," said Premier Ford. "We need to stop the spread of this deadly virus. That's why, on the advice of Dr. Williams and other health experts, we are taking the difficult but necessary decision to shutdown the province and ask people to stay home. Nothing is more important right now than the health and safety of all Ontarians."

In response to these exceptional circumstances, the Provincewide Shutdown would put in place time-limited public health and workplace safety measures similar to those in other jurisdictions. It would help stop the trend of high COVID-19 transmission in communities, preserve health system capacity, safeguard vulnerable populations and those who care for them, and save lives. Measures include, but are not limited to:

- Restricting indoor organized public events and social gatherings, except with members of the same household (the people you live with). Individuals who live alone may consider having exclusive close contact with one other household.
- Prohibiting in-person shopping in most retail settings - curbside pickup and delivery can continue. Discount and big box retailers selling groceries will be limited to 25 per cent capacity for in-store shopping. Supermarkets, grocery stores and similar stores that primarily sell food, as well as pharmacies, will continue to operate at 50 per cent capacity for in-store shopping.
- Restricting indoor access to shopping malls - patrons may only go to a designated indoor pickup area (by appointment only), essential retail stores that are permitted to be open (e.g. pharmacy, grocery store), or, subject to physical distancing and face covering requirements, to the food court for takeout purchases. Shopping malls may also establish outdoor designated pickup areas.
- Prohibiting indoor and outdoor dining. Restaurants, bars and other food or drink establishments will be permitted to operate by take out, drive-through, and delivery only.

On the advice of the Chief Medical Officer of Health, all Ontarians are advised to stay home as much as possible with trips outside the home limited to necessities such as food, medication, medical appointments, or supporting vulnerable community members. Employers in all industries should make every effort to allow employees to work from home.

The current COVID-19 Response Framework will be paused when the Provincewide Shutdown comes into effect. The impacts of these time-limited measures will be evaluated throughout the 14 days in Northern Ontario and 28 days in Southern Ontario to determine if it is safe to lift any restrictions or if they need to be extended.The Chief Medical Officer of Health will assess and apply lessons learned thus far to the COVID-19 Response Framework to ensure appropriate and effective measures are in place to protect the health of Ontarians and enable economic recovery after the Provincewide Shutdown ends. This will include an assessment of how a revised approach for the safe reopening of retail may be operationalized, according to the latest available evidence.

"This was not an easy decision before the holidays, but we have reached a tipping point," said Minister Elliott. "We continue to see sharp increases in hospitalizations and occupancy in intensive care units is reaching concerning levels. Urgent action must be taken to prevent our health care system from becoming overwhelmed. By implementing a Provincewide Shutdown, we can work to stop the virus in its tracks, safeguard hospital capacity, and save lives."

The government is also providing $12.5 million to implement a High Priority Communities Strategy to contain the virus in high-risk communities. The strategy will take a tailored, community-based approach to fund community agencies in 15 priority communities in the York, Peel, Durham, Ottawa, and Toronto regions. The funding will also allow for the hiring of community ambassadors to make people aware of available services and assistance, for coordination of increased testing opportunities and for the arrangement of wraparound supports for those who are COVID-positive. Additional funding of $42 million will also be available to establish isolation centres.

The province will work with our local municipal partners to establish new isolation centres to help those who may need to isolate following testing.

"We continue to see the number of cases in the province grow and the trends in public health indicators worsen. Additional measures are needed provincewide in order to interrupt this concerning growth," said Dr. Williams. "We must work together to enable everyone to follow these new and time-limited restrictions and protect our health system and our communities."

The government is working to limit the transmission of COVID-19 in workplaces by supporting essential businesses in doing whatever is necessary to keep workers safe. The Ministry of Labour, Training and Skills Development is leading a multi-ministry COVID-19 Safety Team. The team will partner with local authorities to carry out additional enforcement blitzes in sectors where they are needed most.

New School Protocols

While transmission in schools remains low, all publicly funded and private elementary and secondary schools are to move to teacher-led remote learning when students return from the winter break on January 4, 2021. This action is being taken in support of the Government's broader efforts to limit the spread of COVID-19.

Schools located in the following Public Health Unit regions can resume in-person instruction on January 11, 2021 for both elementary and secondary students:

- The District of Algoma Health Unit
- North Bay Parry Sound District Health Unit
- Northwestern Health Unit
- Porcupine Health Unit
- Sudbury and District Health Unit
- Thunder Bay District Health Unit
- Timiskaming Health Unit

For schools in all other Public Health Unit regions, elementary school students are planned to be able to return to in-person learning on January 11, 2021, and secondary school students will continue learning remotely until January 25, 2021, at which point they may resume in-person learning. During this period, child care centres, authorized recreational and skill building programs and home-based child care services will remain open. From January 4-8, 2021, when elementary students move to remote learning, before and after school programs will be closed and emergency child care for health care and frontline workers will be provided. As part of the government's efforts to protect the most vulnerable, boards will be required to make provisions for continued in-person support for students with special education needs who cannot be accommodated through remote learning for whom remote learning is challenging.

"While our schools are not a source of rising community transmission, we can play an important part of the solution to save lives from COVID-19," said Minister Lecce. "During this period, students will pivot to teacher-led online learning, with child care provided for our frontline workers. We are taking proactive and preventative action to protect schools following the holiday break to ensure kids can continue in-class learning — something we believe is so important — for the remainder of the year."

The New Ontario Small Business Support Grant

The government recognizes that small businesses impacted by these necessary public health measures will require additional support so they can continue serving their communities and employing people in Ontario once the COVID-19 pandemic is over. That is why the government is announcing the new *Ontario Small Business Support Grant*, which will provide a minimum of $10,000 and up to $20,000 to eligible small business owners to help navigate this challenging period.

"Ontario's business owners have shown remarkable resolve and ingenuity throughout the pandemic. They know better than anyone what they need to come through this very difficult time, so they can continue to serve and employ people in their communities," said Rod Phillips, Minister of Finance. "The new *Ontario Small Business Support Grant* will provide significant financial support to eligible small business owners in addition to the other supports made available to our small business community."

Small businesses required to close or restrict services under the Provincewide Shutdown will be able to apply for this one-time grant. Each small business will be able to use the support in whatever way makes the most sense for their individual business. For example, some businesses will need support paying employee wages or rent, while others will need support maintaining their inventory.

Eligible small businesses include those that:

- Are required to close or significantly restrict services subject to the Provincewide Shutdown effective 12:01 a.m. on December 26, 2020;
- Have less than 100 employees at the enterprise level; and
- Have experienced a minimum of 20 per cent revenue decline in April 2020 compared to April 2019.

Starting at $10,000 for all eligible businesses, the grant will provide businesses with dollar for dollar funding to a maximum of $20,000 to help cover decreased revenue expected as a result of the Provincewide Shutdown. The business must demonstrate they experienced a revenue decline of at least 20 per cent when comparing monthly revenue in April 2019 and April 2020. This time period was selected because it reflects the impact of the public health measures in spring 2020, and as such provides a representation of the possible impact of these latest measures on small businesses.

Essential businesses that are allowed to remain open will not be eligible for this grant. More information about the *Ontario Small Business Support Grant* is available here. Further details, including how to apply, will be announced in January 2021.

Businesses that are impacted by the Provincewide Shutdown will also be eligible for the property tax and energy cost rebates. In November, the government launched a program to provide rebates to offset fixed costs such as property tax and energy bills for businesses that are required to shut down or significantly restrict services due to provincial public health measures. These rebates will continue to be available for businesses impacted by the Provincewide Shutdown and earlier restrictions. Business can apply for the rebates here.

Quick Facts

- Currently, hospitalizations for COVID-19 have increased by 74 per cent over the last four weeks and are more than 15 times higher than they were at the beginning of September. Intensive care unit (ICU) occupancy for COVID-19 has more than doubled over the last four weeks and is 20 times higher than at the beginning of September.
- Ontario currently has 915 COVID-19 patients requiring acute care, 265 patients in ICU, with 152 on a ventilator.
- Based on the latest modelling data, cases across the province are continuing to grow and the number of people requiring an intensive care bed is projected to rise well above 300 people within the next 10 days.
- Some jurisdictions around the world, including those in Canada have implemented similar time-limited measures to respond to a dramatic resurgence in cases. Based on their experiences, measures of four to six weeks are expected to interrupt transmission of COVID-19 in Ontario.
- Municipalities and local medical officers of health may have additional restrictions or targeted requirements in their region.
- Get tested if you have symptoms compatible with COVID-19, or if you have been advised of exposure by your local public health unit or through the COVID Alert App. Visit Ontario.ca/covidtest to find the nearest testing location.
- The Ontario Small Business Support Grant is part of the Province's more than $13.5 billion in support for people and jobs outlined in the 2020 Budget, Ontario's Action Plan: Protect, Support, Recover. It is also in addition to $4.8 billion to address critical areas to support a strong long-term recovery that helps workers, employers and communities get back on their feet, while building the foundation for recovery and growth.
- To find the right supports, visit COVID-19: Support for People, which has information about the many available and free mental health services and supports.
- To stay safe you can download the COVID Alert App free from the Apple and Google Play app stores.
- To date, as part of the province's COVID-19 immunization program, over 3,000 frontline health care workers have been vaccinated.
- Schools continue to be safe, and according to data reported by school boards, as of Friday, December 18: approximately 99.64 per cent of students in Ontario have not reported a case of COVID-19; approximately 92 per cent of schools across

the province have had either no cases or one case reported within the last 14 days; and approximately 80 per cent of schools do not have an case of COVID-19.

EXHIBIT I

This is Exhibit "I" referred to
in the Affidavit of
Jacob Reaume

Sworn before me this 4th day
of June A.D., 2021

A Commissioner for Oaths in and for Ontario

TRINITY
BIBLE CHAPEL

Mr. Bryan M. Larkin
Chief of Police
Waterloo Regional Police Service
[redacted]

cc:
Her Worship Sandy Shantz
Mayor of Woolwich Township
[redacted]

December 23, 2020

Dear Mr. Chief Larkin,

On December 18, 2020, a Christian pastor in India's Jarkhand State was shot in the head. On December 10, 2020, extremists in Alexandria, Egypt attacked three Christian men, leaving one dead and two injured with their private property destroyed. On November 17, 2020, three Christians were hacked to death, one burned to death, and four properties destroyed in Sulawesi, Indonesia. On October 29, 2020, three Christians were stabbed to death in Nice, France while worshipping at a church. Globally, one Christian is martyred every two hours simply because he obeys Jesus Christ by faith.[1]

The Regional Municipality of Waterloo, effective December 26, 2020 with the rest of Ontario, will be under lockdown, thus restricting churches to 10 person gatherings. Our church has had protocols to mitigate the spread of COVID-19 since the spring. Thanks be to God, not one outbreak has been traced back to our congregation of over 600 people.

After a tragic killing in the United States, a large demonstration and mass gathering took place in Kitchener on June 3, 2020. You offered the "full support" of the police, and, to those who gathered, you said, "I want you to know that our members will be there to not only ensure your safeby and the safety of the public, but to show that we stand united with you."[3] Occurring while Ontarians were restricted to outdoor gatherings of 5 or less persons, the "crowd may have been between 12,000 and 20,000 strong."[4] You explained to participants, even as they contravened lockdown orders, that police "will ensure you have the support needed to practice your democratic right and have your voice heard."[5]

We affirm that the constitutional rights of Canadians and matters of justice must be prioritized. As part of our regular public gathered worship of Jesus Christ we plan to meet at church in solidarity with our persecuted Christian brothers and sisters across the globe every Sunday, perhaps with mid-week services, for the duration of the lockdown. We hereby invite you to join us for these gatherings. As already indicated in a letter to our governing officials,[5] Trinity Bible Chapel holds the sincere religious belief that we must continue to regularly gather for worship. We intend to do so in accordance with our ancient freedoms protected under section 2(a) and 2(c) of the Constitution Act, 1982. We are heartened to know that each of your members has taken an oath to uphold the Constitution of Canada, each is accountable to the Office of the Independent Police Review Director, and each stands as our equal under the law. Therefore, we would be honoured to have your "support" as "needed to practice our democratic right and have our voice heard" at our church services.

Note that we will have a policy in place to mitigate the spread of COVID-19. We have offered to work with local health and government authorities on several occasions to prevent another lockdown of our church, and sadly we feel marginalized by the silence they have offered us.

Please support us in sending a message to all Canadians that our constitution must be upheld, that persecuted Christians deserve a voice, and that King Jesus must be honoured above all earthly governments.

We conclude by assuring you that as Christians we believe that law enforcement has been instituted by God to punish evil and protect the good.[6] We are peaceful and productive citizens who hold you in high honour, and as such we believe in a fully funded police force.

Sincerely in King Jesus,

Jacob Reaume,
Sr. Pastor
Trinity Bible Chapel

A Commissioner for Oaths in and for Ontario

REGIONAL MUNICIPALITY OF WATERLOO

OFFICE OF THE REGIONAL CLERK

[redacted]

February 16, 2021
File: A17-30/2021005

By Email: [redacted]

Dear Mr. Reaume:

Subject: Freedom of Information Request Fee Estimate and Extension

This letter is in response to your freedom of information request for - All emails and/or memos and/or documents containing mention of "Jacob Reaume", and/or "Randy Frey", and/or "Trinity Bible Chapel", and or "King Alfred Academy" from 2020/03/01 to 2021/01/14.

Through searches by our Information and Technology Services program using the search terms you have provided they have found approximately 6,000 emails and 144 documents.

Section 45 of the Municipal Freedom of Information and Protection of Privacy Act (MFIPPA) allows the Region to charge fees for access requests. Regulation 823 under MFIPPA sets the searching fee at $30.00 per hour of search time and processing of the records (redacting out information), and also allows the Region to request a 50% down payment where the fee estimate is $100.00 or more, before taking any further steps to process the request. An initial assessment of searching (fee waived) and processing for the records indicates that it will take an estimated 150 hours for redacting the information.

150 hours processing time @ $30 per hour		$4,500
	TOTAL	**$4,500**

You are asked to pay a 50% **($2,250.00)** down payment in order to proceed with this request.

Alternatively, if you would like to receive an index of the records and select the information you are interested in we can reduce this cost.

Please forward the deposit amount by cheque, payable to the Region of Waterloo, attention to: **Oriana Sharp, 150 Frederick Street, 2nd Floor, Kitchener, Ontario, N2G 4J3.** A sample report and report with attachments can be provided upon request to help you make your decision.

[redacted]

Due to the large volume of records that have to be reviewed for this request and limited staff time due to redeployment for COVID-19 response, a time extension of 90 days after the down payment is received. This time extension is being claimed according to section 20 of MFIPPA.

If you would like to appeal this fee estimate or have a review of the time extension, please contact the Information and Privacy Commissioner of Ontario at 2 Bloor Street East, Suite 1400, Toronto ON M4W 1A8 (Telephone: 1-800-387-0073; Website: www.ipc.on.ca). You must commence an appeal within 30 days, and submit a $25 appeal fee to the Commissioner. If you have any questions about this letter or MFIPPA, please contact me at 519-575-4006 or at osharp@regionofwaterloo.ca.

Yours sincerely,

Oriana Sharp
Manager, Information Management & Archives

Enhanced Epidemiologic Summary

COVID-19 Outbreaks and Cases in Ontario, by Setting: February 16, 2020 to December 26, 2020

This report includes the most current information available from the Ontario Ministry of Health (MOH) Case and Contact Management Solution (CCM) and other case management systems (CCM plus) as of **January 11, 2021.**

Please visit the interactive Ontario COVID-19 Data Tool to explore recent COVID-19 data by public health unit, age group, sex, and trends over time.[1] A Daily Epidemiological Summary, a Weekly Epidemiological Summary, as well as additional Enhanced Epidemiological Reports are available on the Public Health Ontario website.[2,3]

Purpose

This report provides an epidemiologic summary of cumulative confirmed COVID-19 outbreaks and outbreak-associated cases in Ontario by setting, with a focus on outbreaks and cases reported from other settings (i.e., outbreaks and associated cases outside of congregate care, congregate living and education settings). This report includes all COVID-19 cases linked to an outbreak.

Highlights

- In Ontario, from February 16, 2020 to December 26, 2020, there were 39,774 confirmed COVID-19 cases associated with 4,151 outbreaks reported across all settings. In comparison, there were 136,496 non-outbreak associated cases of COVID-19 reported in Ontario during the same period.
- Of the 4,151 outbreaks, 38.8% were in congregate care settings, 11.3% in congregate living settings, 17.7% in education settings, and 32.2% in other settings (Table 1).
    - Overall, long-term care homes (within congregate care settings) accounted for the largest proportion of all outbreaks (905/4,151, 21.8%).
    - Within other settings, workplaces accounted for the majority of outbreaks (872/1,335, 65.3%).
- Of the 39,774 outbreak-associated cases, 63.2% were in congregate care settings, 7.1% in congregate living settings, 6.2% in education settings, and 23.5% in other settings (Table 2).
    - Overall, long-term care homes accounted for the largest proportion of all reported outbreak-associated cases (18,475/39,774, 46.4%).

    - Within other settings, workplaces accounted for the majority of outbreak-associated cases (6,991/9,344, 74.8%).

    - Overall, across all setting types, a median of 2 cases (interquartile range [IQR]: 1-6) per outbreak was reported, with the highest median associated with farm workplace outbreaks (median of 14 cases per outbreak, maximum of 240 cases).

- Deaths were reported in 9.3% of all outbreak associated cases (Table 3).

    - Overall, long-term care homes accounted for the largest proportion of all outbreak-associated deaths (2,911/3,681, 79.1%).

- Compared to non-outbreak cases, a higher proportion of females and individuals 80 years and older were associated with outbreaks (Table 4).

- During the first wave of the pandemic, outbreaks were most commonly reported in congregate care settings. While fewer total outbreaks were reported during the first wave, these outbreaks were generally associated with more cases, peaking at 2,929 cases during week 16 (April 12, 2020 to April 18, 2020).

- In wave two, from August 30, 2020 (week 36) onward, the total number of outbreaks reported weekly increased. The number of outbreaks in congregate care continued to be significant, and outbreaks reported within congregate living, education, and other settings increased. Outbreak-associated cases have been steadily rising from week 36 onward.

Limitations

- The findings presented in this report include all cases and settings where local public health units declared an outbreak in a given setting. The outbreaks included in this report do not present the complete picture of settings where COVID-19 is being transmitted in Ontario, and may under-represent outbreaks in settings where contact tracing is more difficult.

- Outbreak-associated cases in this report do not include secondary cases acquired from outbreak-associated cases. As such, this report likely under-represents the true magnitude of cases impacted by a COVID-19 outbreak.

- Outbreak-associated cases in this report include all cases directly linked to an outbreak as determined by the local public health unit, but may not reflect where the case acquired the infection. Cases could represent employees, residents or members of the public.

- Definitions of outbreaks, including the number of cases, vary across settings. In addition, due to variations in data entry processes across public health units, some outbreaks included in this report may not have met the criteria included in an outbreak definition (i.e. size or duration of outbreak). Further there is no provincial outbreak definition for several setting types classified within the other settings category; as such, there may be variation in declaring outbreaks by public health unit.

- Trends in outbreaks reported across settings and within settings over time should be interpreted with caution, as provincial restrictions resulted in closures of several settings (e.g., school settings were subject to closure during wave one, and were permitted to open approximately

around week 36). The results in this report therefore do not represent a comprehensive assessment of risk in different settings.

Outbreak Characteristics

Table 1. Cumulative summary of confirmed COVID-19 outbreaks reported between February 16, 2020 and December 26, 2020, by setting type: Ontario

Setting Type	Number of outbreaks	Median number of cases per outbreak (IQR)	Maximum number of cases per outbreak	Median duration of closed outbreaks in days [1] (IQR)
Congregate care	**1,612**	**2 (1 - 9)**	**316**	**9 (0 - 21)**
Long-term care homes	905	2 (1 - 8)	316	9 (0 - 22)
Retirement homes	475	2 (1 - 7)	128	6 (0 - 18)
Hospitals	232	6 (3 - 12)	103	13 (6 - 21)
Congregate living	**470**	**2 (1 - 6)**	**215**	**6 (0 - 13)**
Correctional facility	16	2 (1 - 18)	114	3 (0 - 20)
Shelter	86	2 (1 - 5)	215	3 (0 - 13)
Group home/supportive housing	309	2 (1 - 6)	84	6 (0 - 13)
Short-term accommodations	7	1 (1 - 3)	5	4 (2 - 4)
Congregate other	52	4 (1 - 8)	75	7 (1 - 14)
Education	**734**	**2 (1 - 4)**	**50**	**6 (2 - 11)**
Child care	238	1 (1 - 2)	28	3 (0 - 9)
School – Elementary[2]	348	3 (2 - 4)	50	7 (4 - 12)
School – Elementary/secondary[2]	24	4 (2 - 6)	46	6 (2 - 14)
School – Secondary[2]	111	2 (2 - 5)	40	9 (5 - 16)
School – Post-secondary[2]	13	2 (2 - 3)	9	5 (5 - 6)

Setting Type	Number of outbreaks	Median number of cases per outbreak (IQR)	Maximum number of cases per outbreak	Median duration of closed outbreaks in days [1] (IQR)
Other settings[3]	**1,335**	**3 (1 - 6)**	**240**	**9 (5 - 16)**
Bar/restaurant/nightclub	122	3 (2 - 5)	40	7 (4 - 11)
Medical/health services	59	3 (1 - 5)	17	7 (4 - 13)
Medical/dental clinics	26	3 (1 - 4)	14	5 (4 - 10)
Other[4]	33	2 (1 - 5)	17	8 (5 - 18)
Personal service settings	11	2 (1 - 4)	16	15 (6 - 22)
Recreational fitness	49	5 (2 - 10)	54	5 (1 - 9)
Gym/fitness studios	14	2 (1 - 7)	54	5 (4 - 10)
Sporting teams/leagues	14	7 (3 - 9)	44	1 (0 - 7)
Other[5]	21	5 (2 - 10)	48	7 (2 - 13)
Retail	141	2 (1 - 4)	47	8 (4 - 12)
Grocery stores/pharmacies	34	2 (1 - 4)	36	12 (9 - 20)
Other[6]	107	2 (1 - 4)	47	6 (4 - 12)
Culture and other recreation	71	5 (2 - 12)	60	8 (4 - 13)

Private events	18	8 (2 - 15)	36	7 (5 - 13)
Other[7]	30	3 (1 - 6)	60	7 (4 - 14)
Workplace	872	3 (1 - 7)	240	11 (6 - 19)
Construction	83	2 (1 - 3)	8	8 (3 - 13)
Logistics	95	3 (1 - 10)	202	15 (8 - 23)
Farm	53	14 (4 - 42)	240	23 (14 - 45)
Food processing	115	5 (2 - 11)	168	17 (8 - 25)

Setting Type	Number of outbreaks	Median number of cases per outbreak (IQR)	Maximum number of cases per outbreak	Median duration of closed outbreaks in days [1] (IQR)
Manufacturing	298	3 (1 - 7)	57	12 (7 - 19)
Other[8]	228	3 (1 - 5)	56	7 (4 - 11)
Unknown	10	2 (0 - 15)	42	3 (0 - 22)
Total	**4,151**	**2 (1 - 6)**	**316**	**8 (2 - 16)**

Notes: Due to reporting delays and potential variations in data entry processes across public health units, there may be additional COVID-19 cases that have not yet been entered in CCM plus, or have not been entered as linked to an outbreak. As such, some outbreaks may have zero linked cases. This includes 121 outbreaks in congregate care, 46 outbreaks in congregate living, 61 outbreaks in education, and 204 outbreaks in other settings. Ongoing re-classification of settings for reported outbreaks can result in outbreak counts that may differ from counts previously reported in other reports. See Appendix A for full descriptions of outbreak categories.

[1]The median duration of outbreaks was only measured for outbreaks with a "Closed" Outbreak Classification status. Outbreak length was calculated using the 'Outbreak Date' as the start date and the 'Outbreak Date End' as the end date. The "Outbreak Date" is a calculated field used to determine the outbreak declared date using the following hierarchy of date fields (Onset date of the first case > Reported Date > Created Date). The "Outbreak Date End" is a calculated field used to determine the end date of the outbreak using the following hierarchy of date fields (Onset date of the last case > Date the outbreak was declared over). Due to variations in data entry practices and variability in case definitions, this can result in outbreaks having a duration length of 0 days (i.e. if only a single case is linked to an outbreak, the symptom onset date for the first and last case will be the same).

[2]Cumulative counts include COVID-19 school outbreaks reported starting week 36 (August 30 to September 5, 2020).

[3]Not all settings were open during the reporting period due to provincial public health measures.

[4]Captures outbreaks classified as having taken place in other medical/health-service related settings, including community health centres, home care services and wellness clinics.

[5]Captures outbreaks classified as having taken place in recreational settings including athletic facilities, recreational/community centres, golf courses, tennis courts and indoor playgrounds.

[6]Captures outbreaks classified as having taken place in auto dealerships and standalone retailers, as well as big box stores, among other retail settings.

[7]Captures outbreaks classified as having taken place in theatres, banquet halls (not including weddings), private transportation, private residences, and other community settings.

[8]Captures outbreaks classified as having taken place in locations such as: offices, banks, municipal services (e.g., fire station, police station), and veterinary clinics.

Data Source: CCM plus

Characteristics of outbreak-associated Cases

Table 2. Cumulative summary of confirmed COVID-19 cases associated with outbreaks reported between February 16, 2020 and December 26, 2020, by setting type: Ontario

Setting Type	Number of cases	Proportion male[1] (%)	Median age[2] (IQR)
Congregate care	**25,150**	**27.4**	**73 (49 - 87)**

Unknown	86	58.1	30 (21 - 47)
Total	**39,774**	**39.8**	**54 (34 - 81)**

Notes: See Appendix A for full descriptions of outbreak categories.

[1]Not all cases have a gender reported. The denominator for calculating male case percentages includes all cases.

[2]Includes all cases linked to an outbreak regardless of attendance/residence within the outbreak setting. Therefore, the range of ages of cases associated with an outbreak may not align with expected ages within that setting.
[3]Cumulative counts include COVID-19 school outbreaks reported starting week 36 (August 30 to September 5, 2020).
[4]Not all settings were open during the reporting period due to provincial public health measures.
[5]Captures outbreaks classified as having taken place in other medical/health-service related settings, including community health centres, home care services and wellness clinics.
[6]Captures outbreaks classified as having taken place in recreational settings including athletic facilities, recreational/community centres, golf courses, tennis courts and indoor playgrounds.
[7]Captures outbreaks classified as having taken place in auto dealerships and standalone retailers, including big box stores, among other retail settings.
[8]Captures outbreaks classified as having taken place in theatres, banquet halls (not including weddings), public and private transportation, private residences and other community settings.
[9]Captures outbreaks classified as having taken place in offices, banks, municipal services (e.g. fire station, police station), and veterinary clinics, among others.

Other[8]	13 (1.5%)	2 (0.2%)	0.4%	0.1%
Unknown	7 (8.1%)	0 (0.0%)	0.2%	0.0%
Total	**3,460 (8.7%)**	**3,681 (9.3%)**	100.0%	100.0%

Notes: See Appendix A for full descriptions of outbreak categories.
[1]Hospitalized cases associated with outbreaks classified within a hospital can include patients, staff or other hospital visitors. The number of hospitalized cases in hospital outbreak settings is lower than the total number of cases reported in hospital outbreak settings (Table 2), as the total number of cases includes healthcare workers in the facility who may not have been hospitalized.
[2]Includes COVID-19 school outbreaks reported starting week 36 (August 30 to September 5, 2020).
[3]Not all settings were opened during the reporting period due to provincial public health measures.
[4]Captures outbreaks classified as having taken place in other medical/health-service related settings, including community health centres, home care services and wellness clinics.
[5]Captures outbreaks classified as having taken place in recreational settings including athletic facilities, recreational/community centres, golf courses, tennis courts and indoor playgrounds.
[6]Captures outbreaks classified as having taken place in auto dealerships and standalone retailers, including big box stores, among other retail settings.
[7]Captures outbreaks classified as having taken place in theatres, banquet halls (not including weddings), public and private transportation, private residences and other community settings.
[8]Captures outbreaks classified as having taken place in offices, banks, municipal services (e.g. fire station, police station), and veterinary clinics, among others.
Data Source: CCM plus

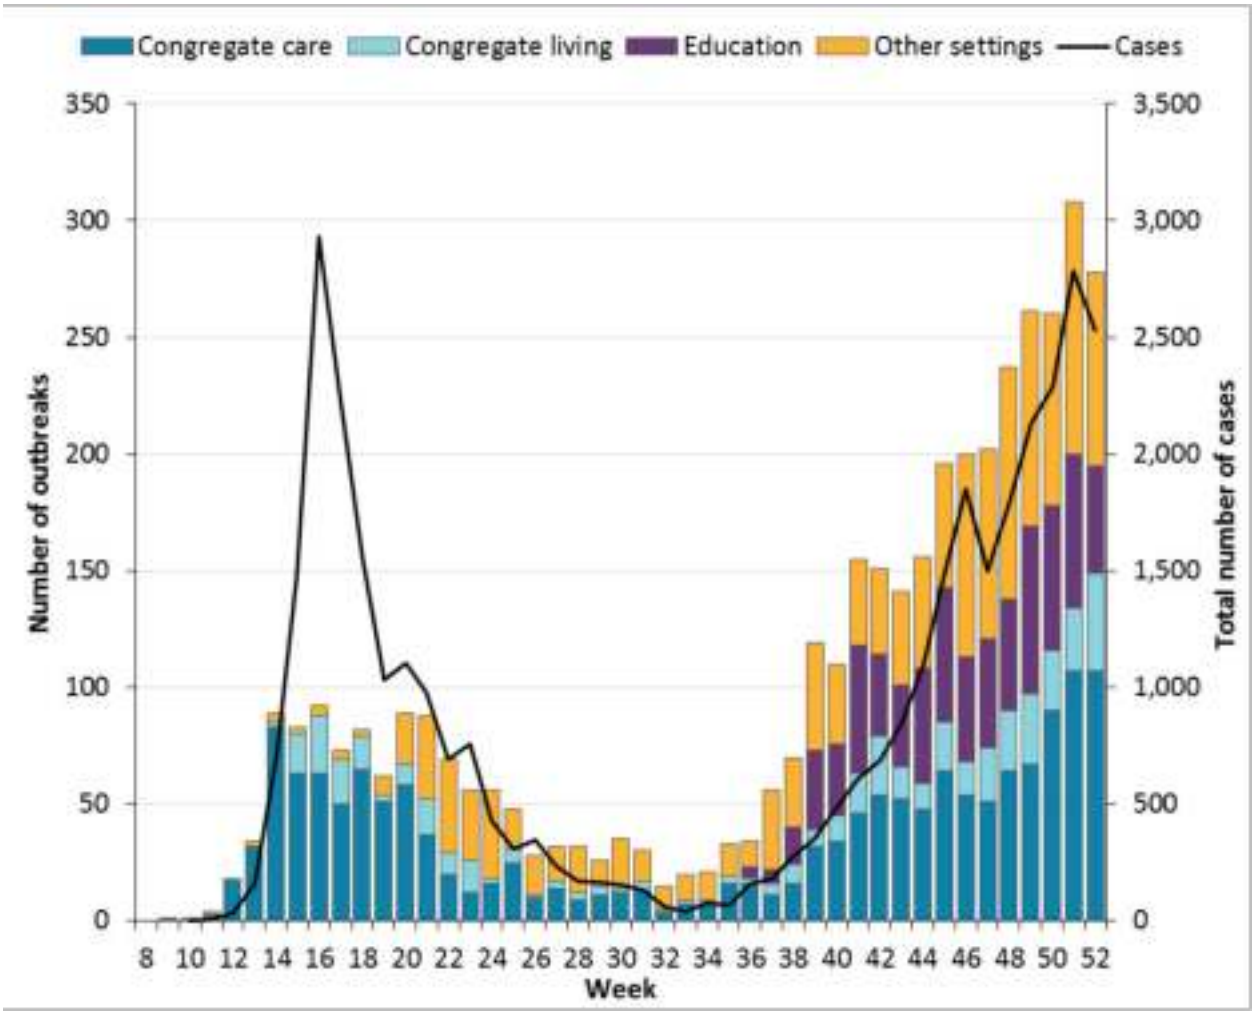
Table 4. Demographic characteristics of non-outbreak and outbreak-associated cases reported between February 16, 2020 and December 26, 2020

	Non-outbreak cases	Outbreak cases
Total number of cases	**136,496**	**39,774**
Gender: Female	65,801 (48.2%)	23,567 (59.3%)
Gender: Male	70,030 (51.3%)	15,840 (39.8%)
Age: 19 and under	19,856 (14.5%)	2,512 (6.3%)
Age: 20-39	54,023 (39.6%)	9,796 (24.6%)
Age: 40-59	40,039 (29.3%)	10,425 (26.2%)
Age: 60-79	19,086 (14.0%)	6,466 (16.3%)
Age: 80 and over	3,473 (2.5%)	10,565 (26.6%)

Note: Not all cases have an age or gender reported. The denominator for calculating percentages includes all cases.
Data Source: CCM plus

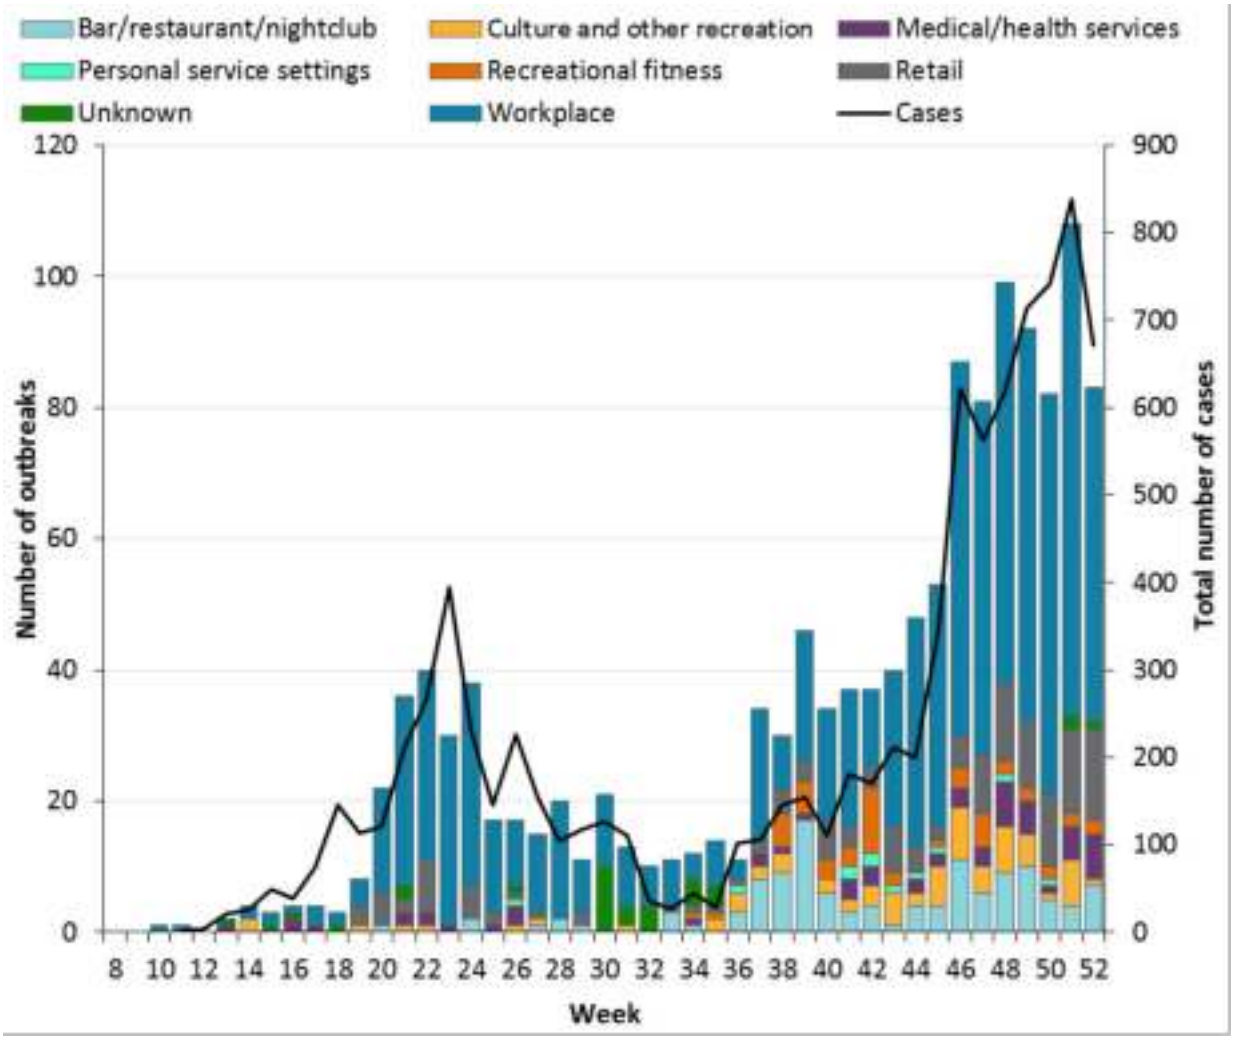
Time Trends

Figure 1a. Total number of public health unit declared COVID-19 outbreaks, and number of confirmed outbreak-associated cases, by setting type and week, reported between week 8 (February 16, 2020) and week 52 (December 26, 2020): Ontario



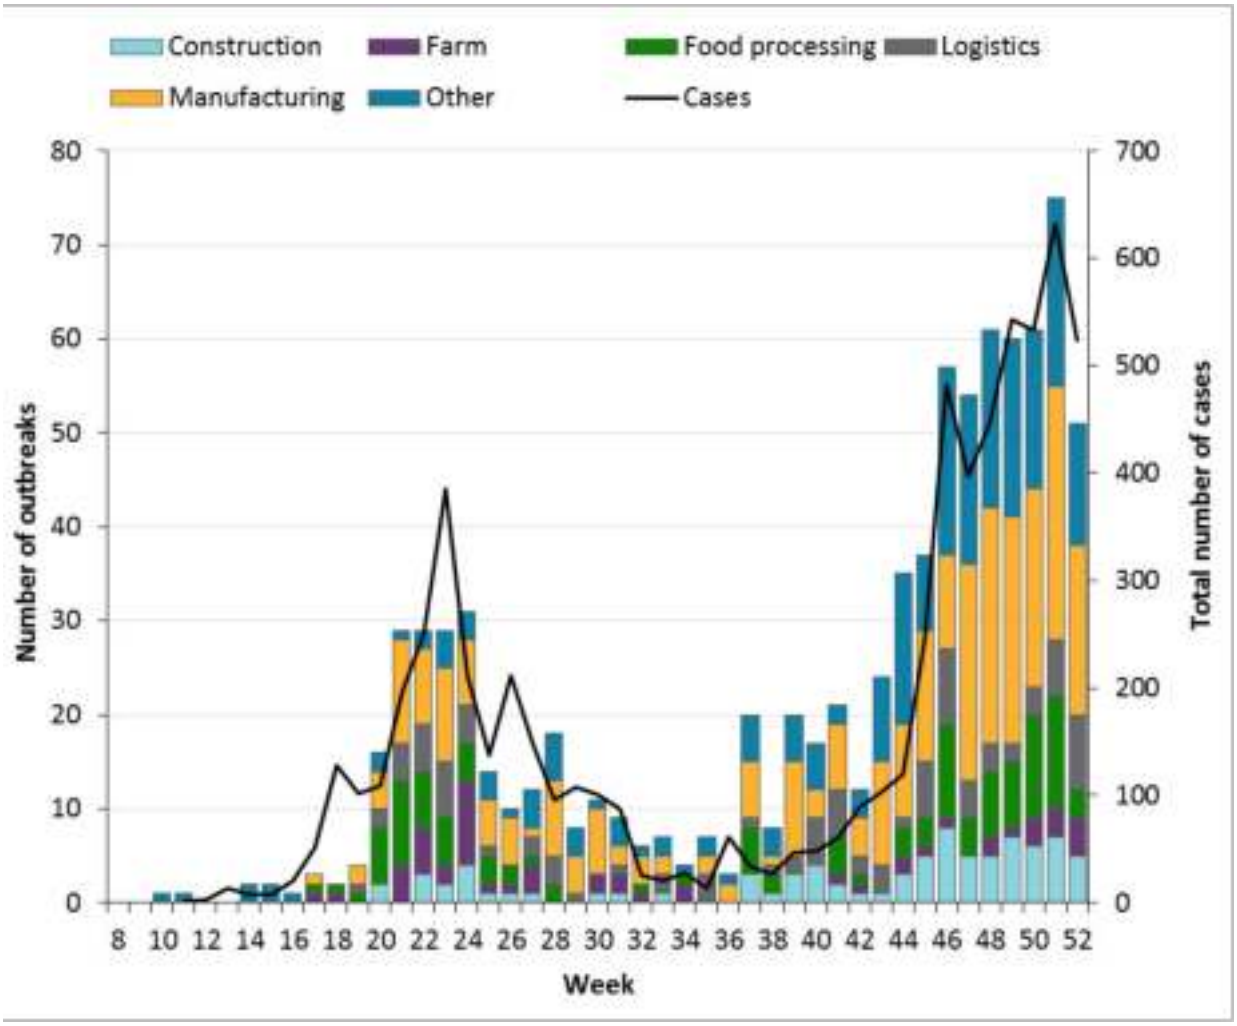
Notes: Number of outbreaks is based on week the outbreak was declared, while total number of cases is based on case reported week. Since many outbreaks are still ongoing, there were 3,261 cases with case reported dates that occurred outside of the week ranges of focus and were therefore not included in the figure. Includes outbreaks that are ongoing and outbreaks that are no longer active. Not all settings were open during the reporting period due to provincial public health measures. See Appendix A for full descriptions of outbreak categories.
Data Source: CCM plus

Figure 1b. Number of public health unit declared COVID-19 outbreaks in other settings, and number of confirmed other setting outbreak-associated cases, by setting type and week, reported between week 8 (February 16, 2020) and week 52 (December 26, 2020): Ontario



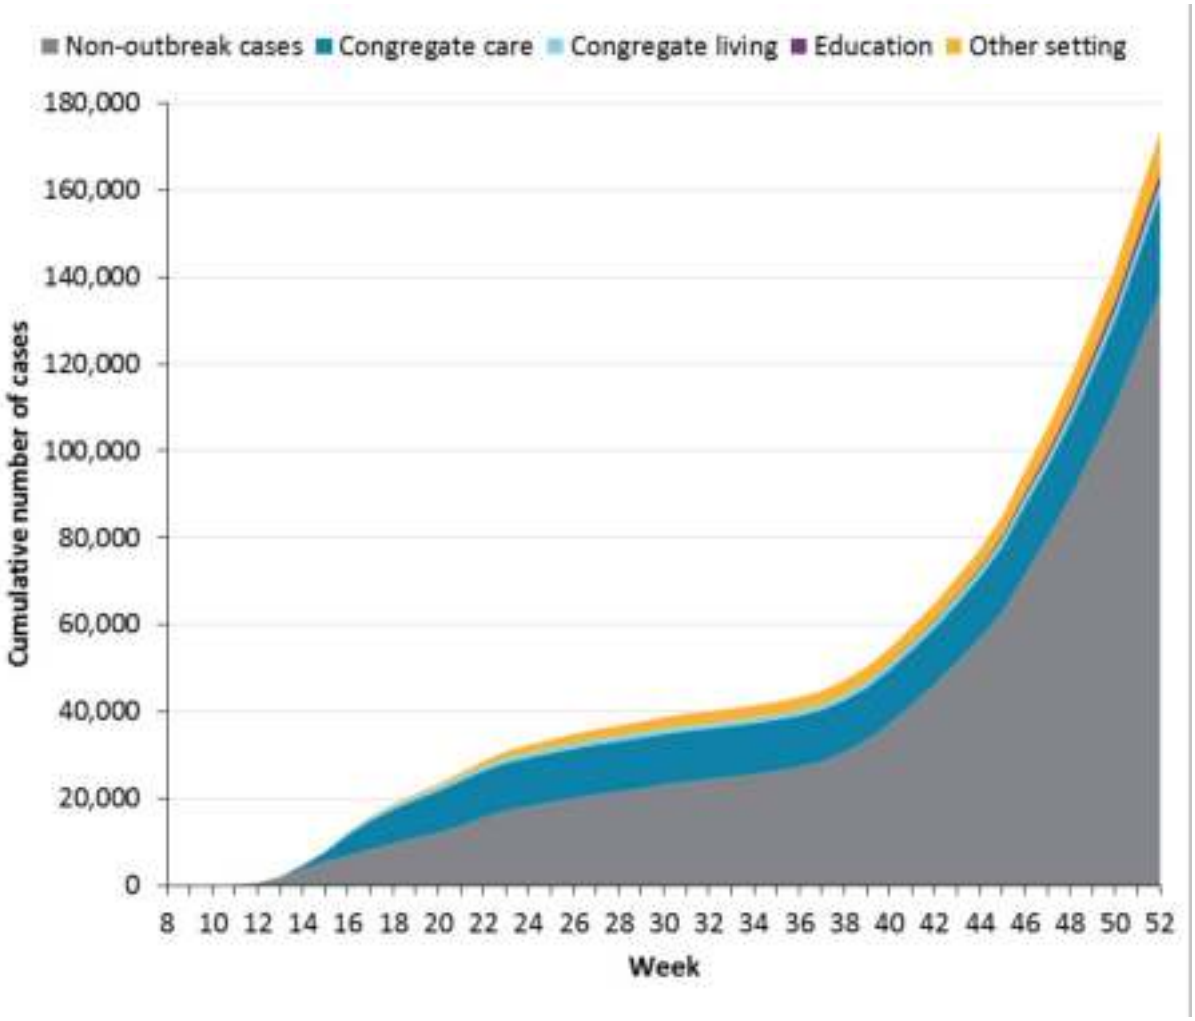
Notes: Number of outbreaks is based on week the outbreak was declared, while total number of cases is based on case reported week. Since many outbreaks are still ongoing, there were 399 cases with case reported dates that occurred outside of the week ranges of focus and were therefore not included in the figure. Includes outbreaks that are ongoing and outbreaks that are no longer active. Not all settings were open during the reporting period due to provincial public health measures. See Appendix A for full descriptions of outbreak categories.
Data Source: CCM plus

Figure 1c. Number of confirmed public health unit declared COVID-19 workplace[1] outbreaks, and number of confirmed workplace outbreak-associated cases, by setting type and week, reported between week 8 (February 16, 2020) and week 52 (December 26, 2020): Ontario



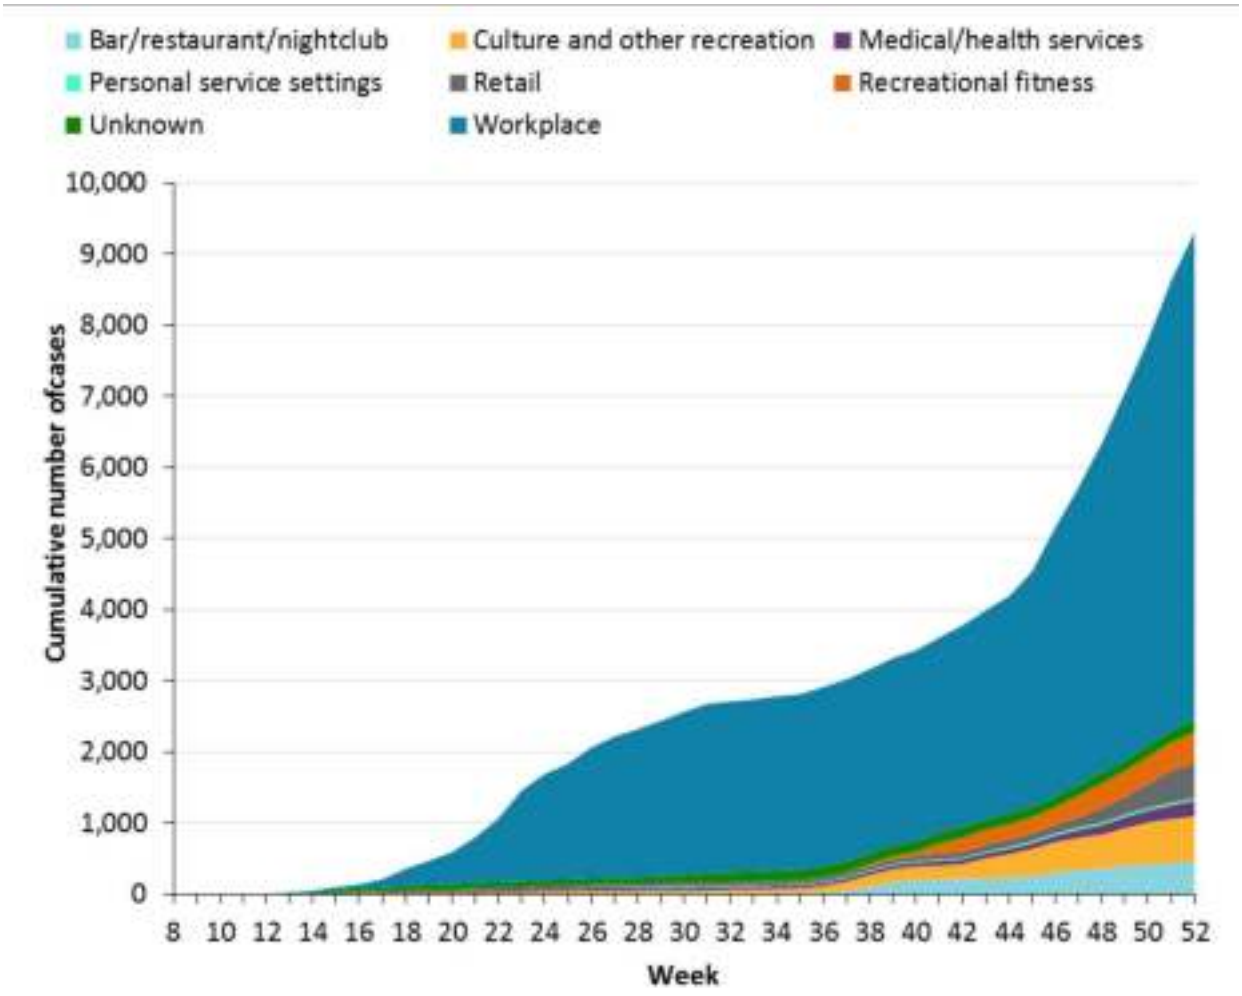
Notes: Number of outbreaks is based on week the outbreak was declared, while total number of cases is based on case reported week. Since many outbreaks are still ongoing, there were 347 cases with case reported dates that occurred outside of the week ranges of focus and were therefore not included in the figure. Includes outbreaks that are ongoing and outbreaks that are no longer active. Not all settings were open during the reporting period due to provincial public health measures. See Appendix A for full descriptions of outbreak categories.
[1]Workplaces do not include publically-accessible settings where people may also work (i.e., restaurants, gyms).
Data Source: CCM plus

Figure 2a. Cumulative number of outbreak and non-outbreak cases, by setting type and week, reported between week 8 (February 16, 2020) and week 52 (December 26, 2020): Ontario



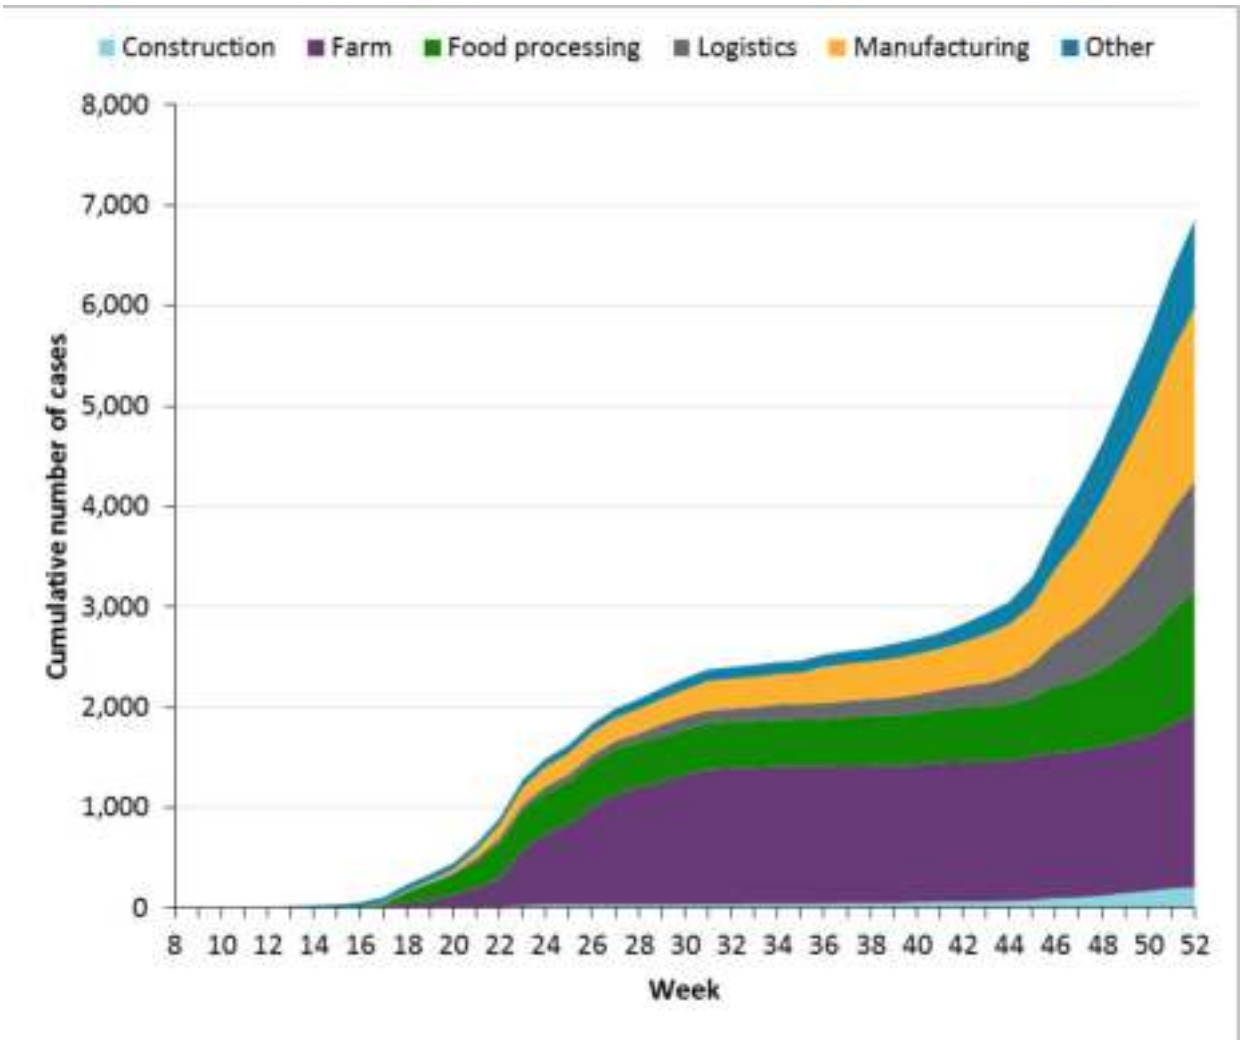
Notes: Based on case reported week. Non-outbreak cases refers to all COVID-19 cases not linked to a declared outbreak reported between weeks 8 and 52. Since many outbreaks are still ongoing, there were 3,267 outbreak-linked cases with case reported dates that occurred outside of the week ranges of focus and were therefore not included in the figure. Includes outbreaks that are ongoing and outbreaks that are no longer active. Not all settings were open during the reporting period due to provincial public health measures. See Appendix A for full descriptions of outbreak categories.
Data Source: CCM plus

Figure 2b. Cumulative number of confirmed cases from other setting outbreaks, by setting type and week, reported between week 8 (February 16, 2020) and week 52 (December 26, 2020): Ontario



Notes: Based on case reported week. Since many outbreaks are still ongoing, there were 399 cases with case reported dates that occurred outside of the week ranges of focus and were therefore not included in the figure. Includes outbreaks that are ongoing and outbreaks that are no longer active. Not all settings were open during the reporting period due to provincial public health measures. See Appendix A for full descriptions of outbreak categories.
Data Source: CCM plus

Figure 2c. Cumulative number of confirmed cases from workplace[1] outbreaks, by setting type and week, reported between week 8 (February 16, 2020) and week 52 (December 26, 2020): Ontario



Notes: Based on case reported week. Since many outbreaks are still ongoing, there were 347 cases with case reported dates that occurred outside of the week ranges of focus and were therefore not included in the figure. Includes outbreaks that are ongoing and outbreaks that are no longer active. Not all settings were open during the reporting period due to provincial public health measures. See Appendix A for full descriptions of outbreak categories.

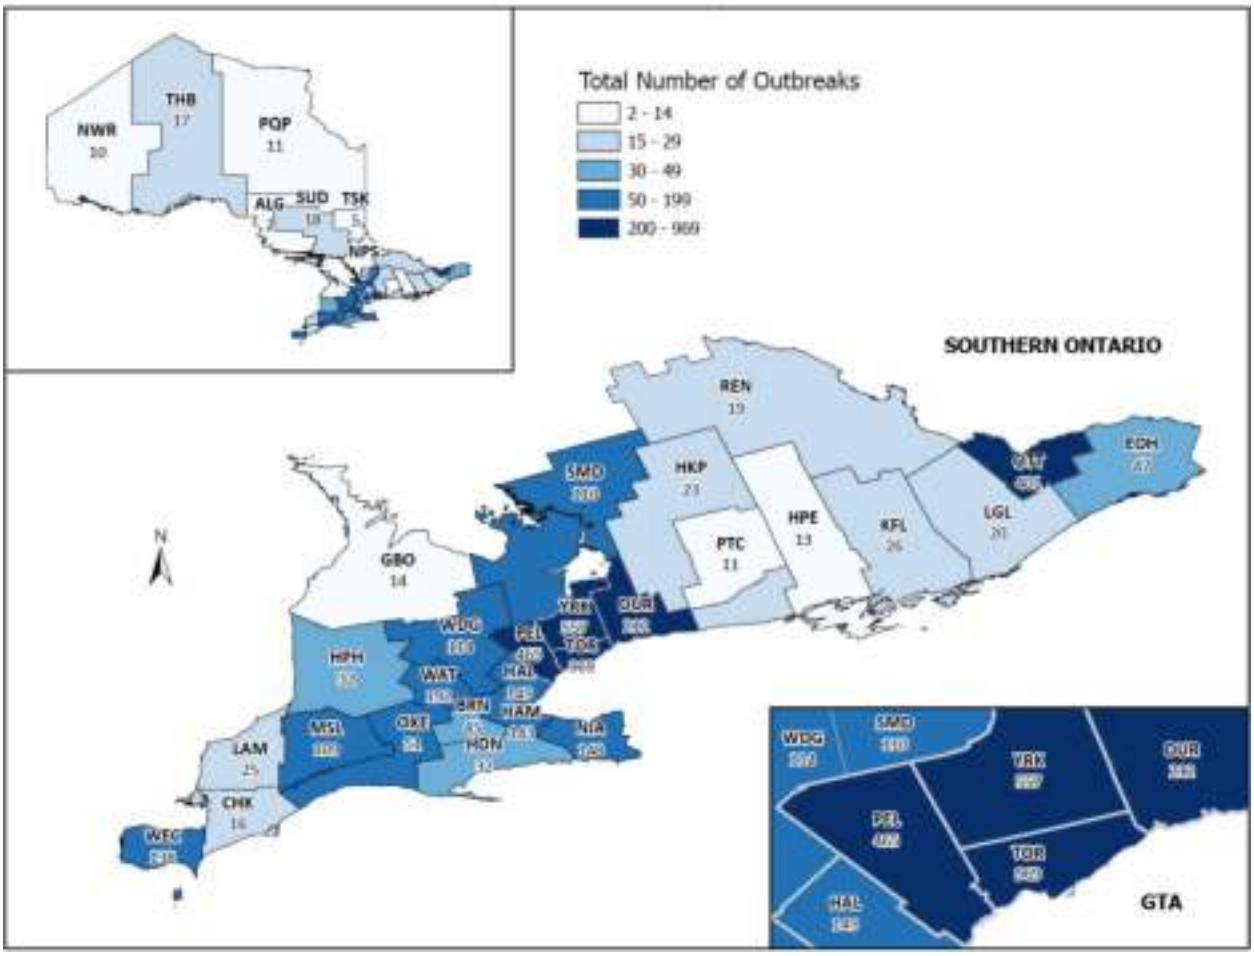
Geography

Figure 3. Number of confirmed COVID-19 outbreaks reported between February 16, 2020 and December 26, 2020 by public health unit: Ontario



Note: Includes outbreaks that are ongoing and outbreaks that are no longer active. Cut-offs for map categories were determined by natural breaks and adjusted for round numbers. Geography is based on public health unit where the outbreak was declared. Not all settings were open during the reporting period due to provincial public health measures. There was one outbreak that involved cases from Ontario and outside of Ontario and was not assigned to a public health unit. The data in this map are also available in Appendix B.
Data Source: CCM plus

Technical Notes

Data Sources

- The data for this report were based on:
    - Information extracted from the Ontario Ministry of Health (Ministry) integrated Public Health Information System (iPHIS) database for Toronto Public Health as of **January 11, 2021 at 1 p.m.**
    - Information successfully uploaded to the Ministry from Local Systems: Toronto Public Health (Coronavirus Rapid Entry System) CORES as of **January 11, 2021 at 2 p.m.**
    - Information successfully extracted from the Public Health Case and Contact Management Solution (CCM) for all other PHUs by PHO as of **January 11, 2021 at 1 p.m.**
- CCM and CCM plus (which includes CCM, iPHIS and CORES) are dynamic disease reporting systems, which allow ongoing updates to data previously entered. As a result, data extracted from CCM and the Local Systems represent a snapshot at the time of extraction and may differ from previous or subsequent reports. This applies to both case and outbreak data.

Data Caveats:

- The data included are for outbreaks reported in Ontario from February 16, 2020 to December 26, 2020 and cases linked to those outbreaks up until January 11th, 2021.
- Only confirmed outbreaks are included in this report.
- The outbreak data for these settings are restricted to those in which an outbreak was declared by the public health unit. The data also do not include cases linked to these settings as an exposure. Outbreaks are declared by the local medical officer of health or their designate in accordance to the Health Protection and Promotion Act and criteria outlined in Ministry guidance documents.[4]
- For outbreaks declared in certain settings such as long-term care, hospitals, educational settings, and workplaces, there are provincial outbreak definitions.[5-7] These definitions may have single case thresholds, and may also include changes in the case thresholds for declaring an outbreak over time (i.e.,., the threshold for declaring an outbreak in a child care setting increased from one to two cases as of November 9, 2020).[8] However, there is no provincial case definition for several other setting types reported as other settings. As such, a standard approach to declaring an outbreak across these settings may differ by public health unit.
    - All other setting outbreaks were manually classified based on the name, address, and additional relevant information available in CCM for the outbreak, as entered by the PHU. other setting outbreaks consisted of outbreaks outside of congregate care settings (i.e., hospitals, long-term care, retirement home), congregate living settings (i.e., correctional facilities, shelters, group homes, other congregate), and education settings (i.e., childcare settings and schools). All outbreak classifications are mutually exclusive. However, an outbreak declared in a restaurant may have been a workplace outbreak if cases were

identified among staff only. For the purposes of this report, a setting-based hierarchy was used.

    - Outbreaks reported in the workplace – arm category may include cases related to shared living amongst farm staff. As such, some of these outbreaks may be more similar to outbreaks in congregate living settings.

- For additional information regarding outbreak setting type classification definitions, please refer to Table 1 in the Appendix. Some outbreaks may be misclassified due to lack of information to assist with the manual classification process.

- All outbreaks reported as confirmed in CCM plus were included in these analyses regardless of whether the case data in CCM plus supported the outbreaks' classification.

- Due to reporting delays and potential variations in data entry processes across public health units, there may be additional COVID-19 cases that have not yet been entered in CCM plus, or have not been entered as linked to an outbreak. As such, some outbreaks may have zero linked cases as of the data extraction date. Results should be interpreted with caution due to potential under-detection of outbreak associated cases.

- The data only represent cases reported to public health units and recorded in CCM plus. As a result, all counts will be subject to varying degrees of underreporting due to a variety of factors, such as disease awareness and medical care seeking behaviours, which may depend on severity of illness, clinical practice, changes in laboratory testing, and reporting behaviours.

- Lags in CCM plus data entry due to weekend staffing may result in lower case counts than would otherwise be recorded.

- Outbreak-associated cases do not include secondary cases acquired from outbreak-associated cases.

- The data for these settings are restricted to those in which an outbreak was declared by the public health unit. They do not include cases linked to these settings as an exposure.

- Cases with unknown or missing ages were excluded from age-specific analyses.

- Only cases meeting the confirmed case classification as listed in the MOH COVID-19 case definition are included in the report counts from CCM plus.[4] This includes persons with a positive detection of serum/plasma immunoglobulin G (IgG) antibodies to SARS-CoV-2, which was added to the confirmed case definition on August 6, 2020.

- Cases of confirmed reinfection, i.e., where genome sequencing indicates the two episodes are caused by different viral lineages, added to the confirmed case definition on November 20, 2020, are counted as unique investigations.

- Case reported week uses the date the case was reported to the public health unit.

    - Outbreak reported week uses the date the public health unit reported the outbreak. If this date is unavailable, the date the public health unit created the outbreak is used.

    - Reported weeks were created to align with the Public Health Agency of Canada (PHAC) influenza surveillance weeks.

- ‘Cases associated with school outbreaks’ include cases that are linked to an outbreak, by school classification type (Elementary, Elementary/Secondary, Secondary, Post-Secondary), that met the definition of a school outbreak.

- School classification types are defined by the Ministry of Education. Some schools classified as secondary may also have an intermediate school in the same location that start in Grade 7.

    - Elementary/Secondary schools include public or private schools educating children in a combination of elementary and secondary grades (e.g., Kindergarten to Grade 8, Grades 9 to 12, and Kindergarten to Grade 12).

- School outbreaks include outbreaks declared on or after week 36 (August 30 to September 5, 2020).

- Hospitalization includes all cases for which a hospital admission date was reported at the time of data extraction. It includes cases that have been discharged from hospital as well as cases that are currently hospitalized. Emergency room visits are not included in the number of reported hospitalizations.

- Deaths are determined by using the outcome field in CCM. Any case marked ‘Fatal’ is included in the deaths data. The CCM field Type of Death is not used to further categorize the data.

- Ongoing outbreaks are those that are reported in CCM plus as ‘Open’ and without a ‘Declared Over Date’ recorded. Closed outbreaks are ‘Closed’ or have a ‘Declared Over Date’ recorded in CCM plus or where the outbreak start date (determined by the onset date of first case, or if missing the reported date, or if missing the created date) is more than 5 months from the current date, even for outbreaks where the outbreak status value selected in CCM/iPHIS is 'OPEN'.

- Orientation of case counts by geography is based on the diagnosing health unit (DHU). DHU refers to the case's public health unit of residence at the time of illness onset and not necessarily the location of exposure. Cases for which the DHU was reported as MOH (to signify a case that is not a resident of Ontario) have been excluded from the analyses.

- COVID-19 cases from CCM plus for which the Classification and/or Disposition was reported as ENTERED IN ERROR, DOES NOT MEET DEFINITION, IGNORE, DUPLICATE, or any variation on these values have been excluded. The provincial case count for COVID-19 includes cases that are counted once across all systems from which the case data are obtained. Duplicate records may exist if these records were not identified and resolved prior to data upload to the Ministry.

Appendix A: Definitions of outbreak settings

Table A1. Definitions for various setting types including congregate care, congregate living, education, and other settings.

Setting type	Definitions
Congregate care	
Long-term care homes	A facility that provides care and services for people who no longer are able to live independently or who require onsite nursing care, 24-hour supervision or personal support. LTC Homes are governed under the Long Term Care Homes Act (LTCHA) and Ontario Regulation 79/10.
Retirement homes	A residential complex or the part of a residential complex, that is occupied primarily by persons who are 65 years of age or older, that is occupied or intended to be occupied by at least the prescribed number of persons who are not related to the operator of the home, and where the operator of the home makes at least two care services available, directly or indirectly, to the residents. Retirement homes are governed under the Retirement Homes Act, 2010, S.O. 2010, c. 11.
Hospitals	Any institution, building or other premises or place that is established for the purposes of the treatment of patients and that is approved under the Public Hospitals Act, R.S.O. 1990, c. P.40.
Congregate living	
Correctional facility	An institution established or continued under section 14, whether it is operated or maintained by the Ministry or by a contractor, but does not include a place of open custody, a place of secure custody, a place of temporary detention or a lock-up established under section 16.1 of the *Police Services Act*; ("établissement correctional"). Ministry of Correctional Services Act, R.S.O. 1990, c. M.22.
Shelter	A facility set up to provide for the needs of homeless people; often including temporary residence, food, sanitation and other forms of support.
Group Home/Supportive Housing	A home providing staff-supported residential accommodation in a group setting for special populations that need a supervised living environment. Common examples include children and youth in care, individuals with developmental or physical disabilities, individuals recovering from substance abuse, teenaged mothers, or victims of domestic violence.

Setting type	Definitions
Short-term accommodations	A short-term rental is all or part of a dwelling unit that is offered for accommodations for less than 28 consecutive days with or without payment. This includes but is not limited to bed and breakfasts (B&Bs), hotels and motels.
Congregate other	Other setting in which persons live in a group setting with shared amenities.
Education	
Child care	Facility that provides temporary care for or supervision of children and is operated under the Child Care and Early Years Act, 2014, S.O. 2014, c. 11.
School – Elementary	Elementary schools include a public or private school educating children in elementary (Kindergarten to Grade 8) grades
School - Elementary/Secondary	Elementary/ Secondary schools include a public or private school educating children in a combination of elementary (Kindergarten to Grade 8) and secondary (Grade 9 to 12) grades (e.g., K-12 combined).
School – Secondary	Secondary schools include a public or private school educating children in secondary (Grade 9 to 12) grades
School - Post-secondary	Educational facility offering the highest level of educational attainment including apprenticeships or trades certificate or diploma; general or vocational college, or other non-university certificate or diploma; university certificate or diploma below bachelor level; or a university degree.
Other settings	
Bar/restaurant/nightclub	A facility for socialization/entertainment where food and/or drinks may be served.

Setting type	Definitions
Medical/Health Service	A facility or business that provides health or medical services in a community or non-institutional setting. This includes but is not limited to doctors offices or clinics, wellness clinics, dental offices, and at home care.
Personal service settings	A facility that provides personal services including invasive services that is operated under the O. Reg. 136/18. (e.g. tattoo parlours, hair salons, tanning studios).
Recreational fitness	A facility that provides activities where the primary purpose of the activity is participation, with the related goals of improved physical fitness, fun, and social involvement.
Retail	A setting in which goods and/or services are sold to individual consumers for their personal use. This includes but is not limited to grocery stores, pharmacies, and shopping malls.
Culture and other recreation	A setting in which social gatherings take place, including places of worship, indoor and outdoor private events (including weddings and funerals), and other community gathering spaces.
Workplace – Construction	A workplace comprised of employees working on developing, maintaining or repairing residential and non-residential buildings, or parts within. Outbreaks and cases captured in this setting include outbreaks associated with construction worksites and may include offices related to the construction industry.
Workplace – Logistics	A workplace comprised of employees working in warehouses, transportation, shipping or postal services.
Workplace – Farm	A workplace comprised of an area of land and its buildings used for growing crops and/or rearing animals, including greenhouses.
Workplace - Food Processing	A food service establishment that is a commercial operation that processes food for human consumption, and provides processed food for sale and distribution to other business entities such as restaurants and grocery stores.
Workplace – Manufacturing	A workplace comprised of employees working at a production line, where labour and machinery are used to produce goods from raw materials and smaller components.

Setting type	Definitions
Workplace – other	Other places of employment including offices, banks, municipal services (e.g. fire station), and veterinary clinics, among others.
Unknown	Setting that cannot be classified due to missing or inadequate data.

Appendix B: Outbreaks across public health units

Table A2. Number of confirmed COVID-19 outbreaks reported between February 16, 2020 and December 26, 2020 by public health unit: Ontario

Public Health Unit Name	Abbreviation	Number of outbreaks
Algoma Public Health	ALG	2
Brant County Health Unit	BRN	45
Chatham-Kent Public Health Services	CHK	16
City of Hamilton Public Health Services	HAM	143
Durham Region Health Department	DUR	212
Eastern Ontario Health Unit	EOH	47
Grey Bruce Health Unit	GBO	14
Haldimand-Norfolk Health Unit	HDN	32
Haliburton, Kawartha, Pine Ridge District Health Unit	HKP	23
Halton Region Public Health	HAL	149
Hastings & Prince Edward Public Health	HPE	13
Huron Perth Public Health	HPH	32
Kingston, Frontenac, Lennox & Addington Public Health	KPL	26
Lambton County Public Health	LAM	25
Leeds, Grenville and Lanark District Health Unit	LGL	20
Middlesex-London Health Unit	MSL	109
Niagara Region Public Health	NIA	148
North Bay Parry Sound District Health Unit	MPS	6
Northwestern Health Unit	NWR	10
Ottawa Public Health	OTT	401

Public Health Unit Name	Abbreviation	Number of outbreaks
Peel Public Health	PEL	465
Peterborough Public Health	PTC	11
Porcupine Health Unit	PQP	11
Public Health Sudbury & District	SUD	18
Region of Waterloo Public Health and Emergency Services	WAT	192
Renfrew County and District Health Unit	REN	19
Simcoe Muskoka District Health Unit	SMD	110
Southwestern Public Health	OXE	51
Thunder Bay District Health Unit	THB	17
Timiskaming Health Unit	TSK	5
Toronto Public Health	TOR	969
Wellington-Dufferin-Guelph Public Health	WDG	114
Windsor-Essex County Health Unit	WEC	138
York Region Public Health	YRK	557

Note: Includes outbreaks that are ongoing and outbreaks that are no longer active. Geography is based on public health unit where the outbreak was declared. Not all settings were open during the reporting period due to provincial public health measures. There was one outbreak that involved cases from Ontario and outside of Ontario and was not assigned to a public health unit.

NEWS RELEASE

Ontario Returning 27 Public Health Regions to Strengthened COVID-19 Response Framework

Province Extending Shutdown and Stay-at-Home Order in Regions at Highest Risk

February 12, 2021
Health

TORONTO — In consultation with the Chief Medical Officer of Health, the Ontario government is transitioning twenty-seven public health regions out of the shutdown and into a revised and strengthened *COVID-19 Response Framework: Keeping Ontario Safe and Open* (the "Framework"). The four remaining public health regions, Toronto Public Health, Peel Public Health, York Region Public Health and North Bay Parry Sound District, will remain in the shutdown, and the Stay-at-Home order and all existing public health and workplace safety measures will continue to apply to these four public health regions.

"The health and safety of Ontarians remains our number one priority. While we are cautiously and gradually transitioning some regions out of shutdown, with the risk of new variants this is not a reopening or a return to normal," said Christine Elliott, Deputy Premier and Minister of Health. "Until vaccines are widely available, It remains critical that all individuals and families continue to adhere to public health measures and stay home as much as possible to protect themselves, their loved ones and their communities."

Based on a general improvement in trends of key indicators, including lower transmission of COVID-19, improving hospital capacity, and available public health capacity to conduct rapid case and contact management, the following public health regions will be moving back to the Framework on Tuesday, February 16, 2021 at 12:01 a.m. and will no longer be subject to the Stay-at-Home order:

Grey-Lockdown:

- Niagara Region Public Health

Red-Control:

- Chatham-Kent Public Health;
- City of Hamilton Public Health Services;
- Durham Region Health Department;
- Halton Region Public Health;
- Middlesex-London Health Unit;
- Region of Waterloo Public Health and Emergency Services;
- Simcoe-Muskoka District Health Unit;
- Southwestern Public Health;
- Thunder Bay District Health Unit;
- Wellington-Dufferin Guelph Public Health; and
- Windsor-Essex County Health Unit.

Orange-Restrict:

- Brant County Health Unit;

- Eastern Ontario Health Unit;
- Haldimand-Norfolk Health Unit;
- Haliburton, Kawartha, Pine Ridge District Health Unit;
- Huron Perth Public Health;
- Lambton Public Health;
- Ottawa Public Health;
- Porcupine Health Unit; and
- Public Health Sudbury and Districts.

Yellow-Protect:

- Algoma Public Health;
- Grey Bruce Health Unit;
- Northwestern Health Unit; and
- Peterborough Public Health.

Green-Prevent:

- Leeds, Grenville and Lanark District Health Unit; and
- Timiskaming Health Unit.

For North Bay Parry Sound District, Peel Public Health, Toronto Public Health and York Region Public Health, it is proposed that the shutdown measures and the Stay-at-Home order will continue to apply until at least Monday, February 22, 2021. Please visit Ontario.ca/covidresponse for the full list of public health region classifications.

After returning to the Framework, public health regions will stay in their level for at least two weeks at which time, the government will assess the impact of public health and workplace safety measures to determine if the region should stay where they are or be moved to a different level. Public health regions will move up through the levels, if necessary, based on the set indicators and thresholds outlined in the Framework.

Visitor restrictions for long-term care homes will once again apply to those homes in the public health regions that are in the Orange-Restrict level or higher. In addition, long-term care homes must implement enhanced testing requirements.

Recognizing the risk posed by new variants to the province's pandemic response, Ontario is introducing an "emergency brake" to allow the Chief Medical Officer of Health, in consultation with the local medical officer of health, to immediately advise moving a region into Grey-Lockdown to interrupt transmission. Local medical officers of health also have the ability to issue Section 22 orders under the *Health Protection and Promotion Act*, to target specific transmission risks in the community.

"While the trends in public health indicators are heading in the right direction, we still have work to do," said Dr. David Williams, Chief Medical Officer of Health. "Everyone is strongly advised to continue staying at home, avoid social gatherings, only travel between regions for essential purposes, and limit close contacts to your household or those you live with."

The Chief Medical Officer of Health will continue to consult with public health and other experts, review data, and provide advice to the government on the appropriate and effective measures that are needed to protect the health of Ontarians.

Quick Facts

- Find out what level and which regional public measures are in place for your area.
- On February 10, 2021, Hastings Prince Edward Public Health, Kingston, Frontenac and Lennox & Addington Public Health, and Renfrew County and District Health Unit moved to the Framework at the Green-Prevent level.

- To help stop the spread of COVID-19 and safeguard health system capacity, Ontarians are strongly urged to continue staying at home and limit trips outside their household and between other regions for essential reasons only, not to gather with individuals outside of their household, and to wear a face covering when within two metres distance of another individual who is not part of their household (both indoor and outdoor) or when required, with limited exceptions.
- Ontario has implemented a six-point plan to deal with the new variants of concern which includes mandatory on-arrival testing of international travelers, enhanced screening and sequencing, maintaining public health measures to keep people safe, strengthening case and contact management to track the spread of new cases, enhanced protections for vulnerable populations, and leveraging the latest data to inform public health decisions.
- To support the province's economic recovery, the government has updated the Framework to allow for a safer approach to retail. Limited in-person shopping in Grey-Lockdown zones will be permitted with public health and safety measures, such as limiting capacity to 25 per cent in most retail settings.
- Digital tools have been an important part of the provincial response to COVID-19. To date, almost 6 million self-assessments have been completed using Ontario's health screening tool to help Ontarians navigate their symptoms and decide on next steps. Now, revised and updated screening tools for workers/employees and customer/visitors will help keep Ontarians safe and healthy by pre-screening for symptoms before leaving for work or to visit a business as the province re-opens. The tools help workplaces and businesses meet screening requirements.
- To support the safe return of in-person learning, Ontario has introduced new measures to continue to protect students and staff against COVID-19 in the classroom.

NEWS RELEASE

Ontario Moving Three Regions to New Levels in the COVID-19 Response Framework

Province also adjusting capacity limits for some events in Grey-Lockdown

March 12, 2021
Health

TORONTO — On the advice of the Chief Medical Officer of Health, the Ontario government is moving three public health regions to new levels in the revised and strengthened *Keeping Ontario Safe and Open Framework*, including moving Lambton Public Health into Grey-Lockdown. Decisions were made in consultation with the local medical officers of health and are based on the trends in public health indicators and local context and conditions.

"The latest modelling suggests we are at a critical stage in our fight against this devastating virus, and that the actions we take now will help ensure people stay safe," said Christine Elliott, Deputy Premier and Minister of Health. "As we near completion of Phase One and prepare to rollout Phase Two of our vaccine distribution plan next month, we urge everyone to continue following all public health measures and advice to help prevent further transmission and protect our health system capacity."

Based on the latest data, the following three public health regions will be moving from their current level in the Framework to the following levels effective Monday, March 15, 2021 at 12:01 a.m.:

Grey-Lockdown

- Lambton Public Health

Red-Control

- Northwestern Health Unit

Yellow-Protect

- Leeds, Grenville and Lanark District Health Unit.

In addition, effective today at 12:01 a.m., the government, on the advice of the Chief Medical Officer of Health, activated an "emergency brake" in the Public Health Sudbury and Districts region, moving it to the Grey-Lockdown level. The decision was made due to the concerning trends in public health indicators and in consultation with the local medical officer of health.

Please visit Ontario.ca/covidresponse for the full list of public health region classifications.

On the advice of the Chief Medical Officer of Health, the province is also adjusting capacity limits for weddings, funerals, and religious services, rites or ceremonies held in regions currently in the Grey-Lockdown level of the Framework. Effective Monday, March 15, 2021 at 12:01 a.m., weddings, funerals, and religious services, rites or ceremonies will be permitted to allow for up to 15 per cent total occupancy indoors, or up to 50 people outdoors.

"While the data shows that Ontario's vaccine rollout is helping to save lives, the next few months are critical" said Dr. David Williams, Chief Medical Officer of Health. "We all must remain vigilant and continue following public health advice and measures to prevent transmission, as variants of concern are continuing to become more prevalent throughout the province and threaten to undue all of the positive gains we have all worked so hard to achieve."

The Chief Medical Officer of Health will continue to consult with public health and other experts, review data, and provide advice to the government on the appropriate and effective measures that are needed to protect the health of Ontarians.

Quick Facts

- Find out what level and which public health and workplace safety measures are in place for your area.
- From March 3 to 9, 2021, Lambton Public Health's case rate increased by 30.9 per cent, to 110.0 cases per 100,000 people, well above the provincial average. During the same period of time, the number of COVID-19 hospitalizations in the region have increased by 33.3 per cent.
- Based on the latest modelling data, Ontario's vaccine rollout is making a positive difference and helping to save the lives of some of our most vulnerable, however, the rate of decline in the number of new cases and positivity rates are showing signs of slowing down. As variants of concern continue to spread throughout the province, the number of patients requiring hospitalization and intensive care will likely rise once again if public health measures are not followed by all Ontarians.
- To help stop the spread of COVID-19 and safeguard health system capacity, everyone is strongly urged to continue staying at home and limit trips outside their household and to other regions for essential purposes only, and not to gather with individuals outside of their household. In addition, people are required to wear a face covering when within two metres distance of another individual who is not part of their household (both indoor and outdoor), with limited exceptions.
- Local medical officers of health continue to have the ability to issue Section 22 orders under the Health Protection and Promotion Act, and municipalities may enact by-laws, to target specific transmission risks in the community.
- Healthy people are essential for a healthy economy. On March 24, 2021, the government will release the 2021 Ontario Budget. It will focus on protecting people's health, with a plan to defeat COVID-19, and provide support for people and jobs.

Additional Resources

TORONTO -- Ontario Finance Minister Rod Phillips has resigned from his key role in cabinet over his secret vacation to a luxurious Caribbean island as the COVID-19 pandemic ran rampant in the province.

"Today, following my conversation with Rod Phillips, I have accepted his resignation as Ontario's Minister of Finance," Ontario Premier Doug Ford said in a statement.

"At a time when the people of Ontario have sacrificed so much, today's resignation is a demonstration that our government takes seriously our obligation to hold ourselves to a higher standard," he said.

Related Stories

- **Ford admits he knew of Ontario finance minister's vacation two weeks ago, regrets not asking him to return**
- **Ontario's finance minister apologizes after leaving country for personal trip earlier this month**

The Ajax MPP left for St. Barts, a tiny, 10,000-inhabitant island known as a hideaway for yachts and boutique luxury hotels, on Dec. 13, calling the decision a "dumb, dumb mistake."

"It was a significant error in judgment – a dumb, dumb mistake, I apologize for it, I regret it," he told CP24's Steve Ryan at Pearson International Airport upon his return on Thursday morning.

He said that he could not really explain why he went ahead with the trip at the time that he did.

“I have been asking myself that same thing over the last number of days,” he said

With his departure, Treasury Board President Peter Bethlenfalvy has been tapped to assume the role of minister of finance in addition to his existing duties.

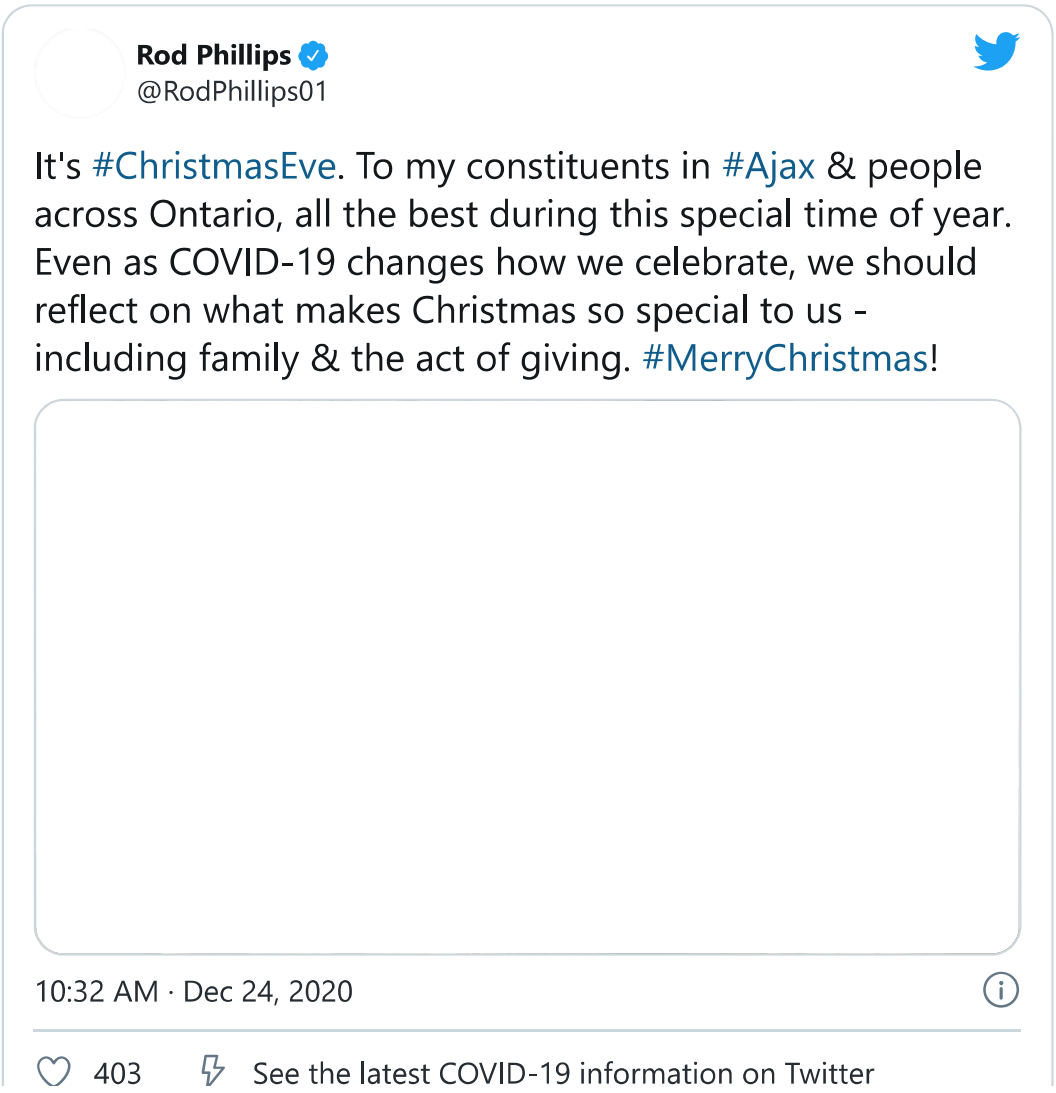
He will be the Ford government's third finance minister in as many years.

"I know that important work will continue and I wish Minister Bethlenfalvy all the best as he takes on this additional responsibility," Phillips said in a statement released after his resignation was made public.

"I would like to thank my family, political staff and the officials at the Ministry of Finance."

His office released a plethora of tweets and Instagram posts during the time he was away, including one where he sat next to a gingerbread house and a glass of eggnog and thanked healthcare workers dealing with packed hospitals, as “we all make sacrifices this Christmas.”

Many of the posts made it appear as if he was in his riding when he was not.



Phillips said it was not his intention to deceive anyone about the trip when he sent the videos, tweets and Instagram posts.

"I understand why some people believe that is the case but it is not – many politicians, in fact most politicians pre-plan and pre-load messages on social media," he said.

But he said the messages may have made it look that way given where he was and he knows the public is upset.

"I do understand that I have angered many people – I have to work to regain their confidence."

In a Zoom call Phillips participated in while he was away, first pointed out by the Ontario Liberal Party, the sound of the ocean tide crashing into the beach can be heard when he unmuted himself to speak.

Ontario Liberal Party | Parti Libéral de l'Ontario
@OntLiberal

.@RodPhillips01 are those waves we hear behind your Queen's Park Zoom background? This is disgraceful, and Ford knew about it for two weeks.
#onpoli

Date: Dec. 16, 2020

Ontario's two top public health officials both expressed concerns about foreign travel at the time he departed for the vacation.

The federal government has also been warning Canadians not to embark on non-essential travel since early November.

Ford said Wednesday he wasn't told about the trip ahead of time, but did learn about it shortly after it began, and should have demanded Phillips return immediately.

Phillips said that he didn't tell Ford about the trip because the Premier has better things to do.

"Premier Ford has far more important things to do than worry about the travel of his ministers," he said.

Ford has said it's "unacceptable" for any public official to ignore the province's COVID-19 guidelines, which urge residents to avoid non-essential travel.

Phillips said earlier this week he chose to go ahead with the trip not knowing the province would be placed under lockdown on Boxing Day.

In an interview with CP24 on Thursday afternoon, Liberal Leader Steven Del Duca said that the incident is yet another example of the Ford government failing to "lead by example."

"He clearly undermined the confidence that the people of Ontario had in him but there is a much bigger question for me and I think for everyone living in this province and that is the fact that Doug Ford has not held himself and his members of caucus and cabinet to the same level of accountability, not just in this case but all the way through this pandemic," he said.

"From Doug Ford going up to his cottage when he told the people of Ontario not to, him celebrating Mother's Day with his family when he told the rest of us not to, his MPP Sam Oosterhoff from Niagara gathering without proper physical distancing and boasting about it on social media and now Rod Phillips."

Ontario NDP leader Andrea Horwath also released a statement on Thursday in which she pointed out that Ford "knew about Rod Phillips' trip to St. Barts two weeks ago."

She said than rather than asking for Phillips resignation then, Ford "helped him keep the trip a secret."

"Phillips' resignation from cabinet today is not because of Phillips' vacation, it's because they got caught," she said.

Phillips will remain in the Progressive Conservative caucus as the MPP for Ajax.

His salary will decline from $165,450 to $116,500.

He will now self-isolate until Jan. 13.

Hospital CEO resigns from Ontario COVID-19 advisory table after holiday trip to Dominican Republic

BY NEWS STAFF

Posted Jan 5, 2021 10:01 pm EST Last Updated Jan 6, 2021 at 5:54 am EST

CEO of St. Joseph's Health System Dr. Tom Stewart. Photo credit: https://sjhs.ca/

The CEO of St. Joseph's Health System and Niagara Health, Dr. Tom Stewart, has resigned from Ontario's COVID-19 advisory board after travelling to the Dominican Republic over the holidays.

A statement from the Senior Vice President of St. Joseph's Brian Guest said Stewart had been approved for vacation from Dec. 18 and Jan. 5 and during that time, he travelled to the Dominican Republic.

Stewart said he "regret[s]" this non-essential travel and apologized. "I recognize everyone should be avoiding non-essential travel now, including me."

> "As a health system leader, my actions in no way reflect the tireless dedication and commitment of the staff at St. Joseph's Health System, who continue to live the legacy of our organization every day," said Stewart in the statement.

He is currently self-isolating at home for two weeks.

St. Joseph's Health System is made up of several different health sites in Niagara, Hamilton, Brantford, Kitchener & Guelph.

RELATED: Here's a list of politicians who travelled abroad despite pandemic era advice to stay home (https://www.680news.com/2021/01/03/heres-a-list-of-politicians-who-travelled-abroad-despite-pandemic-era-advice-to-stay-home/)

Deputy Minister of Health Helen Angus release a statement late Tuesday night saying she had accepted his resignation from the Ontario COVID-19 Science Advisory Table, the LTC Incident Management System Table and the Health Coordination Table,.

> "The people of Ontario have made countless sacrifices during the pandemic and it remains critically important that everyone continues to follow public health advice," read the statement.

In March, the Ministry of Health welcomed Stewart to the government's Command Table that was set up to provide strategic direction to the province about the novel coronavirus outbreak.

A number of politicians have recently admitted to leaving the country over the December holiday period, even as their constituents adhered to public health guidance meant to curb the spread of COVID-19, including Ontario Finance Minister Rod Phillips who has since resigned from his role.

The federal and provincial government have both repeatedly asked Canadians not to travel abroad during the pandemic and urged citizens to avoid gathering with family outside their household over the holidays.

Earlier Tuesday, Prime Minister Justin Trudeau expressed disappointment in federal and provincial politicians who have travelled abroad, despite months of recommendations against non-essential travel.

KITCHENER -- Downtown Kitchener is getting a temporary festive makeover as a Canadian film crew arrives to shoot a movie.

Crews will start shooting "Loving Christmas" on Monday at the corner of King and Queen streets. The shoot is expected to continue through Friday.

The city said that it expects minimal disruption for residents and businesses in the area. On Monday, for example, the sidewalk closest to Queen Street will be closed.

- **'Best wishes, warmest regards': Ont. motel featured in 'Schitt's Creek' up for sale**
- **Late night hosts return to filming their shows remotely due to surging COVID-19 cases**

Under its stay-at-home order, the provincial government allows film and television production to go ahead, the city said in a news release.

Crew members must follow certain COVID-19 safety guidelines, which the city said were developed by the Ontario Ministry of Health and the film industry.

Some of these measures include having an on-site COVID-19 officer, daily testing, enhanced cleaning, the use of masks and physical distancing on sets and medical-grade air purification systems when working indoors.

The province stopped both film and television production in Ontario for several months last year as it worked to get the first wave of the pandemic under control.

The Ontario government allowed those activities to restart on June 12.

Wilmot Township anti-racism rally in response to 'White Lives Matter' march sees no opposition

Heather Senoran
CTV News Kitchener Videographer

BADEN -- Despite being organized in response to an anticipated "White Lives Matter" march, an anti-racism rally in Wilmot Township saw no opposition on Saturday.

Roughly 50 people could be seen at Castle Kilbride around noon with signs that displayed inclusive and anti-racism messages.

Aashay Dalvi, an organizer the rally, was met with a different message at the very same location a year ago.

Related Stories

- **Anti-racism rally planned in Wilmot Township amid posters promoting 'White Lives Matter' parade**

"They told me I need to go back to my country," said Dalvi. "Told me I look like a monkey."

Dalvi and others planned the rally after a poster circulated in Wilmot Township promoting a "White Lives Matter" march scheduled for May 8.

"Oppression continues to exist," said Dalvi. "The posters are evident of that."

Karen Redman, the chair of the Region of Waterloo, says the timing for any kind of in-person gathering isn't right.

"This is during a stay-at-home order," she said. "We still see a lot of COVID-19 being spread in the community, so that's a huge concern."

Organizers of the rally say there were volunteers going around to make sure everyone was properly spaced. There was also a PPE table out for anyone who needed it.

"White supremacy is a public health crisis," said Dalvi. "It is time we recognized it as it is."

Some at the rally say it was worth it to show up despite the current COVID-19 restrictions.

"As white people we need to recognize that and stop it out," one protester tells CTV News.

Redman acknowledges that racism exists in the region, and pointed to the anti-racism advisory committee meant to combat systemic racism.

"It has been community led and continues to inform both policies and practices within the region," she said.

Waterloo regional police were on site of the rally to monitor and ensure public safety and say that they will work with bylaw on potential charges under the reopening Ontario act.

Police add that the hate crime team is still working to find the people behind the posters.

Vigil held to honour 215 Indigenous children found at former residential school

a[illegible]ut 14 hours ago By: Aastha Shetty

1 / 3 The sound of drumming filled Victoria Park on Thursday evening during the vigil for the 215 children whose remains were recovered in a mass grave site at Kamloops Residential School. | Aastha Shetty / Kitchener Today

A deep rumble from the drum circle vibrated through Victoria Park Thursday, as people hummed and chanted in memory of the 215 Indigenous children whose remains were recovered at Kamloops Residential School.

Those children -- lost for years, were finally found last month, buried in a mass grave at the residential school.

The pain of the tragedy continues to ripple through the local Indigenous community, who placed pairs of shoes around the clock tower to help people visualize the severity of the finding. Attendees also placed toys and candles.

"We need people to know the magnitude of the situation," said organizer of the vigil, Jack Skye Forler.

"We are still facing ignorance, we are still facing discrimination, our communities are still being marginalized and this is the time everyone is starting to listen," they said. "We just need people to listen."

Forler said allies can help by lowering their flags, amplifying Indigenous voices and calling on the government to thoroughly search every residential property for mass grave sites.

"There are so many countless children who have perished in these schools and nobody knows where they are. Families were never notified. They never came home. It's completely obvious to us that there are these mass grave sites scattered across Turtle Island. So it's important to us that we bring these children home."

With deep emotion in their voice, Forler added they are speaking out for children who can't anymore -- and they want to tell all the children who have not been found yet that they are loved.

"It's emotional because I am sitting here and I am allowed to embrace my culture and I am allowed to grow my hair and I am allowed to be alive. But those children did not have the same fate as I did," they said.

"It's important that we get the message out and that people understand where we are coming from and understand the magnitude of the situation."

They noted Kitchener bylaw had contacted organizers in advance to inform them that bylaw officers will not be attending the event.

"As far as I am aware, we will not be worrying about tickets, but I do have a GoFundMe set in place if tickets do become a problem."

More than a hundred people were seen attending the vigil on Thursday.

TRINITY BIBLE CHAPEL IS OPEN SUNDAY (DV): YOU'RE INVITED!

By Jacob Reaume | January 22, 2021 | Tagged: *covid-19*

Dear Neighbours and fellow Ontarians:

I hereby cordially invite you to learn of the good news of Jesus Christ and experience the joy of Christian worship. We are opening the doors of Trinity Bible Chapel this Sunday when we will hold in-person Lord's Day services at both 9:00 AM and 11:15 AM.

Ten months have passed since our provincial government called us to shutdown our regular lives for fourteen days to flatten the curve. Since that time, officials and media have provided regular updates on case and death counts. As of today, 98.03% of Canadians have not tested positive for COVID-19 and more than 99.9499% of Canadians have not died of COVID-19.

While I see every death as tragic, I believe that life is much greater than avoiding a virus. We will never get this time back, and we are not guaranteed tomorrow. The focus on mitigating the risk of spreading this contagion has now superseded nearly every aspect of our lives. Commerce has slowed almost to a halt. Childhood education has been compromised. Families are forbidden from visiting each other. Weddings and funerals are impeded. Most importantly, as I pointed out in an earlier blog, the Christian Church is forbidden to exist in its most basic essence which is as a gathering.

People are lonely, afraid, despairing of life itself, and facing financial ruin, among many other deprivations and tribulations. This is all during the darkest and coldest season of the year. If ever our fellow Ontarians needed hope, it is now. Out of neighbourly love, I am personally openly inviting anyone and everyone to experience the hope of the Gospel and the warmth of Christian worship at Trinity Bible Chapel this Sunday during our two Lord's Day services at 9:00 AM and 11:15 AM.

I understand that some will libel me as selfish and unneighbourly for making this offer. Please note that as a disciple of Jesus Christ I am fully committed to both the Golden Rule and Christ's second greatest commandment: "So whatever you wish that others would do to you, do also to them, for this is the Law and the Prophets" (Matthew 7:12) and "You shall love your neighbour as yourself" (Matthew 22:39). Even as I am committed to obeying those commandments in faith, I am also committed to applying them in a way consistent with the teachings of Jesus.

Jesus visited the sick and lonely because He loves them. Jesus asks us to welcome the destitute because He is full of mercy. Jesus taught us to show hospitality to our neighbours because people need our presence. Jesus desires for us to gather together for worship because the church is a gathering. Jesus commands us to be together because He became a man to be with us. Not once did Jesus ever tell us to love our neighbours with saying, "Stay home. Stay safe." In fact, He completed His earthly ministry by commissioning His disciples to go into all the nations to teach people His way of mercy and love (Matthew 28:18-20). He did this amidst the scorn of effete and sanctimonious Pharisees who libeled Him and demanded His crucifixion in part for spending time with unclean sinners. Jesus commanded us to love our neighbours, and Jesus has sufficiently taught us how to love our neighbours by His Word and example.

Risking reputation and financial viability to offer eternal hope and warm Christian fellowship to a world in despair is an act of love that I am certain Jesus smiles on.

Some have suggested that the church is not being specifically targeted by our government, and therefore we must set aside Christ's command to meet for the sake of obeying the government's command not to meet. Do people not gather at *Walmart*, at *Costco*, on movie sets, and at the *Beer Store*? Is the mission of the church not more important than a bottle of whiskey at the *LCBO* or a bag of *Cheetos* at the *Dollar Store*, both entities being deemed "essential" while the church is deemed "unessential"? How can one say the church is not targeted when these establishments are full of people? In Daniel's time, King Darius decreed to "establish an ordinance and enforce an injunction" (Daniel 6:7) to cease public worship, irrespective of creed. Daniel openly and publicly resisted Darius under threat of being fed to lions (Daniel 6:10). In the end God vindicated Daniel (Daniel 6:25-28). Persecution by the state is generally not specifically targeted on Christians, but rather it targets those who dissent from state dogma. Christians have often found themselves under the ire of overreaching states, not because they are singled out, but rather because their allegiance to God transcends state doctrine. Nowhere does Scripture actually say Christians should only resist the state's imposition upon the church if the state is specifically targeting them. Rather, we have historically resisted when the state forbids what God commands or commands what God forbids. In this case, the state has forbidden the church from existing because the church is not less than a gathering. Obedience to God over the state is necessary.

Some are very much in line with that thinking, but they wonder when such resistance is necessary. Should it not only occur after a specific timeframe? We have now been under some type of government restrictions for ten months. Christ's public earthly ministry lasted roughly three years. We have been impeded by our government from fully discharging our duties for ten months now, almost one third of the time Christ spent publicly ministering to the crowds and to His disciples. I contend that that is far too long. I further contend that our government's timeline and our government's objectives in this effort can no longer be trusted. They regularly change deadlines of lockdowns ending even as they regularly change goals. "Hope deferred makes the heart sick, but a

desire fulfilled is a tree of life" (Proverbs 12:12). How many deadlines have they now missed since this all began? Eventually one needs to ask whether he can be considered reasonable and wise to continue believing their promises. The acceptable timeframe for compliance has come and gone.

Trinity Bible Chapel exists to glorify God by fulfilling the great commission in the spirit of the great commandment. The great commission to go into the whole world with His Gospel is in full effect and has not been put on hiatus by this lockdown. The great commandment to love our neighbours must be upheld. I am choosing to love our neighbours and fellow Ontarians by inviting whoever reads this to church Sunday. To the lonely, to the downcast, to the impoverished, to the hopeless, to the downtrodden. To the Christians wanting to worship. To the curious who wonder what the big deal is. To the skeptic who would like to see a smile. Do you need to be around people? Do you need to have your spirits lifted? Do you need help? Do you need hope? Do you need encouragement? Would you like some light in the darkness? We as a church are eager to serve you.

We have, since our founding, provided an essential service to our members and to our community. We intend to continue to proclaim in word and deed the mercy of our Saviour, the forgiveness of sins by the cross, and the hope of eternal life in Christ to a broken world. Please come. Please be welcomed. Please have hope. Please know that you are loved.

Sincerely,

Pastor Jacob B. Reaume

Sr. Pastor of Trinity Bible Chapel

P.S. Our Risk Mitigation Strategy to help prevent the spread of contagion will be in effect.

Section 3 – Statement on the sanctity of human life 5
Section 4 – Concerning religious separation 5
Section 5 – Concerning church membership 6
Section 6 – Gender roles 7

ARTICLE V: Amendments **8**

ARTICLE I: PURPOSE

The object of Trinity Bible Chapel ("TBC"), as set out in its Letters Patent, is to advance and teach the religious tenets, doctrines, observances and culture associated with the Christian faith. Specifically, the purpose and mission of TBC is to glorify God through the fulfillment of the Great Commission in the spirit of the Great Commandment (Matthew 28:19-20; Matthew 22:37-39).

ARTICLE II: PILLARS

At the outset of Trinity Bible Chapel, four pillars were established as the biblical priorities for this ministry.

1. Proclaiming the authority of God's Word without apology (Hebrews 4:12; 2 Timothy 4:1-5).
2. Lifting high the name of Jesus Christ in worship (John 12:32; 4:23, 24).
3. Believing firmly in the power of prayer (Ephesians 6:18; James 5:16; Jeremiah 33:3).

4. Sharing the good news of Jesus Christ with boldness (Ephesians 6:19-20; Romans 1:16; Matthew 9:36-38).

ARTICLE III: DOCTRINAL STATEMENT

THE SCRIPTURES

We believe the sixty-six books of the Old and New Testaments to be the full record of God's self-disclosure to mankind. Different men, while writing according to their own styles and personalities, were supernaturally moved along by the Holy Spirit to record God's very words, inerrant in the original writings. Therefore, those applying themselves to study its literal, historical-grammatical context can accurately understand God's Word. Scripture is fully trustworthy as our final and sufficient authority for all of life (2 Timothy 3:16-17; 2 Peter 1:20-21).

THE TRIUNE GOD

We believe in the one living and true God, eternally existing in perfect unity as three equally and fully divine Persons: the Father, the Son, and the Holy Spirit. Each member of the Godhead, while executing distinct but complementary roles in redemptive history, has precisely the same nature, attributes, and being, and is equally worthy of the same glory and honor and obedience (John 17:3; Matthew 28:19-20; John 1:1-4; Acts 5:3-4).

GOD THE FATHER

We believe God the Father created all things in six literal days for His glory according to His own will, through His Son, Jesus Christ. He upholds all things by the Word of His power and grace, exercising sovereign headship over all creation, providence, and redemption (Revelation 4:11; Colossians 1:17, Hebrews 1:1-3).

GOD THE SON

We believe that Jesus Christ, the eternal Son of God, moved by love in accordance with the will of the Father, took on human flesh. Conceived through the miraculous work of the Holy Spirit, He was born of the virgin Mary. He, being fully God and fully man, lived a sinless life and sacrificially shed His blood and died on the cross in our place accomplishing redemption for all who place their faith in Him. He arose visibly and bodily from the dead three days later and ascended into heaven, where, at the Father's right hand, He is now Head of His Body the Church, the only Savior and Mediator between God and man, and will return to earth in power and glory to consummate His redemptive mission (John 1:1, 14, 18; John 14:8-9; 1 Timothy 3:16; Acts 1:3, 9; Hebrews 7:25-26; 1 John 2:1).

GOD THE HOLY SPIRIT

We believe that the Holy Spirit, in all that He does, glorifies the Lord Jesus Christ during this age. He convicts the world of sin, righteousness, and judgment. He draws the unredeemed to repentance and faith, and at salvation imparts new spiritual life to the believer, bringing that person into union

with Christ and the Body of Christ. The Holy Spirit sanctifies, seals, fills, guides, instructs, comforts, equips, empowers, permanently indwells at salvation, and bestows spiritual gifts to the believer for Christ-like living and service (John 16:8; 13:15; Titus 3:5; Ephesians 1:22; 4:11-12; Romans 8:9-17; 12:4-8; 1 Corinthians 3:16; 12:4-5, 11-13, 19; Galatians 5:25; Hebrews 2:1-4; 2 Corinthians 12:12).

MANKIND

We believe that God created mankind—male and female—in His own image and likeness, free of sin, to glorify Himself and enjoy His fellowship. Tempted by Satan but in the sovereign plan of God, man freely chose to disobey God, bringing sin, death and condemnation to all mankind. All human beings therefore, are totally depraved sinners by nature and by choice. Alienated from God without defense or excuse and subject to God's righteous wrath, all of mankind is in desperate need of the Savior (Genesis 3:1-6; Romans 3:10-19; Romans 1:18, 32).

SALVATION

We believe that the Lord Jesus Christ died for our sins according to the Scriptures, as the substitutionary atonement in our place, and that salvation is found in none other than Jesus Christ. Before Creation, God chose those who would be saved and granted this unearned grace solely based on His sovereign good pleasure. Jesus Christ's death on the cross was the sole and complete payment for sins, fully satisfying God's righteous wrath, for each person that turns from sin in repentance and places his or her faith in Christ alone by grace alone. At salvation each person is made a new creation by the Holy Spirit, declared righteous before God, and secured as an adopted child of God forever. Genuine faith continues in obedience and love for Jesus Christ with a life eager to glorify God and persevere to the end (Romans 8:37-39; 2 Corinthians 5:17, 21; 1 John 2:4-6; Philippians 1:6; 1 Thessalonians 5:23-24).

THE CHURCH

We believe that upon placing one's faith in the Lord Jesus Christ as Savior, the believer is made part of the Body of Christ, the one universal Church, of which Jesus Christ is the Head. The Scriptures command believers to gather locally in order to devote themselves to worship, prayer, teaching of the Word, fellowship, the ordinances of baptism and communion, service to the local body through the development and use of talents and spiritual gifts, and outreach to the world to make disciples. Wherever God's people meet regularly in obedience to this command, there is the local expression of the Church under the watchful care of a plurality of elders. A church's members are to work together in love and unity, intent on the ultimate purpose of glorifying Christ (Ephesians 1:22-23; Acts 2:42-46; 1 Corinthians 14:26; Matthew 28:18-20; Ephesians 4:16).

BAPTISM AND COMMUNION

We believe Christian baptism is the immersion of a believer in water in the name of the Father, the Son and the Holy Spirit. It is an act of obedience and symbolizes the believer's faith in the crucified, buried and risen Saviour, the believer's death to sin, burial of the old life, and resurrection to walk in newness of life in Christ Jesus. It is a public testimony to the believer's faith in the final resurrection of the dead.

The Lord's Supper is the united commemoration, by believers, of Christ's death until He comes and should be preceded by a careful self-examination (Acts 2:41; Romans 6:3-6; 1 Corinthians 11:20-29).

MISSIONS

We believe it is the aim, duty, and privilege of every believer and local church fellowship to glorify God by responding as active participants in the Great Commission call of Jesus Christ to go and make disciples of all nations. We believe the primary focus and priority of this call is centered on efforts that establish, strengthen, and reproduce biblically-based churches, which will then plant churches that plant churches for future generations and God's glory (Matthew 28: 18-20).

THE INTERMEDIATE STATE

At death the soul separates from the body. Believers' souls pass into the conscious blissful presence of God until the resurrection when they will be reunited with their bodies to inherit their eternal reward. Unbelievers' souls pass into a state of conscious punishment until they are reunited with their bodies to face the final judgment (2 Corinthians 5:6-8; Philippians 1:23; 1 Thessalonians 4:13-18; Luke 23:43; Luke 16:24-26).

THINGS TO COME

We believe in and expectantly await the glorious, visible and personal return of the Lord Jesus Christ. The blessed hope of His return has vital bearing on the personal life, service, and mission of the believer. We believe in the bodily resurrection of both the saved and the lost. The lost will be raised to judgment and consciously experience eternal wrath in the lake of fire. The saved will be raised to eternal joy in the new heaven and new earth in the manifested presence of God (1 Thessalonians 4:13-18; Acts 1:3, 9; Hebrews 7:25-26; Revelation 20:11-15; Revelation 21).

ARTICLE IV: CHRISTIAN LIVING

SECTION 1 – CONCERNING CONDUCT

The Bible teaches that all believers are saints, set apart unto God and are thus called to live godly, obedient lives honoring Christ in all they do. As well they are responsible to live in such a manner as not to bring reproach upon their Saviour and Lord (Romans 12:1-2; 1 Peter 1:14-19; 2 Timothy 2:19; Titus 2) lest the Word of God be blasphemed (1 Timothy 6:1; Titus 2:5). As Christians we should obey the Word of our Lord, seek the things which are above, walk as He walked, and accept as our responsibility the duty and privilege of bearing the Gospel to a lost world (1 John 2:3; Colossians 3:1; Matthew 28:19-20).

A victorious and fruitful Christian life is possible only for those who have presented themselves wholly to Christ and walk by the power of the Holy Spirit, which all believers are called to do (Romans 12:1-2; Galatians 5:16; Ephesians 5:18; Romans 6-7).

SECTION 2 – STATEMENT ON MARRIAGE, GENDER AND SEXUALITY

We believe that God wonderfully and immutably creates each person as male or female. These two distinct complementary genders together reflect the image and nature of God (Genesis 1:26-27). Rejection of one's biological sex is a rejection of the image of God within that person.

We believe that the term "marriage" has only one meaning: the uniting of one man and one woman in a single, exclusive and lifelong union, as delineated in Scripture. We believe that God intends sexual intimacy to occur only between a man and a woman who are married to each other. We believe that God has commanded that no intimate sexual activity be engaged in outside of a marriage between a man and a woman (Genesis 2:18-25; 1 Corinthians 6:18; 7:2-5; Hebrews 13:4). Further, we reject the notion that two people of the same gender can marry each other; this is unnatural and evil before the Lord.

We believe that any form of sexual immorality (including but not limited to adultery, fornication, homosexual behavior, bisexual conduct, bestiality and use of pornography) is sinful and offensive to God (Matthew 15:18-20; 1 Corinthians 6:9-10; Ephesians 5:3).

We believe that in order to preserve the function and integrity of TBC as the local Body of Christ and to provide a biblical role model to the TBC members and the community, it is imperative that all persons employed by TBC in any capacity, or who serve as volunteers, agree to and abide by this Statement on Marriage, Gender and Sexuality (Matthew 5:16; Philippians 2:14-16; 1 Thessalonians 5:22).

We believe that God offers redemption and restoration to all who confess and forsake their sin, seeking His mercy and forgiveness through Jesus Christ (Acts 3:19-21; Romans 10:9-10; 1 Corinthians 6:9-11).

We believe that every person must be afforded compassion, love, kindness, respect and dignity (Mark 12:28-31; Luke 6:31). Hateful and harassing behavior or attitudes directed toward any individual are to be repudiated and are not in accord with Scripture nor the doctrines of TBC.

SECTION 3 – STATEMENT ON THE SANCTITY OF HUMAN LIFE

We believe that all human life is sacred and created by God in His image. Human life is of inestimable worth in all its dimensions, including pre-born babies, the aged, the physically or mentally challenged, and every other stage or condition from conception through natural death. We are therefore called to defend, protect and value all human life (Psalm 139.)

SECTION 4 – CONCERNING RELIGIOUS SEPARATION

Because of God's holy nature and the believers' high calling, Scripture teaches and commands personal and ecclesiastical separation from religious apostasy (2 John 7-11; Romans 16:17; Titus 3:10), from all worldly and sinful pleasures, practices, and associations (1 John 2:15-17; James 4:4; 2 Timothy 3:1-5), and from professing believers living in willful and unrepentant disobedience to the Word of God (2 Thessalonians 3:6, 14-15).

This does not include separation from unbelievers who need the Word of God and the Gospel of Jesus Christ (1 Corinthians 5: 9-13).

SECTION 5 – CONCERNING CHURCH MEMBERSHIP

The New Testament clearly indicates that groups of people who were followers of the Lord Jesus Christ identified themselves with and committed themselves to a particular local church body.

Therefore, in order to implement the principles of accountability and commitment to the local body of Christ, as defined in the New Testament and practiced in the early churches, TBC recognizes the need for a formal membership covenant. Membership at TBC is for all who are believers in the Lord Jesus Christ, have publicly been recognized as a believer through baptism by immersion in water, and are willing to submit to the authority of the local church (Matthew 16:19).

The New Testament expects believers to belong to a local church. Membership in a local church is good and proper in that it is the expression of fellowship, accountability and identification with a group of believers in the furtherance of the Gospel (Acts 2:42-46; Hebrews 10:25; 1 John 2:9-11; Ephesians 4:1-4).

Each member of TBC is required to sign and adhere to the following Membership Covenant:

> Having been brought by divine grace to repentance and genuine faith in the Lord Jesus Christ and to give ourselves completely to Him for the furtherance of His kingdom, and having been baptized by immersion upon our profession of faith in the name of the Father and of the Son and the Holy Spirit, we do now, relying on His gracious aid, solemnly and joyfully renew our covenant with each other.
>
> We will work and pray for the unity of the Spirit in the bond of peace.
>
> We will walk together in brotherly love, as becomes the members of a Christian church, exercise affectionate care and watchfulness over each other and faithfully admonish and entreat one another as occasion may require.
>
> We will not forsake the assembling of ourselves together, nor neglect to pray for ourselves and others. We will regularly participate together in the ordinance of the Lord's Supper.
>
> We will endeavour to seek the salvation of our family and friends.
>
> We will rejoice at each other's joy, and with tenderness, sacrificial love and sympathy bear one another's burdens and sorrows.
>
> We will seek to restore anyone who is caught in any transgression, while watching ourselves lest we too be tempted. We will seek the purity of the church by supporting restorative church discipline as it is taught in Scripture.
>
> We will seek, with God's help, to live carefully in the world, denying ungodliness and worldly lusts, and remembering that we have been buried by baptism and raised again from the symbolic grave, and so there is on us a special obligation now to lead a new and holy life.
>
> We will work together for the continuance of a faithful evangelical ministry in the church, as we sustain its worship, ordinances, discipline and doctrines.
>
> We will financially contribute regularly, cheerfully, willingly, and sacrificially to support the expenses and ministries of TBC, the relief of the poor, and the spread of the Gospel through all nations.
>
> We consent to and give TBC permission to take, keep and use photo or video images of us for the purposes of TBC, including promoting the church.

We will, under the Lordship of Christ, submit to and follow the elders as they care for our souls as men who will give an account.

If we leave TBC, we commit that as soon as possible, we will seek to unite with another Bible-believing church, where we can faithfully carry out the spirit of this covenant and the principles of God's Word.

We agree to live under and abide by the Constitution and By-Laws of Trinity Bible Chapel and the Elder-led governance structure they reflect.

May the grace of the Lord Jesus Christ, and the love of God, and the fellowship of the Holy Spirit be with us all. Amen.

We believe that every Christian should give of their means as God enables, as a positive command of Scripture and as an act of worship. Members of TBC should financially support the church regularly, sacrificially, willingly and gladly as God directs. The offering of one's resources to God through the local church is the normal and expected behavior of every Christian. Old Testament tithing is not required in the New Testament church but we believe that the giving of the first fruits of God's provision modeled in the Old Testament is a worthy pattern to be followed (Exodus 23:19; Deuteronomy 26:1-11; Proverbs 3:9; 1 Corinthians 16:2; 2 Corinthians 9:5-15; Matthew 6:19-21; Luke 12:34).

All members are required to regularly participate in services of the Church including Sunday worship service, prayer meetings and member meetings. Members are strongly encouraged to participate regularly in the small group ministry. Members who give reasons for absences to the satisfaction of the Elders shall remain members in good standing. Such reasons may include illness, military service, missionary work or schooling.

Members should financially support the Church regularly, sacrificially, willingly and gladly as God directs.

All members are expected to follow the commands and principles which are clearly taught in the Word of God and to demonstrate this daily in every area of their lives. Examples of disobedience to these commands and principles include illegal use of drugs, use of pornography, substance abuse, sexual immorality, homosexual activities, adultery, divorce, abortion and abuse of others.

SECTION 6 – GENDER ROLES

We believe that both Adam and Eve were created in God's image, equal before God as persons and distinct in their manhood and womanhood (Genesis 1:26-27, 2:18). Distinctions in masculine and feminine roles are ordained by God as part of the created order, and should find an echo in every human heart (Genesis 2:18, 21-24; 1 Corinthians 11:7-9; 1 Timothy 2:12-14). Adam's headship in marriage was established by God before the Fall, and was not a result of sin (Genesis 2:16-18, 21-24, 3:1-13; 1 Corinthians 11:7-9).

The Fall introduced distortions into the relationships between men and women (Genesis 3:1-7, 12, 16). In the home, the husband's loving, humble headship tends to be replaced by domination or passivity; the wife's intelligent, willing submission tends to be replaced by usurpation or servility. In the church, sin inclines men toward a worldly love of power or an abdication of spiritual

responsibility, and inclines women to resist limitations on their roles or to neglect the use of their gifts in appropriate ministries.

The Old and New Testaments emphasize the equally high value and dignity which God attached to the roles of both men and women (Genesis 1:26-27, 2:18; Galatians 3:28), and affirm the principle of male headship in the family and in the covenant community, the church (Genesis 2:18; Ephesians 5:21-33; Colossians 3:18-19; 1 Timothy 2:11-15).

Redemption in Christ aims at removing the distortions introduced by the curse. In the family, husbands should forsake harsh or selfish leadership and grow in love and care for their wives; wives should forsake resistance to their husbands' authority and grow in willing, joyful submission to their husbands' leadership (Ephesians 5:21-33; Colossians 3:18-19; Titus 2:3-5; 1 Peter 3:1-7). In the church, redemption in Christ gives men and women an equal share in the blessings of salvation; nevertheless, some governing and teaching roles within the church are restricted to men (Galatians 3:28; 1 Corinthians 11:2-16; 1 Timothy 2:11-15). In all of life Christ is the supreme authority and guide for men and women, so that no earthly submission-domestic, religious, or civil-ever implies a mandate to follow a human authority into sin (Daniel 3:10-18; Acts 4:19-20, 5:27-29; 1 Peter 3:1-2).

In both men and women a heartfelt sense of call to ministry should never be used to set aside biblical criteria for particular ministries (1 Timothy 2:11-15, 3:1-13; Titus 1:5-9). Rather, biblical teaching should remain the authority for testing our subjective discernment of God's will. The office of elder/pastor/bishop/overseer is scripturally reserved only for qualified men, not women. Within the church, women are not to serve in positions in which they exercise authority over men or in which they teach doctrine to men (1 Timothy 2:12). We desire to see qualified women serving in all positions within the church, except those which are specifically forbidden by Scripture.

ARTICLES III (Doctrinal Statement) and IV (Christian Living) do not exhaust the extent of our beliefs. The Bible itself, as the inspired and infallible Word of God that speaks with final authority concerning truth, morality, and the proper conduct of mankind, is the sole and final source of all that we believe. For purposes of TBC's faith, doctrine, practice, policy, and discipline, the elders are TBC's final interpretive authority on the Bible's meaning.

ARTICLE V: AMENDMENTS

On the rare occasion that amendments to this Constitution are needed, such amendments must be unanimously agreed upon by all the elders.

EXHIBIT X

in the Affidavit of
Jacob Reaume

Sworn before me this 4th day
of June A.D., 2021

A Commissioner for Oaths in and for Ontario

OUR $83,000 ACT OF WORSHIP

By Jacob Reaume | February 25, 2021 | Tagged: *covid-19*

On January 22, 2021, the Ontario Superior Court of Justice ordered that Trinity Bible Chapel and her elders not hold gatherings of more than 10 persons. Upon receiving the order, I invited the community to church on January 24:

> People are lonely, afraid, despairing of life itself, and facing financial ruin, among many other deprivations and tribulations. This is all during the darkest and coldest season of the year. If ever our fellow Ontarians needed hope, it is now. Out of neighbourly love, I am personally openly inviting anyone and everyone to experience the hope of the Gospel and the warmth of Christian worship at Trinity Bible Chapel this Sunday during our two Lord's Day services at 9:00 AM and 11:15 AM.

I noted, this was done in love for God and neighbour:

> Risking reputation and financial viability to offer eternal hope and warm Christian fellowship to a world in despair is an act of love that I am certain Jesus smiles on.

That's precisely what we did. Personally, I have never experienced a more palpable manifest presence of God's Holy Spirit during public worship than I did on that Sunday. Many others – I have lost track of how many – shared similar experiences. Pastor Will Schuurman recounted his experience of that Lord's Day on Twitter:

Pastor Will later posted this:

On Sunday, February 21, we baptized 13 individuals, some of whom traced their conversion to those weeks in January, especially January 24.

This week the Ontario Superior Court of Justice handed down our sentence for having church on January 24. The service cost us $83,000. That is our fine, and here is how it breaks down. Pastor Will and I each owe $5,000. Pastor Randy owes $4,000. Each of the other elders owe $3,000. The church itself owes $15,000. And we have been ordered to pay $45,000 to cover the legal fees of the Ministry of the Attorney General. The Ministry of the Attorney General claims their lawyers spent 104 hours to prosecute us for holding services on January 24 – charges for which we pled guilty. Evidently, the MAG was very motivated, and the prosecutors

worked tirelessly against our church. So that is a grand total of $83,000. These fines will not and cannot be appealed. They are final.

If you would like to help cover the costs please visit the Go Fund Me page that a member of our church setup (click here), but please note you will not receive a receipt for the Go Fund Me contributions. Money donated to the Go Fund Me can be used to cover all and any of these fines.

If you would like to make a larger contribution to our legal fund, you can donate to the church (click here and select legal fund), but please note that, while the church will provide a tax receipt, money donated to the church cannot be used to cover the fines of the individual elders or pastors. It can be used to cover church fines.

We remain grateful to the legal team at the Justice Centre for Constitutional Freedoms. They have been representing us *pro bono* throughout this ordeal. We ask that you please consider donating to them to support their ongoing advocacy for liberty (click here and select the "defending religious freedom" campaign).

We will pay $83,000 for having church on January 24. I could say it was the most extravagantly priced service I've ever held, but that would not be factual. Every service I've held has cost Christ His very own blood, which is worth infinitely more than any dollar amount.

I was heartened by something Pastor Steve Richardson recently pointed out. In reference to Matthew 26:6-13, he explained the anointing of Christ by Mary with the alabaster jar. The alabaster jar of ointment would have been worth the equivalent of a retirement savings. It was expensive, and that dear woman paid a lot of money for one quick act of worship. She thought Christ was worth it. The disciples, however, were "indignant, saying, 'Why this waste? For this could have been sold for a large sum and given to the poor?" Jesus defended her saying, "She has done a beautiful thing for me." Chief among the woman's accusers was Judas (John 12:4-5). The woman thought Christ was worth the money, but Judas thought He wasn't. She went down in history for doing good, but Judas was a traitor who would have been better off not being born.

On January 24, we worshipped Christ extravagantly at the price of $83,000. He is worth that and so much more. Our fine is nothing near what Mary spent on Jesus for her one quick extravagant act of worship. And we cannot compare it to the price of blood He paid so that we would worship Him. As we've sung many times:

> Were the whole realm of nature mine,
>
> That were a present far too small;
>
> Love so amazing, so divine,

> Demands my soul, my life, my all.

The most difficult thing to us is not the dollar value. Rather, we are troubled by how the court has perceived our actions as disrespectful. In his citation, the Honourable Justice noted the following:

> "The position of the Contemnors appears to be as follows: we will abide as long as this does not go on too long, and if it does, we may not comply."
>
> "There is no apology or demonstration of remorse for the conduct of the case. The Contemnors assert that they are conflicted. However, they do not apologize for their breach of this Order."
>
> "There was no sincere apology, and as I have noted, there was no apology at all."
>
> "The Contemnors reject the authority of the court by their actions."

To be absolutely clear, we respect the court and its authority. The Bible teaches us to honour all those in authority, and we do. But like all authority, the authority of our courts is derived. The court's authority comes from above. "Let every person be subject to the governing authorities. For there is no authority *except from God*, and those that exist have been *instituted by God*" (Romans 13:1). God has designed all authorities, courts included, as delegated powers. He has given them power, and that power must be held in high regard by all men.

Our offence is that we believe that God is our Supreme Authority, above and beyond all parliaments and courts. We agree with the preamble to the Canadian Charter of Rights and Freedoms, which reads, "Whereas Canada is founded upon principles that recognize the supremacy of God and the rule of law." God is supreme. Jesus Christ is the King of kings and Lord of lords, and, I add, He is the Judge of judges. His Law is the rule of all law.

Christians, throughout history, have often found themselves conflicted when earthly rulers order them to do what God forbids or forbids them from doing what God commands. In such instances, we must obey God over government. We believe that the church must meet. We further believe that Christ, not the government, has crown rights over the church and His worship.

The enemies of Christ prosecuted him before a court on the charge that Christ claimed supremacy over Caesar (John 19:12). In essence, they claimed He held Caesar's laws in contempt. The prosecutors won, and Christ was sentenced to crucifixion.

Early Christians suffered similar allegations. The message they preached was called "gospel" which means "good news." Their proclamation was contemptuous to Caesar. "Good news" or "gospel" was how the Empire announced the birth or ascension of an emperor. By calling the message of Christ "gospel" Christ's early disciples proclaimed that Christ is something better than Caesar.

Christ is the Emperor of emperors, and the gospel proclaims that He is supreme over all kings and lords. Furthermore, the early Church articulated the simple doctrinal statement that "Jesus is Lord" (1 Corinthians 12:3; Romans 10:9; Philippians 2:11). By saying that they were saying that Caesar is not lord. Saying "Jesus is Lord" and acting on it was considered treasonous. The Roman Empire was totalitarian, and it did not offer Christians the opportunity to conscientiously dissent from Caesar's claim as supreme lawgiver. For claiming that Jesus is Lord and with their proclamation of "gospel," the early Christians were tried in courts. The courts found them guilty so they paid.

If Caesar had left them alone to self-govern, he would have found them to be his best citizens. After all, the New Testament admonishes us to "Honour the emperor" (1 Peter 2:17). But Caesar demanded more than honour. He wanted first place in their lives, and that was something they could not give him. First place is reserved for Christ. Christ has purchased us by His blood, and therefore Christ, not Caesar, owns us.

On a smaller scale, we at Trinity Bible Chapel find ourselves in a similar place. Proclaiming the "good news" of stopping the spread of a virus, our lawmakers have made laws that forbid what God commands and command what God forbids. The Ontario Superior Court of Justice ordered us to comply with those laws. We didn't. Those laws violate our consciences because our consciences are held captive by Jesus. He is Lord, and He has the best good news. We acted on our consciences.

In our $83,000 act of worship, may King Jesus receive His crown rights and may He find a reward for His suffering.

If you would like to help cover the costs please visit the Go Fund Me page that a member of our church setup (click here), but please note you will not receive a receipt for the Go Fund Me contributions. Money donated to the Go Fund Me can be used to cover all and any of these fines.

If you would like to make a larger contribution to our legal fund, you can donate to the church (click here and select legal fund), but please note that, while the church will provide a tax receipt, money donated to the church cannot be used to cover the fines of the individual elders or pastors. It can be used to cover church fines.

We remain grateful to the legal team at the Justice Centre for Constitutional Freedoms. They have been representing us *pro bono* throughout this ordeal. We ask that you please consider donating to them to support their ongoing advocacy for liberty (click here and select the "defending religious freedom" campaign).

COURT FILE NO: CV-21-95-0000

ONTARIO SUPERIOR COURT OF JUSTICE

BETWEEN

THE ATTORNEY GENERAL OF ONTARIO

Applicant (Responding Party)

-and-

TRINITY BIBLE CHAPEL, JACOB REAUME, WILL SCHUURMAN, DEAN WANDERS, RANDY FREY, HARVEY FREY, AND DANIEL GORDON

Respondents (Moving Parties)

AFFIDAVIT OF CRAIG WILLIAMS
(Sworn June 4, 2021)

I, M. CRAIG WILLIAMS, of the [redacted] in the Province of Ontario, MAKE OATH AND SAY:

1. I attend church services at Trinity Bible Chapel, and as such have personal knowledge of the matters hereinafter deposed to, except where they are based on information and belief, in which case I verily believe them to be true.

2. I am 54 years of age and the married father of one teenage son, currently in grade 12. I reside in Cambridge, Ontario, and am presently on long-term disability, although I used to be an insurance salesman.

3. I have been a churchgoer for my entire adult life, and even attended Bible College, although I would not have considered myself “saved”. I think I was going through the motions and trying to come to terms with whether God could even love

someone like me (I grew up in an abusive home, and that has had long-term impacts).

4. Over the years, I have struggled with my mental health (one of the reasons for being on disability) and developed personally destructive behaviours, such as drinking, showing anger, watching pornography, and gluttony.

5. For the first nine months of the lockdown, I participated in online services with my regular church. The church did open within the capacity restrictions when that was permitted; however, they also enforced social distancing and masking, even during singing. My faith was weak already, and this didn't help.

6. In about late November, I saw a YouTube video with Pastor Jacob Reaume speaking at a rally. I was moved by his words. He preached "God first" and that really came through him and resonated with me in a way that is difficult to describe. My wife and I decided to start attending his church, even though it was a bit of a drive from our home.

7. The improvement in my life since attending Trinity Bible Chapel has been dramatic. I have lost 30 pounds, and have stopped drinking and using pornography. My wife and I are in a very good place in our marriage. I've started writing again (I was a published author a decade ago) and feel renewed purpose in my life.

8. I am in the process of becoming a member at Trinity Bible Chapel, and hopefully will have completed the necessary steps by September. On February 21, 2021, I was baptized at TBC with great joy and celebration. I am finally saved.

9. Attending church in person has been so important for me personally, psychologically and spiritually, and for my marriage too. But for my teenage son, I believe that attending Trinity Bible Chapel in person has saved his life.

10. My son has been struggling with the lockdowns, the loss of his social connections, and worries about his future as a current grade 12 student. He advises me, and I verily believe, that even when attending school, the rules and restrictions have

been unnatural and unbearable. Most days, he could barely pull himself out of bed. As a parent, I wanted to be able to provide him with encouragement and hope, and I have tried to do that, but there seems to be no end in sight to these restrictions, even with the promise of vaccines. Hope was in short supply.

11. Last November or so, when my son was participating in an online youth group meeting with our former church, he apparently drew a picture of himself with a gun to his head. The youth pastor contacted the police, who arrived at our home. Our son was not deemed to be imminently at risk of suicide, so he remained in our home and we tried to work through his fears and hopelessness with him.

12. Then, in December, we all started going to Trinity Bible Chapel. We heard a genuine love for Jesus and his people in Pastor Jacob's message, and felt a deep connection to those around us in the service. When we go to church, we see people's faces, hug one another, sing praise to God. Fear and terror dissipate, and we are human again.

13. My son's mental state had improved immensely, thanks to being able to attend church and youth Bible studies in person. He had hope again.

14. When the court locked the church's doors on May 1, 2021, I attended the informal gathering in the church parking lot that day to sing and pray before the locks were changed. The police turned up and noted who was in attendance.

15. The following Monday evening, the police came to my home around 9 p.m. to hand deliver a ticket. Although the conversation was cordial, my son was badly shaken by it. He was unable to sleep, despite reassurance from his mother and me. It took a visit from Pastor Reaume to calm our autistic son down and help get him back to a semblance of normal.

16. We have been immensely grateful to Pastor Reaume and the Trinity Bible Chapel leadership. They have saved us in more ways than one.

17. To me, and to my family, it is utterly essential to our lives—physically, mentally, spiritually, and emotionally—to be able to assemble together for worship with other Christians and to practice our faith fully as God commands.

18. I swear this affidavit *bona fide*, in support of the motion, and for no other or improper purpose.

SWORN REMOTELY by videoconference by Craig Williams at the [redacted] before me at the City of London, in the County of Middlesex, this 4th day of June, 2021 in accordance with O.Reg. 431/20 Administering Oath or Declaration Remotely

A Commissioner, etc.

THE CHURCH OF GOD (RESTORATION) AYLMER, HENRY HILDEBRANDT, ABRAM BERGEN, JACOB HIEBERT, PETER HILDEBRANDT, SUSAN MUTCH, ELVIRA TOVSTIGA and TRUDY WIEBE

Respondents

AFFIDAVIT OF HEINRICH HILDEBRANDT
(Sworn June 4, 2021)

I, HEINRICH (HENRY) HILDEBRANDT, of the [redacted] in the Province of Ontario, MAKE OATH AND SAY:

1. I am one of the Respondents herein, and as such have personal knowledge of the matters hereinafter deposed to, except where they are based on information and belief, in which case I verily believe them to be true.

2. I am the pastor at The Church of God ("**the Church**"), located in Aylmer, Ontario, and have held that position since April of 1993. The Church is a not-for-profit non-denominational religious organization, incorporated in 1992. I was born in Mexico and immigrated to Canada in 1985, becoming a Canadian citizen in 1989. I have been married since 1982 and have two adult sons.

3. The other personal Respondents are elders or former elders of the Church.

4. Since its inception, the Church has been the spiritual home for a congregation comprised mainly of small-town and rural parishioners, many of whom come from a Mennonite background and speak Low German. The congregation currently numbers approximately 260 people. Our facility can safely house over 400 people.

5. Church is not merely a Sunday morning event for our congregation. It is a way of life for us, as a traditional community. We would normally hold full services at least three times per week (Sunday mornings and evenings, and Wednesday evenings) as well as prayer services on Saturdays. We operate a school in our building and our parishioners have always used it as a sort of community centre. It was the home base for social events, support groups, BBQs and soccer nights. Our church members dress in distinctive plain and modest clothing, which is also a reflection of how central to our way of life the Church is.

6. Given the demographics of my parishioners, and the fundamental importance to my congregation of communal worship, it has been of utmost importance to me as their pastor to at least bring them together for one worship service per week throughout the lockdown, and I tried to do so creatively while honouring the government's restrictions from the outset.

Initial Response to Covid-19 and Government Restrictions

7. On or about March 17, 2020, the Ford government declared a state of emergency due to the outbreak of Covid-19 and began issuing unprecedented lockdown orders.

8. On March 24, 2020, we learned through an Order in Council that church was not essential, as the cabinet ordered the closing of "non-essential" businesses and institutions, including churches and other faith settings. The Church initially abided by these restrictions.

9. On Sunday, April 12, 2020, which was the Christian holy celebration of Easter, and by then nearly a month into the lockdown, we held a small "drive-in" sunrise service at the

Church. We followed the guidance from Saskatchewan, which had just permitted drive-in services as along as certain rules were followed.

10. We had prepared official signage instructing congregants to remain in their vehicles with the windows rolled up, and not to leave their cars or enter the church building for any reason. The signs were placed along the driveway into the church, and in prominent locations around the parking lot. A platform was built overlooking the parking lot, with markings to show where up to five different members of the worship team would stand – each 2 meters apart. We purchased and set up an FM low-frequency broadcast system to deliver our own service to the car radios of each attendee. We did not collect offerings, nor did we encourage or require anyone to roll down their windows. To our knowledge, none did, nor did they exit their vehicles.

11. While we were in the parking lot, two Aylmer Police constables came by to speak with us in a very friendly manner. Constable Nelson DaCosta said that this seemed to be an innovative way to do church. He and Constable Jordan Babb advised that it was not necessary to space out the vehicles, and that we could use the entire parking lot. Constable DaCosta asked us to let him know if we were planning to do this again.

12. With the blessing of police, the encouragement of my congregation, and having conducted a successful and safe service, I decided to continue with the drive-in services. Unfortunately, someone in the community took a photo of the vehicles in the parking lot and made a post on Facebook about it, leading to complaints to police.

13. Rather than assure those who complained that the Church and I were not breaking any laws and were not in fact “gathering” as prohibited under the order, since congregants never left their personal vehicles, the Police chose to crack down. I am advised by my son, Herbert Hildebrandt, and verily believe that Inspector Nick Novacich called him on April 22, 2020 to advise that we were not to proceed with a further service, or that I and my parishioners would face tickets of $750 or other penalties of up to $100,000 and a year in jail.

14. In a statement released publicly on April 24, 2020, Aylmer Police Chief Zvonko Horvat advised that, after consultation with county prosecutors, “it has been determined that this gathering is in violation of the EMCPA and that those attending could be subject to facing charges for failing to comply with an order during a declared emergency.” The Chief went on to state, “We would like to assure our residents that this is an active investigation and we will be monitoring all faith based groups in our community to ensure that these Emergency Orders are being followed. Those who do not adhere to these orders will result in the Aylmer Police taking enforcement action.” Attached hereto and marked as **Exhibit “A”** to this affidavit is a copy of the Chief’s statement, as posted on Facebook on April 24, 2020.

15. This was the genesis of a toxic relationship in the Town of Aylmer, between our Church, which was trying to meet the needs of our congregation in a completely safe manner, the police chief, who chose a heavy-handed approach to dealing with churchgoers, and some townspeople, who behaved like Stasi informants as they regularly harassed our Church and monitored us every Sunday, looking for any transgression and calling in complaints to the police.

16. All of this forced my congregants and the Church leadership into a difficult bind – we were made to choose between our peaceful Christian deference to authorities, and the exercise of our fundamental freedoms of peaceful assembly and religion, since it is our sincerely held religious belief that we are called to regular communal worship.

17. Efforts to resolve the matter of drive-in services through discussion with the Police Chief and our local Member of Provincial Parliament, as well as a legal demand letter, proved unsuccessful. In a statement I posted to the Church website, I noted, “Liquor stores are considered essential and their parking lots are not under any scrutiny. Liquor is essential, but God is not? Drive-thru establishments are under no threat of closure and their parking lots are regularly filled with customers looking to have a chat with their friends. We are not asking for special treatment or privileges, equality would be satisfactory.” Attached hereto and marked as **Exhibit “B”** to this affidavit is a printout of my statements and press releases on the Church of God of Aylmer website.

18. On April 25, 2020, I announced on our church website and social media that we would proceed to hold a third service on April 26, under threat of penalty. I condemned any show of force or resistance to police, stating “Christians are peaceful people and have always sought the opportunity for peaceful assembly, as guaranteed in the *Canadian Charter of Rights and Freedoms*.” The service proceeded without incident on April 26, and all congregants remained in their vehicles, with windows rolled up. Police attended on the property without a warrant and videotaped all of the parishioners and their vehicles during the Sunday service. The Police had advised by a public statement in advance that no tickets would be issued at the service, but the results of their investigation would be presented to a Crown Attorney to determine whether charges would be laid.

19. On April 30, 2020, I issued a press release on behalf of the Church, media interest having grown significantly in light of the public dispute. In it, I expressed gratitude to the police for their forbearance, and noted that this provided the Premier and his cabinet the opportunity to clarify their guidance surrounding drive-in services, as many other jurisdictions across Canada and the United States were then doing; however, the government failed to do so at that time.

20. In May of 2020, we commenced a constitutional challenge against the Aylmer Police and the Ontario government over the harassing and threatening behaviour concerning drive-in services. Shortly after the application was filed, Ontario amended the regulations to permit drive-in services. Attached hereto and marked as **Exhibit “C”** to this my Affidavit, is a copy of a news release from our lawyers, the Justice Centre for Constitutional Freedoms, detailing that information.

21. We did continue to meet with drive-in services until the Ontario Government announced that houses of worship would be permitted to open to 30% capacity, effective June 12, 2020. This was also the result of lobbying efforts by a coalition of faith leaders in which our lawyer, my son Herbert and the Church were involved.

22. Although we did make do with drive-in services, they are a poor substitute for in-person gatherings, as people are not able to partake of the Lord’s Supper or participate in

other important practices and ceremonies such as baptism, and cannot meaningfully interact with one another. Following the announcement that churches were able to open, we immediately switched back to in-person services, which was a great joy and relief to us.

23. At that time, we implemented public health protocols such as posting signs and making masks and sanitizer available. In conversation with the police, we established the appropriate capacity of the building and adhered to that limit. If people wanted extra space for physically distanced seating, that was made available in the overflow room. We also accommodated drive-in services for those who weren't yet ready to come in the building. And, as we had always done even before Covid, we reminded people to stay away if they or a family member were feeling unwell.

24. It was a wonderful blessing to our community to meet in person over the summer months. However, as the fall approached the government began making public comments about potential further restrictions. On September 28, 2020, our lawyer sent a letter to the Premier reminding him of our *Charter*-guaranteed right to freedom of peaceful assembly and worship, and the essential nature of corporate or communal worship for people of faith. Our lawyer asked that, at a minimum, places of worship remain open at 30% capacity. Attached hereto and marked as **Exhibit "D"** to this my Affidavit is a true copy of the letter.

25. On or about November 3, 2020, the Ontario Government abandoned its three-stage regime, and introduced a colour-coded system and some apparently objective benchmarks for imposing further restrictions on a regional basis. For each of the colours, including "red", houses of worship were to remain at 30% capacity.

26. It was not long before the Government changed gears again, and introduced a more restrictive "grey zone", modelled on the earlier Stage 1 restrictions. Toronto and Peel were the first areas to go back into the grey zone, which permitted houses of worship to only have ten (10) persons in attendance, regardless of building capacity, however that did not apply to us.

The Second Lockdown – Community and Police Hostility Grows

27. On December 21, 2020, the Premier announced that the entire province, regardless of case counts or the presence or absence of any crisis regionally, would begin a four-week lockdown on Boxing Day. Attached hereto and marked as **Exhibit "E"** to this my Affidavit is a copy of the province's news release.

28. On or about December 26, 2020, Ontario placed the entire province under a "shutdown", which severely restricted many of the activities of Ontarians, including their attendance at places of worship which were limited to a hard cap of 10 persons indoors, regardless of capacity. However, numerous businesses were granted exemptions, including but not limited to "big box" or discount retailers and liquor stores, provided they limited the number of persons inside to 25% of their building capacity; warehouses and distribution centres that support online retail (such as Amazon); various manufacturing facilities; construction activities; and fitness centres catering to "elite" athletes.

29. As a result of my early dispute with the police, which the media reported on widely, I become somewhat well known as a spokesperson for the importance of our *Charter* freedoms, and gave various speeches in person and online. In November, I was invited by a local couple to speak at a rally in Aylmer. This rally apparently angered many in the community, some of whom held a counter protest. Organized opposition and hostility toward me, my family and our Church began to pick up steam.

30. On December 27, we held a drive-in service in accordance with the law. Unfortunately, during the service some people had stepped out of their cars and the police, who were monitoring, charged my son Herbert with organizing a gathering over 10 people. The police called him over in the middle of the service. That was the first charge in relation to a service that anyone in our church had faced. We had worked very hard to try to comply over the preceding nine months, despite the hardships this entailed for our community.

31. On that Sunday, local community members held a full demonstration against us, which they called “Plague Rat Tour”. This “tour” started at the church, where at least 15 or more vehicles lined up along both sides of the highway in front of our church. Throughout our drive-in service, they honked their horns and blasted through a megaphone, trying to disrupt the service as much as possible. Although the police were in attendance, as they almost always were for our services, they left these protestors alone. Part way through the service, the protestors left and did a drive-by of the homes of our parishioners that they knew of, and others who were part of the “movement”, including the local couple who invited me to join their protest in November. Security camera footage, as well as advice from members of my congregation who had stayed home from church that day, informed me of this and I verily believe it to be true.

32. This community group, calling itself “Canadians Against Freedom Rallies and Misinformation”, has continued to harass me, my family and our Church. Posters with my face or my son’s have been plastered around the town, saying “Lock Him Up!” Attached hereto and marked as **Exhibit “F”** to this Affidavit are true photos of one depicting Herbert, and another poster affixed to a post with our church shown in the background. Both of these photos were taken by Herbert, and he advises and I believe them to be accurate depictions.

33. We continued with permissible drive-in services until January 24. At the conclusion of the service, we allowed people into the building for a “tour” and received charges for that.

34. The following week, on January 31, we joined other Ontario congregations in holding our service inside the Church as an act of civil disobedience. This resulted in the Attorney General obtaining an interim order on February 5, followed by a final order on February 12, enforcing compliance with the regulations. We reverted back to drive-in services for Sunday February 7 and 14.

35. From about February 16 until just before Easter Sunday, capacity for religious services in our region was at 30%. There were no charges laid for our indoor services during that period.

36. The Ford government reduced capacity again to 15%, just in time for Easter Sunday, the holiest day in the Christian calendar. This remained in effect until April 19, at which time (and continuing presently) the limit for religious services was further reduced to 10 people, indoors or out.

37. Ultimately, we as a church decided that we could no longer refrain from in-person services. We held a service on Easter Sunday, as well as the following Sunday.

38. On April 14, 2021, we were served through our lawyer with a Motion for Contempt by the Attorney General's office for the services held on April 4 and 11.

39. On April 18, we had police surveilling our property from the woods behind the building.

40. On April 20, I am aware that there was a gathering of fewer than ten people in a choir practice at the Church, while a business meeting occurred in another wing of the building, also with fewer than ten people. Our members were in compliance with the regulations, as far as I understood. The business meeting involved two police officers, who went outside when the Aylmer Police turned up. According to the CBC, police were tipped off by a complaint, which is typical. A heated exchanged occurred between the officers, and the off-duty police (from a different force) were charged. Attached hereto and marked as **Exhibit "G"** is a CBC article dated April 23, 2021.

41. After a brief adjournment, we were in court for the contempt proceedings on April 30, 2021, at which time Justice B.G. Thomas found church elder Peter Wall, the Church, and me guilty of contempt of his order of February 12, 2021.

42. On May 14, 2021, we returned for the sanctions hearing and were ordered to pay a total of $117,000 in fines and costs, payable within 90 days. The Sheriff was also ordered to lock our church doors.

43. Later that day, while we were in the Church holding a service, the Sheriff, a locksmith and numerous police officers arrived and entered the building. All parishioners were asked to leave, and did so in an orderly fashion. A video recording of the event was

taken by my son, Herbert, and posted to YouTube at this link: https://www.youtube.com/watch?v=WJbEl8XWak4

44. On May 16, we held an outdoor service on the lawn of the church, which attracted approximately 300 people. There was a police drone circling over the church. This was a greater number than usual.

45. We were then served on May 21 with a second Notice of Motion for a finding of contempt, with a hearing before Justice Thomas scheduled later that same day. A brief adjournment was granted to May 31.

46. We held outdoor services on May 23 and May 30, before returning to court on May 31, 2021. The services grew in size each week, as punitive measures by the government increased. During the service on May 30, I asked if anyone felt ready to commit themselves to Christ, and at least a dozen people, not normally part of our church, came forward. There was much tearful rejoicing as these individuals felt the power of God working in their lives and committed themselves to Christ. To me, this made every penny of every fine worthwhile.

47. On May 31, 2021, Justice Thomas again found the Church, church elder Peter Wall, and me in contempt of the court order of February 12, 2021. We were ordered to pay a total of $66,000 in fines and costs, forthwith.

48. The Church has now received about six charges, each with a maximum penalty of $10 million. I have personally received twelve charges, each carrying a maximum penalty of $100,000 and one year in jail.

49. Many of our members have been charged too. After one service, the police made late evening visits to their homes while it was dark outside to give them tickets.

50. We are under constant threat of more summonses, potential jail time, and are now locked out of our church building. The stress on our leaders and parishioners, as normally law-abiding citizens, cannot be overstated; although our commitment to following God's Word and our resolve to accept any punishment, including

imprisonment, fortifies us. To say that our *Charter*-guaranteed freedoms to worship, assemble, associate, and express ourselves have been infringed is an understatement.

51. While we met outdoors for peaceful religious services on May 16, many other gatherings likewise took place outdoors that weekend, including pro-Palestinian demonstrations. I am not aware of charges being laid. Indeed, the Prime Minister tweeted on May 16, 2021, that "Everyone has the right to peacefully assemble and express themselves freely in Canada…." Attached hereto and marked as **Exhibit "H"** to this Affidavit is a screenshot of the tweet.

52. To the best of my knowledge, information and belief, there have been no Covid outbreaks associated with the Church, despite our meetings and the very close observation of our church by local public health officials, police and the broader community. I have not buried a single person who has died from Covid.

53. Meanwhile, the nearby Police College has had at least three outbreaks, yet has argued that it should be permitted to continue with in-person learning. Attached hereto and marked as **Exhibit "I"** to this Affidavit is a copy of a newspaper article, dated March 15, 2021, containing this information which I believe to be true.

54. While the church could not legally meet, LCBO stores, marijuana dispensaries and many other businesses the government has deemed "essential" remain open.

Why We Continue to Meet

55. To our parishioners, church is indeed an essential service, and we believe it is not for the government to decide what is essential to us.

56. Although the Church of God is non-denominational, most of our congregants come from a Mennonite tradition, which has a long history of state persecution, societal disdain for its pacifism and way of life, and movement of its people from country to country in order to be able to worship in peace without unreasonable state interference.

57. Those of us now living in Canada place great trust in the *Charter of Rights and Freedoms* to protect our right to worship, assemble, associate and express ourselves freely, and have marched in many rallies over the last year to remind Canadians to treasure our inheritance of a free society.

58. As a pastor, ministering to my church and the broader community that has reached out to me over the last year, I verily believe that the government's unprecedented actions have harmed people and society by perpetuating loneliness, hopelessness, fear, poverty, division, anger, the deterioration of relationships.

59. The effect of these restrictions was a gross and substantial interference in the practice of our faith, individually and collectively. Our faith is fundamental to our lives. It is not a "non-essential" service – it goes to the core of who we are as Christians.

60. We, being myself and the Church's membership and leaders, are bound by our faith to gather for corporate worship, and to engage in communal prayer, preaching, singing, and partaking of the Lord's Supper and other important rites. The government's restrictions have prohibited, limited, and punished us for worshiping as our faith and consciences require.

61. We sincerely believe that Scripture commands us to meet for worship in person, that the definition of "church" requires us to gather in person, and that the Law of God demands we gather at least weekly.

62. We are peaceful people. We do not desire conflict with government. In fact, we seek to avoid it and to live at peace with all people (Rom 12:18; 1 Tim 2:1; Heb 12:14). However, when the church is forced by the state to be closed (ten people permitted is essentially a closure) or drastically limited in attendance for such a protracted period with no clear end in sight, I believe the cost is simply too great to my parishioners, to my conscience and to the principles of a free society on which this country was founded.

63. I swear this affidavit *bona fide*, in response to these proceedings, and for no other or improper purpose.

SWORN REMOTELY by videoconference by Henry Hildebrandt at the [redacted] in [redacted] before me at the City of London, in the County of Middlesex, this 4th day of June, 2021 in accordance with O.Reg. 431/20 Administering Oath or Declaration Remotely

The Aylmer Police Service respects everyone's rights to peaceful assembly for freedom of expression, and religion. Our role throughout this CoVID-19 response is to maintain the health and safety of all the residents of Aylmer by ensuring that the Emergency Management Civil and Protection Act, O.Reg 52/20 is adhered to.

The *Emergency Management and Civil Protection Act* (EMCPA), was enacted by our Provincial Government on March 17th, 2020 and several emergency orders have been made under the Act to contain the spread of COVID-19 and to ensure that essential services continue to be provided and Ontarians are supported.

One of these orders that have been made under Ontario Regulation 52/20 states the following:

> SCHEDULE 1
> ORGANIZED PUBLIC EVENTS, CERTAIN GATHERINGS
> Prohibition
> **1.** (1) Subject to subsection (3), no person shall attend,
> (a) an organized public event of more than five people, including a parade;
> (b) a social gathering of more than five people; or
> (c) a gathering of more than five people for the purposes of conducting religious services, rites or ceremonies.
> (2) For greater certainty, subsection (1) applies to an event or gathering even if it is held at a private dwelling.
> (3) Subsection (1) does not apply to the following:
> 1. A gathering of members of a single household.
> 2. A gathering for the purposes of a funeral service that is attended by not more than 10 persons. O. Reg. 99/20, s. 3.

Last Sunday, April 19th, 2020 our communications centre received over (15) calls of reports that a certain Faith based group had gathered in a parking lot in their vehicles to listen to a service being delivered outside by their Pastor.

After consultation with our Elgin County Prosecutor(s), it has been determined that this gathering is in violation of the EMCPA and that those attending could be subject to facing charges for failing to comply with an order during a declared emergency.

We would like to assure our residents that this is an active investigation and we will be monitoring all faith based groups in our community to ensure that these Emergency Orders are being followed. Those who do not adhere to these orders will result in the Aylmer Police taking enforcement action.

Join us Sunday for a livestreamed service at 10:30 AM Eastern. An hour prior to the service, app.gospeltrumpet.com will go live with all the relevant links for audio and video feeds.

For those of you that would like to listen live in our parking lot, please review the instructions in the graphic below. These guidelines are not suggestions and we will strictly enforce them. You must be in a vehicle and remain in your vehicle at all times with your windows rolled up to park in the parking lot at any time. This includes all members of the congregation, visitors, and media.

Tune in to 87.9 FM to listen live to the broadcast within a 750 meter radius of our meetinghouse.

Alberta, Saskatchewan, Manitoba, and New Brunswick have all endorsed outdoor, drive-in services as allowable under their Emergency Acts, as well as California, Mississippi, Kentucky, Tennessee, Ohio, Kansas, Florida, and many other countries across the globe.

Ontario, now it's your turn. Cars in a parking lot are not gathering, they are parking. Gatherings are defined by physical presence without barriers.

PRESS RELEASES

RE: FREEDOM OF RELIGIOUS ASSEMBLY

April 30, 2020 – 14:00

We extend our gratitude to Canadians across the country that have prayed, called, emailed, commented, and messaged us this past week. The support and passion for freedom in this country has been overwhelming. God is sovereign and His Word will prevail. This nation was founded on the principles of religious freedom and peaceful assembly and we pray that we will enjoy these privileges for many years to come.

This afternoon, we received notice that the Aylmer Police Service will not proceed with charges for those that parked in our parking lot and tuned into the service that was broadcast last Sunday morning, as well as the persons that

conducted the service from our outdoor platform. We are grateful for that and believe it is the right decision. This allows the Premier and his cabinet the opportunity to swiftly provide clear enforcement directives pertaining to the Emergency Act that uphold public safety while respecting the right of people to express their faith in a safe manner. We continue to hope for a political resolution to this situation that does not put our local police in an unenviable position, and we thank the Aylmer Police for their continued service and protection to our community.

Provinces across Canada and countries around the globe are endorsing drive-in services as a temporary measure as it allows for an expression of community without violating public health objectives.

Pastor Henry Hildebrandt

RE: FREEDOM OF RELIGIOUS ASSEMBLY

April 25, 2020 – 17:00

This past week has been defined by an unexpected amount of upheaval for our faith community. As a matter of fact, it has been a moment of truth for Christians across Ontario and the country.

Last Sunday morning we held our second drive-in service in as many weeks, with the full approval, permission, and encouragement of the Aylmer Police Service. A follow-up call from a constable on Sunday afternoon confirmed no violations were observed by the officers present and that we were cleared continue to worship in this manner until this crisis abates.

Tomorrow morning, at 10:30, the Lord willing, we will hold our third drive-in service under the threat of hefty fines, disruption, and physical roadblocks by order of the Aylmer Chief of Police. We have attempted, unsuccessfully, to reach an acceptable compromise with him these past 6 days. Regrettably, he has allowed his judgement to be clouded by one inaccurate post on Facebook that generated hundreds of comments and 15 complaint calls to the police service (this post has since been deleted). Our offer to hire off-duty officers from the Aylmer force, to ensure compliance with the law, was unceremoniously dismissed. Unfortunately, the Chief has also decreed that his officers must enforce the law as he interprets it, recklessly abandoning the discretion and interpretation used successfully in the past weeks, both here in Aylmer and across the country and the continent. One thing is clear to us at

this moment, he finds himself on the wrong side of history and we extend our gratitude and pray for blessings and wisdom on the officers of the Aylmer Police Service as they are thrust into this unenviable position.

Our local MPP, Minister Jeff Yurek, has been a tremendous help for us during this crisis. We are grateful to him and his constituency office for their advocacy on our behalf. Their communication has been consistent and responsive, but we are still awaiting further guidance from the Attorney General. The Justice Centre for Constitutional Freedoms deserves special mention for their assistance. They have worked overtime to find a solution and clarify any legal questions we had. Several prominent London law firms have reached out to us and provided invaluable, precise legal advice and we expect to hear more from them in the coming days.

Drive-in services at a place of worship are not illegal and there is absolutely no legal foundation for such a claim. Parades are specifically forbidden under the Ontario EMCPA and yet no fines are levied for such daily displays across Ontario, and, I might add, rightfully so. In fact, police officers are actively participating in such parades, with impunity. Liquor stores are considered essential and their parking lots are not under any scrutiny. Liquor is essential, but God is not? Drive-thru establishments are under no threat of closure and their parking lots are regularly filled with customers looking to have a chat with their friends. We are not asking for special treatment or privileges, equality would be satisfactory.

We have considered returning to our livestream broadcasts alone and complying with an interpretation of the Emergency Act that is an abrogation of the rights of all Canadians of faith. However, we cannot do so in good conscience. We have arrived at a point where we must draw a line in the sand and stand up for all who value justice and reject unreasonable, unjustifiable curbs of our freedoms.

Everyone is welcome to join us tomorrow in a livestream broadcast of our service that will be posted on our website at www.churchofgod.com. We will not be gathering for a service as defined by the Act, but our parking lot will be open to anyone that wishes to park there, stay in their vehicle at all times with their windows rolled up, and tuned in to the station that will be posted on the signage onsite.

We will not condone any show of force or resistance to the police. In fact, we strongly condemn it. Christians are peaceful people and have always sought the opportunity for peaceful assembly, as guaranteed in the Canadian Charter of Rights and Freedoms.

"And the LORD, He it is that doth go before thee; He will be with thee, He will not fail thee, neither forsake thee: fear not, neither be dismayed." Deuteronomy 31:8

Pastor Henry Hildebrandt

April 22, 2020 – 14:00

We are grateful to our federal, provincial, and municipal government leaders for their commitment to public service during this time of crisis and appreciate their responsibility for the wellbeing of the people they serve.

The COVID-19 crisis has rapidly changed a lot of what our society considers normal and essential in a few short weeks. Faith communities have not been unaffected, in fact they have been singled out in many cases across the world and especially in Canada and certain states, south of the border. The Bible teaches Christians to be good citizens and obey the reasonable demands of our government. It does not, however, teach blind obedience to the authorities when onerous restrictions are placed on our freedoms. In fact, we are guaranteed the right to religious freedom and peaceful assembly in the Canadian Constitution, subject only to such reasonable limits prescribed by law as can be demonstrably justified in a free and democratic society. We now find ourselves debating what constitutes a justifiable, reasonable limit.

This past Sunday, April 19, 2020, we conducted a drive-in service at our meetinghouse parking lot in Aylmer, Ontario. Contrary to widely shared social media posts, attendees listened in to the service via low-power FM transmission while remaining in their vehicles, with their windows rolled up to ensure physical distancing requirements were adhered to. Strict guidelines were prescribed prior to the service and compliance was strictly enforced by our team. The service itself was conducted by 5 persons from an open-air platform that was visible to those in the parking lot. The meetinghouse itself was closed to the use of anyone, including bathroom facilities. There was no physical gathering at this location that contravened the Emergency Act, at any time.

Prior to this, our congregation continued to meet in accordance with previous guidelines of 50 or fewer persons in our building and on Easter Sunday there was a smaller drive-in service where those that participated in their vehicles livestreamed a service from another congregation, but, again, with no physical

livestreamed a service from another congregation, but, again, with no physical interaction. The Aylmer Police attended each one of these services and found no one in violation of the current Emergency Act. We have actively reached out to them and informed them of our intentions prior to the April 19th service.

We were informed Monday, April 20th, by the Aylmer Police that they had sought the opinion of the Crown Attorney's Office and that they were of the opinion that we were, in fact, in violation of the Emergency Act and that they would be taking active enforcement action if any further drive-in services were held in the future.

Now, we find ourselves confronted with a much greater dilemma than just deciding on what we do next Sunday. The question is, what is essential? If faith and the communal expression of faith is not essential, then is this an attack on faith (for we strictly followed all physical contact guidelines)? We are not asking for special treatment, just equal treatment. Christians have always believed that their faith and the reasonable expression of that faith is essential to their general well-being, as well as their mental and spiritual health. We believe that being arbitrarily separated from each other is detrimental to our community.

Just 300 meters south of us, during our service, hundreds of people interacted in a local grocery store and its parking lot. The same thing happened at the local Beer Store, LCBO, Tim Horton's parking lot, Dollarama, and the list goes on. Our drive-in service did not endanger the public, in fact we took far more stringent measures than any major retailer has done during this entire crisis. Yet, it is our faith community that is singled out for public criticism, false accusations, and a directive to cease any active operations, whether they follow the guidelines provided by the government or not.

It is imperative that we find a resolution to this as quickly as possible. There must be an allowable expression of faith that is deemed essential while we are allowing the interaction of customers at establishments that exist solely for the sale of alcohol, coffee, donuts, and fast food.

Ford government amends prohibition on gatherings to permit drive-in religious services

May 19th, 2020

AYLMER, ONTARIO: The Justice Centre is pleased to report that the Ford government in Ontario has amended its order prohibiting gatherings to now expressly allow for drive-in religious services.

The amendment, posted on May 16, 2020 to the government's website, follows the filing of a Charter challenge by the Justice Centre against the Aylmer Police Service and the Ontario government last week. This court action challenged the government's infringement of a church's freedom of peaceful

assembly, and asked the court for clarification as to what is permitted under emergency legislation. The Aylmer Police had repeatedly threatened to fine the Church of God of Aylmer, despite the church using strict "social distancing" measures to comply with the law while hosting drive-in-only church services. Police attended the drive-in services in a show of force, and filmed both church representatives and parishioners in their cars during the worship service. The police were fully aware that worshipers were not leaving their parked cars, and that they were not interacting with each other in person.

The province's order under the *Emergency Management and Civil Protection Act* previously prohibited gatherings of more than five people, including for the purposes of conducting religious services, rites or ceremonies. Despite the fact that many stores and businesses remained open, with varying degrees of success in limiting physical contact between customers, churches and other religious centres had been singled out and effectively closed.

Like all laws in this country, the *Emergency Management and Civil Protection Act* is subject to the *Canadian Charter of Rights and Freedoms*, which guarantees citizens that the government will not infringe their freedoms of peaceful assembly and religion, among other fundamental freedoms, unless the restriction on freedom is demonstrably justified. Where there is a pressing and substantial concern, such as a declared public health emergency, the government may impose reasonable and narrow restrictions on *Charter* freedoms, but the government must violate those freedoms as little as possible, only to the extent necessary to achieve an important goal.

"We are pleased that the Ford government has finally clarified the order, and is now permitting this congregation and others to worship in peace" said Justice Centre staff lawyer Lisa Bildy. "However, this could have been done six weeks ago without putting congregants in the uncomfortable position of exercising their freedoms, even in a manner which posed no public health risks, under constant threat of punishment."

"As the province continues to reopen, I am hopeful that faith groups will not be an afterthought again, but will be permitted to broaden their ability to come together for worship in lockstep with the reopening of other businesses and institutions. Other provinces are already allowing outdoor services, and even indoor ones with reduced numbers and appropriate spacing. Ontario is quite a bit behind on this."

BARRISTER & SOLICITOR

Justice Centre
for Constitutional Freedoms

September 28, 2020

The Honourable Doug Ford
Premier of Ontario
[redacted]

Dear Premier Ford,

Re: Restrictions on Religious Freedoms and Further Lockdowns

I write on behalf of a coalition of faith leaders in Ontario, who are concerned about ongoing and potentially increasing restrictions on religious gatherings heading into the fall season.

Currently, places of worship are limited to 30% capacity. With attendance ramping up following the summer vacation period, this sometimes means turning parishioners away or coordinating multiple services which do not permit the faith community to meet as one body.

Faith groups have gone above and beyond to comply with restrictions and intrusive public health requirements over the past challenging six months, but have typically been an afterthought for your government. As you know, it took legal action or the threat thereof to legalize drive-in services and to get the doors open even to 30%, even though other groups, including non-essential businesses, were operating. Our clients would like to be able to conduct their worship services as they deem appropriate for the general wellbeing of their parishioners, including increasing access to their facilities – but at a minimum, they are asking that you not impose any further limitations or restrictions.

As faith leaders, our clients see the damage first-hand that these measures have on people, as their physical, mental, spiritual and emotional well-being is jeopardized. And citizens' freedoms to assemble and associate with one another, whether for religious reasons or otherwise, are so vital to the human condition and to Canada's liberal democratic order, that they are described as "fundamental freedoms" and are enshrined in our constitution. Attempts to restrict them must be subject to the most exacting scrutiny.

We understand that you are facing enormous political pressure from some quarters to "do something" about the increasing numbers of positive test results, including further lockdowns (although the overwhelming majority of these "cases" will never amount to

illness, let alone death, and may even reflect significant "false positives"[1]). However, there are also burgeoning numbers of citizens who believe that restrictions on their ability to worship, assemble and associate are unconstitutional and unjustified, and widespread protests can be expected to continue and grow.

Indeed, the Justice Centre has been reminding federal and provincial governments, through published reports and litigation, that infringements on the *Charter* rights and freedoms of Canadians are unconstitutional unless they can be demonstrably justified in a free and democratic society. In June, we published a paper on the Ontario lockdown measures entitled "*Unprecedented and Unjustified: A Charter Analysis of Ontario's Response to Covid-19*"[2]. That which was already evident in June is even more obvious in September – widespread lockdowns of healthy individuals are not minimally impairing, proportional or rational.

There is also no compelling evidence that lockdowns work, particularly when one considers the experiences of various countries around the world such as Peru (which locked down heavily and still suffered large losses) and Sweden (which did not lock down but appears to be avoiding the recent significant uptick in positive tests seen in other European countries).[3]

With recent news that your government is being lobbied by various doctors to impose another lockdown[4], we are concerned that insufficient consideration is being given to opposing views. We hope that your Command Table is avoiding groupthink, and an undue and unrelenting deference to the "precautionary principle", by hearing from doctors and experts who do not agree with the assessment contained in the news article cited in this paragraph. Should that not be the case, we would be pleased to connect you with such experts by arranging a meeting with members of your health team and cabinet.

Our clients and a growing number of Ontarians are troubled by the shifting goals of restrictive measures: from initially protecting the health care system, to what appears to be the unattainable objective of eradicating or supressing this virus at any cost. Increasing case tallies are seldom placed in the proper context, by explaining that the number of individuals being tested has risen vastly since we saw similar case numbers in the spring (naturally exposing a greater number of "cases", particularly asymptomatic ones); and, that there has been a dramatic decline in the numbers of hospitalizations and deaths since the spring. This perpetuates fear in those citizens who do not appreciate that context; while at the same time, engenders distrust of government and experts in those who do – a situation that is extremely detrimental to our civic health.

---

[1] https://www.nytimes.com/2020/08/29/health/coronavirus-testing.html

[2] https://www.jccf.ca/published_reports/unprecedented-and-unjustified-ontario-lockdown/

[3] https://www.msn.com/en-us/news/world/sweden-shows-lockdowns-were-unnecessary-no-wonder-public-health-officials-hate-it/ar-BB1904YN

[4] https://www.newswire.ca/news-releases/tighter-restrictions-needed-now-to-halt-spread-of-covid-19-in-ontario-856947463.html

We wish to remind you that, while you may be hearing some clamoring to close things down again, your government has an obligation to uphold the *Charter* rights of citizens even in difficult times and even in the face of public pressure, and must take back control of the province from public health officials who do not consider and are not equipped to consider the broader social and economic impacts of their policies.

While our clients are quite prepared to continue incorporating reasonable, science-based recommendations to help protect the health of their parishioners, they will not tolerate further restrictions on their freedom of religion, and are prepared to take legal action immediately should that happen.

We trust that will be unnecessary.

Yours very truly,

Lisa D.S. Bildy, JD, BA

NEWS RELEASE

Ontario Announces Provincewide Shutdown to Stop Spread of COVID-19 and Save Lives

Government Providing Grants of up to $20,000 to Small Businesses Impacted by New Public Health Measures

December 21, 2020
Office of the Premier

TORONTO — As COVID-19 cases continue to rise at an alarming rate, the Ontario government, in consultation with the Chief Medical Officer of Health and other health experts, is imposing a Provincewide Shutdown. Additional restrictions will be put into place and reinforce that Ontarians should stay at home as much as possible to minimize transmission of the virus and prevent hospitals from becoming overwhelmed. The Provincewide Shutdown will go into effect as of Saturday, December 26, 2020, at 12:01 a.m.

Details were provided today by Premier Doug Ford, Christine Elliott, Deputy Premier and Minister of Health, Stephen Lecce, Minister of Education, Dr. David Williams, Chief Medical Officer of Health, and Dr. Naveed Mohammad, President and CEO, William Osler Health System.

"The number of daily cases continue to rise putting our hospitals and long-term care homes at risk," said Premier Ford. "We need to stop the spread of this deadly virus. That's why, on the advice of Dr. Williams and other health experts, we are taking the difficult but necessary decision to shutdown the province and ask people to stay home. Nothing is more important right now than the health and safety of all Ontarians."

In response to these exceptional circumstances, the Provincewide Shutdown would put in place time-limited public health and workplace safety measures similar to those in other jurisdictions. It would help stop the trend of high COVID-19 transmission in communities, preserve health system capacity, safeguard vulnerable populations and those who care for them, and save lives. Measures include, but are not limited to:

- Restricting indoor organized public events and social gatherings, except with members of the same household (the people you live with). Individuals who live alone may consider having exclusive close contact with one other household.
- Prohibiting in-person shopping in most retail settings - curbside pickup and delivery can continue. Discount and big box retailers selling groceries will be limited to 25 per cent capacity for in-store shopping. Supermarkets, grocery stores and similar stores that primarily sell food, as well as pharmacies, will continue to operate at 50 per cent capacity for in-store shopping.
- Restricting indoor access to shopping malls - patrons may only go to a designated indoor pickup area (by appointment only), essential retail stores that are permitted to be open (e.g. pharmacy, grocery store), or, subject to physical distancing and face covering requirements, to the food court for takeout purchases. Shopping malls may also establish outdoor designated pickup areas.
- Prohibiting indoor and outdoor dining. Restaurants, bars and other food or drink establishments will be permitted to operate by take out, drive-through, and delivery only.

On the advice of the Chief Medical Officer of Health, all Ontarians are advised to stay home as much as possible with trips outside the home limited to necessities such as food, medication, medical appointments, or supporting vulnerable community members. Employers in all industries should make every effort to allow employees to work from home.

The current COVID-19 Response Framework will be paused when the Provincewide Shutdown comes into effect. The impacts of these time-limited measures will be evaluated throughout the 14 days in Northern Ontario and 28 days in Southern Ontario to determine if it is safe to lift any restrictions or if they need to be extended.The Chief Medical Officer of Health will assess and apply lessons learned thus far to the COVID-19 Response Framework to ensure appropriate and effective measures are in place to protect the health of Ontarians and enable economic recovery after the Provincewide Shutdown ends. This will include an assessment of how a revised approach for the safe reopening of retail may be operationalized, according to the latest available evidence.

"This was not an easy decision before the holidays, but we have reached a tipping point," said Minister Elliott. "We continue to see sharp increases in hospitalizations and occupancy in intensive care units is reaching concerning levels. Urgent action must be taken to prevent our health care system from becoming overwhelmed. By implementing a Provincewide Shutdown, we can work to stop the virus in its tracks, safeguard hospital capacity, and save lives."

The government is also providing $12.5 million to implement a High Priority Communities Strategy to contain the virus in high-risk communities. The strategy will take a tailored, community-based approach to fund community agencies in 15 priority communities in the York, Peel, Durham, Ottawa, and Toronto regions. The funding will also allow for the hiring of community ambassadors to make people aware of available services and assistance, for coordination of increased testing opportunities and for the arrangement of wraparound supports for those who are COVID-positive. Additional funding of $42 million will also be available to establish isolation centres.

The province will work with our local municipal partners to establish new isolation centres to help those who may need to isolate following testing.

"We continue to see the number of cases in the province grow and the trends in public health indicators worsen. Additional measures are needed provincewide in order to interrupt this concerning growth," said Dr. Williams. "We must work together to enable everyone to follow these new and time-limited restrictions and protect our health system and our communities."

The government is working to limit the transmission of COVID-19 in workplaces by supporting essential businesses in doing whatever is necessary to keep workers safe. The Ministry of Labour, Training and Skills Development is leading a multi-ministry COVID-19 Safety Team. The team will partner with local authorities to carry out additional enforcement blitzes in sectors where they are needed most.

New School Protocols

While transmission in schools remains low, all publicly funded and private elementary and secondary schools are to move to teacher-led remote learning when students return from the winter break on January 4, 2021. This action is being taken in support of the Government's broader efforts to limit the spread of COVID-19.

Schools located in the following Public Health Unit regions can resume in-person instruction on January 11, 2021 for both elementary and secondary students:

- The District of Algoma Health Unit
- North Bay Parry Sound District Health Unit
- Northwestern Health Unit
- Porcupine Health Unit
- Sudbury and District Health Unit
- Thunder Bay District Health Unit
- Timiskaming Health Unit

For schools in all other Public Health Unit regions, elementary school students are planned to be able to return to in-person learning on January 11, 2021, and secondary school students will continue learning remotely until January 25, 2021, at which point they may resume in-person learning. During this period, child care centres, authorized recreational and skill building programs and home-based child care services will remain open. From January 4-8, 2021, when elementary students move to remote learning, before and after school programs will be closed and emergency child care for health care and frontline workers will be provided. As part of the government's efforts to protect the most vulnerable, boards will be required to make provisions for continued in-person support for students with special education needs who cannot be accommodated through remote learning for whom remote learning is challenging.

"While our schools are not a source of rising community transmission, we can play an important part of the solution to save lives from COVID-19," said Minister Lecce. "During this period, students will pivot to teacher-led online learning, with child care provided for our frontline workers. We are taking proactive and preventative action to protect schools following the holiday break to ensure kids can continue in-class learning — something we believe is so important — for the remainder of the year."

The New Ontario Small Business Support Grant

The government recognizes that small businesses impacted by these necessary public health measures will require additional support so they can continue serving their communities and employing people in Ontario once the COVID-19 pandemic is over. That is why the government is announcing the new *Ontario Small Business Support Grant*, which will provide a minimum of $10,000 and up to $20,000 to eligible small business owners to help navigate this challenging period.

"Ontario's business owners have shown remarkable resolve and ingenuity throughout the pandemic. They know better than anyone what they need to come through this very difficult time, so they can continue to serve and employ people in their communities," said Rod Phillips, Minister of Finance. "The new *Ontario Small Business Support Grant* will provide significant financial support to eligible small business owners in addition to the other supports made available to our small business community."

Small businesses required to close or restrict services under the Provincewide Shutdown will be able to apply for this one-time grant. Each small business will be able to use the support in whatever way makes the most sense for their individual business. For example, some businesses will need support paying employee wages or rent, while others will need support maintaining their inventory.

Eligible small businesses include those that:

- Are required to close or significantly restrict services subject to the Provincewide Shutdown effective 12:01 a.m. on December 26, 2020;
- Have less than 100 employees at the enterprise level; and
- Have experienced a minimum of 20 per cent revenue decline in April 2020 compared to April 2019.

Starting at $10,000 for all eligible businesses, the grant will provide businesses with dollar for dollar funding to a maximum of $20,000 to help cover decreased revenue expected as a result of the Provincewide Shutdown. The business must demonstrate they experienced a revenue decline of at least 20 per cent when comparing monthly revenue in April 2019 and April 2020. This time period was selected because it reflects the impact of the public health measures in spring 2020, and as such provides a representation of the possible impact of these latest measures on small businesses.

Essential businesses that are allowed to remain open will not be eligible for this grant. More information about the *Ontario Small Business Support Grant* is available here. Further details, including how to apply, will be announced in January 2021.

Businesses that are impacted by the Provincewide Shutdown will also be eligible for the property tax and energy cost rebates. In November, the government launched a program to provide rebates to offset fixed costs such as property tax and energy bills for businesses that are required to shut down or significantly restrict services due to provincial public health measures. These rebates will continue to be available for businesses impacted by the Provincewide Shutdown and earlier restrictions. Business can apply for the rebates here.

Quick Facts

- Currently, hospitalizations for COVID-19 have increased by 74 per cent over the last four weeks and are more than 15 times higher than they were at the beginning of September. Intensive care unit (ICU) occupancy for COVID-19 has more than doubled over the last four weeks and is 20 times higher than at the beginning of September.
- Ontario currently has 915 COVID-19 patients requiring acute care, 265 patients in ICU, with 152 on a ventilator.
- Based on the latest modelling data, cases across the province are continuing to grow and the number of people requiring an intensive care bed is projected to rise well above 300 people within the next 10 days.
- Some jurisdictions around the world, including those in Canada have implemented similar time-limited measures to respond to a dramatic resurgence in cases. Based on their experiences, measures of four to six weeks are expected to interrupt transmission of COVID-19 in Ontario.
- Municipalities and local medical officers of health may have additional restrictions or targeted requirements in their region.
- Get tested if you have symptoms compatible with COVID-19, or if you have been advised of exposure by your local public health unit or through the COVID Alert App. Visit Ontario.ca/covidtest to find the nearest testing location.
- The Ontario Small Business Support Grant is part of the Province's more than $13.5 billion in support for people and jobs outlined in the 2020 Budget, Ontario's Action Plan: Protect, Support, Recover. It is also in addition to $4.8 billion to address critical areas to support a strong long-term recovery that helps workers, employers and communities get back on their feet, while building the foundation for recovery and growth.
- To find the right supports, visit COVID-19: Support for People, which has information about the many available and free mental health services and supports.
- To stay safe you can download the COVID Alert App free from the Apple and Google Play app stores.
- To date, as part of the province's COVID-19 immunization program, over 3,000 frontline health care workers have been vaccinated.
- Schools continue to be safe, and according to data reported by school boards, as of Friday, December 18: approximately 99.64 per cent of students in Ontario have not reported a case of COVID-19; approximately 92 per cent of schools across

the province have had either no cases or one case reported within the last 14 days; and approximately 80 per cent of schools do not have an case of COVID-19.

Toronto police investigate reports 2 officers charged at Aylmer church for allegedly defying COVID-19 rules

Man, 42, and woman, 41, from suburban Toronto among 4 who received $880 tickets from Aylmer police

Colin Butler · CBC News · Posted: Apr 23, 2021 12:53 PM ET | Last Updated: April 23

Toronto police are investigating this social media video

18 days ago | 3:48

Investigators are looking over this video circulating on social media to see if two Toronto Police officers were among the four people charged for allegedly violating pandemic health restrictions at an Aylmer, Ont., church. 3:48

The Toronto Police Service is investigating reports two of its off-duty officers were among people charged at a gathering at an Aylmer, Ont., church known for its rebellious stance against Ontario's pandemic health rules.

Connie Osborne, a spokesperson for Toronto police, said in an email Friday to CBC News that TPS is aware of a social media video that's been circulating and the information has been passed on to the law enforcement agency's Professional Standards Investigation Unit.

The video was published Thursday on social media channels belonging to Independent MPP Randy Hillier, who has taken defiant stances on the government's public health measures.

"Watch this video of Police Officers being charged for exercising their Charter rights," says Hillier. "You won't hear this in the news, but two officers attending a meeting in the Aylmer Church of God and practicing their right to assembly have been charged under the Reopening Ontario Act," he said on Facebook.

Complaints focused on large gathering

The two off-duty officers were reportedly among four people charged by the Aylmer Police Service on Tuesday night at the Church of God in connection with complaints about a large gathering at the house of worship.

Each of the following individuals was given an $880 ticket under the provincial act:

- A man, 42, from the Toronto suburb of North York.
- A woman, 41, from the Toronto suburb of Scarborough.
- Two men, 34 and 20, from Aylmer.

CBC News has tried to confirm the identities of the two individuals from the Greater Toronto Area, but the Aylmer and Toronto police services, and Ontario's Ministry of the Attorney General were unable to verify the information.

Ontario defends recruit influx before latest police college COVID outbreak

The province is defending its decision to resume in-person training at the Ontario Police College, saying a shortage of new police officers would have put communities at risk.

Dale Carruthers
Mar 15, 2021 • March 15, 2021 • 2 minute read • 6 Comments

The Ontario Police College north of Aylmer. (Mike Hensen/The London Free Press)

The province is defending its decision to resume in-person training in January at the Ontario Police College despite its latest COVID-19 outbreak, saying a shortage of new police officers would have put communities at risk.

All in-person classes have been suspended at the Aylmer-area campus since last month after a COVID-19 outbreak led to 112 infections — 104 of them resolved — since Feb. 22, the Solicitor General's Ministry said.

The college's latest outbreak — the third since it reopened in June — comes after the school resumed in-person classes in January, taking in 438 recruits from police forces across Ontario, even as the province's elementary and secondary schools were closed amid a stay-at-home order.

The government has been in close consultation with health officials and various ministries to develop safety measures to deliver the basic constable training program, the ministry's Brent Ross said.

“The ministry also engaged police services and policing organizations across the province,” Ross said by email.

“Our policing partners made it clear that the safety of their communities relied on new police officers being trained for duty on a regular basis and a shortage of officers would place their communities at risk.”

Solicitor General Sylvia Jones wasn’t available for an interview, Ross said.

Classes at the college initially were suspended for 14 days Feb. 25, but that suspension has been extended indefinitely.

“The college is working with local public health to determine when it is safe to return to the in-person format, as well as any additional protocols necessary to ensure the continued health and safety of all,” Ross said.

A Southwestern Public Health spokesperson said the college must remain closed until at least March 24. No timeline for reopening was offered.

MPP Jeff Yurek (PC-Elgin–Middlesex–London), whose riding takes in the college, said he’s heard some concern from constituents about possible spread of the virus in the community.

Following the most recent outbreak, all of the roughly 700 recruits, instructors and staff were tested — some high-risk individuals were tested twice — and those who tested positive are isolating at the college or at home.

The school also strengthened safety measures, including screening staff and students for COVID

symptoms, adding isolation rooms, wearing personal protective equipment when social distancing isn't possible, and increasing cleaning.

"All the necessary cautions were put in place," Yurek said of the steps taken to reopen the school. "There was a definite need for police officers' training to be completed due to retirements and such going on throughout the province."

AFFIDAVIT OF KAREN BERGEN
(Sworn June 4, 2021)

I, KAREN BERGEN, of the [redacted] in the Province of Ontario, MAKE OATH AND SAY:

1. I am a member of the Church of God (Restoration) Aylmer ("**the Church**"), and as such have personal knowledge of the matters hereinafter deposed to, except where they are based on information and belief, in which case I verily believe them to be true.

2. I have been attending the Church for twenty-seven years. That is as long as I have been alive because my mother started attending the church before I was born. She was one of the original members in the Aylmer area. In fact, Pastor Hildebrandt, along with his family, came to visit my parents and me in the hospital when I was born.

3. The Church has been my life ever since, from my earliest memories of Sunday school and grade school, school-end celebrations and potlucks, down to my baptism, graduation, wedding, and now more than ever, my life as a wife and mother.

4. I am a stay-at-home mother, and my husband works in the trades currently. I met my husband when we went to school at the Church together. Since graduating, I have taught at the school (mainly science, math and history), and my eldest daughter will attend there in the fall. I also sing in the choir, and sometimes teach adult Bible study.

5. The people with whom we have attended for all these years are so much more than Sunday associates—they are family. We are a community. Our lives are so interwoven and connected that is impossible to separate them. We rejoice together at the births of our babies, celebrate together at our weddings, and grieve together at the passing of friends. We work together to educate our children and improve the lives of others.

6. To deny us our right to physically gather is to attempt to destroy the very backbone of our culture and way of life. It is not just the four walls of our building that we want, though they do hold sentimental value. It is the relationship with our people that we must have. There is no way that closeness can be replaced by watching an image on a screen.

7. Drive-in services cannot replace this connection either. Yes, it is nice to see your brother's vehicle and know he is there—about as nice as it would be to have him come and see you in prison where you can wave at him through the bars. Forget about any one-on-one conversations.

8. The feeling of loneliness and isolation that comes after a few weeks of these virtual methods is simply devastating to us, and to our children especially, who cannot develop good social skills when they have no one they are allowed to be social with.

9. Our lives cannot exist isolated and separated. Although other people may find the idea foreign these days, this desire to be connected to each other in a tight community drives us to meet and be reassured by each others' presence, regardless of the consequences.

10. And there have been consequences. When our church became targeted, there was a noticeable shift in the behavior of our previously friendly townspeople. The first change was in the police officers. Up to this point we had enjoyed a good standing relationship with the majority of the officers. Some years back, Pastor Henry mentioned, and I verily believe, that he had been complimented by one of the officers on the good behavior of our people, specifically the teenagers. But now, that relationship has regressed to pure, unabashed animosity in the case of some, though definitely not all, of our local officers.

11. The attitude of many, though again, definitely not all, of the store owners in town has become so hostile that I would sometimes rather do my shopping fifteen to thirty minutes out of town to avoid the unpleasant local experience. I try to spare my daughters from this by not bringing them with me on local shopping trips.

12. With the attention that our congregation has received, and the influx of people wanting to show solidarity with us or join us for worship, it has been quite a change for us. We have gone from knowing everyone personally, where they live and what they do for a living, to being surrounded by many new faces. It has, however, opened my eyes to how many people hunger for this same sense of community, as they join us to share our vision and burden.

13. I swear this affidavit *bona fide*, and for no other or improper purpose.

AFFIDAVIT OF DR. THOMAS WARREN
(Sworn May 25, 2021)

I, **THOMAS WARREN**, of the [redacted] in the Province of, Ontario MAKE OATH AND SAY:

1. I am an Infectious Diseases consultant and Medical Microbiologist currently practicing in Oakville, Milton and Georgetown, Ontario, and as such have knowledge of the matters hereinafter deposed to.

2. I have been a member of the College of Physicians and Surgeons of Ontario since 2009. My curriculum vitae is attached hereto and marked as **Exhibit "A".**

3. I obtained my Doctor of Medicine (MD) from the University of Western Ontario in 2005, after which I completed a three-year residency in Internal Medicine through the University of Ottawa. Following my Internal Medicine residency, I completed a Fellowship in Infectious Diseases and a second residency in Medical Microbiology, both at the University of Toronto. During my residencies and fellowship, I regularly taught medical students and junior residents.

4. I have practiced in these specialty areas for ten (10) years. As part of my clinical practice, I teach through my appointment as an Assistant Clinical Professor (Adjunct) at McMaster University in Hamilton, ON. This includes supervising Infectious Diseases Clinical Rotations for physician assistant students, medical students, and Infectious Diseases fellows.

5. I am currently enrolled in a Master of Science (Epidemiology) at the London School of Hygiene and Tropical Medicine, University of London, with an expected completion date of 2022. Areas of study include the framework for understanding the epidemiology of infectious diseases and the mathematical theory underlying epidemiological studies.

6. In my medical microbiology residency, I was trained to develop, use and interpret reverse transcription polymerase chain reaction (RT-PCR) testing. I have practiced as a microbiologist for ten years in a microbiology laboratory that uses a variety of PCR tests. As an infectious diseases consultant, I interpret PCR test results in the context of clinical care.

7. The Moving Parties' counsel contacted me about providing expert testimony in support of their motion to set aside the enforcement order against them. I have

been asked to address issues surrounding the virus SARS-CoV-2 and Covid-19 disease, specifically: their description, PCR testing, asymptomatic transmission, and the utility of masks.

8. I acknowledge that in preparing this report and providing expert evidence, the Moving Parties' counsel explained that my role is to assist the court to determine the matters in issue. I further acknowledge that it is my duty to provide evidence that is fair, objective and non-partisan and to opine only on matters that are within my area of expertise. This duty prevails over any obligation that I may owe to any party on whose behalf I am engaged.

SARS-CoV-2 and COVID-19

9. Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is a novel coronavirus. There are six other coronaviruses that are known to infect humans. Four coronaviruses, HCoV-NL63, HCoV-HKU1, HCoV-229E, and HCoV-OC43 circulate worldwide and together are the second most common cause of the common cold[1, 2]. Severe acute respiratory syndrome coronavirus 1 (SARS-CoV-1) infected 8096 people in 2003 resulting in 774 deaths[3]. After 2003 there has not been any further human to human transmission. Middle East respiratory syndrome coronavirus (MERS-CoV) was first identified in humans in 2012[4]. MERS-CoV continues to cause sporadic infection and outbreaks in the Arabian peninsula, as well as occasional other cases and outbreaks in other parts of the world linked to travelers to the Arabian peninsula[5].

10. Bats were the source of SARS-CoV-1[6] and are known to be a natural reservoir for related coronaviruses[7,8]. SARS-CoV-2 was likely circulating in bats for decades[9]. In late 2019, SARS-CoV-2 was first detected in humans and is established as the cause of the disease now designated coronavirus disease 2019 (COVID-19). Approximately 10-20% of persons with SARS-CoV-2 infection are asymptomatic[10,11]. In those who are symptomatic, there is a wide range of illness from those with mild symptoms such as runny nose to those with severe disease affecting particularly the respiratory tract with high mortality[12]. Most people with

SARS-CoV-2 infection are asymptomatic or have mild-moderate symptoms not requiring hospitalization. In one study of a relatively healthy population, those with COVID-19 requiring hospital care was < 2%, and the mortality rate was < 0.1%[11].

SARS-CoV-2 transmission and mortality

11. The timing of peak SARS-CoV-2 transmission is primarily affected by seasonal patterns (i). The scale of SARS-CoV-2 transmission in a susceptible population is primarily determined by population density (ii). The mortality of COVID-19 is primarily determined by the age structure of the population (iii). Each of these important factors for SARS-CoV-2 transmission and mortality is non-modifiable.

(i) The timing of peak SARS-CoV-2 transmission is primarily affected by seasonal patterns

12. The four human coronaviruses (OC43, 229E, NL63, HKU1) are known to have a seasonal pattern of increased transmission[1]. The peak of the transmission wave in the United States is in the coldest months of the year, usually January. SARS-CoV-2 transmission appears to have a similar seasonal pattern of transmission to the other seasonal human coronaviruses[13]. There are numerous studies that show climate (season) is one of the most important factors for SARS-CoV-2 transmission[14-26]. In general, colder temperatures are associated with increased SARS-CoV-2 transmission.

(ii) The scale of SARS-CoV-2 transmission is primarily determined by population density.

13. The transmission of SARS-CoV-2 is strongly associated with population density, particularly population-weighted density[15-18, 24, 27-31]. In the United States, incidence and mortality are ten times higher in the most densely populated areas compared to the least densely populated areas [32,33]. The association between population density and SARS-CoV-2 transmission has been identified in Europe[34], Italy[35], India[36,37], Argentina[38], Turkey[39], Algeria[40], Brazil[22], Japan[25], and China[41].

14. This is also evident in Canada. Provinces with the highest population density (e.g. Ontario) have the highest number of cases. Within provinces (e.g. Ontario), regions with the highest population density have the highest number of cases (e.g. Toronto).

(iii) The mortality of COVID-19 is primarily determined by the age structure of the population.

15. Age is the most important risk factor for COVID-19 mortality. Compared to persons under age 40, persons over the age of 80 have a greater than 300 times chance of dying from COVID-19[42]. The infection fatality ratio (IFR) in persons over 80 is approximately 1000 times the IFR in those under 20[43]. In Canada, 68% of deaths are in persons over 80, 87.5% of deaths are in persons over 70, and > 95% of deaths are in persons over 60[13].

16. The risk of death due to COVID-19 in persons under 60 is very small[44]. In Canada, there have been 1,010 COVID-19 deaths in persons < 60 years old as of April 16, 2021[13]. In Canada in 2018 there were 1,191 motor vehicle fatalities in persons under 55[45]. So, the risk of death due to COVID-19 in persons < 60 is less than the risk of death due to a motor vehicle fatality.

Asymptomatic transmission

17. A *British Medical Journal* editorial concisely summarizes the risk of asymptomatic transmission: "The transmission rates to contacts within a specific group (secondary attack rate) may be 3-25 times lower for people who are asymptomatic than for those with symptoms."[46] This is consistent with the conclusions from several peer-reviewed systematic reviews and meta-analyses[47-50].

18. To further exemplify the risk of asymptomatic transmission, it is useful to look specifically at a few large or comprehensive studies. A very large study in Wuhan China of 9,899,828 city residents found 300 asymptomatic cases but there were

no positive tests amongst 1,174 close contacts of asymptomatic cases[51]. Similarly, a very thorough study of 100 cases from Taiwan, found that "none of the 9 asymptomatic case patients transmitted a secondary case."[52]

19. Household transmission is one of the most important modes of transmission. In a meta-analysis of household transmission, which included 54 studies and 77 758 participants[53], transmission from asymptomatic cases was 0.7% compared to 18% transmission from symptomatic cases. In other words, symptomatic transmission was roughly 25 times higher than asymptomatic transmission.

20. Asymptomatic transmission does occur but the rates of transmission from asymptomatic persons is substantially less than from symptomatic persons and does not warrant being considered a significant contributor to the overall transmission burden.

Evidence for lockdown measures, including closing churches, to control SARS-CoV-2 transmission

21. Almost all of the research done prior to 2020 examining the effectiveness of interventions such as avoiding crowding (which would include church closure) to control respiratory tract infections was done with influenza. Prior to 2020, social distancing was a term that included quarantine, school closures, work closures as well as avoiding crowding.[54]

22. As noted in a recent systemic review, "clear biological and epidemiologic rationale supports the potential effectiveness of social distancing measures"[55] in the control of viral respiratory tract infections; however, the actual evidence for avoiding crowding by the general public for the control of viral respiratory tract infections is negligible.

23. A 2019 WHO review[54] of non-pharmaceutical public health measures for mitigating the risk and impact of epidemic and pandemic influenza found only three studies[56-

[58] relevant to "avoiding crowding". In all three studies the quality of evidence was rated as very low. Two of those studies were retrospective analysis of the 1918 pandemic,[56-57] both published in 2007. The limitations of studies done almost a century after an event should be self-evident, and hence the quality of that evidence is rated as very low. Importantly, in reference to "avoiding crowding" (which would include church closure) the WHO document notes[54]:

> Ethical considerations
>
> In urban locations it can be difficult to avoid crowding without considerable social costs.
>
> Modification, postponement or cancellation of mass gatherings may have cultural or religious considerations, in addition to public health aspects.
>
> Knowledge gaps
>
> There are still major gaps in our understanding of person-to-person transmission dynamics. Reducing mass gatherings is likely to reduce transmission in the community, but the potential effects are difficult to predict with accuracy. Large-scale RCTs [randomized controlled trials] are unlikely to be feasible.

24. A 2020 Cochrane systematic review[59] "found only one RCT [randomized controlled trial] of quarantine, and no trials of screening at entry ports or physical distancing [emphasis added]." Since there is a complete absence of high-quality evidence regarding physical distancing, the authors state: "Physical distancing represents another major research gap which needs to be addressed expediently, especially within the context of the COVID-19 pandemic setting as well as in future epidemic settings."[59]

25. In summary, while there is clear biological and epidemiological rationale for avoiding crowding, there is an absence of high-quality evidence, such as randomized-controlled trials, that prove the effectiveness of lockdown measures to avoid crowding in particular groups or contexts, including churches.

COVID-19 cases and deaths related to church outbreaks in the Canadian epidemiological context

26. The majority of deaths related to COVID-19 in Canada are related to outbreaks. As of April 3, 2021 there were 23,050 COVID-19 deaths in Canada, and 13,634 (59.1%) of those deaths were related to outbreaks[60]. Outbreaks are known to be important in the transmission of SARS-CoV-2, with perhaps 80% of all transmissions related to approximately 20% of infections, so-called superspreader events[61]. In Canada, 99.8% (13,600/13,634) of outbreak-related deaths are in settings that might be considered non-modifiable - long term care (12,473 deaths), healthcare (812 deaths), corrections/shelters (226 deaths), communities such as Indigenous communities (89 deaths)[60]. It is hard to imagine closing long term care homes, hospitals, corrections facilities and Indigenous communities - yet outbreaks in those settings account for 99.8% of outbreak-related COVID-19 deaths in Canada.

27. Religious gatherings appear to be grouped in the "Other" category which includes "social gatherings, office workplaces, recreational facilities, etc." in the Canadian epidemiologic summary[60]. The number of cases related to outbreaks in the "Other" category is 5,331. That is less than 1% (5,331/1,001,658) of all cases. Presumably, cases related to religious gatherings outbreaks make up only a fraction of cases in the "Other" category, with cases related to other social events more common, so the number of cases related to religious gatherings outbreaks is actually only a fraction of <1%.

28. Outbreak data from Ontario[62] show that less than 1% of all outbreaks (23/4151) are due to places of worship. Less than 1% of all outbreak cases (221/39774) are due to outbreaks at places of worship. Places of worship account for only 0.1% (5/3460) of all outbreak associated hospitalizations, and places of worship account for 0% (0/3681) of all outbreak associated deaths.

Evidence for masks in churches to prevent the spread of SARS-CoV-2

29. In short, and as stated by the World Health Organization (WHO), "there is only limited and inconsistent scientific evidence to support the effectiveness of masking of healthy people in the community to prevent infection with respiratory viruses, including SARS-CoV-2"[63].

30. The best evidence for any medical intervention comes from large randomized controlled trials or meta-analysis of randomized trials. There are no randomized controlled trials or meta-analysis of randomized controlled trials that support the effectiveness of masking of healthy people in the community to prevent infection with respiratory viruses, including SARS-CoV-2.

31. There is only one published randomized controlled trial on the effectiveness of masking of healthy people in the community to prevent infection with SARS-CoV-2. That study found there was no significant difference in SARS-CoV-2 infection rates between those who wore masks and those who did not wear masks[64].

32. Three recent meta-analyses show no benefit of masking healthy people in the community to prevent infection with respiratory viruses. Cochrane systematic reviews are widely recognized in the medical community as authoritative. A 2020 Cochrane meta-analysis of masks versus no masks in preventing viral respiratory illness found no difference in preventing influenza-like illness or laboratory confirmed illness[65]. Similarly, another meta-analysis published in 2020 showed that masks make no difference in preventing pandemic influenza in nonhealthcare settings[66]. Another meta-analysis by the WHO in 2019 also failed to show a substantial protective effect of face masks[67].

33. When the analysis is limited to the strongest types of evidence (randomized trials and meta-analyses of randomized trials), there is no evidence that healthy persons wearing masks in non-healthcare settings prevents the spread of SARS-CoV-2.

34. In the absence of evidence from randomized controlled trials and meta-analyses, the WHO's report on masking from December 1, 2020[63] references a number of other types of studies that purport to show that healthy persons wearing masks in non-healthcare settings prevents the spread of SARS-CoV-2; however, these studies have significant limitations that need to be considered.

35. The majority of the studies referenced by the WHO are ecological studies,[68-89] also called correlational studies. The ecological studies referenced by WHO compare mask use and COVID-19 rates between geographic region, such as country, state or city. The descriptive analysis of these rates does not provide an evidentiary base for concluding causation. Ecological studies have "many methodologic problems that severely limit causal inference, including ecologic and cross-level bias, problems of confounder control, within-group misclassification, lack of adequate data, temporal ambiguity, collinearity, and migration across groups."[90] The WHO report also acknowledges those studies have "have important limitations to consider"[63,91-93].

36. Cohort studies[94], case control[95-97] and case series[98-100] are all referenced in the WHO document, but these study types are considered much weaker than randomized controlled trials or meta-analysis. Due to the limitation of the study designs, particularly bias and confounding, the true effect of masking is uncertain. Many of these studies also have limited generalizability. For example, a study looking at secondary transmission of SARS-CoV-2 in households[94] has limited generalizability to universal masking in the wider general public. The findings from case series of persons who traveled on the same flight[98,99] cannot be generalized to universal masking.

37. Finally, a comment should be made on the study[101] by Chu et al. as that study is referenced by the WHO and has been widely cited in the media. As noted in the 2020 Cochrane review referenced above, the Chu et al. study "has been criticised for several reasons: use of an outdated 'Risk of bias' tool; inaccuracy of distance

measures; and not adequately addressing multiple sources of bias, including recall and classification bias and in particular confounding. Confounding is very likely, as preventive behaviours such as mask use, social distancing, and hand hygiene are correlated behaviours, and hence any effect estimates are likely to be overly optimistic."[65]

38. In summary, there is "inconsistent scientific evidence to support the effectiveness of masking of healthy people in the community to prevent infection with respiratory viruses, including SARS-CoV-2"[63]. Studies that support the effectiveness of masking are of poorer methodological quality and hence provide weaker evidence. Randomized controlled trial and meta-analysis, which provide stronger scientific evidence, do not support the effectiveness of masking of healthy people in the community to prevent infection with respiratory viruses, including SARS-CoV-2.

Polymerase chain reaction (PCR) for diagnosis of SARS-CoV-2 infection

39. Polymerase chain reaction (PCR) is a technology to amplify DNA fragments[102,103]. It is widely used in molecular biology, biotechnology, and medicine. Real time reverse transcription-polymerase chain reaction (real time RT-PCR) is a modification of PCR with an additional step of reverse transcription (RT) of RNA to DNA to enable amplification of an RNA target rather than a DNA target.

40. PCR is a relatively quick and inexpensive process that is highly sensitive. The process detects genetic material (DNA or RNA), even in minute quantities, and then copies it in a series of steps (cycles) that is usually done by a machine in a fully automated process. Each cycle doubles the amount of target DNA, and the newly created DNA is labeled with a fluorescent dye for detection. If a certain level of fluorescence is surpassed and detected by the machine, the test is considered positive. The cycle of the test that passes this threshold is called the cycle threshold (Ct).

41. PCR is commonly used in microbiology laboratories for the diagnosis of infectious diseases. While PCR can be the best diagnostic tool to diagnose many infections, it does have important limitations that also need to be considered.

Limitations of PCR

42. The World Health Organization (WHO) recognizes the limitations of PCR and advises that "health care providers must consider any result in combination with timing of sampling, specimen type, assay specifics, clinical observations, patient history, confirmed status of any contacts, and epidemiological information"[104]. The WHO guidance goes on to say that "disease prevalence alters the predictive value of test results; as disease prevalence decreases, the risk of false positive increases. This means that the probability that a person who has a positive result (SARS-CoV-2 detected) is truly infected with SARS-CoV-2 decreases as prevalence decreases, irrespective of the claimed specificity."

43. A positive RT-PCR result represents the identification of SARS-CoV-2 virus fragments, but a positive RT-PCR result does not necessarily indicate the entire virus is present, replication competent virus is present, or the patient has COVID-19. If the entire virus is not present in the person, or the virus is not replication competent, then the person is not infectious.

44. A study from Singapore[105] showed that the higher the Ct value, the larger degree of viral fragmentation and the less likely that an entire viral genome is actually present. In other words, the higher the Ct, the more likely it is that only bits of virus are being detected, and less likely that entire virus is present in the patient. Only complete virus particles can be replication competent and therefore infectious and transmissible.

45. Many studies have convincingly shown that the higher the Ct, the less likely replication-competent virus (infectious virus) can be detected through cell culture[106-113]. An editorial in *Clinical Infectious Diseases* concluded "that PCR

positivity is likely not a reliable surrogate marker for determining the infectious status of COVID-19 patients"[114]. A systematic review on the topic concluded that test results "with high cycle threshold are unlikely to have infectious potential."[115]

46. That a positive test does not necessarily indicate infectiousness is indicated by recommendations for stopping isolation in persons previously positive for SARS-CoV-2. The WHO[116-117], CDC[118], and Canadian jurisdictions[119] recommend discontinuing isolation of persons with COVID-19 ten days after symptom onset, and in persons who have tested positive for SARS-CoV-2 without symptoms ten days after their first positive RT-PCR result, even though it is well established that many persons in these groups will continue to have positive RT-PCR results after those time frames. Those guidelines recommend against RT-PCR testing in these groups because it is known that positive tests in these groups does not indicate infectiousness. This is a concrete application of the evidence that late in the course of SARS-CoV-2 infection, which corresponds to increasing Ct, there is no risk of transmission. In another example, Ontario uses point-of-care tests, that are less sensitive than RT-PCR, to rule out SARS-CoV-2 infection[120] in persons who are symptomatic without known contact with a positive case. In this case, even though a more sensitive test such as RT-PCR might detect more positives, a less sensitive test[121] is sufficient to rule out significant infection.

47. Evidence shows that the higher the Ct value, the more likely it is that a person is in the later stages of the infection, and therefore less infectious. The nearer the Ct value approaches 40, the closer the likelihood that the patient is infectious approaches zero. A report from the Emerging Sciences Group of the Public Health Agency of Canada[122] concludes that in symptomatic persons there is "a peak in viral load ranging from just before to during the first week after onset of illness" and in asymptomatic persons "viable virus and viral RNA was highest during the first week of infection and declined in subsequent weeks." In persons that are asymptomatic or mildly symptomatic, late in the course of illness the Ct value is

higher[110] and viable virus cannot be detected though cell culture. The likelihood of a positive cell culture correlates with disease severity[123], and therefore risk of infectiousness correlates with disease severity.

48. The Ct value early in the course of illness is significantly lower than the Ct value late in the course of illness[124]. The Ct value of pre-symptomatic persons has been shown to be low, and not be significantly different from symptomatic persons; in one study, the Ct value was 23.1 for pre-symptomatic persons compared to 24.8 in persons with typical symptoms[10]. There is a clear association between Ct value and stage of infection; the higher the cycle threshold[123], the more likely the patient is in the later stages of the infection, and the less likely the patient is infectious or at risk of transmitting the virus to another person.

SARS-CoV-2 infection versus COVID-19 disease

49. It is important to recognize the difference between SARS-CoV-2 infection and COVID-19 disease. This is an important distinction that is made with many other infections. As noted in a *British Medical Journal* editorial: "Unusually in disease management, a positive test result is the sole criterion for a Covid-19 case. Normally, a test is a support for clinical diagnosis, not a substitute."[125] In other words, for COVID-19, a positive test is sufficient to make the diagnosis, which is not done in other infections that are similarly mild and short-lived.

50. A positive SARS-CoV-2 PCR test means that a person has or recently had SARS-CoV-2 (virus) in their body; however, it does not mean that the person is infectious or that they have COVID-19 disease (i.e. symptoms). If we wanted to define specificity as diagnosing infectiousness or disease (i.e. symptoms or pathology), then the specificity of RT-PCR would be dramatically lower. This distinction can be better understood if we look at how PCR is used in other infections.

51. To cite just a few examples, positive PCR tests for Group A Streptococcus, Salmonella, E. coli O157, Campylobacter, C. difficile, Epstein-Barr Virus (EBV),

Cytomegalovirus (CMV) do not necessarily indicate disease. In the absence of symptoms or other tests indicating pathological effects, persons with positive PCR tests for those infections are not considered to have disease and they are usually not treated. The distinction between infection and disease is important. Over 50% of adult Canadians will be infected with EBV or CMV for most of their life; once acquired, those infections persist lifelong and PCR tests can detect those viruses, to varying degrees, throughout their lifetime. It would be inaccurate to say that over 50% of Canadians have disease associated with those viruses even though they can be detected by PCR.

52. A positive PCR result also does not necessarily indicate infectiousness. At any time, about 10% of school-aged children will have throat swabs positive for Group A Streptococcus (GAS)[126,127]. GAS can cause pharyngitis (strep throat), scarlet fever, rheumatic fever, and necrotizing fasciitis (flesh eating disease), but a positive test in an asymptomatic person is not considered significant in most cases.

53. Even a positive RT-PCR result in a person living with HIV does not necessarily mean that the person is considered infectious. According to Canadian law[128], "the combined effect of condom use and low viral load precludes a realistic possibility of transmission of HIV". Similarly, the Ontario Court of Appeal stated that "viral loads below a defined level, standing on their own, are sufficient to negate the realistic possibility of HIV transmission"[129].

54. The presence of SARS-CoV-2 virus as detected by PCR is necessary but not sufficient to indicate either infectiousness or COVID-19 *disease* properly defined. If a true positive is defined as the presence of complete virus, or replication competent virus (i.e. infectious virus) then the specificity of PCR is much lower and the number of false positives associated with PCR would be considered much higher.

Outdoor transmission of SARS-CoV-2

55. The risk of outdoor transmission of SARS-CoV-2 at outdoor religious services is negligible when physical distancing is maintained. The evidence for this assertion can be examined in two domains: First, by examining the evidence for outdoor transmission of other important respiratory tract infections such as tuberculosis (TB) and influenza; second, by examining the evidence for transmission of SARS-CoV-2 itself.

56. Since we only have just over one year of experience with SARS-CoV-2, it is helpful to look at the risk of outdoor transmission of two other very important respiratory tract infections, TB and influenza. TB is a respiratory tract infection that is transmitted through airborne particles. The *Canadian Tuberculosis Standards* published by the Public Health Agency of Canada state that TB "transmission is rarely thought to occur outdoors"[130] and the "risk of [outdoor] transmission is negligible provided they are not in very close contact with susceptible individuals for prolonged periods of time"[131]. The result is that "outdoor exposures are not investigated during a contact tracing exercise"[132].

57. Influenza is another important respiratory tract infection. In a systematic review of outdoor mass gatherings and respiratory disease (mostly influenza) performed by the United States Centers for Disease Control and Prevention, "no single-day mass gathering-related outbreaks were identified in our review"[133]. Similarly, a global review of outbreaks (including influenza outbreaks) at outdoor large gatherings from 1980 to July 2012 did not identify any outbreaks associated with single day gatherings[134]. These studies and others were included in a systematic review of outdoor transmission of SARS-CoV-2 and other respiratory viruses; influenza outbreaks only occurred in the context of multiday outdoor events or communal housing[135].

58. The primary mode of SARS-CoV-2 transmission is known to occur indoors. Household transmission (indoors) accounted for 78%-85% of all SARS-CoV-2 transmission in China in one report from the World Health Organization[136]. Household contacts and travel together were the most important sources of SARS-CoV-2 transmission in another study[137]. Outbreaks in indoor contexts such as long-term care facilities, hospitals and shelters have been established as an important source of indoor transmission in the Canadian context[138].

59. The evidence for outdoor SARS-CoV-2 transmission, when present, is negligible. In one comprehensive study from China[139], only one outdoor outbreak involving two cases occurred out of 7324 identified cases. The reason for negligible outdoor transmission is that airflow outdoors rapidly dilutes any SARS-CoV-2 virus present to negligible amounts not considered to be infectious[140].

60. As shown above, outdoor religious gatherings of short duration (less than 24 hours; no overnight component) should be considered safe based on the evidence. The risk of outdoor transmission of SARS-CoV-2 is negligible, similar to other important respiratory infections such as TB and influenza. As long as physical distancing can be maintained, outdoor religious gatherings should be considered safe.

61. I make this affidavit *bona fide*.

SWORN REMOTELY by videoconference by Dr. Thomas Warren at [redacted] before me at the City of London, in the County of Middlesex, this 25th day of May, 2021 in accordance with O.Reg. 431/20 Administering Oath or Declaration Remotely

A Commissioner, etc.

LISA D.S. BILDY
BARRISTER & SOLICITOR

DR. THOMAS WARREN

Employment

2011 -	**Infectious Diseases consultant & Medical Microbiologist** Halton Healthcare, Oakville ON
2010-2011	**Internal Medicine specialist – locum coverage** St. Michael's Hospital, Toronto ON Hamilton Health Sciences, Hamilton ON Lakeridge Health, Oshawa ON
2010-2011	**University of Toronto** Department of Laboratory Medicine & Pathobiology, Toronto ON *Resident, Medical Microbiology*
2008-2010	**University of Toronto** Department of Medicine, Division of Infectious Diseases, Toronto ON *Fellow, Infectious Diseases*
2005-2008	**University of Ottawa** Department of Medicine, Ottawa ON *Resident, Internal Medicine*
1997-2003	**University of Western Ontario** Department of Medicine, London ON *Computer Programmer & Web Developer*

Education

2018 -	**London School of Hygiene and Tropical Medicine, University of London** *Master's of Science (Epidemiology)* Expected Completion 2022
2010-2011	**Royal College of Physicians & Surgeons of Canada** *Residency in Medical Microbiology*

2008-2010	**Royal College of Physicians & Surgeons of Canada** *Fellowship in Infectious Diseases*
2005-2008	**Royal College of Physicians & Surgeons of Canada** *Residency in Internal Medicine*
2001-2005	**University of Western Ontario** Schulich School of Medicine & Dentistry *Doctor of Medicine*
1997-2001	**University of Western Ontario** *Bachelor of Science - Honors Microbiology & Immunology* *(Scholar's Electives Program)* Graduated With Distinction

Continuing Medical Education

2018	**IDEAS Foundations of Quality Improvement Program** May 30 McMaster University Hamilton, ON
2018	**Clinical Teaching Fundamentals** January - March McMaster University Hamilton, ON

Peer-Reviewed Publications

2015	**Warren T**, Lau R, Ralevski F, Rau N, Boggild AK. Fever in a visitor to Canada: a case of mistaken identity. *J Clin Microbiol.* 53:1783-1785.
2012	**Warren TA**, Yau Y, Ratjen F, Tullis E, Waters V. Serum galactomannan in cystic fibrosis patients colonized with *Aspergillus* species. *Medical Mycology.* 2012; 50: 858-860.
2010	**Warren TA**, McTaggart L, Richardson SE, Zhang SX. Candida bracarensis Bloodstream Infection in an Immunocompromised Patient. *Journal of Clinical Microbiology.* 2010; 48: 4677–4679.

Abstracts & Conference Presentations

2011 **Warren TA**, Yau Y, Waters V.
Serum galactomannan in cystic fibrosis patients colonized with Aspergillus species.
Poster session presented at: Association of Medical Microbiology and Infectious Disease (AMMI) Canada 2011 Annual Conference
2011 April 7-9; Montreal, QC.

2010 **Warren TA**, Yau Y, Waters V.
Serum galactomannan in cystic fibrosis patients colonized with Aspergillus species.
Poster session presented at: North American Cystic Fibrosis Conference
2010 October 21-23; Baltimore, MD.

2010 **Warren TA**, Govindapillai S, Tullis E, Devlin HR, Ferris W, Matukas LM.
Evaluation of Etest Combination Testing of Antibiotics Against Isolates from Patients with Cystic Fibrosis.
Poster session presented at: 50th Interscience Conference on Antimicrobial Agents and Chemotherapy
2010 September 12-15; Boston, MA.

2010 **Warren TA**, Rotstein C, Cole EH, Singer LG, Keshavjee SH, Husain S.
Posaconazole therapy in solid organ transplant recipients refractory to or intolerant of standard therapy.
Poster session presented at: Canadian Society for Transplantation Annual Conference
2010 August 12-15; Vancouver, BC.

2010 **Warren TA**, McTaggart L, Zhang S. Candida bracarensis
Blood Stream Infection in an Immunocompromised Patient: Case Report.
Poster session presented at: Focus on Fungal Infections
2010 March 3-5; New Orleans, LA.

2007 **Warren TA**, McCarthy AE.
A Ten-Year Retrospective Study of Vaccination Rates, Prophylactic Antibiotic Use, Serious Infection and Overwhelming Postsplenectomy Sepsis Rates in Splenectomized Patients.
Poster session presented at: Annual Meeting of the Infectious Diseases Society of America
2007 October 4-7; San Diego, CA.

Awards

2011 **Best Student Poster Award – 2011 Annual Conference**
Association of Medical Microbiology and Infectious Disease (AMMI) Canada
Montreal, QC

2010 **ASM ICAAC Infectious Diseases Fellows Grant**
2010 Interscience Conference on Antimicrobial Agents and Chemotherapy
Boston, MA

2008 **Internal Medicine CanMeds Award for Communication**
University of Ottawa, Department of Medicine
Ottawa, ON

2006 **Resident Research Day Award of Excellence – PGY1**
University of Ottawa, Department of Medicine
Ottawa, ON

2001 Laurene Paterson scholarship
University of Western Ontario
London, ON

1997-2001 **Dean's Honor List**
University of Western Ontario, Faculty of Science
London, ON

1997 **Western Scholarship of Excellence**
University of Western Ontario
London, ON

Appointments

2013 - **McMaster University**
Assistant Clinical Professor (Adjunct)
Department of Medicine, Faculty of Health Sciences
Hamilton, ON

Teaching

2012-2021 **Infectious Diseases** – Clinical Rotations
Supervised physician assistant students, medical students, residents and infectious diseases fellows from the University of Toronto and McMaster University
Oakville, ON

2009	**Pathobiology of Disease** *Taught microbiology to second year medical students* University of Toronto Toronto, ON
2008	**Pathobiology of Disease** *Taught microbiology to second year medical students* University of Toronto Toronto, ON
2008	**Physical Skills Development Course** *Taught physical exam skills to first year medical students* University of Ottawa Ottawa, ON

ACKNOWLEDGMENT OF EXPERT'S DUTY

---

1. My name is Dr. Thomas Warren. [redacted], Ontario.

2. I have been engaged on behalf of the Moving Parties, Trinity Bible Chapel et al. and The Church of God, et al., to provide evidence in relation to the above-noted court proceeding.

3. I acknowledge that it is my duty to provide evidence in relation to this proceeding as follows:

   (a) to provide opinion evidence that is fair, objective and non-partisan;

   (b) to provide opinion evidence that is related only to matters that are within my area of expertise; and

(c) to provide such additional assistance as the court may reasonably require, to determine a matter in issue.

4. I acknowledge that the duty referred to above prevails over any obligation which I may owe to any party by whom or on whose behalf I am engaged.

Date: May 25, 2021

Signature

NOTE: This form must be attached to any expert report under subrules 53.03(1) or (2) and any opinion evidence provided by an expert witness on a motion or application.

ABSTRACT

Background: Human coronaviruses (HCoVs) -OC43, -229E, -NL63 and -HKU1 cause upper and lower respiratory tract infections. HCoVs are globally distributed and the predominant species may vary by region or year. Prior studies have shown seasonal patterns of HCoV species and annual variation in species prevalence but national circulation patterns in the US have not yet been described.
Objectives: To describe circulation patterns of HCoVs -OC43, -229E, -NL63 and -HKU1 in the US.
Study design: We reviewed real-time reverse transcription polymerase chain reaction (rRT-PCR) test results for HCoV-OC43, -229E, -NL63 and -HKU1 reported to The National Respiratory and Enteric Virus Surveillance System (NREVSS) by U.S. laboratories from July 2014–June 2017. We calculated the total number of tests and percent positive by week. For a subset of HCoV positive submissions with age and sex of the patient available, we tested for differences in age and sex across the four HCoV species using Chi Square and Kruskal Wallace tests.
Results: 117 laboratories reported 854,575 HCoV tests; 2.2% were positive for HCoV-OC43, 1.0% for HCoV-NL63, 0.8% for HCoV-229E, and 0.6% for HCoV-HKU1. The percentage of positive tests peaked during December – March each year. No significant differences in sex were seen across species, although a significant difference in age distribution was noted.
Conclusions: Common HCoVs may have annual peaks of circulation in winter months in the US, and individual HCoVs may show variable circulation from year to year. Different HCoV species may be detected more frequently in different age groups. Further years of data are needed to better understand patterns of activity for HCoVs.

1. Background

Human coronaviruses (HCoVs) HCoV-NL63, HCoV-HKU1, HCoV-229E, and HCoV-OC43 circulate worldwide and cause a range of respiratory symptoms [1]. Infections are often asymptomatic or associated with mild to moderate upper respiratory tract illness in immunocompetent children and adults; HCoVs are considered the second most common cause of the common cold [2]. Infections can also result in lower respiratory tract illness including bronchiolitis and pneumonia, especially in immunocompromised individuals, infants, and older adults [1]. Increased availability of molecular test methods and more frequent testing for multiple respiratory pathogens have allowed for opportunities to characterize circulation patterns of individual HCoVs.

Although HCoVs are globally distributed, the predominant species may vary by region or year [3–5]. Previous studies have shown seasonal patterns of HCoV species and annual variation in species prevalence [3,4,6]. However, national circulation patterns across the United States have not been described and few studies have described circulation of all four HCoVs across multiple years [6].

2. Objectives

Our objective was to describe laboratory detections of HCoVs

-NL63, -HKU1, -229E, and -OC43 in the United States during 2014–2017, using data collected by The National Respiratory and Enteric Virus Surveillance System (NREVSS) [7].

3. Study design

NREVSS is a passive surveillance network established by the U.S. Centers for Disease Control and Prevention (CDC) in the 1980s that collects specimen test results for several respiratory and enteric viruses from multiple laboratories across the United States [7]. NREVSS currently collects data from three different sources: directly from clinical, state, and local laboratories; indirectly from state or local partners on behalf of laboratories within their jurisdictions; and indirectly through the Public Health Laboratory Interoperability Project (PHLIP).

PHLIP is a collaborative partnership between CDC, state and local public health labs (PHLs), and the Association of Public Health Laboratories (APHL) to strengthen the submission of automated specimen-level surveillance laboratory test results directly to CDC [8]. Laboratories submitting to NREVSS via PHLIP submit specimen level results for respiratory virus tests along with patient demographics, such as sex and age. The remaining majority of NREVSS participants (i.e. non-PHLIP submitters) submit weekly aggregates of positive detections for the four HCoV species by RT-PCR along with the aggregate number of RT-PCR HCoV tests performed.

To better understand HCoV circulation in the US, we assessed reports of specimens tested for HCoVs, and submitted to NREVSS during July 1, 2014–June 30, 2017. Reporting laboratories were excluded if they did not report HCoV results at the species level. We summarized the total number of HCoV tests submitted during the study period and calculated the overall percent positive for each HCoV species by week. Test numbers and positive HCoV results were also summarized separately for individual US census regions.

To understand demographics of patients with HCoV detections we further analyzed the subset of NREVSS data reported through PHLIP. We selected reports of specimens tested for all four HCoV species and calculated the percent positive for each HCoV species. We used all PHLIP reports with a single positive HCoV detection to test differences in age distribution among the four HCoV species using the Kruskal Wallis Test. Differences in sex distribution among the four HCoV species were tested using the Chi Square Test. We then summarized viral co-detections for each HCoV species using reports of specimens tested for all four HCoVs and which were also tested for the following viruses: parainfluenza viruses 1–4, respiratory syncytial virus (RSV), human metapneumovirus, human adenovirus, rhinovirus/enterovirus, influenza A and influenza B. Analysis was performed using R version 3.3.1.

4. Results

During July 1, 2014–June 30, 2017, 854,575 HCoV tests were reported by 117 laboratories in 42 states submitting to NREVSS. Overall, 18,804 (2.2%) were positive for HCoV-OC43, 8558 (1.0%) for HCoV-NL63, 7001 (0.8%) for HCoV-229E and 5225 (0.6%) for HCoV-HKU1. The number of HCoV tests submitted to NREVSS per week varied seasonally, with the testing peak occurring each year in winter, generally between December and March (Fig. 1A). Overall HCoV testing increased during the three years (Fig. 1A). The percent of HCoV positive tests varied throughout each year, and also peaked each year between December and March. The percent positive varied annually by HCoV species (Fig. 1B). HCoV-OC43 demonstrated a distinct peak each of the three years, with a less pronounced peak in 2016. HCoV-NL63 and HCoV-HKU1 demonstrated similar patterns to one another; both had a small peak in 2015 and larger peaks in 2016, although only HCoV-NL63 had a small peak in 2017. HCoV-229E showed a slight peak in 2015, no peak in 2016 and a relatively large peak in 2017 (Fig. 1B). The highest percent positive for any single species was 7.6% of tests positive for HCoV-OC43 in the week beginning December 31, 2016. Across each census region, minimal differences in seasonal and annual patterns of percentage of tests positive for each HCoV species were seen compared to national data (Fig. 2). The most notable difference was in the percentage of positive HCoV-OC43 tests during the 2016–2017 season, with the West region showing a peak percent positive of 5.0% and the Midwest region showing a peak percent positive of 12.4%.

Data reported to NREVSS through PHLIP was further analyzed to understand sex and age characteristics. During the study period, 20,806 specimens tested for all four HCoVs were submitted via PHLIP from six laboratories. Overall 1569 tests (7.5%) were positive for any HCoV; 852 (4.1%) were positive for HCoV-OC43, 255 (1.2%) for HCoV-NL63, 335 (1.6%) for HCoV-229E and 154 (0.7%) for HCoV-HKU1. The majority of specimens with a single HCoV detection (92.2% of 1543 specimens) included the sex of the patient, and approximately half (50.6%) of all these HCoV detections were reported as male. No significant difference was seen in the sex distribution between the four HCoVs ($p = 0.19$). Age was available for 1016 (67%) of specimens with a single HCoV detection and the median patient age of these specimens was 23 years (range 0–96 years). The patient age distribution of specimens with a single HCoV detection was significantly different between species

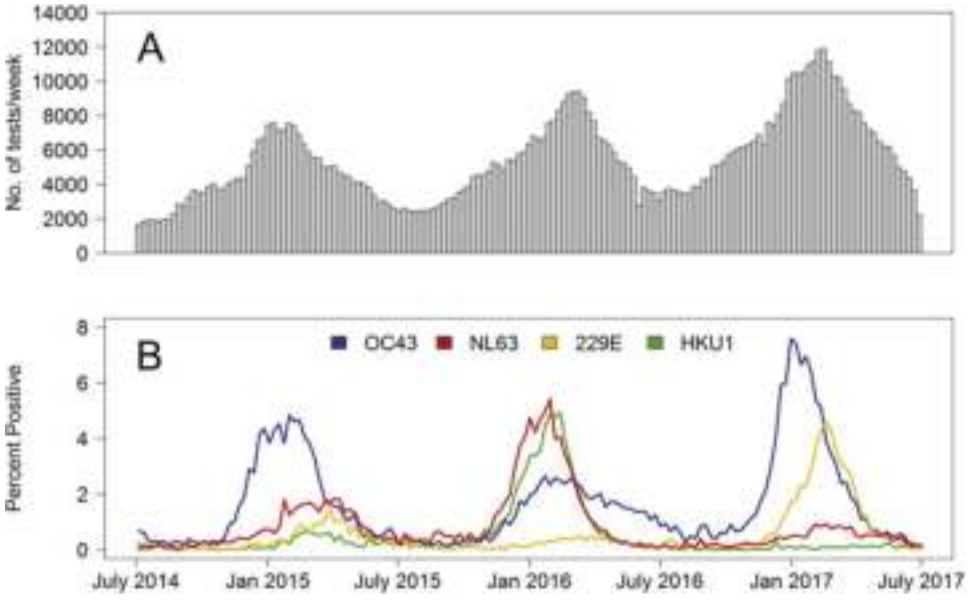

Fig. 1. A) The number of tests performed to detect any of the four human coronaviruses (HCoVs) -OC43, -NL63, -229E, and -HKU1 reported to the National Respiratory and Enteric Viruses Surveillance System (NREVSS) by week, July 2014–June 2017, B) The percentage of tests positive for HCoVs -OC43, -NL63, -229E, and -HKU1 reported to NREVSS by week, July 2014–June 2017.

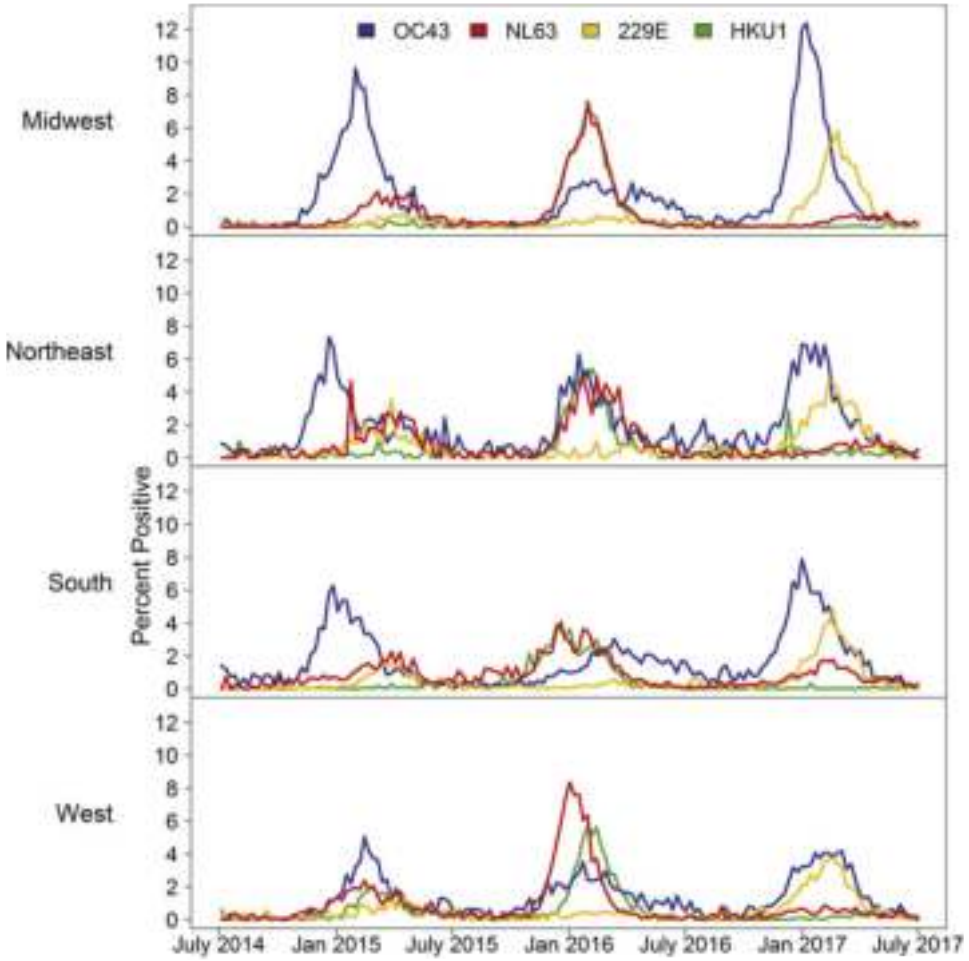

Fig. 2. The percentage of tests positive for human coronaviruses (HCoVs) -OC43, -NL63, -229E, and -HKU1 reported to the National Respiratory and Enteric Viruses Surveillance System (NREVSS) by week, stratified by US Census Region, July 2014–June 2017.

($p < 0.01$) (Fig. 3). The median ages of patients with specimens testing positive for a single HCoV species were as follows: HCoV-OC43, 24 years; HCoV-NL63, 11 years; HCoV-229E, 30 years; and HCoV-HKU1, 19 years. For HCoV-OC43, HCoV-NL63, and HCoV-HKU1 > 45% of detections were in children < 18 years old (Fig. 3). By contrast, 31% of HCoV-229E detections were in children < 18 years old (Fig. 3).

Among the 1569 HCoV positive detections reported via PHLIP, 1538 (98%) were also tested for parainfluenza viruses 1–4, respiratory syncytial virus (RSV), human metapneumovirus, human adenovirus, rhinovirus/enterovirus, influenza A and influenza B. Among these, 68.6% reported a single HCoV species detection only, 1.7% reported two or more HCoV species, and 30.2% detected another respiratory virus. The most common HCoV co-detections were HCoV-OC43 with HCoV-NL63 (8 specimens, 0.5%), and HCoV-OC43 with HCoV-229E (8 specimens, 0.5%). The most common co-detected non-HCoV viruses were RSV (11% of HCoV positive specimens), rhinovirus/enterovirus (6.6%), and influenza A (5.7%); 51 (3.3%) specimens had ≥2 viral species detected in addition to HCoV. Co-detection patterns were broadly similar among the four HCoVs (Table 1).

5. Discussion

This report is the first to describe the national patterns of circulation of the four common HCoV species in the United States during a multi-year period. During the study period, HCoVs showed a peak prevalence during December– March each year, which coincides with the winter respiratory virus season [7,9]. HCoV-OC43 was the most commonly detected HCoV with 2.2% of all tests positive. Different HCoV species predominated in different years; HCoV-OC43 appeared to peak annually, while HCoV-NL63, HCoV-HKU1, and HCoV-229E showed more variability, with distinct peaks in one or two of the three years studied. This is consistent with previously published site-specific data indicating that individual species may only demonstrate peak activity every 2–3 years [10,11].

Factors associated with annual differences in activity for HCoV species are currently unknown. Individual HCoV species activity could fluctuate independently, or cross-immunity within or between *Alphacoronavirinae* (HCoV-229E and HCoV-NL63) and *Betacoronavirinae* (HCoV-HKU1 and HCoV-OC43) might affect annual activity of the four HCoVs [4,12]. During the study period, HCoV-229E and HCoV-NL63 did not show large contemporaneous peaks of activity, although both showed smaller peaks of activity in 2014–2015. When data was visualized by census region, annual and seasonal patterns were similar to those seen nationally (Fig. 2).

The age distribution of patients with reported HCoV infections differed between HCoV species (Fig. 3). HCoV-229E detections were more common in adults > 18 years old compared to HCoV-HKU1, -NL63, and -OC43. HCoV-229E has previously been reported as disproportionately affecting immunocompromised individuals relative to the other HCoV species [4], possibly affecting the median reported age at infection. HCoV-NL63 showed the lowest median age of infection, and has been shown to be associated with croup in young children [13], which may lower the average age of infection. Non-HCoV viral co-detections were seen in 30% of specimens positive for HCoV, and 3.3% of specimens had two or more co-detected viral species. The clinical impact of coronaviruses in co-detections is not fully understood, with prior studies

0003

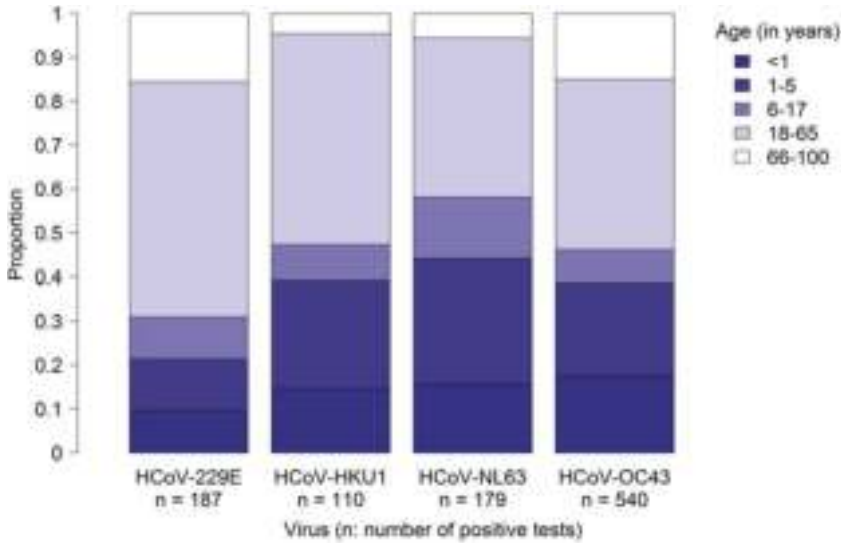

Fig. 3. Age distribution of human coronaviruses (HCoVs) -229E, -HKU1, -NL63 and -OC43 positive tests with age available reported to NREVSS via the Public Health Laboratory Interoperability Project (PHLIP), from July 2014–June 2017. Note, specimens with more than one coronavirus detected were excluded (n = 18).

reporting both increased and unchanged morbidity and mortality with respiratory viral co-detections [14]. Single infections with HCoVs have been associated with morbidity due to lower and upper respiratory tract infections [4], however Prill et al demonstrated that HCoVs were not found more frequently in children hospitalized for acute respiratory illness and/or fever than asymptomatic controls [15].

There were limitations to this report. NREVSS is a passive, voluntary surveillance system, collecting results from specimens submitted to U.S. laboratories. Many HCoV infections are subclinical or mild, and do not require clinical care; therefore these infections are unlikely to require laboratory testing and would not be captured by NREVSS. The relative proportions of HCoV species reported here may not be representative of all HCoV infections. Within NREVSS all reporters of HCoV surveillance data at the species level were included, including those inconsistently reporting over time. This may result in certain laboratories or regions being overrepresented at certain times e.g. during winter, when the majority of respiratory virus tests are conducted.

Data reported to NREVSS through PHLIP represent a smaller subset of six laboratories that also report additional data including sex and age; data reported through PHLIP may not be representative of the entire NREVSS population. The overall percent of HCoV positive tests varied between PHLIP and NREVSS; the percent of HCoV positive tests submitted to NREVSS via PHLIP was 7.5%, vs 4.6% for NREVSS as a whole. This may result from differences in reporting laboratories; reporting through PHLIP is limited to military, state and public health laboratories, whereas data submitted directly to NREVSS through non-PHLIP sources primarily includes clinical laboratories. State and local public health laboratories test for a variety of reasons including surveillance and public health response to outbreaks and clusters of cases, whereas clinical laboratories often test in the course of managing individual cases.

Within the peak in detections noted during December-March, we were not able to define precise seasonal onset and offset periods for any individual HCoV species. Additionally, we assessed HCoV percent positivity over time based on the date of submission of a report to NREVSS rather than the date of specimen collection, and we anticipate that our findings may reflect this slight delay. Finally, aggregate data reported to NREVSS via PHLIP might include multiple specimens from the same patient, potentially impacting the demographic characteristics of reported cases.

Surveillance of HCoVs is important to determine seasonality and annual circulation patterns. Continued use of respiratory virus multiplex assay panels could facilitate further definition of HCoV circulation through public health surveillance in the future. Further years of data are needed to better understand patterns of activity for HCoVs, and studies with additional epidemiologic data will be useful to better characterize HCoV burden and spectrum of illness.

Review

Epidemiology, Genetic Recombination, and Pathogenesis of Coronaviruses

Shuo Su,[1,*] Gary Wong,[2,3,4] Weifeng Shi,[5] Jun Liu,[4,6] Alexander C.K. Lai,[7] Jiyong Zhou,[1] Wenjun Liu,[3,4] Yuhai Bi,[2,3,4,*] and George F. Gao[2,3,4,6,8,9,*]

Human coronaviruses (HCoVs) were first described in the 1960s for patients with the common cold. Since then, more HCoVs have been discovered, including those that cause severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS), two pathogens that, upon infection, can cause fatal respiratory disease in humans. It was recently discovered that dromedary camels in Saudi Arabia harbor three different HCoV species, including a dominant MERS HCoV lineage that was responsible for the outbreaks in the Middle East and South Korea during 2015. In this review we aim to compare and contrast the different HCoVs with regard to epidemiology and pathogenesis, in addition to the virus evolution and recombination events which have, on occasion, resulted in outbreaks amongst humans.

Trends

Six coronaviruses (CoVs) are known to infect humans: 229E, OC43, SARS-CoV, NL63, HKU1, and MERS-CoV.

Many CoVs are simultaneously maintained in nature, allowing for genetic recombination, resulting in novel viruses.

Recombination of CoV in camels has resulted in a dominant MERS lineage that caused human outbreaks in 2015.

A Brief Introduction to Human and Animal Coronaviruses

Coronaviruses (CoVs), of the family Coronaviridae, are enveloped viruses with a single-strand, positive-sense RNA genome approximately 26–32 kilobases in size, which is the largest known genome for an RNA virus [1]. The term 'coronavirus' refers to the appearance of CoV virions when observed under electron microscopy, in which spike projections from the virus membrane give the semblance of a crown, or *corona* in Latin [2,3]. All coronaviruses share similarities in the organization and expression of their genome, in which 16 nonstructural proteins (nsp1 through nsp16), encoded by open reading frame (ORF) 1a/b at the 5′ end, are followed by the structural proteins spike (S), envelope (E), membrane (M), and nucleocapsid (N), which are encoded by other ORFs at the 3′ end. CoVs are separated into four genera based on phylogeny: alpha-CoV (group 1), beta-CoV (group 2), gamma-CoV (group 3) and delta-CoV (group 4) (http://ictvonline.org/proposals/2008.085-122 V.v4.Coronaviridae.pdf). Within the beta-CoV genus, four lineages (A, B, C, and D) are recognized. Distinct from other beta-CoV lineages, lineage A viruses also encode a smaller protein called hemagglutinin esterase (HE), which is functionally similar to the S protein [4].

Since the early 1970s, a variety of pathological conditions in domestic animals have been attributed to CoV infections [5]. With the exception of infectious bronchitis virus (IBV), which causes avian infectious bronchitis in chickens [6], canine respiratory coronavirus (CRCoV), which causes respiratory disease in dogs [7], and mouse hepatitis virus (MHV), which can cause a progressive demyelinating encephalitis in mice [3,8], other CoV infections typically result in

gastrointestinal symptoms. For instance, transmissible gastroenteritis coronavirus (TGEV) [9,10], bovine coronavirus (BCV) [11], feline coronavirus (FCoV) [12], canine coronavirus (CCoV) [13], and turkey coronavirus (TCV) [14] are known to cause enteritis in their respective hosts [1].

In humans, CoV infections primarily involve the upper respiratory tract and the gastrointestinal tract, and vary from mild, self-limiting disease, such as the common cold, to more severe manifestations, such as bronchitis and pneumonia with renal involvement [15]. The first human coronavirus (HCoV) was isolated during 1965 from the nasal discharge of patients with the common cold and termed B814 [16]. Currently, six different CoV strains are known to infect humans. These include: HCoV-229E (229E), HCoV-OC43 (OC43), severe acute respiratory syndrome coronavirus (SARS-CoV), HCoV-NL63 (NL63), HCoV-HKU1 (HKU1), and Middle East respiratory syndrome coronavirus (MERS-CoV) [17]. 229E and OC43 are the prototype viruses from the two main HCoV lineages (Alpha and Beta, respectively) that cause 15–29% of all common colds, and are the best characterized [18]. SARS-CoV is the aetiological agent that was behind an outbreak of severe respiratory disease through China during 2002–2003 [19], and MERS-CoV is the pathogen responsible for an ongoing outbreak of severe respiratory disease centered in the Middle East since 2012 [20]. In this review, we first compare and contrast the epidemiology and pathogenesis of the known CoVs infecting humans, in which CoVs that cause mild to severe disease in humans are newly emerged from a zoonotic source. Second, we describe the ecology of CoVs, and highlight evidence for viral recombination between the different CoVs within animal populations, which may result in the generation of novel CoVs that are transmissible and lethal to humans. Finally, we summarize the phylogeny, evolution, and genetic recombination of CoVs in detail.

Epidemiology and Pathogenesis of HCoV

The epidemiology and pathogenesis of each HCoV are discussed within the following sections and summarized in Table 1 and Figure 1, respectively. In general, 229E, OC43, and NL63 are distributed globally (Figure 1A) and tend to be transmitted predominantly during the winter season in temperate-climate countries [21], while NL63 showed a spring–summer peak of activity from a study in Hong Kong [22].

Human Coronavirus 229E (alphacoronavirus)

Strain 229E was discovered during 1966, when researchers were characterizing five novel agents that were isolated from the respiratory tract of humans who had contracted the common cold [23]. 229E was adapted to grow in WI-38 lung fibroblast cell lines, and was later shown to be morphologically identical to IBV and MHV [24]. Symptoms of 229E infection include general malaise, headache, nasal discharge, sneezing, and a sore throat [25]. A small portion of patients (10–20%) will also exhibit fever and cough. The incubation time is approximately 2–5 days, followed by illness lasting between 2 and 18 days, and clinically indistinguishable from respiratory tract infections caused by other pathogens, such as rhinovirus and influenza A [18]. 229E is distributed globally (Figure 1A).

Human Coronavirus OC43 (betacoronavirus, lineage A)

Strain OC43 was discovered, during 1967, in the nasopharyngeal wash of a patient with the common cold, and is adapted to grow in organ cultures containing suckling mouse brains. Similar to 229E, OC43 is morphologically indistinguishable from IBV and MHV [24], and patients infected with OC43 present the same clinical symptoms as that of 229E [24]. However, there is no serological cross-reactivity between 229E and OC43 [24]. OC43 is also distributed globally (Figure 1A).

SARS-CoV (betacoronavirus, lineage B)

Patients infected with SARS-CoV initially present with fever, myalgia, headache, malaise, and chills, followed by a nonproductive cough, dyspnea, and respiratory distress generally

Table 1. Comparison of Clinical Symptoms, Incubation Time, Median Time to Death, and Case Fatality Rates of Human Coronaviruses

HCoV	Clinical Symptoms	Case Fatality Rate	Incubation Period	Median Time to Death	Refs
229E	General malaise Headache Nasal discharge Sneezing Sore throat Fever and cough (10–20% of patients)	N/A[a]	2–5 days	—	[18,81,82]
OC43	General malaise Headache Nasal discharge Sneezing Sore throat Fever and cough (10–20% of patients)	N/A	2–5 days	—	[18,82–84]
SARS-CoV	Fever Myalgia Headache Malaise Chills Nonproductive cough Dyspnea Respiratory distress Diarrhea (30–40% of patients)	9%	2–11 days	23 days	[19,42,85–88]
NL63	Cough, Rhinorrhea Tachypnea Fever Hypoxia Obstructive laryngitis (croup)	N/A	2–4 days	—	[89–92]
HKU1	Fever Running nose Cough Dyspnea	N/A	2–4 days	—	[2,32–34,93,94]
MERS-CoV	Fever Cough Chills Sore throat Myalgia Arthralgia Dyspnea Pneumonia Diarrhea and vomiting (one-third of patients) Acute renal impairment	36%	2–13 days	14 days	[41–43,95,96]

[a]N/A, not applicable.

5 to 7 days later, which may result in death (http://www.who.int/csr/sars/en/WHOconsensus.pdf?ua=1). Other notable features in some cases include infection of the gastrointestinal tract, liver, kidney, and brain. Diffuse alveolar damage, epithelial cell proliferation, and an increase in macrophages is seen in SARS-CoV infection of the lung. Lymphopenia, hemophagocytosis in the lung, in addition to white-pulp atrophy of the spleen observed in SARS patients, are similar to fatal H5N1 influenza virus infections [1]. Diarrhea is observed in approximately 30–40% of SARS infections (http://www.cdc.gov/sars/about/faq.html).

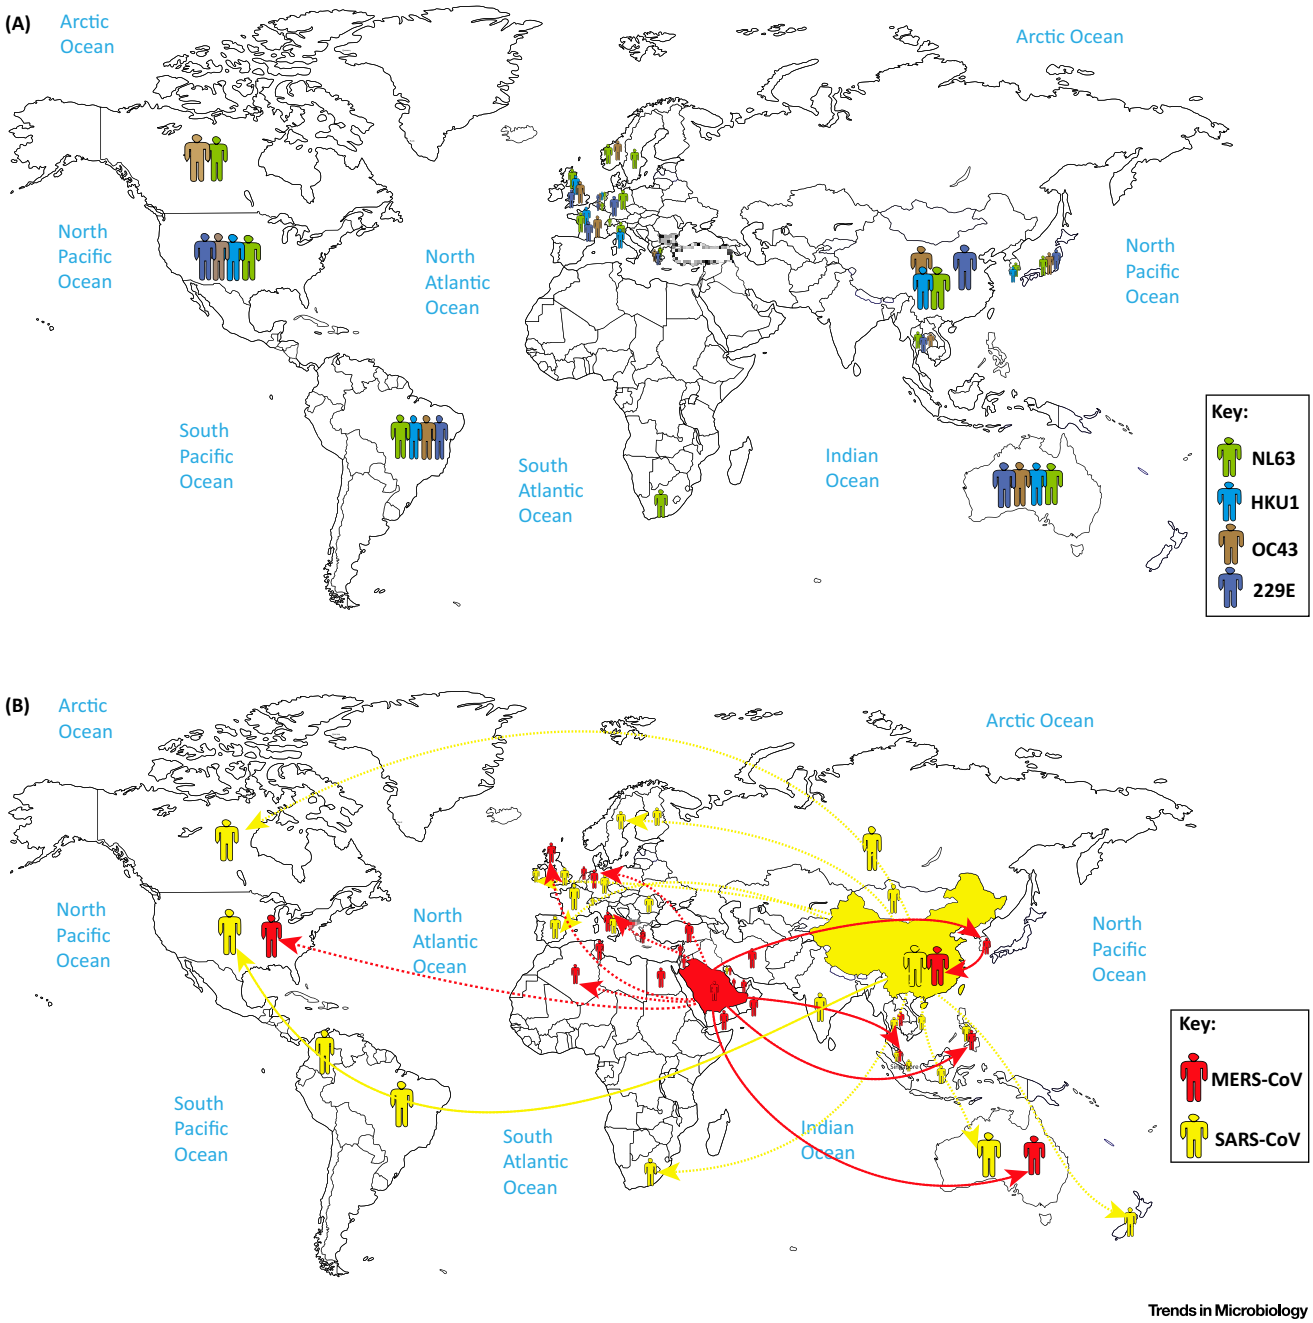

Figure 1. Global Distribution of Human Coronaviruses. (A) Green, blue, brown, and purple represent the global distribution of the NL63, HKU1, OC43, and 229E human coronaviruses, respectively. (B) Red and yellow represent the global distribution of MERS-CoV and SARS-CoV, respectively.

An outbreak of disease caused by SARS-CoV, originating from Guangdong Province in southern China during November 2002, eventually spread to other countries in Asia, in addition to North America and Europe (37 countries/regions in total) over 9 months (http://www.who.int/ith/diseases/sars/en/) (Figure 1B). An eventual 8273 cases were reported, with 775 deaths for a case fatality rate (CFR) of 9%, and the majority of cases and deaths occurred in mainland China and in Hong Kong [19]. The elderly were more susceptible to SARS disease, with a mortality rate of over 50% (http://www.cdc.gov/sars/surveillance/absence.html).

Human Coronavirus NL63 (alphacoronavirus)

NL63 is primarily associated with young children, the elderly, and immunocompromised patients with respiratory illnesses [26]. NL63 was a novel HCoV isolated from a 7-month-old child with coryza, conjunctivitis, fever, and bronchiolitis in the Netherlands during late 2004 [26], and an independent investigation described the isolation of virtually the same virus from a nasal sample collected from an 8-month-old boy suffering from pneumonia in the Netherlands [27]. NL63 was also detected in New Haven, USA, during 2005 amongst 79 of 895 children, and was initially called HCoV-NH (NH), but genetic and phylogenetic analyses showed that NH and HKU1 likely are the same species [26,28]. Infections with NL63 typically result in mild respiratory disease similar to the common cold, characterized by cough, rhinorrhea, tachypnea, fever, and hypoxia, and resolve on their own [29]. Obstructive laryngitis, also known as croup, is frequently observed with NL63 infections. A study estimated that NL63 accounts for an estimated 4.7% of common respiratory diseases [26]. NL63 is distributed globally (Figure 1A).

Human Coronavirus HKU1 (betacoronavirus, lineage A)

HKU1 was first discovered during January 2005 in a 71-year-old patient from Hong Kong who had been hospitalized with pneumonia and bronchiolitis [30]. The symptoms of HKU1 respiratory tract infections are not able to be separated from those caused by other respiratory viruses. Most patients present with fever, running nose, and cough for infections in the upper respiratory tract, whereas a fever, productive cough, and dyspnea are the common symptoms presenting for infections in the lower respiratory tract [31]. Most HKU1 infections are self-limiting, with only two deaths reported in patients with pneumonia due to HKU1 [32]. Although HKU1 is clinically relatively mild in children, HKU1 infection is associated with a high incidence of seizures, and was found in a patient with meningitis [33,34]. HKU1 cases outside Asia were detected in New Haven, USA, in 2 out of 851 children [35], and also in Australia [36], France [37], and Brazil [38], indicating a global distribution for the virus (Figure 1A).

MERS-CoV (betacoronavirus, lineage C)

MERS-CoV was first isolated from the lungs of a 60-year-old patient who had died from a severe respiratory illness in Jeddah, Saudi Arabia, 2012 [39]. Clinical manifestations of MERS-CoV infection range from asymptomatic to severe pneumonia with acute respiratory distress, septic shock, and renal failure resulting in death [40]. A typical disease course begins with fever, cough, chills, sore throat, myalgia, and arthralgia, followed by dyspnea and rapid progression to pneumonia [40–43]. Approximately one-third of patients present with gastrointestinal symptoms, such as diarrhea and vomiting. Acute renal impairment was the most striking feature of disease caused by MERS-CoV, which is thus far unique for human CoV infections [40,44]. Seventy-five percent of patients with MERS disease also had at least one other comorbidity, and patients who died were more likely to have a pre-existing/underlying condition [40]. Countries around the Arabian Peninsula are known to be endemic for MERS-CoV, and Saudi Arabia has reported the most cases, but since its discovery in 2012, cases have been occasionally exported to other countries through travel, sometimes causing clusters of secondary outbreaks (Figure 1B) [45]. As of December 31, 2015, a total of 1621 laboratory-confirmed infections have been reported, with 584 deaths (CFR = 36.0%) over 26 countries (http://www.who.int/csr/disease/coronavirus_infections/en), making MERS-CoV one of the most dangerous viruses known to humans.

Ecology of Human Coronaviruses

Based on currently available evidence, 229E, OC43, NL63, and HKU1 are well adapted to humans, and the viruses widely circulate in the human population (Figure 2), with most cases causing mild disease in immunocompetent adults, and none of these viruses have been found to be maintained within an animal reservoir. However, in the case of SARS-CoV and MERS-CoV, the viruses are not as well adapted to being maintained in humans, and thus are likely spread

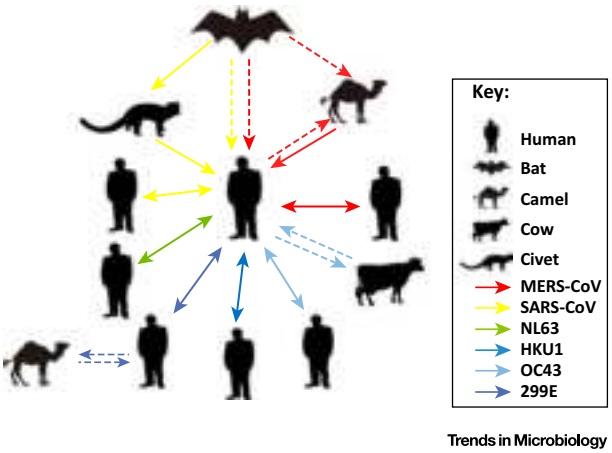

Figure 2. Intra- and Inter-Species Transmission of Human Coronaviruses. Red, yellow, green, blue, brown, and purple arrows represent transmission of MERS-CoV, SARS-CoV, NL63, HKU1, OC43, and 229E, respectively, between bats, camels, cows, humans, and masked palm civets (shown in a legend on the side of the figure). Unbroken arrows represent confirmed transmission between the two species in question, and broken arrows represent suspected transmission.

mainly in zoonotic reservoir(s), with occasional spillover into the susceptible human population, possibly via an intermediate host species.

Regarding SARS-CoV, epidemiology data implicated masked palm civets (*Paguma larvata*) from live animal markets (LAM) in Guangdong Province, China, as a route of exposure to SARS-CoV [46]. However, masked palm civets from the wild or from farms without LAM exposure were largely negative for SARS-CoV [47]. This suggests that palm civets were an intermediate host, but not a reservoir for SARS-CoV [48]. Subsequent studies have shown that wild horseshoe bats (Rhinolophidae family), which can also be found in LAM in China and served in some Chinese restaurants in Guangdong, China, have detectable levels of antibodies against SARS-CoV and a SARS-CoV-like virus (SARSr-Rh-Bat CoV) [49,50], suggesting a bat origin for SARS-CoV. An evolutionary relationship between coronaviruses and bats was proposed, in which the ancestor for SARS-CoV first spread to bats of the Hipposideridae family, then Rhinolophidae, then masked palm civets and eventually humans [51]. Recently, two new SARS-like CoVs were isolated in horseshoe bats, and these viruses showed the highest relationship to SARS-CoV from all known bat coronaviruses [52]. ORF8 analysis of the SARS-like CoVs in bats suggests that Chinese horseshoe bats are the natural reservoirs of SARS-CoV [52,53], and that intermediate hosts might not be needed for direct human infection, particularly for some bat SARS-CoV-like viruses [52].

In the case of MERS-CoV, studies in Oman, Saudi Arabia, Qatar, United Arab Emirates, and Jordan have shown that dromedary camels are seropositive for neutralizing antibodies against MERS-CoV [54], as well as camels of Middle East origin in Africa, including Egypt, Kenya, Nigeria, Ethiopia, Tunisia, Somalia, and Sudan [55]. Subsequent studies on dromedary camels in Saudi Arabia [56], Qatar [57], and Egypt [58] show that live MERS-CoV can be isolated primarily from the nasal swabs of camels, showing that camels are potential source of MERS-CoV infection. However, many confirmed cases lack contact history with camels [59], suggesting direct human-to-human transmission, or through contact with a yet-to-be-identified animal species that is maintaining MERS-CoV. Studies on HKU4, a coronavirus of bat origin and the most phylogenically closely related to MERS-CoV, had shown that HKU4 is able to utilize the CD26 receptor for virus entry [60]. As CD26 is a known receptor for MERS-CoV [61], the similarity in receptor specificity of these two CoVs supports the hypothesis that MERS-CoVs is also a bat-originated CoV. However, live MERS-CoV has not been isolated from wild bats, nor have viral sequences been detected.

A recent investigation discovered that multiple HCoV species, including MERS-CoV, beta-CoV group A, and a 229E-like virus, circulate amongst dromedary camels in Saudi Arabia [62]. Furthermore, multiple lineages of circulating MERS-CoV in these camels had resulted in a dominant,

recombinant MERS-CoV strain that was responsible for the MERS-CoV outbreaks during 2015 [62]. These results show that various CoVs of human and animal origin are currently circulating in the wild, providing ample opportunity for CoVs to undergo evolution and genetic recombination, thereby resulting in recombinant CoVs that may potentially be more deadly to humans. In the following sections, we summarize the evolution and genetic recombination of the current HCoVs.

Phylogeny, Evolution and Genetic Recombination in Human Coronaviruses

Phylogenetic Analysis

The phylogenetic tree for the CoVs of zoonotic and human origin was constructed based on the full genome. It can be observed that 229E and NL63 belong to the alpha-CoV genus and are

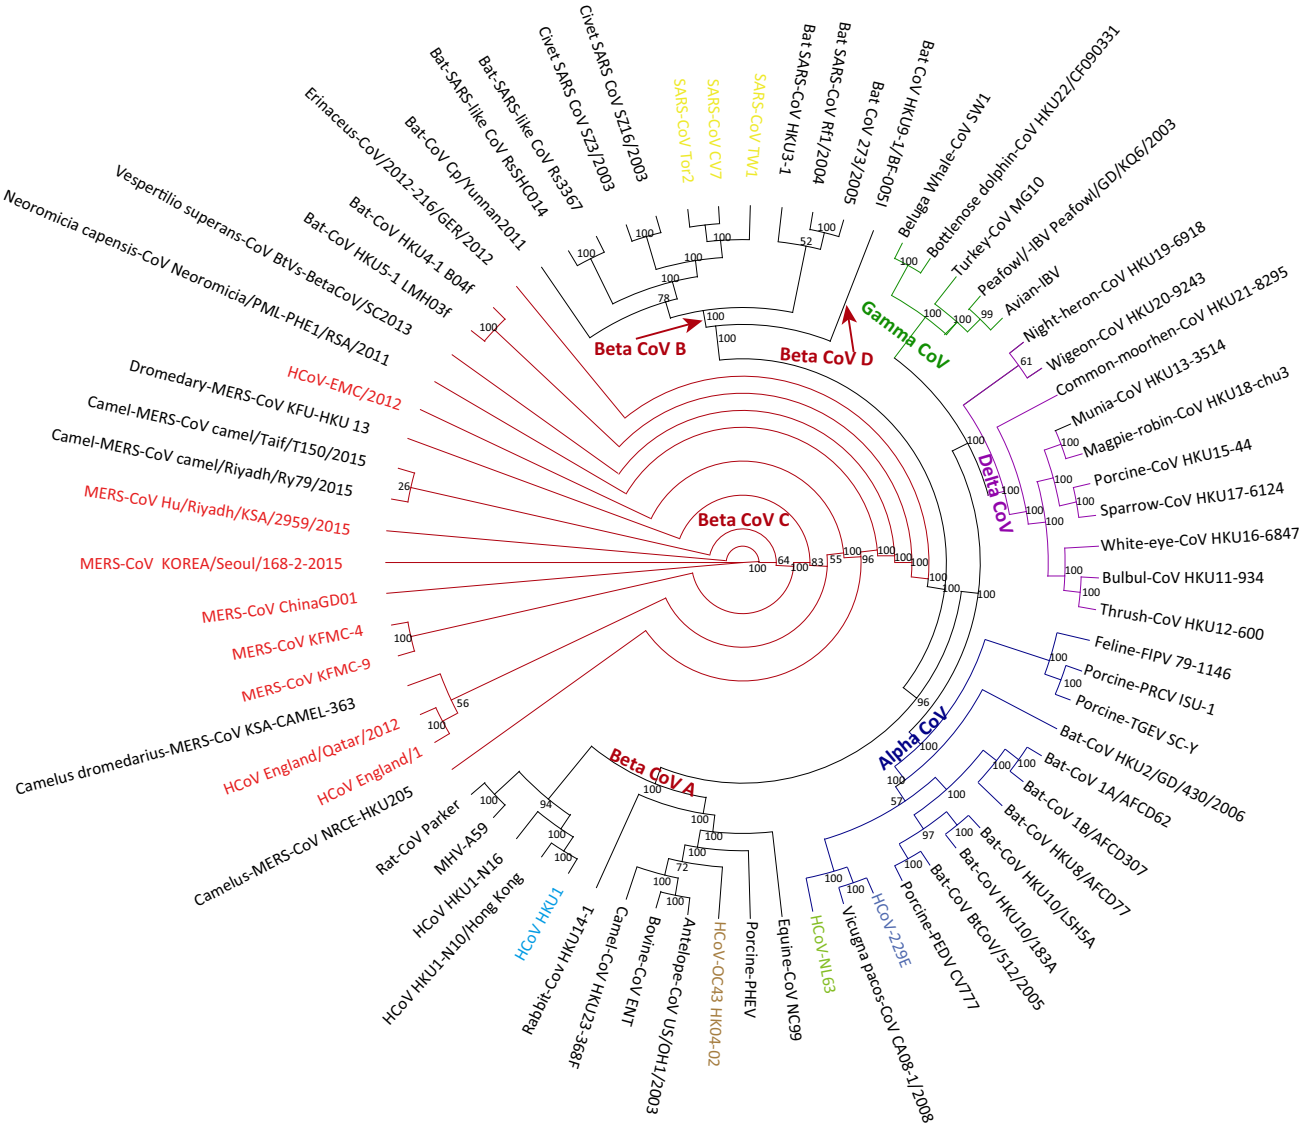

Figure 3. Phylogenetic Tree of Known Animal and Human Coronaviruses. Phylogenetic analysis of the full-length genome sequences of coronaviruses publicly available in GenBank was performed using RAxML, with 1000 bootstrap replicates. Lines with different colors represent different coronavirus species, Alpha-coronaviruses (blue lines), Beta-coronaviruses (red lines for Beta-coronavirus C, and black lines for Beta-coronavirus A, B, and D), Gamma-coronaviruses (green lines), and Delta-coronaviruses (purple lines). Human isolates are highlighted with different colors, whereas strains from other hosts are shown in black. Numbers at the branches represent bootstrap values obtained in the phylogenetic analysis.

grouped together with porcine epidemic diarrhea virus (PEDV), TGEV, porcine respiratory coronavirus (PRCV), feline infectious peritonitis virus (FIPV), and some bat-derived coronaviruses (Figure 3). The topology of the phylogeny is similar to the tree constructed based on the RNA-dependent RNA polymerase gene [55].

OC43, HKU1, SARS-CoV, and MERS-CoV belong to the beta-CoV genus. Lineage A includes OC43 and HKU1, MHV, porcine hemagglutinating encephalomyelitis virus (PHEV), in addition to equine, rabbit, camel, bovine, antelope-derived animal coronaviruses. Lineage B includes SARS-CoV, SARS-like viruses of bat and palm civet origin, and some bat-derived CoVs. Lineage C includes MERS-CoV and some bat-derived viruses. Lineage D contains only bat-derived coronavirus (Figure 3). In contrast to alpha- and beta-CoVs, gamma-CoVs consist mainly of avian coronaviruses (such as IBV), as well as CoVs isolated from aquatic animals, whales, and dolphins. CoVs of wild-bird origin are clustered into the delta-CoV, which also contains some swine-derived CoVs (Figure 3).

In general, alpha- and beta-CoVs primarily include CoVs from mammals, whereas gamma- and delta-CoVs mostly include CoVs of avian origin. Notably, all currently known HCoVs belong to either the alpha- or betacoronavirus genera, which also contain CoVs of mainly bat origin.

Mutation and Genetic Recombination in Coronaviruses

The estimated mutation rates in CoV are moderate to high compared to other single-stranded RNA (ssRNA) viruses, and the average substitution rate for CoVs was $\sim 10^{-4}$ substitutions per year per site [63]. The nucleotide mutation rate of IBV for the hypervariable region in the S gene was estimated to be $0.3–0.6 \times 10^{-2}$ per site per year [64]. The S gene of OC43 possessed an average rate of $6.410.58 \times 10^{-4}$ substitution rates per site per year [65]. Additionally, the S gene of 229E possessed a rate of $\sim 3 \times 10^{-4}$ substitutions per site per year [63]. For SARS-CoV, the mutation rate in the whole genome was estimated to be $0.80–2.38 \times 1^{-3}$ nucleotide substitutions per site per year, and the nonsynonymous and synonymous substitution rates were estimated to be $1.16–3.30 \times 10^{-3}$ and $1.67–4.67 \times 10^{-3}$ per site per year, respectively, which is similar to other RNA viruses [66]. The evolutionary rate for MERS-CoV genomes was estimated as 1.12×10^{-3} substitutions per site per year (95% credible interval [95% CI], 8.76×10^{-4}; 1.37×10^{-3}) [67]. Furthermore, the large RNA genome in CoV allows for extra plasticity in genome modification by mutations and recombinations, thereby increasing the probability for intraspecies variability, interspecies 'host jump', and novel CoVs to emerge under the right conditions [68–70].

The major reason for recombination may be at the replication step in the virus life cycle. During replication, a set of subgenomic RNAs is generated, increasing the homologous recombination rate among closely related genes from different lineages of CoVs or other viruses by template switching [33]. Concurrently, circulating CoVs in multiple host species likely contribute to increases in the rate of recombination events. However, the exact mechanism of genetic recombination in CoVs remains unclear: recombination site 'breakpoints' in the viral genome – the crossing point of the recombinant genes between two distinct viral strains or genotypes – appear to be random, as different recombinant strains have different breakpoints.

Genetic recombination has been previously documented for animal CoVs, for instance: MHV [71], TGEV [72], as well as feline and canine coronaviruses [73,74]. Genetic recombination for other HCoVs including OC43, NL63, HKU1, SARS-CoV [51], and MERS-CoV have also been documented and are discussed in detail below.

OC43 has diverged into five distinct genotypes (A to E). Genotype A is typified by the prototype VR759 strain that was isolated in 1967 [75]. Genotypes B and C are two naturally circulating viruses. Genotype D emerged via recombination between genotypes B and C viruses at the

Key Figure

Genetic Recombination in Human Coronaviruses

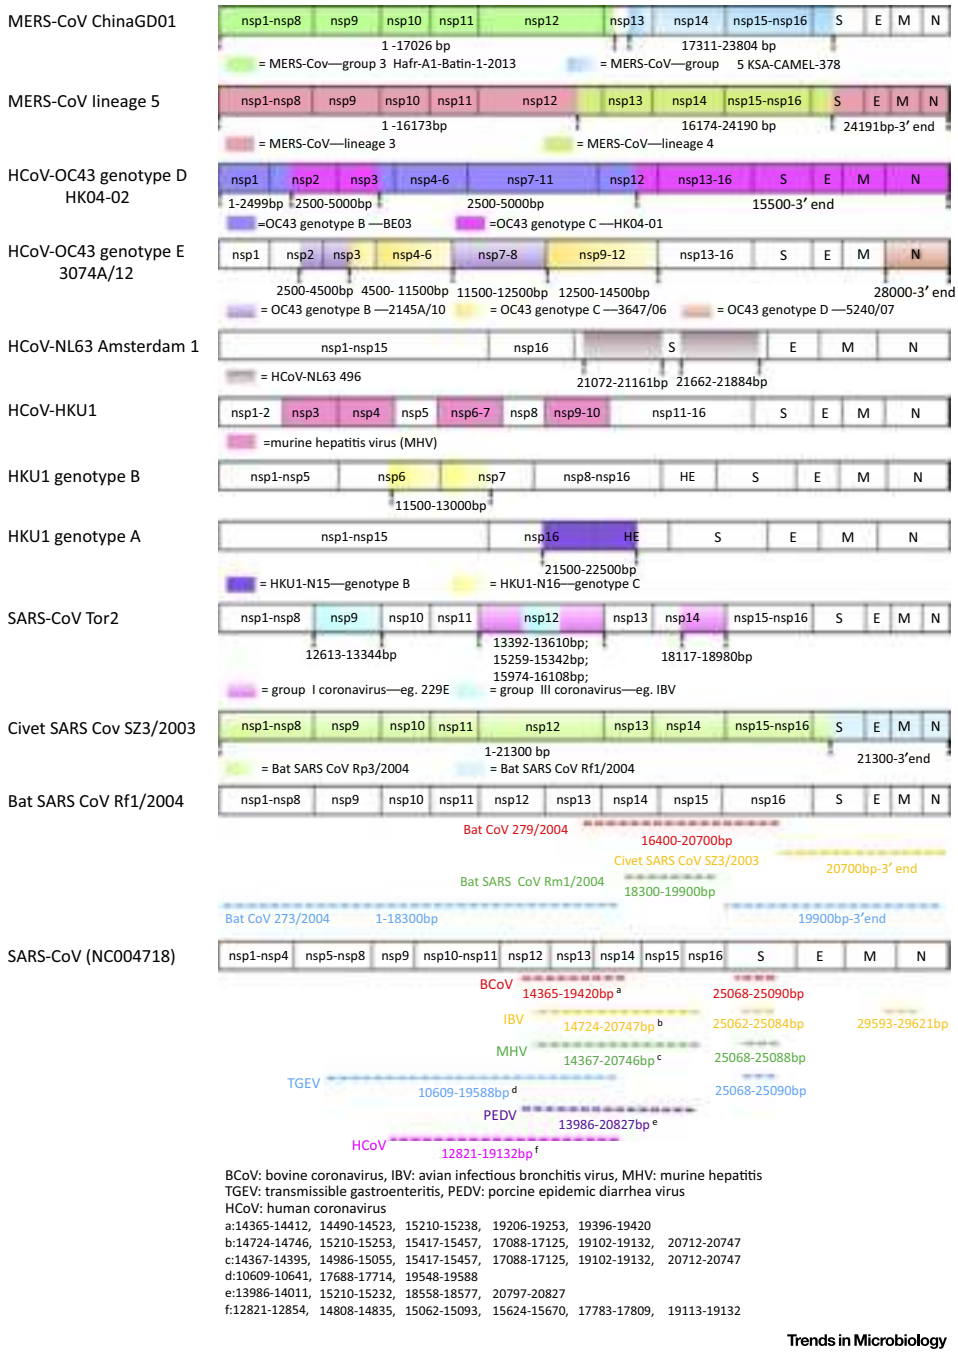

Figure 4. The colored regions of each human coronavirus indicate genetic recombination at the genomic sites with coronaviruses of zoonotic origin. Specific nucleotide locations where recombination occurred are also shown in broken lines.

breakpoint of 2500–5000 bp in the NSP2–NSP3 gene and 15500 bp-3′end in NSP12-N genes [75] (Figure 4, Key Figure). Genotype E, identified in 2014, emerged by recombination amongst the genotype B, C, and D viruses with different breakpoints in the genes compared to the generation of genotype D [76] (Figure 4). A study in France, between 2001 and 2013, demonstrated that OC43 strains have more recombination patterns in Lower Normandy, and circulating OC43 viruses have a high genetic diversity [17].

NL63 also has the potential for genetic recombination, and one such example is between the Amsterdam 1 and 496 strains. Recombination site breakpoints were identified in two parts of the S gene [63] (Figure 4).

Recombination events have been observed for different genotypes of HKU1, in which recombination breakpoints were found on genotypes B and C in the nsp6-nsp7 and nsp16-HE genes, respectively [70] (Figure 4). HKU1 was also shown to be able to recombine with other animal beta-CoVs, such as MHV, at the nsp3, nsp4, nsp6, nsp7, nps9, and nsp10 genes [77] (Figure 4).

SARS-CoV has a possible recombinant history with lineages of alpha- and gamma-CoV [78]. Many specific breakpoints and a large number of smaller recombinant regions had been identified in the RNA-dependent RNA polymerase (RDRP, nsp12 gene) at the following locations: nucleotides 13 392–13 610, 15 259–15 342, and 15 974–16 108 based on the sequence of the SARS-CoV TOR2 strain [78]. Recombination locations were also identified in the nsp9 and most of nsp10 gene located at 12 613–13 344, and parts of nsp14 (18 117–18 980) [78]. Another study analyzing the genome of the SARS-CoV CV7 strain had shown that seven putative recombination locations were found between SARS-CoV and six other coronaviruses: PEDV, TGEV, BCV, 229E, MHV, and IBV (Figure 4). This further suggests that SARS-CoV emerged via serial horizontal transmission and by genetic recombination, enhancing the adaptation process to its new host [79].

Recombination was also detected between the SARS-related bat-associated CoV (SARSr-Bat CoVs), in which recombination between the Rp3 strain from Guangxi Province and Rf1 strain from Hubei Province, China, generated a new strain (SARSr-Civet CoV SZ3) in civets, with a breakpoint at the nsp16/spike and S2 region [51] (Figure 4). Furthermore, the SARS-CoV Rf1/2004 strain is itself a recombinant from the bat CoV 279/2004, bat CoV Rm1/2004 and civet CoV SZ3/2003 [51] (Figure 4).

A recent study showed that the epidemic MERS-CoV experienced recombination events between the different lineages, which occurred in dromedary camels in Saudi Arabia [62]. Lineages 3 and 5 viruses were predominant during July and December 2014; however, lineage 5 became dominant within the camel population by 2015. Lineage 5, which is closely associated with the MERS-CoV causing the outbreak in South Korea in 2015, as well as recent human infections in Riyadh, Saudi Arabia, is a recombinant virus between lineages 3 and 4, or groups 3 and 5 of clade B (Figure 4) [62,80].

Concluding Remarks

The result from a high frequency of recombination events in CoVs is the generation of novel viruses with a high genetic diversity, with unpredictable changes in virulence during human infections. With multiple species of CoVs circulating in the wild amongst different animal species that may constantly interact with one another, it is likely not a matter of if, but when, the next recombinant CoV will emerge and cause another outbreak in the human population. As such, some crucial future areas of investigation include: (i) the prevalence of HCoVs already circulating within the animal population, (ii) the commonality of coronavirus recombination in animals, (iii) animals which may potentially serve as mixing vessels for the generation of novel recombinant

Outstanding Questions

How common is coronavirus recombination in animals?

Can coronavirus undergo recombination in animal hosts other than camels?

Is there a way to predict the potential emergence of a novel recombinant coronavirus in the human population?

CoVs, and (iv) a surveillance network to monitor and predict the potential emergence of a highly virulent, recombinant CoV from animals (see Outstanding Questions). Furthermore, lessons from the SARS-CoV and MERS-CoV outbreaks must be urgently learned in advance to effectively prepare for the next CoV outbreak.

REVIEW

What Have We Learned About Middle East Respiratory Syndrome Coronavirus Emergence in Humans? A Systematic Literature Review

Patrick Dawson,[1] Mamunur Rahman Malik,[2] Faruque Parvez,[3] and Stephen S. Morse[1]

Abstract

Background: Middle East respiratory syndrome coronavirus (MERS-CoV) was first identified in humans in 2012. A systematic literature review was conducted to synthesize current knowledge and identify critical knowledge gaps.
Materials and Methods: We conducted a systematic review on MERS-CoV using PRISMA guidelines. We identified 407 relevant, peer-reviewed publications and selected 208 of these based on their contributions to four key areas: virology; clinical characteristics, outcomes, therapeutic and preventive options; epidemiology and transmission; and animal interface and the search for natural hosts of MERS-CoV.
Results: Dipeptidyl peptidase 4 (DPP4/CD26) was identified as the human receptor for MERS-CoV, and a variety of molecular and serological assays developed. Dromedary camels remain the only documented zoonotic source of human infection, but MERS-like CoVs have been detected in bat species globally, as well as in dromedary camels throughout the Middle East and Africa. However, despite evidence of camel-to-human MERS-CoV transmission and cases apparently related to camel contact, the source of many primary cases remains unknown. There have been sustained health care-associated human outbreaks in Saudi Arabia and South Korea, the latter originating from one traveler returning from the Middle East. Transmission mechanisms are poorly understood; for health care, this may include environmental contamination. Various potential therapeutics have been identified, but not yet evaluated in human clinical trials. At least one candidate vaccine has progressed to Phase I trials.
Conclusions: There has been substantial MERS-CoV research since 2012, but significant knowledge gaps persist, especially in epidemiology and natural history of the infection. There have been few rigorous studies of baseline prevalence, transmission, and spectrum of disease. Terms such as ''camel exposure'' and the epidemiological relationships of cases should be clearly defined and standardized. We strongly recommend a shared and accessible registry or database. Coronaviruses will likely continue to emerge, arguing for a unified ''One Health'' approach.

Keywords: MERS, MERS-CoV, coronaviruses, zoonotic disease, severe acute respiratory infection (SARI), MERS epidemiology

Introduction

SEPTEMBER 2012 SAW THE identification of a novel human coronavirus, now known as Middle East respiratory syndrome coronavirus (MERS-CoV) (ProMED-mail 2012, Zaki et al. 2012). MERS-CoV is a beta-coronavirus distinct from but genetically related to the SARS (severe acute respiratory syndrome) coronavirus (Hilgenfeld and Peiris 2013, de Wit et al. 2016).

As MERS was identified a few years after the 2003 SARS outbreak, which spread across continents and raised pandemic concerns, there has been continuing concern about the

pandemic potential of MERS-CoV (Hilgenfeld and Peiris 2013, de Wit et al. 2016). To assess and anticipate potential epidemic spread of MERS-CoV, it is essential to better understand the virology; human clinical characteristics, possible therapeutic and preventive options; epidemiology and transmission; and animal interfaces and possible origins and natural hosts.

MERS was first identified in a patient with lower respiratory disease by a physician in Saudi Arabia, and subsequently, the virus was identified and characterized from this patient's sputum sample by researchers in Saudi Arabia and at Erasmus Medical Center in the Netherlands. Since then (to December 2018), 2266 laboratory-confirmed MERS-CoV cases and 804 deaths across 27 countries (35.5% crude case

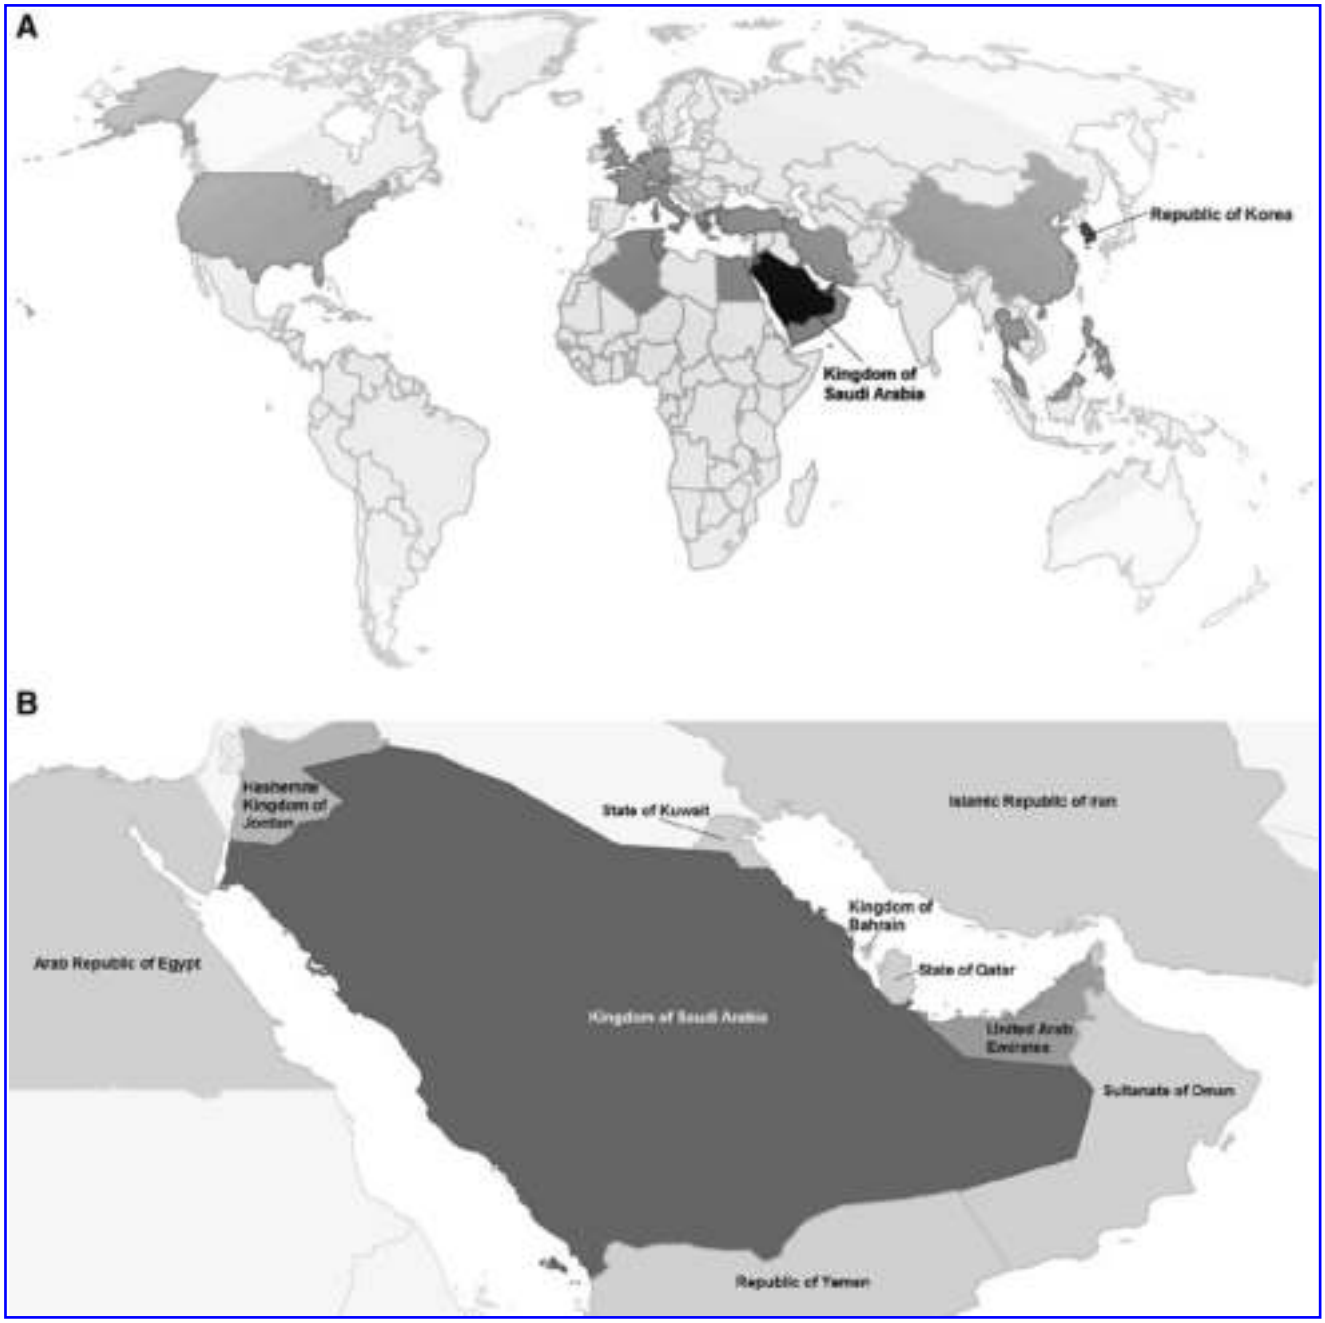

FIG. 1. **(A)** Map of countries having at least one laboratory-confirmed human MERS-CoV case, 2012–2016. *Darker shades* indicate greater numbers of laboratory-confirmed cases. **(B)** *Inset* of Fig. 1A showing Gulf countries having at least one laboratory-confirmed human MERS-CoV case. *Darker shades* indicate greater numbers of laboratory-confirmed cases. Data Source: World Health Organization (www.who.int/emergencies/mers-cov/en *and* www.who.int/emergencies/mers-cov/risk-assessment-july-2017.pdf). This map was generated using R software (*R Foundation* for Statistical Computing, Vienna, Austria) and the ''googleVis'' package (Gesmann et al. 2017). MERS-CoV, Middle East respiratory syndrome coronavirus.

fatality rate [CFR]) have been reported to the WHO (Fig. 1), with the majority of cases (1888) and deaths (730) reported from Saudi Arabia (World Health Organization 2018a, World Health Organization/EMRO 2018). Cases continue to occur (World Health Organization/EMRO 2018).

Although the first known MERS-CoV cases were from Jordan (confirmed retrospectively, and the source is still unknown) (Hijawi et al. 2013), about 80% of MERS-CoV cases originate from or passed through Saudi Arabia. The infection is likely zoonotic; although origins and transmission are poorly understood, the dromedary camel is the one documented source of human zoonotic infection (Memish et al. 2014e).

A systematic review of MERS-CoV research was conducted to survey our current understanding of MERS-CoV and to identify research gaps in four major areas: (1) virology; (2) clinical characteristics, outcomes, and therapeutic and preventive options; (3) epidemiology and transmission; and (4) animal interface and the search for natural hosts of MERS-CoV.

Materials and Methods

We conducted a systematic literature review, using Embase, Google Scholar, MEDLINE/PubMed, supplemented by Thomson-Reuters ''Web of Science''™ (all databases), to identify peer-reviewed published articles on MERS-CoV available by July 14, 2017. All searches were for articles published from 2012 onward, since MERS was first identified in 2012. The following search terms were used in all the databases for matches in title only (Google Scholar), title or abstract (Embase and MEDLINE/PubMed), or topic (''Web of Science''): ''novel coronavirus,'' ''novel coronavirus EMC,'' ''novel coronavirus Erasmus,'' ''hCoV-EMC,'' ''MERS-CoV'' (a PubMed ''MeSH'' term), ''MERS coronavirus,'' ''Middle East Respiratory Syndrome,'' and ''Middle East Respiratory Syndrome Coronavirus'' (a PubMed MeSH term).

We reviewed the titles and abstracts of all resulting citations to identify relevant articles for this systematic review, following PRISMA guidelines (Fig. 2) (Moher et al. 2009). For all nonduplicate articles, excluding opinion and editorial pieces, on MERS-CoV or a related topic, we retrieved the full-text version and indexed the citation. Inclusion criteria were peer-reviewed primary research articles about MERS-CoV published between 2012 and mid-July 2017 (inclusive, with periodic updates to 2018) and adding unique information about MERS-CoV to the knowledge base within at least one of the four key themes: (1) virology; (2) clinical characteristics, outcomes, and therapeutic and preventive options; (3) epidemiology and transmission; and (4) animal interface and search for natural hosts of MERS-CoV.

Only English language publications (or with an English-language abstract available) were included. Of the 3364 titles retrieved, 407 were unique (nonduplicate), scientific research works relevant to MERS-CoV, and of these, 208 were originally included in the review based on the inclusion criteria (some interim updates have been made during article preparation).

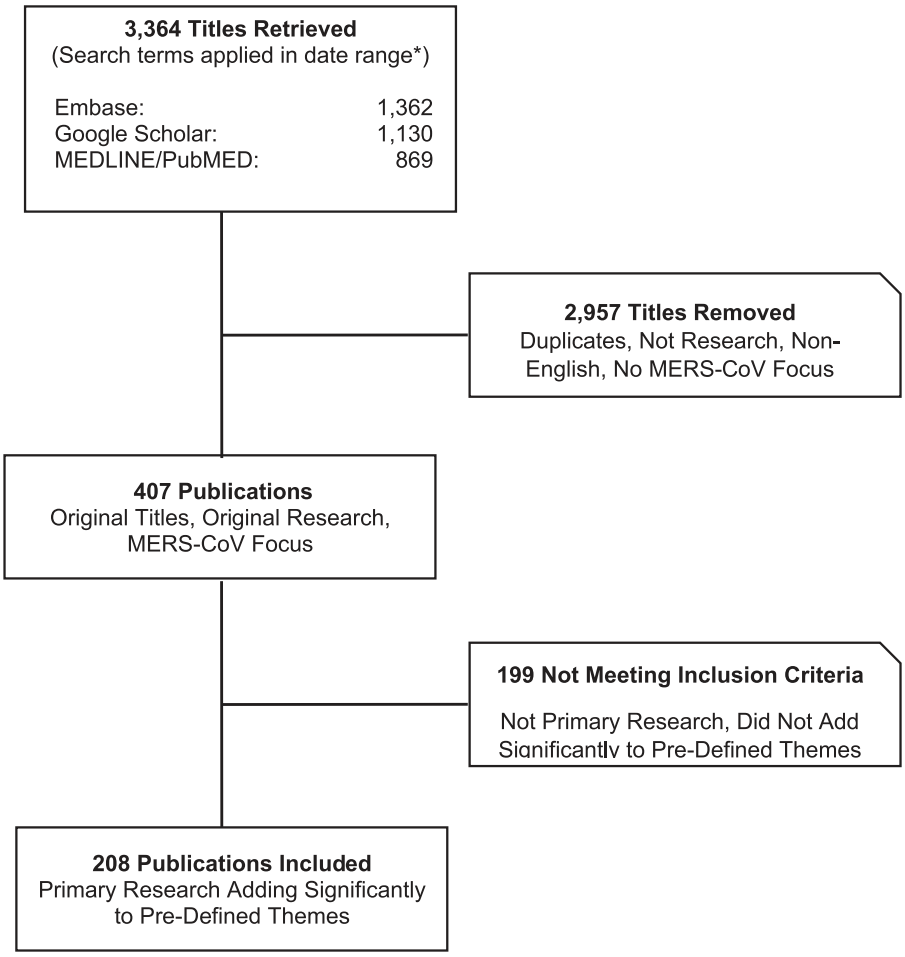

FIG. 2. Study selection diagram for systematic literature review on MERS-CoV (*For complete search terms and applicable date ranges, see the Materials and Methods section.).

Results

Virology

The pathogen causing MERS has been identified as a coronavirus, now named MERS-CoV, classified in the family *Coronaviridae* (subfamily *Coronavirinae*) (ICTV 2016). Coronaviruses are a family of enveloped, approximately spherical, positive-sense, single-stranded RNA viruses with genome length 26–32 kilobases (kb). Of the four described coronavirus genera, alpha- and beta-coronaviruses are believed to originate from bat species, whereas gamma- and delta-coronaviruses are believed to be of avian origin (Woo et al. 2012).

Within the beta-coronavirus genus, four lineages have been described: A, B (which includes SARS-CoV), C, and D. MERS-CoV is a beta-coronavirus of lineage C (Cotten et al. 2013), the first of this lineage known to infect humans. There are two main recognized clades (genetic sublineages) of MERS-CoV, clade A, which includes the earliest known MERS-CoV strains (EMC/2012 and Jordan-N3/2012), and clade B, which includes newer cases (Cotten et al. 2013), although additional genotypes are revealed by genomic sequencing (Chu et al. 2015), suggesting the existence of additional clades.

The genome of MERS-CoV is ~30 kb and encodes 10 proteins: 2 replicase polyproteins (ORFs 1a and 1b), including the RNA-dependent RNA polymerase (RdRp); 4 structural proteins: envelope (E), M (membrane), N (nucleocapsid), and S (surface spike glycoprotein), and 4 nonstructural proteins (ORFs 3, 4a, 4b, and 5) (Kim et al. 2015; review: de Wit et al. 2016).

Particular attention has understandably focused on the S (spike) surface protein, which confers receptor specificity (Qian et al. 2013) and is considered the major determinant of coronavirus host range (Graham and Baric 2010, Hulswit et al. 2016). The main route of entry for MERS-CoV is dipeptidyl peptidase 4 (DPP4, also known as CD26) on the host cell surface (Raj et al. 2013), which is utilized by the receptor-binding domain of the MERS-CoV spike protein (Chen et al. 2013, Raj et al. 2013, 2014).

The virus readily replicates in A549 (human lung), Huh-7 (human liver), and the widely used Vero E6 (African green monkey kidney) cell lines (Raj et al. 2013, Eckerle et al. 2014), among others. Culture, *in vitro* and *ex vivo*, has also been used to help determine cell tropism and identify potential natural hosts of the virus. MERS-CoV can infect a variety of human cell types and tissues in culture, including macrophages, fibroblasts, and endothelial cells (Scobey et al. 2013, Tao et al. 2013, Hin et al. 2016). In an *ex vivo* study using human lung explants, MERS-CoV infected both alveolar epithelial cells and macrophages (Type II pneumocytes), with resulting alveolar damage (Hocke et al. 2013).

Interestingly, although kidney failure is frequently described in fatal cases and the virus grows well in a number of kidney and liver cell lines, in the one autopsy report that has been published, viral antigen was detected by immunohistochemical staining only in pneumocytes and lung interstitial epithelial cells, and not in the kidney or other extrapulmonary sites (Ng et al. 2016).

Replication was demonstrated in goat, camel (Eckerle et al. 2014), and equid origin cell lines (Meyer et al. 2015), but was not detected in cattle, sheep, or rodent cell lines tested (Eckerle et al. 2014).

Given the interest in bats as a natural host for many coronaviruses, especially since SARS, and the currently unknown origin of MERS-CoV, several bat cell lines have been tested to determine if they could support MERS-CoV replication (Müller et al. 2012, Cai et al. 2014, Eckerle et al. 2014).

As a broad generalization, the virus was reported to replicate well (roughly comparable with growth in Vero E6 cells) in kidney and lung cells from *Rousettus aegyptiacus* and other Old World pteropid (fruit) bats (Müller et al. 2012, Cai et al. 2014), to a lesser degree in cell lines from Old World insectivorous bats (Müller et al. 2012, Eckerle et al. 2014), and very little, if at all, in lung cells from several New World bats (Müller et al. 2012, Cai et al. 2014). However, as a caveat, no replication was found in the *Rousettus aegyptiacus* embryo cell lines tested (Cai et al. 2014).

Adaptation to cells from other bat species that are normally refractory to infection because of having a somewhat different DPP4 protein was recently demonstrated *in vitro* (Letko et al. 2018), resulting from selection of spike protein mutations that permitted binding to the new DPP4. A similar change, from bat to human-type receptor, was observed with SARS in 2003 (Letko et al. 2018).

Animal models for MERS-CoV include transgenic mice expressing human DPP4 (Cockrell et al. 2014, Zhao et al. 2014, Agrawal et al. 2015), which develop respiratory disease and are the most widely used model; marmosets (Falzarano et al. 2014); rhesus macaques (de Wit et al. 2013, Munster et al. 2013, Yao et al. 2014); camels (Barlan et al. 2014); horses (Barlan et al. 2014), and alpacas (Adney et al. 2016). However, there is no animal model that clearly mimics human clinical MERS (review: Baseler et al. 2016).

Diagnostic assays. The main laboratory assays for MERS-CoV are molecular tests to detect viral RNA, and serology (for prior infection) (CDC 2014, World Health Organization 2018b).

Reverse transcription PCR either real time or conventional, is now standard. For diagnostic screening, PCR primer sets to regions upstream of the E gene (''up-E'') are most frequently used, with ORF1a or ORF1b for confirmation (Corman et al. 2012a, 2012b). Sensitivity was reported as ~3.4 viral gene copies/25 μL reaction for up-E and ~64 copies for ORF1b, with specificity approaching 100% using a test panel of other known coronaviruses and clinical respiratory samples (Corman et al. 2012a). ORF1a PCR was reported to have comparable sensitivity and specificity to up-E (Corman et al. 2012b). Commercial kits are available, with comparable results reported (Corman et al. 2014c, Seong et al. 2016, Mohamed et al. 2017).

For sequencing, tests have been developed that may be better suited for strain differentiation, targeting regions of the RdRp (RNA polymerase) or N (nucleocapsid) genes (Corman et al. 2012b); there are a number of publications reporting on their use (Corman et al. 2012b; CDC 2014, Lu et al. 2014).

Another PCR test, targeting the S (spike) region, was developed to monitor circulation of MERS-CoV variants (Abd et al. 2013, Smits et al. 2015). Other types of nucleic acid tests have also been used (Shirato et al. 2014), as has immunohistochemistry (Ng et al. 2016).

Serologic samples are usually screened using enzyme-linked immunosorbent assay (ELISA) (Reusken et al. 2013a). If the sample is ELISA positive, CDC and other agencies formerly recommended confirmatory testing, first

by immunofluorescence assay (IFA) and then by the gold standard plaque-reduction neutralization test or microneutralization (CDC 2014), but now recommend going directly to microneutralization assay (CDC 2014, revised). Other serological tests such as pseudoparticle neutralization (Perera et al. 2013) and array-based serology (Reusken et al. 2013a) have also been developed.

Unfortunately, there are pitfalls in serology, including cross-reactivity and false negatives. In 2014, CDC preliminarily reported a MERS-CoV case with a positive ELISA and IFA, but later retracted the case report due to a negative microneutralization result (Breakwell et al. 2015). Consequently, CDC no longer recommends IFA but instead now recommends using two different ELISA tests, with microneutralization for confirmation (CDC 2014, revised). Conversely, low or waning antibody response after infection, which would yield false negatives, has also been reported (Alshukairi et al. 2016, Choe et al. 2017). False negatives are further discussed below in the section on Host Response.

Clinical characteristics and outcomes

Clinical findings have been described and reviewed in detail (Assiri et al. 2013a, Saad et al. 2014, Rasmussen et al. 2015, World Health Organization 2015). The incubation period is ~5–7 days (in some cases up to 12 days) (Assiri et al. 2013a, 2013b). Fever, cough, shortness of breath, and pneumonia (with abnormal chest radiography) are the most frequently noted signs; myalgia, diarrhea, vomiting, abdominal pain, chills or rigors, or malaise are also seen (Assiri et al. 2013a, Drosten et al. 2013, Eckerle et al. 2013, Guery et al. 2013, Ajlan et al. 2014, Arabi et al. 2014, Faure et al. 2014, Kapoor et al. 2014, Scheuplein et al. 2015, Hunter et al. 2016). Renal failure or pulmonary failure and shock were commonly described in severe and fatal cases. Overall CFR is ~35.5% (World Health Organization 2018a).

Viral excretion from the respiratory tract has been documented through the first month of illness (Memish et al. 2014d, Poissy et al. 2014, Spanakis et al. 2014), with greater viral loads detected in lower respiratory tract specimens compared with upper respiratory tract (Drosten et al. 2013, Guery et al. 2013, Kapoor et al. 2014). Viral excretion for short periods was reported in urine and stool, although viral loads were low (Drosten et al. 2013). There was at least one report that MERS-CoV secondary cases (individuals infected by a primary case) clear infection earlier than primary cases (Memish et al. 2014d).

Disease outcomes differed by age and comorbidities (Assiri et al. 2013a, 2013b, Khalid et al. 2014, Saad et al. 2014, Alsahafi and Cheng 2016). Most cases in Saudi Arabia have occurred among men, ages 45 or older, and those living in areas of lower relative humidity and high temperature (Alghamdi et al. 2014). A review of 939 cases in Saudi Arabia found that CFR increases with age, from 12.5% among those 19 years or younger to 86.2% among those 80 years or older (Alsahafi and Cheng 2016). Mortality was more frequent and rapid in individuals with comorbidities such as diabetes, chronic renal disease, and, in one study, higher body mass index (Assiri et al. 2013a, 2013b, Al-Tawfiq et al. 2014, Khalid et al. 2014, Saad et al. 2014, Alsahafi and Cheng 2016). More severe disease has been associated with higher viral load (Feikin et al. 2015).

There are a handful of case reports on MERS outcomes in other vulnerable populations, including three cases in pregnant women and one in an HIV-positive individual.

In the three documented cases of pregnant women with MERS-CoV infection, one woman in her second trimester of pregnancy (~5 months) experienced a stillbirth; the mother survived (Payne et al. 2014). The two other women were reported to be in their third trimester (32 weeks) when they presented with MERS. A healthy infant was delivered in each of these cases, although one mother died despite interferon (IFN) treatment (Malik et al. 2016), and one recovered despite the severity of her symptoms (Alserehi et al. 2016). Both were apparently healthy before infection and in their 30s. It is therefore possible that infection during the third trimester may be associated with better fetal outcomes, while other factors may be more critical for maternal outcome, but the numbers are too small to generalize.

There has been at least one published case of an individual with HIV/AIDS acquiring MERS-CoV (Shalhoub et al. 2015). This patient was probably infected with MERS-CoV during a hospital stay and subsequently shed virus for 38 days. The patient recovered after treatment (Shalhoub et al. 2015).

Host response

There have been a number of studies on immune function (Corman et al. 2016, Zhao et al. 2017). Neutralizing antibodies were detected in many patients, but several studies suggested that neutralizing antibodies induced during infection did not appear to be protective (Corman et al. 2016, Zhao et al. 2017), and it has been suggested that higher antibody titers may be more closely correlated with greater viral load and consequently worse prognosis (Zhao et al. 2017).

Kinetics of response may also be important. An antibody kinetics study with 17 patients in South Korea (from the same research group that later reported waning antibody titers in patients over a 1-year follow-up) found that most patients produced a robust neutralizing IgG antibody response beginning at about 2 weeks and peaking by about 3 weeks; delayed response was generally correlated with a less favorable prognosis (Park et al. 2015).

Persistence of antibody generally seems to follow a similar pattern. Detectable neutralizing antibody titers (≥20) have been reported in some patients up to 34 months (Payne et al. 2016). However, results varied considerably even within this group, and most reports indicate that duration of antibody response, as well as its magnitude, seemed most closely correlated with disease severity and that antibodies could be low or even absent in mild or asymptomatic infection (Alshukairi et al. 2016, Choe et al. 2017). These reports of low or waning antibody titers, especially in asymptomatic or mildly symptomatic individuals, may make serology problematic as a marker of population prevalence.

There is evidence that innate immunity, including IFNs and cytokines, and cellular immunity by $CD8^+$ (presumably ''killer'') T cells may play important roles in host defense and recovery (Faure et al. 2014, Zhao et al. 2017). Zhao et al. (2017) compared the role of antibodies and T cells in human MERS cases, and found that survivors mounted a vigorous $CD8^+$ T cell response even in the absence of a detectable antibody response.

Macrophages also appear to play an important role, but there are limited and somewhat ambiguous data from the mouse model (Coleman et al. 2017), human cells (Zhou et al. 2014), and patients (Faure et al. 2014). With a number of viruses, it is not unusual for resting macrophages to be permissive for replication but for macrophages to show antiviral activity after activation (such as by IFN-γ) (Morse and Morahan 1981). Dendritic cells have been reported to produce IFN in response to infection (Scheuplein et al. 2015).

One challenge to overcome is the effect of the virus on host defenses. A caveat is that much of this research (although not all) has been done *in vitro* and may not necessarily be comparable with the immunological results described above in patients. MERS-CoV has been reported to inhibit host innate immunity (Lau et al. 2013). Impaired IFN and cytokine responses may mediate some of these effects, based on assays on cells from MERS patients (Faure et al. 2014, Scheuplein et al. 2015), although the numbers of patients were small. *In vitro* studies have shown that MERS-CoV could downregulate expression of IFN-stimulated gene subsets (Yang et al. 2013), chemokines (Mielech et al. 2014), and IFN-β. Another study found that MERS-CoV may cause delayed induction of proinflammatory cytokines together with suppression of the host's innate antiviral response (Lau et al. 2013).

Virus replication in human monocyte-derived macrophages has been described, with increased expression of tumor necrosis factor α (up to a 3-fold increase over normal levels), interleukin 6 (up to almost a 6-fold increase), interleukin 12, IFN-γ, and chemokines (some at a 10-fold or more increase and even more prominently than with SARS-CoV) being reported (Zhou et al. 2014).

Therapeutic and preventive options

Currently, the main treatment strategy is symptomatic supportive care; mechanical ventilation and ICU admission are usually required for severe cases.

Published data on applied therapeutic regimens for MERS-CoV patients are scarce, but there have been efforts to develop interventions.

Two case reports have documented the use of a combination of ribavirin and IFN α2b as a therapy for MERS-CoV patients, with divergent results. In one report, this therapy was given to five patients but all five died. However, all five patients had comorbidities and were diagnosed late in the course of their illness, suggesting the therapy may have been delivered too late to prove effective (Al-Tawfiq et al. 2014). In another report, this therapy was given to one patient who eventually recovered (Khalid et al. 2015).

In a retrospective cohort study of 44 patients with severe MERS (requiring ventilatory support), treatment with ribavirin and pegylated IFN α2a (note, not 2b) appeared to increase short-term survival (14 days), although by 28 days only 10 of the patients were still living (6/20 survivors in treated group compared with 4/24 surviving in the comparison group) (Omrani et al. 2014).

Among promising studies evaluating therapies in animal models, one *in vivo* study found that the combination of ribavirin and IFN α2b therapy significantly improved outcomes among MERS-CoV-infected rhesus monkeys (Falzarano et al. 2013). In another study, using the common marmoset model, lopinavir/ritonavir and IFN α1b (separately and in combination) also proved promising (Chan et al. 2015).

Although neutralizing antibodies induced during infection did not appear to be protective during natural infection (Corman et al. 2016, Zhao et al. 2017), human convalescent sera containing neutralizing antibodies conferred dose-dependent protection in a mouse model (Zhao et al. 2017). The readily available sera from MERS-immune camels apparently were also an effective treatment for MERS-infected mice and reduced the severity of pathological changes in murine lung tissue (Zhao et al. 2015). Several monoclonal antibodies (mAbs) (Mou et al. 2013, Ohnuma et al. 2013, Du et al. 2014, Jiang et al. 2014, Tang et al. 2014, Ying et al. 2014, Houser et al. 2016) and conventional antibodies (Zhao et al. 2013) have demonstrated effective neutralization of MERS-CoV, and could serve as potential therapeutic agents, at least in the interim.

High-throughput screening and other methods have identified additional promising compounds in several classes (Chan et al. 2013, de Wilde et al. 2013, 2014, Gao et al. 2013, Shirato et al. 2013, Adedeji et al. 2014, Dyall et al. 2014, Hart et al. 2014, Lu et al. 2014, Lundin et al. 2014, Tao et al. 2014, Wrensch et al. 2014, Corti et al. 2015, Liu et al. 2015). These include inhibitors against both viral (Kilianski et al. 2013, Lei et al. 2014, Kumar et al. 2017) and host (Gierer et al. 2015) proteases needed to process the virus. However, it was reported that inhibiting proprotein convertases inhibits host cell processing of the spike protein but did not affect viral infectivity or cell-to-cell spread (Gierer et al. 2015).

Other targets studied have included viral entry inhibitors (Zhao et al. 2013, Du et al. 2015) and protein 4a, which the researchers found suppressed innate antiviral response (Siu et al. 2014).

Vaccine development. Development of a human (and possibly camel) vaccine for MERS-CoV should be a key priority, given concerns about its spread and pandemic potential, but vaccine development can be a long process that is often driven by economics (Modjarrad 2016).

Much of the focus thus far has centered on the identification of the residues within the receptor-binding domain of the spike protein, conferring the best chance of protection (Du et al. 2013a, 2013b, Lan et al. 2014, Ma et al. 2014a, 2014b). A number of other antigens, some in viral vectors, have been tested in the laboratory (Song et al. 2013, Kim et al. 2014).

A replication defective full-length cDNA clone of the MERS-CoV genome has been developed for identifying future vaccine candidates (Almazán et al. 2013). Vaccine candidates for dromedary camels have also been investigated, and have been reported to elicit protective responses (using the MERS-CoV spike protein in a poxvirus vector) (Haagmans et al. 2016).

There are special challenges to developing a MERS vaccine. The sporadic nature of human MERS-CoV infection and the difficulty of identifying suitable animal models for challenge studies make controlled trials difficult. Disease in camels usually appears mild (Adney et al. 2014), reducing the economic incentive for immunization. A camel vaccine could also be given in combination with a required vaccine, e.g., rabies, as suggested by Wirblich et al. (2017), or camelpox, as suggested by Haagmans et al. (2016).

Correlates of protection and duration of immunity are also uncertain. There are reports of strong antibody responses (Haagmans et al. 2016), but it has been suggested that the presence of neutralizing antibodies may not be protective in camels (Hemida et al. 2014) or humans (Corman et al. 2016, Zhao et al. 2017), and waning antibody titers have been reported in humans who have recovered from MERS-CoV infection (Choe et al. 2017). On the contrary, the reports of protection of mice by passive transfer of neutralizing antibodies suggest that this might be overcome by optimizing timing and dose (Zhao et al. 2017).

Research on MERS-CoV vaccine candidates is ongoing, and at least one candidate vaccine has now progressed to a Phase I human clinical trial (Modjarrad 2016, CEPI 2017). In a promising development, the recently launched Coalition for Epidemic Preparedness Innovations (CEPI) has listed MERS vaccine as one of its initial targets.

Epidemiology and transmission

The source of infection for most primary cases (the first known human case in a potential or putative chain of transmission) remains unknown. Baseline incidence and prevalence are unknown as only clinical cases or those found through contact tracing are generally identified. The few population-based studies that have been done appear to show low prevalence in the general population. A serological study of 10,009 individuals in Saudi Arabia found 15 seropositive for MERS-CoV, 7 of whom were occupationally camel-exposed (shepherds and slaughterhouse workers) (Müller et al. 2015), although the occupational samples were collected for a separate study and therefore may not be representative. In another study of 57,363 persons with suspected MERS-CoV infection tested by Saudi Arabia from April 2015 to February 2016, only 384 (0.7%) tested positive (Bin Saeed et al. 2017).

Most work has been done on symptomatic MERS patients because they are most likely to be detected and identified. Even so, one analysis suggested that at least 62% of even symptomatic cases were undetected (Cauchemez et al. 2014), and a study using data from travelers suggested that there may have been as many as 3250 severe cases from September 2012 to January 2016, about 2.3 times the number of cases confirmed (O'Hagan et al. 2016).

Determination of primary versus secondary cases is also challenging. One estimate is that 61% of MERS-CoV are primary cases, who tend to be mostly middle-aged males, compared with secondary cases who tend to be younger and distributed more evenly by sex (Gossner et al. 2016). The official overall CFR stands at ~35.5% (World Health Organization 2018a). However, it has been suggested that the CFR among primary cases, estimated to be 74%, is likely inflated due to detection bias; CFR among secondary cases is estimated to be 20% (Cauchemez et al. 2014).

The main known exposures are health care-associated infections and contact with camels. Aside from the health care setting, the mechanisms for the introduction of the virus into human populations are poorly understood. Occupational exposure risks are also poorly characterized, both in health care and for those who work with camels.

As with SARS, many cases have been health care facility-associated (Drosten et al. 2015), but the mechanism of infection is unclear for many individuals (Fanoy et al. 2014). Active case finding, typically among perceived risk groups or those hospitalized with pneumonia, has been used with varying success to identify cases (Gierer et al. 2013, Aburizaiza et al. 2014, Memish et al. 2014a).

Nosocomial transmission due to inadequate infection control is well established as a significant driver of MERS-CoV infections in humans (Al-Abdallat et al. 2014, Maltezou and Tsiodras 2014, Oboho et al. 2015, Alraddadi et al. 2016, Assiri et al. 2016, Hastings et al. 2016), notably during the spring 2014 outbreak in Saudi Arabia and the late spring 2015 outbreak in South Korea. A review (Maltezou and Tsiodras 2014) of 536 known MERS-CoV cases at the time of the review using publicly available data found 11 possible or confirmed health care-associated transmission events leading to substantial morbidity and mortality, often involving patients having comorbidities.

Infection control lapses were apparently responsible for virtually all reported health care transmission events, highlighting the need for strengthened infection control capacity worldwide. However, specific breaches in infection control were usually not identified and probably varied (Maltezou and Tsiodras 2014). Some high-risk procedures were identified, usually aerosol generating procedures, including hemodialysis and respiratory intensive care (Assiri et al. 2013b).

Secondarily infected health care workers tended to have milder symptoms and better prognoses. In the 2014 outbreak in Saudi Arabia, one study analyzed 191 symptomatic cases of MERS-CoV and found that 20.9% were health care workers (additional infected health care workers were asymptomatic, so that 30.6% of the 255 total cases analyzed were health care workers), and most patients had contact with a health care facility (Oboho et al. 2015). In a cluster of 9 MERS-CoV cases in Jordan, 6 were health care workers at the outbreak hospital, and no MERS-CoV transmission was detected at 2 transfer hospitals with adequate infection control (Al-Abdallat et al. 2014).

A health care-associated outbreak occurred in South Korea in the late spring of 2015 through July 2015, arising from one infected individual returning from the Gulf states (Cowling et al. 2015, Hui et al. 2015, Park et al. 2015). An analysis of 185 South Korean MERS-CoV cases using publicly available data delineated three generations of secondary infections (more than half of the cases were from the second generation) (Lee and Wong 2015). Overall, 154 cases were hospital-associated (Lee and Wong 2015), primarily affecting non-health care workers, spread by conditions such as close contact with the patients in crowded hospital or emergency rooms (Lee 2015b) and patients switching facilities (Lee 2015a, 2015b).

Direct contact could be inferred in only about 10% of the cases, and some authors suggested that fomite transmission could be important (Lee and Wong 2015, Seo et al. 2016, also reviewed in Otter et al. 2016). Earlier reports demonstrated that MERS-CoV is relatively stable in the environment, reported recoverable on surfaces after 48 h at 20°C and 48% relative humidity and for at least 12 h at 30°C with 30% humidity (van Doremalen et al. 2013), or in liquid at 25°C after 2 h (Leclercq et al. 2014). In a study of four laboratory-confirmed MERS-CoV patient rooms in two South Korean hospitals, MERS-CoV viral RNA was found on environmental

surfaces, including bedsheets and medical equipment, up to 5 days after a patient's last PCR-positive respiratory specimen; viable virus was also detected (Seo et al. 2016).

However, there were apparently few reports of infections in hospital laundry or maintenance workers, contrary to what would be expected for environmental transmission. It is possible that they were not identified or reported. We could find only two publications specifically mentioning infection in hospital cleaners (Hastings et al. 2016, Liu et al. 2016). Hastings et al. (2016) investigated a 2014 outbreak in King Fahd General Hospital and reported 1 MERS-CoV case among 1295 maintenance or housekeeping personnel. However, it appears that only symptomatic cases were tested, and specific details on this case were not provided.

Many reports from contact tracing identified family members, friends, coworkers, and other persons who had close contact with the patient. These include reports from Saudi Arabia (Memish et al. 2013b, Omrani et al. 2013, Drosten et al. 2014), as well as the United Kingdom (Pebody et al. 2012, Health Protection Agency (HPA) UK Novel Coronavirus Investigation Team 2013, Thomas et al. 2014), Iran (Yavarian et al. 2015), Tunisia (Abroug et al. 2014), China (Wu et al. 2015), Greece (Tsiodras et al. 2014), Germany (Buchholz et al. 2013, Reuss et al. 2014), Malaysia (Premila Devi et al. 2014), France (Mailles et al. 2013), and Italy (Puzelli et al. 2013).

Family clusters were identified in a number of these reports, but at most only a small percentage of contacts became cases, suggesting that close contact is not as important a risk factor as health care-associated transmission, and direct human-to-human transmission appears limited. Although the outbreak in South Korea also involved close contact among family members and other patients in hospital rooms, this may be more appropriately categorized as health care-associated transmission (Kang et al. 2017).

However, there is relatively little information on asymptomatic individuals, most of whom are detected by contact tracing. In one study, an asymptomatic health care worker excreted MERS-CoV for over 5 weeks (Al-Gethamy et al. 2015). In the spring 2014 outbreak in Saudi Arabia, an estimated 25.1% of laboratory-confirmed MERS-CoV was asymptomatic (Oboho et al. 2015). An analysis of 65 MERS-CoV patients in United Arab Emirates found that 35% were asymptomatic, and 1 individual yielded positive lower respiratory tract specimens for more than 2 weeks (Hosani et al. 2016). Al Hammadi et al. reported two asymptomatic men who had contact with infected camels; infection was confirmed by PCR in both men, and in all eight camels in the group (Al Hammadi et al. 2015). However, the actual frequency of asymptomatic individuals compared with symptomatic individuals is largely unknown.

Parameters for transmission dynamics are important for mathematical modeling of spread. Due to the heterogeneity in transmission, an important characteristic of infection dynamics, R_0 (the basic reproductive rate in a susceptible population), has been difficult to pinpoint. Estimates have ranged from 0.50 to 0.69 (Breban et al. 2013, Poletto et al. 2014) to between 0.8 and 1.3 (Cauchemez et al. 2014). $R_0 > 1$ is required for an outbreak to be self-sustaining (Anderson and May 1991). For specific locations, one model suggested an R_0 of 3.5–6.7 in Jeddah and 2.0–2.8 in Riyadh (Majumder et al. 2014), but these likely did not correct for effect of superspreading in health care settings (Kucharski and Althaus 2015). One mathematical model suggested the risk of secondary transmission following an imported MERS-CoV case is 22.7% (95% CI: 19.2–25.1%), with the risks of generations 2, 3, and 4 estimated to be 10.5%, 6.1%, and 3.9%, respectively (Nishiura et al. 2015).

Travel-related cases. Despite the mass gathering of individuals at the annual Hajj pilgrimage (Khan et al. 2013), to date it has not resulted in any known MERS-CoV transmission events (Barasheed et al. 2014, Benkouiten et al. 2014, Gautret et al. 2014, Memish et al. 2014b, 2014c, Aberle et al. 2015, Annan et al. 2015), confirming modeling estimates for the 2014 Hajj (Lessler et al. 2014). Two travelers returning to the Netherlands from a separate pilgrimage (Umrah) in May 2014 were found to have MERS-CoV (Kraaij-Dirkzwager et al. 2014). Many of the travel-related cases have been tabulated (Pavli et al. 2014, Sridhar et al. 2015, Carias et al. 2016). In all these cases, casual transmission (outside of family and health care settings) has not been observed.

The animal interface and search for natural and reservoir hosts of MERS-CoV

Dromedary camels are the only documented zoonotic source of human infection, and there is considerable circumstantial evidence supporting camel-to-human transmission, including evidence of camels and humans becoming infected with an identical MERS-CoV (Azhar et al. 2014, Ferguson and Kerkhove 2014, Memish et al. 2014e). Identical genomic sequences of MERS-CoV were isolated from a camel owner who died from MERS-CoV and his camel who had rhinorrhea at that time; identical MERS-CoV RNA fragments were later detected in the air at the camel barn (Azhar et al. 2014). Serology suggested that the camel was infected before the owner (Azhar et al. 2014). Critics have suggested that the identical sequences may be due to cross-contamination (Drosten et al. 2014), but the authors maintain that the isolates were collected on different days and processed in different facilities. Other epidemiologic investigations have found similar evidence, but directionality was not implied (Ferguson and Kerkhove 2014, Memish et al. 2014e).

In outbreak sites, viral genomic sequences from camels have matched those published for humans, and one analysis of MERS-CoV among camels showed that many of the camel viruses can be classified into clades that correlate with human outbreaks (Alagaili et al. 2014). Interestingly, three dromedary camel strains of MERS-CoV had similar viral replication competence to human strains in Vero-E6 cells and human respiratory tract explants (Chan et al. 2014).

This evidence suggests that camels would appear involved in cross-species transmission of MERS-CoV, although the precise mechanism and frequency remain uncertain.

Occupational exposure to camels would seem a particularly strong risk factor for infection, but its relative importance and relative risk of different exposures are not well documented (Hemida et al. 2015). As camels are widely used in the region for a variety of purposes, many people have contact with camels, and exposure is often invoked in non-occupational primary cases. Assessment of camel exposure is further complicated by the varying and sometimes vague

Table 1. Location, Methods, and Results of Recent Middle East Respiratory Syndrome Coronavirus Camel Seroprevalence Studies

Countries (reference)	*Year(s)*	*Test(s) used*[a]	*No. of samples*	*No. of positives (%)*
Egypt (Perera et al. 2013)	2013	ppNT	110	108 (98.2)

[a]ppNT, pseudoparticle neutralization; rELISA, recombinant enzyme-linked immunosorbent assay; MNT, microneutralization; PRNT, plaque reduction neutralization test; rIFA, recombinant immunofluorescence assay; Nt, serum neutralization.
[b]Seroprevalence reported higher in camels imported from Sudan (543/594; 88.7%) and East Africa (71/98; 72.4%) than resident (257/339; 5.8%); total 41/1078 nasal swabs reported PCR positive, 35/41 from Sudan.
[c]The exact number was not reported, and has been imputed from the reported percentages.

definitions used to classify camel exposure, and the multiple types of possible exposures. Even so, it has been hypothesized that camel exposure is commonly underreported (Gossner et al. 2016). There is a critical need for clearer definitions and measurements of ''camel exposure,'' and to standardize methodology.

Evidence to date indicates that MERS-like coronaviruses have been circulating in camels since at least the 1980s, before the first detection of MERS-CoV in humans (Müller et al. 2014). Seropositivity has been found consistently in African and Middle Eastern camels since 1983 (Table 1). There is virologic evidence of MERS-CoV infection in camels in Qatar (Ferguson and Kerkhove 2014, Haagmans et al. 2014, Raj et al. 2014), Egypt (Chu et al. 2014, Ali et al. 2017a, 2017b), Oman (Nowotny and Kolodziejek 2014), Saudi Arabia (Hemida et al. 2014), Sudan, and elsewhere (Chu et al. 2015, Ali et al. 2017a).

Increasing genomic evidence suggests a diversity of coronaviruses in camels throughout the Middle East and Africa, including in major source countries for camel imports to the Middle East, cross-neutralizing with MERS-CoV but having divergent sequences and probably not human pathogens (Chu et al. 2015, 2018). This may explain the high apparent seropositivity in camels in Africa in the absence of known human cases of MERS.

Maintenance of the virus in the camel population remains an open question. Symptomatic MERS-CoV infection has been documented in both calves and adult camels (Adney et al. 2014), and viral shedding was detected in nasal secretions up to 7 days postinoculation with MERS-CoV (Adney et al. 2014), as well as in milk and possibly feces (Hemida et al. 2014, Reusken et al. 2014a). Camel milk has been suggested as a possible source of infection for both humans and camel foals (Hemida et al. 2014, Reusken et al. 2014a, van Doremalen et al. 2014). One study demonstrated that added MERS-CoV can survive in milk for at least 48 h at both 4°C and 22°C, although not detected after pasteurization (van Doremalen et al. 2014).

Other possible livestock hosts for MERS-CoV have been investigated, and have generally been negative (Hemida et al. 2013, Perera et al. 2013, Reusken et al. 2013b, 2013c, Alagaili et al. 2014, Alexandersen et al. 2014, van Doremalen et al. 2014, Meyer et al. 2015). One study found 15 seropositive alpacas, which are members of the camelid family, in Qatar (Reusken et al. 2016). Experimentally infected alpacas in one study demonstrated upper respiratory tract infection, viral shedding, and transmission to other alpacas (Adney et al. 2016).

The search for the origins and natural hosts of MERS-CoV continues. Bat species across the world are known to host a wide variety of coronaviruses, including beta-coronaviruses (the genus to which MERS-CoV belongs) (Anthony et al. 2013, Corman et al. 2013, Lelli et al. 2013, Memish et al. 2013a), and bats tend to show greater coronavirus diversity than other mammals (Drexler et al. 2014, Anthony et al. 2017). Consequently, much research has focused on the possible origin of MERS-CoV in bats. Possibly further supporting this hypothesis, in bat cell lines MERS-CoV has been reported to replicate only in those cell lines that express DPP4, the functional human receptor for the virus, and not in bat cell lines lacking DPP4 expression (Raj et al. 2013, Cai et al. 2014).

It is possible that MERS-CoV itself may be a relatively new introduction in humans. A phylogenetic analysis utilizing 65 complete or partially complete MERS-CoV genomic sequences (32 from Saudi Arabian cases in 2013) estimated that the most recent common ancestor was in March 2012 (95% CI: December 2011–June 2012) (Cotten et al. 2014).

One study, from analysis of an S1 subunit in its spike gene, suggested that MERS-CoV may have arisen from intraspike

recombination between two ancestral coronaviruses (Corman et al. 2014).

The virus has not been isolated from a bat, although a portion of MERS-CoV RNA sequence apparently was identified in a bat (the insectivorous bat *Taphozous perforatus*, the Egyptian tomb bat) in Saudi Arabia in the same site as an early human case (100% nucleotide match, although this was only ~180 nucleotides in the relatively well-conserved RdRp region) (Memish et al. 2013a). MERS-like coronaviruses, including the closely related HKU4, which also uses a DPP4 receptor, and HKU5, first identified by Woo et al. in 2006 (Woo et al. 2006, Lau et al. 2013, Matthews et al. 2014, Wang et al. 2014), and others have been identified in bat species in China (Matthews et al. 2014, Yang et al. 2014), Mexico (Anthony et al. 2013), South Africa (Ithete et al. 2013, Corman et al. 2014a), and Uganda (Anthony et al. 2017).

Discussion and Conclusions

Since the detection of MERS-CoV in 2012, a large body of research has been amassed, as evidenced by the hundreds of unique results from our database searches. The virus has rapidly been characterized, and its functional human receptor swiftly identified. Species and cellular tropism studies have complemented clinical investigations, and laboratory work has provided further insights on MERS-CoV pathogenesis.

Observational research from outbreaks in the Middle East and South Korea has generated a growing repository of clinical data, basic epidemiology, and genome sequences. Other studies have evaluated the roles of human/animal interfaces, health care settings, family clusters, and travel in MERS-CoV transmission. Furthermore, bats have been implicated as the possible origin of MERS-CoV, while dromedary camels have been shown to be likely sources of many human infections. There has been progress in developing therapeutics and vaccines. Although these have not yet progressed to full clinical trials, they could in the foreseeable future.

A major reason we undertook this review was to determine what gaps still exist. Of the publications we originally identified, the largest category (80 publications) was in laboratory or basic science studies, followed by surveillance (59), animal interfaces (55), clinical aspects and health care (50), therapeutics and vaccines (42), while human transmission and epidemiology was one of the sparsest (35, including investigations of hospital outbreaks and travel-related cases), noting that these categories are not necessarily exclusive and there is overlap.

In general, continued surveillance for MERS-CoV in affected countries should continue, prioritizing surveillance in humans, camels, and bats, given their apparent importance. As serology may not be reliable, due to cross-reactions and possibly waning antibodies, virologic surveillance and sequencing should also be attempted on selected specimens whenever feasible.

Although the role of bats is yet to be fully elucidated, and evidence is lacking that bats are a source of human infection, the diversity of coronaviruses, including MERS-like coronaviruses, in bat species across the globe indicates that continued research and ongoing surveillance of coronaviruses in bats are justified (Lau et al. 2013, Lelli et al. 2013, Yang et al. 2014).

A number of key gaps remain in epidemiology, including transmission, population-based incidence or prevalence rates, and geographic and demographic distributions of infections. Based on the limited human seroprevalence data so far, it seems likely that population prevalence is low, but the baseline should be established. It is also not clear whether seropositivity is a reliable indicator of prior infection. The finding of variable low antibody titers at 1 year postinfection (Choe et al. 2017) indicates that methods other than traditional serosurveys may be required (Reusken et al. 2013a, Malik et al. 2016). If serology is not reliable, this raises the question of how to screen populations. There are methods that are both more sensitive and more specific for antibody detection (Mishra et al. 2018), as well as assays of cellular immunity (Zhao et al. 2017), but are costlier and more difficult for population screening.

Contact tracing has identified asymptomatic infections, but studies of their frequency and transmissibility have been limited. Many of those infected are health care workers in whom these questions could be systematically studied. Relatively little is known about the natural history of human asymptomatic infections. Further studies of virus shedding, seroconversion, and transmission in asymptomatic infections are needed. Some evidence suggests that secondary cases have lower average CFRs and that subsequent links in the chain of MERS-CoV infection may decrease in severity.

Exposure in most primary cases is still largely inferential at best. While camels are apparently often the likely source, the definitions of camel exposure are varied, preventing clear epidemiological inferences. Definitions of the exposures and the methodology and metrics for determining exposure should be clarified and standardized. Even if camels are a principal source of human infections, this would still not explain a substantial portion of primary human cases that did not have apparent camel exposure before infection. This raises questions about how and where these other primary cases acquired MERS-CoV infection, whether through other animal species, unidentified zoonotic exposure, unrecognized infectious persons (such as asymptomatic infectious individuals), or environmental contamination.

Consequently, clarifying the routes of transmission remains crucial and should receive emphasis. To date, there is no compelling evidence of direct human-to-human transmission, such as through droplets, but secondary infection has been reported. It is often unclear how health care workers become infected. There is possible evidence of environmental contamination (fomites) in health care settings (nosocomial transmission) and close contact with an active MERS-CoV case.

Various infection control lapses have been documented, but rarely a specific event or route (Ben Embarek and Van Kerkhove 2015, Alraddadi et al. 2016, Van Kerkhove et al. 2016). Rigorous infection control therefore remains essential and could prevent many secondary cases. In the interim, better documentation or identification of the specific lapses that led to infection would be of great value in understanding mechanisms of transmission and is one of the greatest knowledge gaps. Much of the evidence for fomite transmission, for example, remains anecdotal (Van Kerkhove et al. 2016).

The mechanisms supporting chains of human MERS-CoV transmission need to be more fully evaluated. These gaps indicate a need for additional research, and also for consistent

terminology and clear definitions. Although the epidemiological literature on MERS-CoV is large, much of it is fragmented and inconsistently reported. It is often difficult to deduce the sequence of infections, relationships between cases, or specific exposures. A comprehensive and consistent database or registry should be a priority.

Genome sequencing has proved useful in several respects. Genome sequencing was used to help determine viral circulation and ancestry (Cotten et al. 2014), and to differentiate apparently similar and serologically cross-reacting coronaviruses in camels, addressing the (still unresolved) question of why MERS seems regionally limited, while many camels are imported from other places (Chu et al. 2015, 2018). It has also been used to reconstruct the transmission events and help to establish chains of infection (Assiri et al. 2013b, Cotten et al. 2013), but it must be noted that there is a pressing need for more rigorous conventional epidemiology as well to validate the methodologies. These approaches might well serve a complementary function in advancing our understanding.

There remains a need for effective therapeutics and vaccines. Treatment remains symptomatic, with insufficient clinical data on other therapeutic options. These options will always be limited in number, but their development should be approached more systematically with shared protocols and critical comparison of results. As a number of drug and vaccine candidates have been identified, there may be more options available for future clinical trials. There appear to be efforts underway to develop some clinical trials based on standardized protocols. This is needed, despite the challenges presented by the sporadic nature of the cases, and the relative rarity of clinical MERS.

There were several limitations in this systematic review of MERS-CoV. Only publications in English or with English language abstracts were eligible for inclusion, although most of the cases have been in Arabic-speaking areas and Korea. However, hundreds of English language reports were available from countries around the world, including the Middle East and South Korea, minimizing this concern. Second, this review contains publications indexed by these databases by July 2017, so it is possible that some publications, especially recently published articles or manuscripts still in production, were unintentionally excluded from the review. We updated our literature review periodically during the preparation of this article to minimize the number of missed publications. Third, ''gray literature'' was not included, such as government reports and technical documents, and most meeting abstracts, although it is likely that important findings would have been submitted for journal publication.

As an emerging infection of zoonotic origin (Morse 1995), a unified One Health approach that engages the human health, livestock and companion animal, wildlife, and environment sectors will be crucial in dealing with MERS (Morse 2012, Morse et al. 2012). It could serve as an excellent case study for epidemiology and response to a new zoonotic, or emerging, infection.

Middle East respiratory syndrome coronavirus (MERS-CoV)

Overview | Symptoms | Treatment

Middle East respiratory syndrome coronavirus (MERS-CoV) is a virus transferred to humans from infected dromedary camels. It is a zoonotic virus, meaning it is transmitted between animals and people, and it is contractable through direct or indirect contact with infected animals. MERS-CoV has been identified in dromedaries in several countries in the Middle East, Africa and South Asia. In total, 27 countries have reported cases since 2012, leading to 858 known deaths due to the infection and related complications.

The origins of the virus are not fully understood but according to the analysis of different virus genomes it is believed that it may have originated in bats and later transmitted to camels at some point in the distant past.

Human-to-human transmission is possible, but only a few such transmissions have been found among family members living in the same household. In health care settings, however, human-to-human transmission appears to be more frequent.

SARS and MERS: recent insights into emerging coronaviruses

Emmie de Wit[1], Neeltje van Doremalen[1], Darryl Falzarano[2] and Vincent J. Munster[1]

Abstract | The emergence of Middle East respiratory syndrome coronavirus (MERS-CoV) in 2012 marked the second introduction of a highly pathogenic coronavirus into the human population in the twenty-first century. The continuing introductions of MERS-CoV from dromedary camels, the subsequent travel-related viral spread, the unprecedented nosocomial outbreaks and the high case-fatality rates highlight the need for prophylactic and therapeutic measures. Scientific advancements since the 2002–2003 severe acute respiratory syndrome coronavirus (SARS-CoV) pandemic allowed for rapid progress in our understanding of the epidemiology and pathogenesis of MERS-CoV and the development of therapeutics. In this Review, we detail our present understanding of the transmission and pathogenesis of SARS-CoV and MERS-CoV, and discuss the current state of development of measures to combat emerging coronaviruses.

Nosocomial transmission
Transmission of an infectious agent by staff, equipment or the environment in a health care setting.

This century has seen the global spread of two previously unknown coronaviruses. In November 2002, the first known case of severe acute respiratory syndrome (SARS) occurred in Foshan, China[1]. New cases emerged in mainland China, and by February 2003, more than 300 cases had been reported, around one-third of which were in health care workers[1]. Individuals who were infected and subsequently travelled spread the outbreak to Hong Kong[2] and from there to Vietnam, Canada and several other countries[3]. In March 2003, the WHO established a network of laboratories to determine the causative agent of SARS. A remarkable global effort led to the identification of SARS coronavirus (SARS-CoV) in early April of that year[4–6]. By July 2003 and after a total of 8,096 reported cases, including 774 deaths in 27 countries[7], no more infections were detected, and the SARS pandemic was declared to be over. Five additional SARS cases, resulting from zoonotic transmission, occurred in December 2003–January 2004 (REF. 8), but no human SARS cases have been detected since. Measures of infection control, rather than medical interventions, ended the SARS pandemic. However, certain SARS-CoV-like viruses found in bats have recently been shown to be able to infect human cells without prior adaptation[9,10], which indicates that SARS could re-emerge.

In June 2012, 10 years after the first emergence of SARS-CoV, a man in Saudi Arabia died of acute pneumonia and renal failure. A novel coronavirus, Middle East respiratory syndrome coronavirus (MERS-CoV), was isolated from his sputum[11]. A cluster of cases of severe respiratory disease had occurred in April 2012 in a hospital in Jordan and was retrospectively diagnosed as MERS[12], and a cluster of three cases of MERS in the UK was identified in September 2012 (REF. 13). MERS-CoV continued to emerge and spread to countries outside of the Arabian Peninsula as a result of travel of infected persons; often, these imported MERS cases resulted in nosocomial transmission. In May 2015, a single person returning from the Middle East started a nosocomial outbreak of MERS in South Korea that involved 16 hospitals and 186 patients[14]. As of 26 April 2016, there have been 1,728 confirmed cases of MERS, including 624 deaths in 27 countries[15].

This Review highlights the pandemic and epidemic potential of emerging coronaviruses and discusses our current knowledge of the biology of SARS-CoV and MERS-CoV, including their transmission, their pathogenesis and the development of medical countermeasures. Key features of these viruses are the dominance of nosocomial transmission, and pathogenesis that is driven by a combination of viral replication in the lower respiratory tract and an aberrant host immune response. Several potential treatments for SARS and MERS have been identified in animal and *in vitro* models, including small-molecule protease inhibitors, neutralizing antibodies and inhibitors of the host immune response. However, efficacy data from human clinical trials are lacking but are needed to move these potential countermeasures forward.

Replication of SARS-CoV and MERS-CoV

SARS-CoV and MERS-CoV belong to the Coronavirus genus in the *Coronaviridae* family and have large, positive-sense RNA genomes of 27.9 kb and 30.1 kb,

respectively (FIG. 1a). Similarly to all viruses in the order *Nidovirales*, SARS-CoV and MERS-CoV have a unique coding strategy: two-thirds of the viral RNA is translated into two large polyproteins, and the remainder of the viral genome is transcribed into a nested set of subgenomic mRNAs[16,17] (FIG. 1b). The two polyproteins, pp1a and pp1ab, encode 16 non-structural proteins (nsp1–nsp16)[18] that make up the viral replicase–transcriptase complex. The polyproteins are cleaved by two proteases, papain-like protease (PLpro; corresponding to nsp3) and a main protease, 3C-like protease (3CLpro; corresponding to nsp5). The nsps rearrange membranes that are derived from the rough endoplasmic reticulum (RER) into double-membrane vesicles, in which viral replication and transcription occur[19]. One unique feature of coronaviruses is the exoribonuclease (ExoN) function of nsp14 (REF. 20), which provides the proofreading capability required to maintain a large RNA genome without the accumulation of detrimental mutations[21,22]. SARS-CoV and MERS-CoV transcribe 12 and 9 subgenomic RNAs,

respectively, and these encode the four structural proteins spike (S), envelope (E), membrane (M) and nucleocapsid (N), as well as several accessory proteins that are not involved in viral replication but interfere with the host innate immune response or are of unknown or poorly understood function.

The envelope spike glycoprotein binds to its cellular receptor, angiotensin-converting enzyme 2 (ACE2) for SARS-CoV and dipeptidyl peptidase 4 (DPP4) for MERS-CoV[23]. After membrane fusion, either directly with the host cell membrane or with the endosome membrane, the viral RNA genome is released into the cytoplasm, and the RNA is uncoated to allow translation of the two polyproteins, transcription of the subgenomic RNAs and replication of the viral genome (FIG. 1b). Newly formed envelope glycoproteins are inserted in the RER or Golgi membranes; genomic RNA and nucleocapsid proteins combine to form nucleocapsids, and the viral particles bud into the ER–Golgi intermediate compartment (ERGIC). Virion-containing vesicles subsequently fuse with the plasma membrane to release the virus[24].

Reservoirs and transmission

The first indication of the source of SARS-CoV was the detection of the virus in masked palm civets and a raccoon dog and the detection of antibodies against the virus in Chinese ferret badgers in a live-animal market in Shenzhen, China[25]. However, these animals were only incidental hosts, as there was no evidence for the circulation of SARS-CoV-like viruses in palm civets in the wild or in breeding facilities[26]. Rather, bats are the reservoir of a wide variety of coronaviruses, including SARS-CoV-like and MERS-CoV-like viruses[27] (FIG. 2).

Figure 1 | **SARS-CoV and MERS-CoV structure and replication. a** | The single-stranded RNA (ssRNA) genomes of severe acute respiratory syndrome coronavirus (SARS-CoV) and Middle East respiratory syndrome coronavirus (MERS-CoV) encode two large polyproteins, pp1a and pp1ab, which are proteolytically cleaved into 16 non-structural proteins (nsps), including papain-like protease (PLpro), 3C-like protease (3CLpro), RNA-dependent RNA polymerase (RdRp), helicase (Hel) and exonuclease (ExoN). An additional 9–12 ORFs are encoded through the transcription of a nested set of subgenomic RNAs. SARS-CoV and MERS-CoV form spherical particles that consist of four structural proteins. The envelope glycoprotein spike (S) forms a layer of glycoproteins that protrude from the envelope. Two additional transmembrane glycoproteins are incorporated in the virion: envelope (E) and membrane (M). Inside the viral envelope resides the helical nucleocapsid, which consists of the viral positive-sense RNA ((+)RNA) genome encapsidated by protein nucleocapsid (N). **b** | Following entry of the virus into the host cell, the viral RNA is uncoated in the cytoplasm. ORF1a and ORF1ab are translated to produce pp1a and pp1ab, which are cleaved by the proteases that are encoded by ORF1a to yield 16 nsps that form the RNA replicase–transcriptase complex. This complex localizes to modified intracellular membranes that are derived from the rough endoplasmic reticulum (ER) in the perinuclear region, and it drives the production of negative-sense RNAs ((–)RNAs) through both replication and transcription. During replication, full-length (–)RNA copies of the genome are produced and used as templates for full-length (+)RNA genomes. During transcription, a subset of 7–9 subgenomic RNAs, including those encoding all structural proteins, is produced through discontinuous transcription. In this process, subgenomic (–)RNAs are synthesized by combining varying lengths of the 3′end of the genome with the 5′ leader sequence necessary for translation. These subgenomic (–)RNAs are then transcribed into subgenomic (+)mRNAs. Although the different subgenomic mRNAs may contain several ORFs, only the first ORF (that closest to the 5′end) is translated. The resulting structural proteins are assembled into the nucleocapsid and viral envelope at the ER–Golgi intermediate compartment (ERGIC), followed by release of the nascent virion from the infected cell.

Thus, the search for the reservoir of MERS-CoV initially focused on bats, but a serological survey in dromedary camels from Oman and the Canary Islands showed a high prevalence of MERS-CoV-neutralizing antibodies in these animals[28]. In addition, MERS-CoV RNA was detected in swabs that were collected from dromedary camels at a farm in Qatar that was linked to two human cases of MERS, and infectious virus was isolated from dromedary camels in Saudi Arabia and Qatar[29–32]. Serological evidence for the circulation of a MERS-CoV-like virus in dromedary camels has been obtained in the Middle East, Eastern Africa and Northern Africa, dating back as far as 1983 (REF. 33). Dromedary camels in Saudi Arabia harbour several viral genetic lineages[34], including those that have caused human outbreaks. Taken together, these data strongly point to the role of dromedary camels as a reservoir for MERS-CoV. The ubiquity of infected dromedary camels close to humans and the resulting continuing zoonotic transmission may explain why MERS-CoV continues to cause infections in humans, whereas SARS-CoV, without the continuing presence of an infected intermediate host and with relatively infrequent human–bat interactions, has caused no more infections in humans.

Human-to-human transmission of SARS-CoV and MERS-CoV occurs mainly through nosocomial transmission; 43.5–100% of MERS cases in individual outbreaks were linked to hospitals, and very similar observations were made for some of the SARS clusters[35,36]. Transmission between family members occurred in only 13–21% of MERS cases and 22–39% of SARS cases. Transmission of MERS-CoV between patients was the most common route of infection (62–79% of cases), whereas for SARS-CoV, infection of health care workers by infected patients was very frequent (33–42%)[35]. The predominance of nosocomial transmission is probably due to the fact that substantial virus shedding occurs only after the onset of symptoms[37,38], when most patients are already seeking medical care[39]. An analysis of hospital surfaces after the treatment of patients with MERS showed the ubiquitous presence of viral RNA in the environment for several days after patients no longer tested positive[40]. Moreover, many patients with SARS or MERS were infected through super spreaders[14,35,37,41–43].

The pathogenesis of SARS-CoV and MERS-CoV

The clinical courses of SARS and MERS are remarkably similar, although there are subtle differences (BOX 1). Owing to the current sparsity of data on human MERS-CoV infections[44], the pathogenesis of this virus is poorly understood; however, similar mechanisms may underlie the pathogenesis of both MERS and SARS.

The binding of spike protein to ACE2 and the subsequent downregulation of this receptor contribute to lung injury during SARS[45]. Although it seems counter-intuitive that receptor downregulation would increase pathology, it has been shown that ACE2 can protect against acute lung injury. The downregulation of ACE2 results in the excessive production of angiotensin II by the related enzyme ACE, and it has been suggested that the stimulation of type 1a angiotensin II receptor

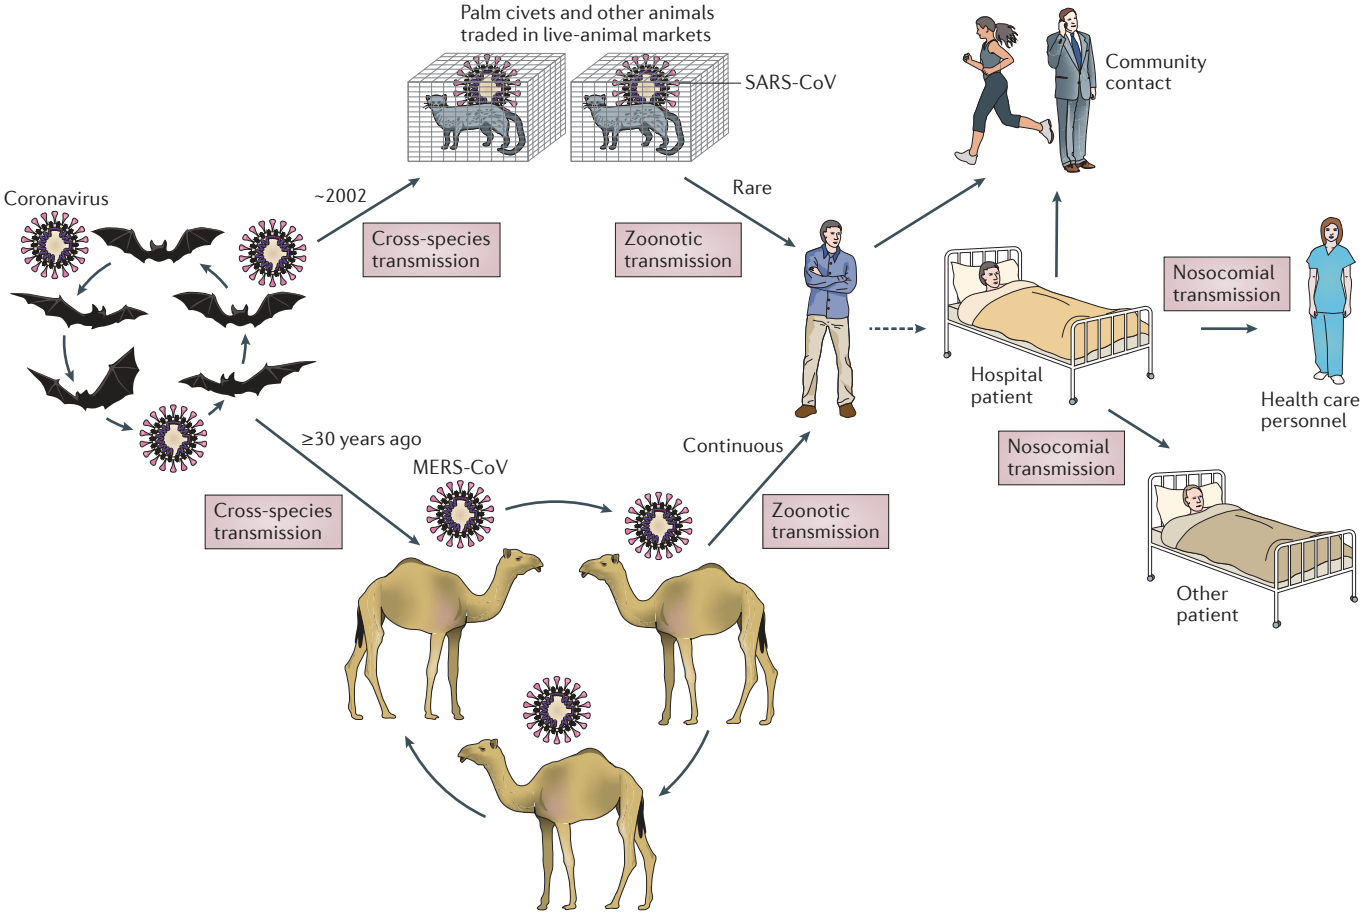

Figure 2 | **The emergence of SARS-CoV and MERS-CoV.** Bats harbour a wide range of coronaviruses, including severe acute respiratory syndrome coronavirus (SARS-CoV)-like and Middle East respiratory syndrome coronavirus (MERS-CoV)-like viruses. SARS-CoV crossed the species barrier into masked palm civets and other animals in live-animal markets in China; genetic analysis suggests that this occurred in late 2002. Several people in close proximity to palm civets became infected with SARS-CoV. A MERS-CoV ancestral virus crossed the species barrier into dromedary camels; serological evidence suggests that this happened more than 30 years ago. Abundant circulation of MERS-CoV in dromedary camels results in frequent zoonotic transmission of this virus. SARS-CoV and MERS-CoV spread between humans mainly through nosocomial transmission, which results in the infection of health care workers and patients at a higher frequency than infection of their relatives.

(AGTR1A) increases pulmonary vascular permeability, thus potentially explaining the increased lung pathology when the expression of ACE2 is decreased[46].

Immunopathology. The immune response is essential for the resolution of an infection, but it can also result in immunopathogenesis. One indication that immunopathogenesis may contribute to SARS was the observation that viral loads were found to be decreasing while disease severity increased[39,47]. It is unclear whether a similar trend applies to MERS[48,49]. Moreover, progression to acute respiratory distress syndrome (ARDS) is associated with the upregulation of pro-inflammatory cytokines and chemokines, particularly interleukin-1β (IL-1β), IL-8, IL-6, CXC-chemokine ligand 10 (CXCL10) and CC-chemokine ligand 2 (CCL2)[50,51]; increased plasma levels of these molecules have been detected in patients with SARS[52–55]. Retrospective longitudinal studies in patients who recovered from SARS versus those who succumbed to the disease have shown an early expression of interferon-α (IFNα), IFNγ, CXCL10, CCL2 and proteins that are encoded by IFN-stimulated genes (ISGs) in all patients, but only patients who survived then had gene expression profiles that are indicative of the development of an adaptive immune response. By contrast, patients who succumbed maintained high levels of CXCL10, CCL2 and ISG-encoded proteins, whereas spike-specific antibodies were present at low levels or were absent[56], which suggests that severe disease is related to the lack of a switch from an innate immune response to an adaptive immune response.

Experiments using Collaborative Cross mouse lines and mouse-adapted SARS-CoV identified one host gene, *Trim55*, as important for SARS pathogenesis. Although there was no difference in clinical signs or viral replication in *Trim55*$^{-/-}$ mice compared with wild-type mice, perivascular cuffing and the number of inflammatory cells in the lungs were reduced in the *Trim55*$^{-/-}$ mice[57].

Acute respiratory distress syndrome
(ARDS). A life-threatening condition in which the accumulation of fluid and inflammatory cells in the lungs decreases the exchange of oxygen and carbon dioxide to dangerously low levels.

Collaborative Cross mouse
One of a panel of recombinant inbred mouse strains derived from a genetically diverse set of founder strains and designed for the analysis of complex traits.

Perivascular cuffing
The aggregation of leukocytes around blood vessels.

Box 1 | **Clinical features of SARS and MERS**

Severe acute respiratory syndrome coronavirus (SARS-CoV) and Middle East respiratory syndrome coronavirus (MERS-CoV) have an incubation period of ~5 days, and 95% of patients develop disease within 13 days of exposure[14,38,144–146]. Common early symptoms are fever, chills, coughing, malaise, myalgia and headache, and less common symptoms include diarrhoea, vomiting and nausea[2,6,39,89,90,92,95,144,146–148]. Upper respiratory tract symptoms and viral shedding are rare, which explains difficulties in obtaining a laboratory diagnosis from nasal or nasopharyngeal swabs[149]. Abnormal chest X-rays are more common in patients with MERS (90–100%)[144,148] than in those with SARS (60–100%)[39,89]. Accordingly, only 20–30% of patients with SARS require intensive care and subsequent mechanical ventilation, whereas 50–89% of patients with MERS require intensive care[2,39,89,90,95,144,147,148]. The higher incidence of acute respiratory distress syndrome (ARDS) in individuals with MERS is reflected in the case fatality rate: this is ~36% for MERS compared with ~10% for SARS[15,145].

Comorbidities have an important role in both SARS and MERS. Several risk factors are associated with poor disease outcome, especially advanced age and male sex[2,14,39,144,146,148,150,151]. For MERS, additional risk factors for a poor outcome include diabetes mellitus, hypertension, cancer, renal and lung disease, and co-infections[14,144,146,148,150,151].

Health care settings seem to increase the risk of viral transmission owing to aerosol-generating procedures such as intubation and bronchoscopy. Appropriate hospital hygiene practices and awareness are crucial to limit future nosocomial outbreaks.

The involvement of the host immune response in the pathogenesis of SARS, and most likely also that of MERS, suggests that drugs which inhibit viral replication will need to be combined with treatments that control detrimental immune responses.

Immune evasion. SARS-CoV and MERS-CoV use several strategies to avoid the innate immune response. Viral pathogen-associated molecular patterns (PAMPs), such as double-stranded RNA (dsRNA) or uncapped mRNA, are detected by pattern recognition receptors (PRRs), such as retinoic acid-inducible gene I protein (RIG-I; also known as DDX58) or melanoma differentiation-associated protein 5 (MDA5; also known as IFIH1)[58]. This triggers complex signalling cascades involving MYD88 that lead to the production of type I IFNs and the activation of the transcription factor nuclear factor-κB (NF-κB). In turn, active NF-κB induces the transcription of pro-inflammatory cytokines (FIG. 3a). Type I IFNs signal through IFNα/β receptor (IFNAR) and downstream molecules such as signal transducer and activator of transcription (STAT) proteins to stimulate the production of antiviral proteins that are encoded by ISGs, such as IFN-induced protein with tetratricopeptide repeats 1 (IFIT1; FIG. 3b). Collectively, this establishes an antiviral immune response that limits viral replication in infected and in neighbouring cells (FIG. 3).

Infection of knockout mice revealed the importance of innate immunity. Infection of *Myd88*$^{-/-}$ and *Stat1*$^{-/-}$ mice, but not mice that were deficient in IFN receptors, with a mouse-adapted strain of SARS-CoV resulted in more severe disease than infection with a non-adapted SARS-CoV strain[59,60]. Moreover, MERS-CoV infection of wild-type mice that were transduced with human DPP4 caused mild disease, but symptoms were more severe in *Myd88*$^{-/-}$ mice and *Ifnar1*$^{-/-}$ mice[61].

SARS-CoV and MERS-CoV avoid host detection of their dsRNA by replicating in virus-induced double-membrane vesicles that lack PRRs[19,62,63]. Moreover, the recognition of SARS-CoV mRNAs, for example, by MDA5 and IFIT1 is prevented by capping of the viral mRNAs by nsp14 and the nsp10–nsp16 complex[64]. Recombinant SARS-CoV that lacks the methylation activity of nsp16 is attenuated and exhibits increased sensitivity to type I IFNs. This effect is dependent on IFIT1 or MDA5, as the same virus is not attenuated in mice that are deficient in either molecule[65]. Although mRNA capping has not yet been shown for MERS-CoV, structural similarity between the MERS-CoV nsp10–nsp16 complex and the SARS-CoV nsp10–nsp16 complex suggests that a similar mechanism exists to avoid host recognition of MERS-CoV mRNAs by cytosolic PRRs[66].

SARS-CoV encodes at least eight proteins that interact with the signalling cascades downstream of PRRs; in MERS-CoV, several proteins have been identified with similar functions (FIG. 3). The nucleocapsid protein of SARS-CoV has been associated with the suppression of RNAi in mammalian cells[67]. Furthermore, this protein antagonizes IFN induction, probably early in the signalling cascade, as downstream signalling molecules relieve the inhibition[68]. MERS-CoV ORF4a has a similar IFN-antagonistic function, involving the binding of dsRNA and subsequent inhibition of MDA5 activation[69], potentially through interaction with IFN-inducible dsRNA-dependent protein kinase activator A (PRKRA; also known as PACT), which interacts with MDA5 and RIG-I[70]. Moreover, MERS-CoV ORF4a, ORF4b, ORF5 and membrane protein inhibit the nuclear trafficking of IFN-regulatory factor 3 (IRF3) and activation of the *IFNB* promoter[71]. These viral proteins, except for ORF5, also inhibit the expression of genes that are under the control of an IFN-stimulated response element (ISRE), and ORF4a reduces the expression of genes that are stimulated by NF-κB[71]. Finally, MERS-CoV ORF4b interacts with TBK1 and inhibitor of NF-κB kinase-ε (IKKε), thereby suppressing the interaction between IKKε and mitochondrial antiviral-signalling protein (MAVS) and inhibiting the phosphorylation of IRF3 (REF. 72).

The membrane protein of SARS-CoV inhibits the formation of a signalling complex that contains IKKε, thus repressing the activation of IRF3 and IRF7 and their induction of type I IFN expression. The membrane protein of MERS-CoV inhibits IRF3 function and the expression of genes that are regulated by an ISRE, including IFNβ[71], but whether this occurs through a mechanism similar to that of SARS-CoV is unclear.

SARS-CoV PLpro disrupts NF-κB signalling[73] and blocks the phosphorylation of IRF3 indirectly[73,74]. Furthermore, SARS-CoV PLpro inhibits the induction of type I IFNs, potentially through the deubiquitylation of phosphorylated IRF3 (REFS 73,75). Similar functions have been described for MERS-CoV PLpro[76].

Experiments involving recombinantly expressed proteins, *in vitro* translation, protein overexpression and minireplicon systems have shown that nsp1 of SARS-CoV blocks the IFN response through the inhibition of

Type I IFNs
(Type I interferons). A group of IFNs, including IFNα and IFNβ, with immune-modulating and antiviral functions.

RNAi
A biological process in which small RNA molecules induce the degradation of specific mRNA molecules, thereby inhibiting gene expression.

Minireplicon systems
Systems in which a DNA molecule is produced that contains the viral leader and trailer sequences, with an assayable reporter replacing the viral ORFs. When combined with the expression of viral proteins in *trans*, this system can be used to model the viral life cycle without the necessity of using infectious virus.

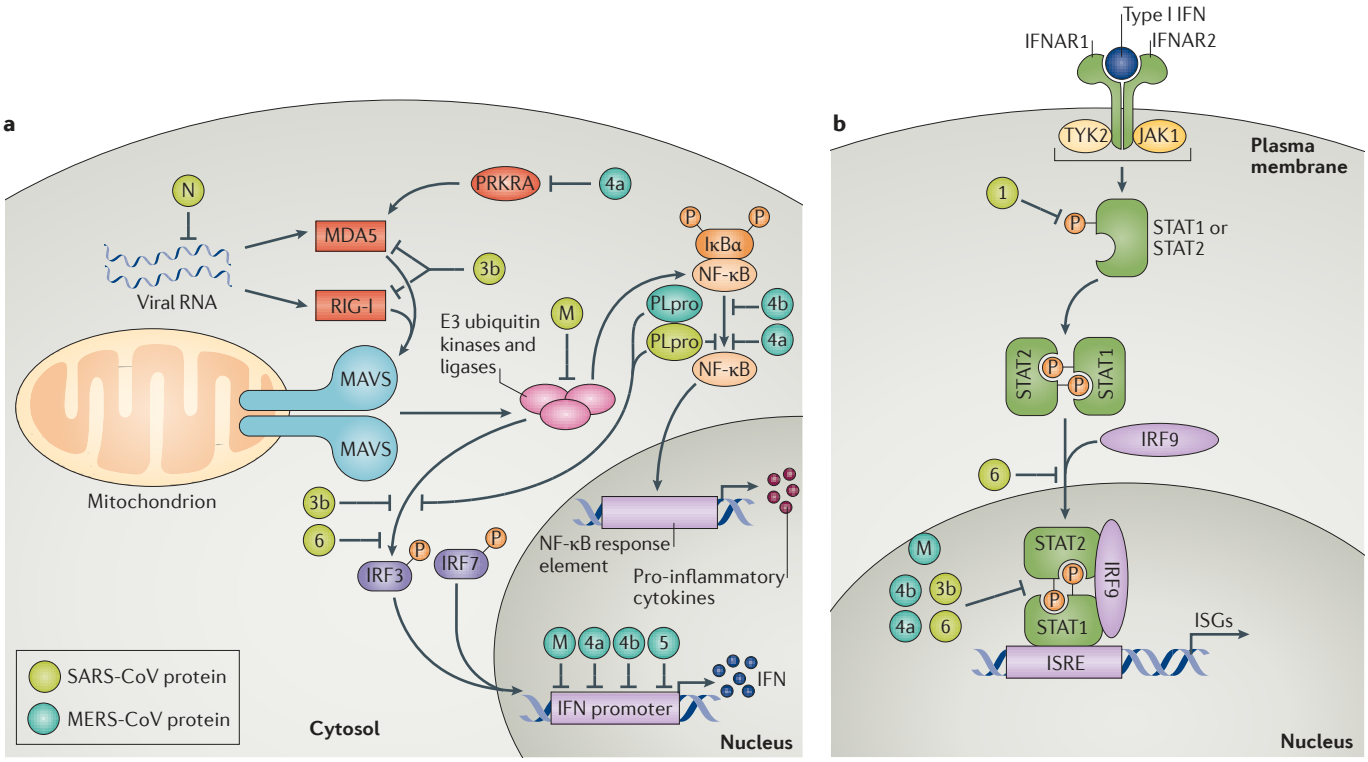

Figure 3 | **Evasion of the innate immune response by SARS-CoV and MERS-CoV. a** | The innate immune response is activated by the detection of viral pathogen-associated molecular patterns (PAMPs), such as double-stranded RNA (dsRNA) or uncapped mRNA. This occurs via host pattern recognition receptors (PRRs), such as retinoic acid-inducible gene I protein (RIG-I) and melanoma differentiation-associated protein 5 (MDA5), potentially via dsRNA-binding partners such as IFN-inducible dsRNA-dependent protein kinase activator A (PRKRA). Following PRR-mediated detection of a PAMP, the resulting interaction of PRRs with mitochondrial antiviral-signalling protein (MAVS) activates nuclear factor-κB (NF-κB) through a signalling cascade involving several kinases. Activated NF-κB translocates to the nucleus, where it induces the transcription of pro-inflammatory cytokines. The kinases also phosphorylate (P) IFN-regulatory factor 3 (IRF3) and IRF7, which form homodimers and heterodimers and enter the nucleus to initiate the transcription of type I interferons (type I IFNs). Both severe acute respiratory syndrome coronavirus (SARS-CoV) and Middle East respiratory syndrome coronavirus (MERS-CoV) have developed mechanisms to interfere with these signalling pathways, as shown; these subversion strategies involve both structural proteins (membrane (M) and nucleocapsid (N)) and non-structural proteins (nsp1, nsp3b, nsp4a, nsp4b, nsp5, nsp6 and papain-like protease (PLpro); indicated in the figure by just their nsp numbers and letters). **b** | Binding of type I IFNs to their dimeric receptor, IFNα/β receptor (IFNAR), activates the Janus kinase (JAK)–signal transducer and activator of transcription (STAT) signalling pathway, in which JAK1 and TYK2 kinases phosphorylate STAT1 and STAT2, which form complexes with IRF9. These complexes move into the nucleus to initiate the transcription of IFN-stimulated genes (ISGs) under the control of promoters that contain an IFN-stimulated response element (ISRE). Collectively, the expression of cytokines, IFNs and ISGs establishes an antiviral innate immune response that limits viral replication in infected and in neighbouring cells. Again, viral proteins have been shown to inhibit these host signalling pathways to evade this immune response. IκBα, NF-κB inhibitor-α.

STAT1, degradation of host mRNAs and inactivation of the host translational machinery through a tight association with the 40S ribosomal subunit[77–80]. Nsp1 of MERS-CoV also inhibits the translation of mRNAs and induces mRNA degradation, although the translational inhibition is achieved through a different mechanism than ribosome binding, which selectively targets the translation of nuclear mRNAs and thereby spares cytoplasmic viral mRNAs[81].

SARS-CoV ORF3b inhibits the production of type I IFN, the phosphorylation of IRF3 and gene expression from an ISRE promoter[82,83]. SARS-CoV ORF6 also blocks the nuclear translocation of STAT1 (REF. 83).

Both nsp7 and nsp15 from SARS-CoV were also suggested to be IFN antagonists, but the underlying mechanism is unknown[73]. nsp15 is an inhibitor of MAVS-induced apoptosis; however, this occurs through an IFN-independent mechanism[84]. Finally, transcriptomic and proteomic analysis of human airway cell cultures showed that MERS-CoV but not SARS-CoV induces repressive histone modifications that downregulate the expression of certain ISGs[85].

It should be noted that most of the interactions of SARS-CoV and MERS-CoV proteins with innate immune pathways were established in *in vitro* systems, which rely on the overexpression of viral and,

sometimes, cellular proteins, and these interactions have rarely been confirmed in the context of viral replication *in vitro* or *in vivo*.

Treatment of severe coronavirus infections

Several strategies are being considered to treat infections with MERS-CoV (TABLE 1) and SARS-CoV, including the use of antibodies, IFNs, inhibitors of viral and host proteases, and host-directed therapies.

Current therapies. In the absence of a clinically proven effective antiviral therapy against SARS-CoV and MERS-CoV, patients mainly receive supportive care, which is often supplemented by different combinations of drugs. Ribavirin[86] and various types of IFN have been given to patients with MERS in Saudi Arabia[87] and China[88], typically in combination with a broad-spectrum antibiotic and oxygen. The efficacy of treatments for SARS-CoV and MERS-CoV infection currently remains unclear. In addition, treatment for MERS is typically started only in a late disease stage, when immunopathology predominates and antiviral drugs are likely to provide little benefit.

Ribavirin was used most frequently during the SARS outbreak, often in combination with corticosteroids, which have an anti-inflammatory effect[2,89–92]. IFNα was also given, usually in combination with immunoglobulins or thymosins, which stimulate the development of T cells, and in a small number of cases in combination with ribavirin[93,94]. None of these treatments was tested in a clinical trial, which makes it difficult to assess their efficacy. In fact, retrospective analysis did not yield a treatment combination that was clearly effective. Moreover, the data from patients are contradictory about whether ribavirin, when used alone, provided a benefit or was possibly even detrimental[89,90,92,95]. *In vitro* coronaviruses have a lower sensitivity to ribavirin than other viruses. Deletion of the nsp14-encoding sequence increases the sensitivity of coronaviruses to ribavirin; however, the underlying mechanism is unclear and is not related to the proofreading function of nsp14 (REF. 96). Therefore, ribavirin should be considered only in combination with other antiviral treatments.

Although IFNs are effective against MERS-CoV *in vitro*[97–99], their effect in humans has yet to be proved. The effectiveness of IFN is increased *in vitro* if ribavirin is added[98,100], and a combined use of the two drugs reduces disease severity in a rhesus macaque model of MERS[101]. The potential side effects of these treatments, such as fatigue, depression and anaemia, have inhibited their use as a first-line treatment for MERS, and they are generally administered only after a patient's condition starts to deteriorate. For example, one study of five patients who were infected with MERS-CoV indicated no survival following ribavirin and IFNα2b therapy; however, therapy was not started until 10 days after admission[87]. A separate study found an improvement in survival 14 days after MERS diagnosis and the start of treatment, but not 28 days after[102]. In a third study, a combination of IFNα2a and ribavirin or IFNβ1a and ribavirin did not improve survival; however, some of the patients were more than 50 years old and had pre-existing renal failure[103]. In a single case in which ribavirin and IFNα2b were started shortly after admission to hospital, the patient started to improve on day 6 after admission and made a complete recovery[104].

IFNβ1b is a more potent inhibitor of MERS-CoV replication *in vitro* than other types of IFN[97,99], and an improved outcome of disease was observed in common marmosets after challenge with MERS-CoV[105]. Thus, the type of IFN that is used for treatment in humans should be reconsidered (usually, IFNα is used). Furthermore, ribavirin and/or IFNs should be tested in clinical trials to determine their efficacy in MERS treatment and to establish treatment protocols.

Additional antiviral treatments. The protease inhibitors lopinavir and ritonavir, which are used in combination to treat infection with HIV, improved the outcome of patients with SARS when combined with ribavirin, compared with patients who were treated with ribavirin alone[106,107]. Lopinavir showed no clear antiviral activity against MERS-CoV *in vitro*[97], and it is thus rarely used in patients with MERS. However, lopinavir and ritonavir improve the outcome in common marmosets when treatment is initiated 6 hours after infection with MERS-CoV[105]. Thus, the testing of lopinavir and ritonavir in clinical trials in patients with MERS should be reconsidered. One patient who received pegylated IFNα, ribavirin, lopinavir and ritonavir in combination had undetectable levels of MERS-CoV in the blood 2 days after the initiation of therapy; however, this patient did not survive[108]. The combination of IFNα, ribavirin, lopinavir and ritonavir was also used for MERS treatment in South Korea, but efficacy data are not yet available. However, three case reports indicate recovery in five out of seven patients who were treated with this combination[109–111].

As 3CLpro and PLpro are essential for cleavage of the viral polyproteins and are distinct from cellular proteases, they are ideal drug targets, in particular PLpro,

Ribavirin
A broadly active antiviral nucleoside analogue with several direct and indirect mechanisms of action; mainly used for the treatment of hepatitis C, in combination with interferon.

Pegylated
Having polyethylene glycol (PEG) attached, to a drug for example; this moiety improves the solubility, decreases the immunogenicity and increases the stability, of the drug of interest, thereby allowing a reduced dosing frequency to be used.

which is involved in both viral replication and IFN antagonism. Indeed, most antiviral drug-like molecules have been developed against 3CLpro and PLpro, which was aided by the rapid report of crystal structures of these proteases[112].

PLpro was initially identified as a drugable target for SARS-CoV; recently, it has been noted that some of the compounds that target PLpro from SARS-CoV are also active against PLpro from MERS-CoV. For example, both 6-mercaptopurine and 6-thioguanine inhibit MERS-CoV and SARS-CoV *in vitro*[113]; however, the efficacy of these molecules has not yet been tested *in vivo*. Mycophenolic acid also inhibits the replication of MERS-CoV *in vitro*[97,99] through the inhibition of PLpro[113], but it had no effect in marmosets[105].

As new coronaviruses are likely to emerge from bats, protease inhibitors were designed against bat coronaviruses with the goal of developing a universal antiviral compound against emerging zoonotic coronaviruses. This approach yielded an inhibitor of Tylonycteris bat coronavirus HKU4 (HKU4-CoV), which is closely related to MERS-CoV[11]. This inhibitor, named SG85, indeed inhibits MERS-CoV replication *in vitro*[112]. Similarly, peptidomimetics that target and inhibit 3CLpro of MERS-CoV, HKU4-CoV and Pipistrellus bat coronavirus HKU5 (HKU5-CoV) have also been identified, but have not yet progressed beyond the *in vitro* stage[114].

Several other drugs that were approved for use in humans were shown to inhibit the replication of MERS-CoV *in vitro*, notably chloroquine, chlorpromazine, loperamide and cyclosporine A[62,99,113,115], although their mechanisms of action are unknown, and the benefit of cyclosporine A in patients is debatable owing to the immunosuppressive effect of the drug. Although cyclophilin inhibitors that do not result in immunosuppression are available, their activity against MERS-CoV has not yet been tested.

Antibody and plasma therapy. Plasma from convalescent patients and/or antibody therapies have been the leading proposed treatment for MERS so far[116]. There are several potential advantages to this approach. For example, as case numbers increase, the pool of survivors becomes larger; provided these individuals have sufficiently high antibody titres and are willing and able to donate plasma, this is a low-tech, reasonably safe treatment option. Furthermore, generation of monoclonal antibodies for use in humans is well established, with a fairly straightforward path to safety and efficacy testing. However, to date, there are very few reports on the use of convalescent plasma and none on the use of monoclonal antibodies as treatments for acute, severe respiratory disease in humans. A post hoc meta-analysis of 32 studies of either SARS or severe influenza found a significant reduction in the pooled odds of mortality when convalescent plasma was used[117]. However, study design was rated as low or very low quality, as there were generally a lack of control groups and a moderate-to-high risk of bias, which suggests that a properly designed clinical trial of convalescent plasma use in severe respiratory infections is needed[117]. Potent monoclonal antibodies that neutralize the MERS-COV spike protein *in vitro* have been developed[118–121]. However, with a few exceptions, *in vivo* data relating to the use of convalescent plasma or monoclonal antibodies in the treatment of MERS are currently lacking. Serum from high-titre dromedary camels decreased MERS-CoV loads in the lungs of mice that had been transduced with human DPP4 (REF. 122). Human polyclonal antibodies against the spike protein were generated by vaccinating transchromosomic bovines, and treatment with these antibodies reduced viral titres in the lungs of DPP4-transduced mice when treatment was administered 24 or 48 hours after challenge with MERS-CoV[123]. DPP4-transduced mice were also treated with humanized neutralizing monoclonal antibody 4C2h, which is directed against the receptor-binding domain of the MERS-CoV spike protein, 1 day after MERS-CoV challenge, and this treatment also decreased viral titres in the lungs[124], as did the neutralizing antibody LCA60, which was obtained from a convalescent patient and produced recombinantly[125]. Human neutralizing monoclonal antibodies REGN3048 and REGN3051 also provided a benefit in mice that expressed human DPP4 and were challenged with MERS-CoV[126]. The human neutralizing monoclonal antibody m332 reduced MERS-CoV replication in the lungs of rabbits following prophylactic, but not therapeutic, treatment[127]. Treatment of rhesus macaques with the human monoclonal antibody 311B-N1 day after challenge resulted in reduced lung pathology[128]. In all of these studies, viral replication was not completely inhibited, and there were some pathological alterations to the lungs, despite the therapy. Furthermore, none of the studies addressed the potential emergence of escape mutants *in vivo*.

Alternatively, antibodies that target the region of DPP4 that binds to the spike protein could be used to prevent entry of MERS-CoV; this approach was successful *in vitro*[129]. However, whether such a treatment would be feasible and would not have substantial adverse effects in humans remains to be determined.

Host-directed therapies. Host-directed strategies can also limit viral replication. For example, the spike protein of SARS-CoV is cleaved by cathepsin B and cathepsin L, transmembrane protease serine 2 (TMPRSS2) and possibly other host proteases[130,131]. Inhibition of host serine proteases by camostat reduced the entry of SARS-CoV and increased survival in a mouse model[132]. However, the targeting of host proteases is more likely to result in undesirable side effects than the targeting of viral proteases.

Another underappreciated strategy is attenuation of detrimental host responses. The development of such treatments would require a thorough understanding of the host responses that are involved in acute lung injury and ARDS, processes that are unfortunately poorly understood at the moment. Nonetheless, *in vitro* studies and limited studies in animal models with other respiratory viruses have shown that anaphylatoxin C5a is important for the development of acute lung injury, and blocking anaphylatoxin C5a can reduce lung pathology[133].

Peptidomimetics
Compounds that mimic biologically active peptides or proteins.

Anaphylatoxin C5a
A complement-activated molecule that is important for the recruitment to and activation of inflammatory cells in the lungs.

© 2016 Macmillan Publishers Limited. All rights reserved.

Subunit vaccines
Vaccines that contain immunogenic parts of a pathogen rather than the entire pathogen.

DNA vaccines
Vaccines based on the direct introduction of a plasmid encoding an antigen; following *in situ* production of this antigen, an immune response is mounted against it.

Changes in gene expression during *in vitro* MERS-CoV infection were used to predict potential effective drugs. One of the drugs with predicted efficacy, the kinase inhibitor SB203580, modestly inhibited SARS-CoV and MERS-CoV replication following the treatment of cells prior to infection, but treatment after infection inhibited replication of only SARS-CoV and not MERS-CoV[134].

Vaccines. Vaccination could be used to prevent infection or to reduce disease severity, viral shedding and thereby transmission, thus helping to control MERS outbreaks. Several vaccination strategies were developed against SARS-CoV and tested in animals, such as an inactivated virus, a live-attenuated virus, viral vectors, subunit vaccines, recombinant proteins and DNA vaccines[135,136]. Similar approaches have been used for the development of experimental MERS-CoV vaccines[137]. To date, three MERS-CoV vaccines have been evaluated in non-human primates. In one study, rhesus macaques were primed with DNA encoding the spike protein, followed by boosts with spike DNA and with recombinant protein consisting of the spike subunit containing the receptor-binding domain, or primed and boosted once with the subunit protein. Both approaches reduced pathological changes in lung function in animals that were infected with MERS-CoV 19 weeks after the last vaccination[138]. Moreover, three vaccinations with a recombinantly expressed protein that contains the receptor-binding domain of the spike protein reduced viral loads and lung pathology in rhesus macaques that were infected 2 weeks after the last vaccination[139]. Three DNA vaccinations with a construct encoding the full-length spike sequence reduced viral loads and pathology in the lungs after challenge with MERS-CoV 5 weeks after the last vaccination[140].

One concern of vaccination in humans is vaccine-mediated enhancement of disease, a process in which the disease following infection is more severe in vaccinated individuals than in unvaccinated individuals. Although this was observed in only a small subset of vaccine studies that were carried out for SARS-CoV[136] and has not yet been observed in any of the published MERS-CoV vaccine studies, it is an important concern. Moreover, it is unclear who to vaccinate against MERS-CoV, as healthy individuals seem to be at little risk of severe disease. Older patients or patients with underlying disease, who have the highest risk of severe MERS, would be important target populations. However, vaccination in such patients can be problematic owing to their poor immune responses, as has been established for influenza virus[141]. In addition, vaccination of people with a high risk of exposure to MERS-CoV, such as health care workers, slaughterhouse workers and camel herders, is advisable[142].

Outlook

As our understanding of the pathogenesis of emerging coronaviruses increases, so will the opportunities for the rational design of therapeutics that target viral replication or immunopathology. The rational design of new drugs and the repurposing of existing compounds have already resulted in the development of PLpro inhibitors and the identification of kinase inhibitors that inhibit the replication of SARS-CoV and MERS-CoV *in vitro*. However, only a few potential treatments have progressed past the identification of an effect *in vitro*, and *in vivo* studies to select the most promising treatment options are required. The development of several mouse models of MERS is thus an important step forward (BOX 2). Owing to the acute nature of MERS and the important role of immunopathology, combination therapies aimed at simultaneously inhibiting viral replication, limiting viral dissemination and dampening the host response are likely to yield the best results. Furthermore, treatment should be started as early as possible, rather than waiting until the patient has already developed extensive lung damage.

The development of therapies against SARS and MERS needs to focus on testing in humans, in properly controlled clinical trials. The current non-standardized, uncontrolled approach to treatment is not informative and may not be beneficial to the patient. The recent Ebola outbreak has demonstrated that rapid clinical trial design and approval are possible and that exceptional situations call for deviations from normal procedures (BOX 3).

While treatments are being developed and evaluated, the prevention of viral transmission is key to reducing the burden of MERS. The large proportion of nosocomial MERS-CoV infections indicates that preventive measures in hospitals are currently either not fully implemented or insufficient. Prevention of zoonotic transmission from dromedary camels is another possibility to decrease the number of MERS cases. The

Box 2 | **Animal models**

Most of our understanding of the pathogenesis of severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS) comes from animal studies. Ideally, these models recapitulate all or specific aspects of human disease. Several mouse models have been established, for example by using mouse-adapted SARS coronavirus (SARS-CoV) or expressing human receptors in mice[152]. Although it has been recognized that mice might poorly mimic specific human responses to infection, the availability of knockout and transgenic mice enables the targeted study of virus–host interactions. Several non-human primate models have been developed for SARS-CoV and MERS coronavirus (MERS-CoV)[152]. The close relationship of non-human primates to humans often allows faithful recapitulation of a disease and the host response. However, these benefits are countered by the need for specialized husbandry, the sometimes limited availability of the animals and reagents, and high costs.

The pathogenesis of SARS-CoV and MERS-CoV in their respective reservoir hosts is not nearly as well studied as that in humans. Currently, only one experimental-infection study has been carried out in bats with MERS-CoV[153], and none has been carried out for other coronaviruses. Thus, data are mostly limited to the detection of coronaviruses in naturally infected bats. The detection of coronaviruses mainly in faecal samples from bats and not in oral swabs suggests that replication in bats occurs predominantly in the gastrointestinal tract[9,154,155]. By contrast, a combination of intratracheal and intranasal inoculation of masked palm civets with SARS-CoV resulted in interstitial pneumonia, with oral and rectal viral shedding[156].

The pathogenesis of MERS-CoV in dromedary camels has been studied experimentally in a limited number of animals. These animals developed transient mild disease; however, large quantities of MERS-CoV were shed from the upper respiratory tract, in line with the predominant replication of MERS-CoV in the nasal turbinates and larynx in these animals, which explains the frequent zoonotic transmission[157].

Box 3 | **Preparing for emerging viruses: lessons from SARS-CoV, MERS-CoV and Ebola virus**

When the severe acute respiratory syndrome (SARS) outbreak developed into the first pandemic of the twenty-first century, it became clear that the medical and scientific communities were not adequately prepared for the emergence of highly pathogenic viruses. Whereas several months elapsed and several thousand cases of SARS were observed before the causative agent was identified as SARS coronavirus (SARS-CoV)[4–6], subsequent advances in molecular diagnostic tools, such as next generation sequencing, meant that Middle East respiratory syndrome coronavirus (MERS-CoV) was identified before it caused a large outbreak of MERS[11]. The availability of the full-length genome of MERS-CoV enabled the rapid development and distribution of diagnostic assays. The first animal models of disease, several treatment efficacy studies and the identification of the reservoir followed soon after. Unfortunately, the SARS pandemic did not yield solid clinical data on the efficacy of treatment regimens. These data are urgently needed for the treatment of MERS, as well as to prepare for novel coronaviruses that may emerge. Several studies have used synthetic biology to study the zoonotic transmission potential of SARS-CoV-like viruses from bats[9,10,158,159].

The Ebola virus outbreak in West Africa has highlighted the need for fast-tracking of potential treatments, as several clinical trials were started only towards the end of the outbreak. The combined experiences of the outbreaks of SARS, MERS and Ebola provide a blueprint for the response to emerging pathogens: after the identification of the causative agent, diagnostic assays need to be developed and distributed rapidly, and simultaneously, awareness of the new syndrome and reporting of (suspected) cases must be increased. In addition, infection control measures in health care facilities are essential. Research needs to focus on understanding the epidemiology, including pathogen transmission and identification of the reservoir and/or intermediate hosts. Animal models need to be developed, as well as therapeutic and prophylactic measures. Finally, promising treatments need to be fast-tracked into clinical trials.

first vaccines against MERS-CoV have been tested in dromedary camels[140,143]; indeed, when camels were vaccinated with a modified vaccinia virus that expresses the MERS-CoV spike protein, subsequent challenge of these animals with MERS-CoV resulted in less viral shedding than in unvaccinated animals[143], thereby potentially limiting the transmission to naive animals or to humans. Certainly, there has been progress in the development of vaccines and therapies against emerging coronaviruses, but more research and rigorous testing is required if we are to successfully combat these novel pathogens.

Review of Bats and SARS

Lin-Fa Wang,* Zhengli Shi,† Shuyi Zhang,‡§ Hume Field,¶ Peter Daszak,# and Bryan T. Eaton*

Bats have been identified as a natural reservoir for an increasing number of emerging zoonotic viruses, including henipaviruses and variants of rabies viruses. Recently, we and another group independently identified several horseshoe bat species (genus *Rhinolophus*) as the reservoir host for a large number of viruses that have a close genetic relationship with the coronavirus associated with severe acute respiratory syndrome (SARS). Our current research focused on the identification of the reservoir species for the progenitor virus of the SARS coronaviruses responsible for outbreaks during 2002–2003 and 2003–2004. In addition to SARS-like coronaviruses, many other novel bat coronaviruses, which belong to groups 1 and 2 of the 3 existing coronavirus groups, have been detected by PCR. The discovery of bat SARS-like coronaviruses and the great genetic diversity of coronaviruses in bats have shed new light on the origin and transmission of SARS coronaviruses.

Severe acute respiratory syndrome (SARS) represents the 21st century's first pandemic of a transmissible disease with a previously unknown cause. The pandemic started in November 2002 and was brought under control in July 2003, after it had spread to 33 countries on 5 continents, resulting in >8,000 infections and >700 deaths (*1*). The outbreaks were caused by a newly emerged coronavirus, now known as the SARS coronavirus (SARS-CoV).

In late 2003 and early 2004, sporadic outbreaks were reported in the region of the People's Republic of China where the 2002–2003 outbreaks originated (*2*). However, molecular epidemiologic studies showed that the viruses responsible for the 2003–2004 outbreaks were not the same as those isolated during the 2002–2003 outbreaks (*3*). These findings indicate independent species-crossing events. They also indicate that a SARS epidemic may recur in the future and that SARS-like coronaviruses (SARS-like–CoVs) that originate from different reservoir host populations may lead to epidemics at different times or in different regions, depending on the distribution of the reservoirs and transmitting hosts. The recent discovery of a group of diverse SARS-like–CoVs in bats supports the possibility of these events and further highlights the need to understand reservoir distribution and transmission to prevent future outbreaks.

Animal Origin of SARS Coronaviruses

Because of the sudden and unpredictable nature of the SARS outbreaks that started in November 2002 in southern People's Republic of China, structured and reliable epidemiologic studies to conclusively trace the origin of SARS-CoV were not conducted. However, accumulated studies from different groups, which used a variety of approaches, indicated an animal origin on the basis of the following findings. 1) Genome sequencing indicated that SARS-CoV is a new virus with no genetic relatedness to any known human coronaviruses (*4*,*5*). 2) Retrospective serologic studies found no evidence of seroprevalence to SARS-CoV or related viruses in the human population (*6*). 3) Serologic surveys among market traders during the 2002–2003 outbreaks showed that antibodies against SARS-CoV or related viruses were present at a higher ratio in animal traders than control populations (*7*–*9*). 4) Epidemiologic studies indicated that early case-patients were more likely than later case-patients to report living near a produce market but not near a farm, and almost half of them were food handlers with probable animal contact (*7*). 5) SARS-CoVs isolated from animals in markets were almost identical to human isolates (*9*). 6) Molecular epidemiologic analyses indicated that human SARS-CoV isolates could be divided into 3 groups from the early, middle, and late phases of the outbreaks and that early-phase isolates were more closely related to the animal isolates (*10*). 7) Human SARS-CoVs isolates from the 2003–2004 outbreaks had higher sequence identity to animal isolates of the same period than to human isolates from the 2002–2003 outbreaks (*3*).

Susceptible Animals in Markets and Laboratories

The first evidence of SARS-CoV infection in animals came from a study conducted in a live animal market in early 2003 (*9*). From the 25 animals sampled, viruses closely related to SARS-CoV were detected in 3 masked palm civets (*Paguma larvata*) and 1 raccoon dog (*Nyctereutes procyonoides*). In addition, neutralizing antibodies against SARS-CoV were detected in 2 Chinese ferret badgers (*Melogale moschata*). This initial study indicated that at least 3 different animal species in the Shenzhen market were infected by coronaviruses that are closely related to SARS-CoV.

Given the vast number of live animals being traded in animal markets in southern People's Republic of China, knowing which other animals are also susceptible to these viruses is crucial. Unfortunately, for a variety of reasons no systematic studies were conducted on traded animals during the outbreak period. Experimental infection of different animals therefore became a component of the SARS-CoV investigation.

Currently, >10 mammalian species have been proven to be susceptible to infection by SARS-CoV or related viruses (Table 1). Rats were also implicated as potentially susceptible animals that may have played a role in the transmission and spread of SARS-CoV in the well-publicized SARS outbreaks in the Amoy Gardens apartment block in Hong Kong Special Administrative Region, People's Republic of China (*23*). In Guangdong in 2004, the first human with a confirmed case of SARS was reported to have had no contact with any animals except rats (*2*). Experimentally, we have obtained serologic evidence that SARS-CoV replicates asymptomatically in rats (B.T. Eaton et al., unpub. data). Further studies are needed to clarify the potential role of rats in the transmission of SARS-CoV. Studies by 2 independent groups suggested that avian species were not susceptible to SARS-CoV infection and that, hence, domestic poultry were unlikely to be the reservoir or associated with the dissemination of SARS-CoV in the animal markets of southern People's Republic of China (*22,24*).

Role of Masked Palm Civets

Although in 1 live animal market, 3 species were found to be infected by viruses related to SARS-CoV (*9*), all subsequent studies have focused mainly on palm civets, possibly because the rate of detection was higher in civets or because the number of civets traded in southern People's Republic of China exceeds that of other wildlife groups.

The isolation of closely related SARS-CoV in civets during the 2002–2003 and 2003–2004 outbreaks and the close match of virus sequences between the human and civet isolates from each outbreak (*3*,*9*,*25*) strongly suggest that civets are a direct source of human infection. However, these studies did not clarify whether animals other than civets were involved in transmission of SARS-CoV to humans or whether civets were an intermediate host or the natural reservoir host of SARS-CoVs.

During the 2002–2003 outbreaks, none of the animal traders surveyed in the markets, who supposedly had very close contact with live civets, displayed SARS symptoms

Table 1. Animal species susceptible to infection by SARS coronavirus*

Animal				
Common name	Taxonomic name	Mode of infection	Clinical signs	References
Masked palm civet	*Paguma larvata*	Natural	None observed	(9)
		Experimental	Fever, lethargy, reduced appetite	(11)
Raccoon dog	*Nyctereutes procyonoides*	Natural	None observed	(9)
Chinese ferret badger	*Melogale moschata*	Natural	None observed	(9)
Cynamolgus macaque	*Macaca fascicularis*	Experimental	Lethargy, skin rash, respiratory distress	(12)
Rhesus macaque	*Macaca mulatta*	Experimental	Fever, low appetite	(13,14)
African green monkey	*Cercopithecus aethiops*	Experimental	None observed	(15)
Ferret	*Mustela furo*	Experimental	Lethargy, mild pulmonary lesions	(16)
Golden hamster	*Mesocricetus auratus*	Experimental	None observed	(17)
Guinea pig	*Cavia porcellus*	Experimental	None observed	(18)
Mouse	*Mus musculus*	Experimental	Aged animal (12–17 mo), weight loss, ruffled pelt, ruffled fur, slight dehydration	(19)
			Young animal (4–5 weeks), none observed	(20)
Rat	*Rattus norvegicus*	Experimental	None observed	B. T. Eaton et al., unpub. data
Domestic cat	*Felis domesticus*	Natural	Not reported	(18)
		Experimental	None observed	(18)
Pig	*Sus scrofa*	Natural	Not reported	(21)
		Experimental	None observed	(22)

*SARS, severe acute respiratory syndrome.

(*7*–*9*). During the 2003–2004 outbreaks, at least 1 human SARS patient had had no contact with civets (*2*). These observations seem to indicate that ≥1 other animal species may play a role in transmission of SARS-CoV to humans.

Most, if not all, civets traded in the markets are not truly wildlife animals; rather, they are farmed animals. Civet farming is relatively new in People's Republic of China and has rapidly expanded during the past 15 years or so. Tu et al. conducted the first comparative study of market and farmed civets (*26*). Serologic testing was performed on 103 serum samples taken from civets in an animal market in Guangdong and several civet farms in different regions of People's Republic of China in June 2003 and January 2004. No significant level of SARS-CoV antibody was detected in any of the 75 samples taken from 6 farms in 3 provinces. In contrast, of the 18 samples taken from an animal market in Guangdong Province in January 2004, 14 (79%) had neutralizing antibodies to SARS-CoV.

In a parallel study conducted between January and September 2004 (*27*), molecular analysis was used to investigate the distribution of SARS-CoV in palm civets in markets and on farms. PCR analysis of samples from 91 palm civets and 15 raccoon dogs in 1 animal market and 1,107 civets from 25 farms in 12 provinces showed positive results for all animals from the market and negative results for all animals from the farms. Similar results were obtained in wild-trapped civets in Hong Kong; none of the 21 wild civets sampled had positive antibody or PCR results for SARS-CoV (*28*).

Although not universally true, natural reservoir hosts tend to have coevolved with their viruses and usually do not display clinical signs of infection (*29*). However, when palm civets were experimentally infected with 2 strains of human SARS-CoV, all developed clinical signs of fever, lethargy, and loss of aggressiveness (*11*).

Civits' high susceptibility to SARS-CoV infection and wide presence in markets and restaurants strongly indicates an important role for civets in the 2002–2003 and 2003–2004 SARS outbreaks. However, the lack of widespread infection in wild or farmed palm civets makes them unlikely to have been the natural reservoir host.

SARS-like Coronaviruses in Bats

The presence of SARS-like–CoVs in different species of horseshoe bats in the genus *Rhinolophus* has recently been reported. We found, in a study of horseshoe bat species in different regions of mainland People's Republic of China in 2004 (*30*), that each of the 4 species surveyed had evidence of infection by a SARS-like–CoV: 2 species (*R. pearsoni* and *R. macrotis*) had positive results by both serologic and PCR tests, and 2 (*R. pussilus* and *R. ferrumequinum)* had positive results by either serologic or PCR tests, respectively. Bats with positive results were detected in the provinces of Hubei and Guangxi, which are >1,000 km apart. A group in Hong Kong (*31*) found that, when analyzed by PCR, 23 (39%) of 59 anal swabs of wild Chinese horseshoe bats (*R. sinicus*) contained genetic material closely related to SARS-CoV. They also found that as many as 84% of the horseshoe bats examined contained antibodies to a recombinant N protein of SARS-CoV. A previous study indicated a certain level of antigenic cross-reactivity between SARS-CoV and some group 1 coronaviruses (*6*) and that several group 1 coronaviruses had recently been found in bats. Therefore, the actual seropositive proportion of *R. sinicus* might be <84%. Nevertheless, the relatively high seroprevalence and wide distribution of seropositive bats is consistent with the serologic pattern expected from a pathogen's natural reservoir host (*29*).

Genome sequencing showed that the genome organization of all bat SARS-like–CoVs is almost identical to that of the SARS-CoVs isolated from humans or civets. They shared an overall sequence identity of 88% to 92%. The most variable regions were located in the 5′ end of the S gene, which codes for the S1 domain responsible for receptor binding, and in open reading frame 10 (ORF10 or ORF8, depending on the nomenclature used) region immediately upstream from the N gene (Figure, panel A, region b), which is known to be also prone to deletions of various sizes (*3*,*9*). Most human SARS-CoVs isolated during the late phase of the 2002–2003 outbreaks have a 29-nt deletion in this region; this deletion is absent in the civet isolates or human isolates from the early phase of the outbreaks (*3*,*9*). The bat viruses also lack the 29-nt deletion, indicating that SARS-CoVs and SARS-like–CoVs share a common ancestor.

Furthermore, sequence analyses indicated the existence of a much greater genetic diversity of SARS-like–CoVs in bats than of SARS-CoVs in civets or humans, which supports the notion that SARS-CoV is a member of this novel coronavirus group and that bats are a natural reservoir for it. The overall genome sequence identities between the human/civit SARS-CoVs and the bat viruses Rp3 (isolated from *R. pearsoni*) and HKU3–1 (isolated from *R. sinicus*) were 92% and 88%, respectively. The sequence identity between the bat isolates Rp3 and HKU3–1 is 89%, which indicates that the genetic divergence among the bat isolates is as great as the divergence between each of the bat viruses and the human/civet isolates. In addition, phylogenetic trees based on different protein sequences display different tree topologies, as shown in the Figure (panel B), which indicates the existence of multiple evolutionary pathways for different regions of the genome.

Diversity of Coronaviruses in Bats

The discovery of SARS-CoV has boosted the search for novel coronaviruses of human and animal origin. Bats

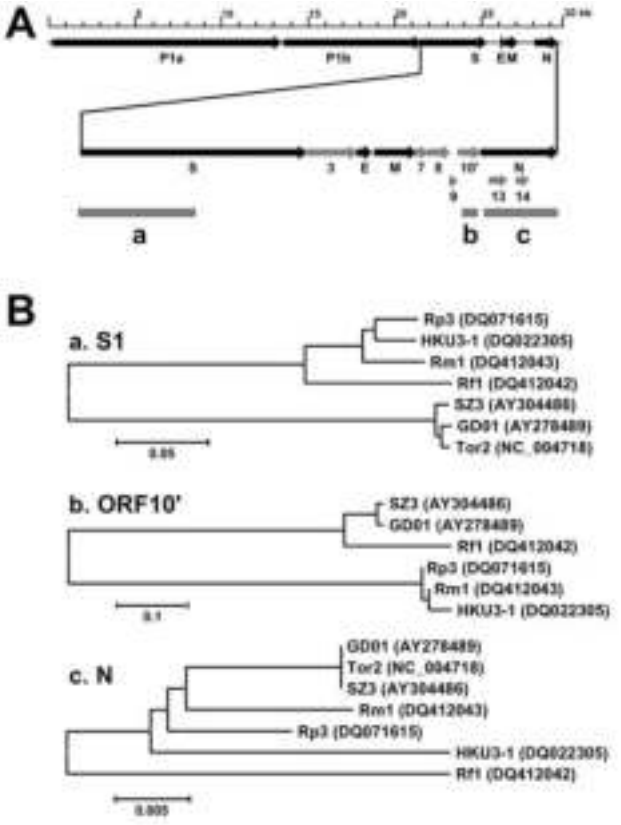

Figure. A) Genome diagram indicating the location of structural (dark arrow) and nonstructural (shaded arrow) genes and the different regions (shaded boxes) used for phylogeny analysis. B) Phylogenetic trees based on deduced amino acid sequences of the spike protein S1 domain (a), the open reading frame (ORF)10' (b), and the N protein (c). Because of lack of the ORF10' coding region in Tor2, Tor2 could not be included for the tree in (b). GD01, human isolate from early phase of the outbreak in 2003; Tor2, human isolate from late phase of the outbreak in 2003; SZ3, civet isolate from March 2003; Rp3, bat isolate from *Rhinolophus pearsoni*, December 2004; Rf1, bat isolate from *R. ferrumequinum*, November 2004; Rm1, bat isolate from *R. macrotis*, November 2004; and HKU3-1, bat isolate from *R. sinicus*, February 2005. GenBank accession nos. appear next to isolate names.

have been chosen as the main target because of their species diversity, large population size, broad geographic distribution, ability for long-distance migration, and habit of roosting in large groups. In addition to the SARS-like–CoVs described above, many other coronaviruses have been detected by PCR among diverse bat populations in Hong Kong (Table 2).

Poon et al. (*28*) conducted a surveillance study in Hong Kong during the summers of 2003 and 2004. From 162 swab samples collected from 12 bat species, they detected a novel group 1 coronavirus by sequencing of PCR products from the RNA-dependent RNA polymerase (RdRp) gene. The same virus or viruses of the same genetic lineage were found in 3 *Miniopterus* species (*M. pusillus, M. magnater,* and *M. schreibersii*). However, attempts to isolate virus by using 3 different cell lines (MDCK, FRhK4, and VeroE6) were unsuccessful.

In another study in Hong Kong during April 2004–July 2005, Woo et al. (*32*) sampled 309 individual bats representing 13 species from 20 different locations in rural Hong Kong. They detected coronavirus-related viral genomic RNA in 37 bats, representing a prevalence of 12%. Partial sequencing of *RdRp* and helicase genes identified 8 coronavirus genome types, 2 of which were the same as those reported previously (*28,30,31*). The other 6 novel types of coronaviruses were obtained from 6 different bat species and phylogenetically positioned in 2 of the existing 3 coronavirus groups. Four were in group 1, derived from bat species *M. magnater, M. pusillus, Myotis ricketti,* and *R. sinicus;* the other 2 were in group 2, from bat species *Pipistrellus abramus* and *Tylonycteris pachypus.* To accommodate the newly discovered genetic diversity of group 2 coronaviruses, the authors proposed the following subdivisions: group 2a (coronaviruses existing before the discovery of SARS-CoV), group 2b (SARS-CoV and SARS-like–CoVs), and group 2c (novel bat coronaviruses discovered in this study). Attempts to isolate virus in VeroE6, MRC-5, LLC-Mk2, FRhK-4, Huh-7.5, and HRT-18 were unsuccessful.

In another extensive study conducted in mainland People's Republic of China during November 2004–March 2006, Tang et al. (*33*) collected samples from 985 bats: 35 species in 14 genera and 3 families at 82 different sites in 15 provinces. A total of 64 (6.5%) bats had positive results from a PCR directed to a highly conserved 440-bp RdRp region. Among the 64 PCR-positive products sequenced, only 3 (all from the genus *Rhinolophus*) were clustered with known bat SARS-like–CoVs (or group 2b), 40 belonged to group 1, and the remaining 22 formed a separate cluster in group 2, most likely clustering with the group 2c viruses reported by Woo et al. (*32*). Attempts to isolate virus in VeroE6, FRHK4, and CV1 were unsuccessful.

In addition to the diversity of coronaviruses in bats, 3 more observations can be drawn from these studies. First, none of the bat coronaviruses discovered so far belonged to group 3. Second, with very few exceptions, most bat coronaviruses seem to be species-specific; i.e., different bat species from a similar location harbor different coronaviruses, whereas the same bat species from different geographic locations carry coronaviruses of the same genetic lineage (*32*,*33*). Third, among the 5 published studies involving bat coronaviruses (*28*,*30*–*33*), no researchers were able to isolate live virus from any of the swab samples collected despite the use of many different cell lines

Table 2. Coronaviruses detected in different species of bats

Group*	Viruses Name/strain	Bat species	Location of detection (People's Republic of China)	Reference
G1	Bat-CoV HKU.5	*Rhinolophus sinicus*	Hong Kong	(32)
	Bat-CoV HKU.6	*Myotis ricketti*	Hong Kong	(32)
	Bat-CoV HKU.7	*Miniopterus magnater*	Hong Kong	(32)
	Bat-CoV HKU.8	*Miniopterus pusillus* *M. magnater* *Miniopterus schreibersii*	Hong Kong	(28,32)

	BtCoV/434/05	*Pipistrellus pipistrellus*	Taiwan	(33)
	BtCoV/365/05	*P. abramus* *R. ferrumequinum*	Anhui, Henan, Sichuan	(33)

*Group 2 was subdivided as in (32). A different classification was used in (33), in which G2b and G2c were designated G4 and G5, respectively.

and the presence of high levels of viral genetic materials shown by quantitative PCR.

Cross-species Transmission

Emergence of zoonotic viruses from a wildlife reservoir requires 4 events: 1) interspecies contact, 2) cross-species virus transmission (i.e., spillover), 3) sustained transmission, and 4) virus adaptation within the spillover species (*34*). These 4 transition events occurred during the SARS outbreaks and contributed to the rapid spread of the disease around the world.

The role of civets in directly transmitting SARS-CoV to humans has been well established. The most convincing case was the infection of a waitress and a customer in a restaurant where SARS-CoV–positive civets were housed in cages (*25*). Two key questions remain: What is the natural reservoir host for the outbreak SARS-CoV strains, and how were the viruses transmitted to civets or other intermediate hosts? Although not conclusive, the data obtained so far strongly suggest that bats (horseshoe bats in particular) are most likely the reservoir host of SARS-CoV. As indicated above, bat coronaviruses seem to be species-specific and SARS-like–CoVs discovered so far are exclusively associated with horseshoe bats. We hope that continued field study will eventually identify the direct progenitor of SARS-CoV among the 69 different known horseshoe species. The facts that the cross-species transmission of SARS-CoV seems to be a relatively rare event and that legal and illegal trading of wildlife animals between People's Republic of China and other countries occurs raise the possibility that the natural reservoir species may not be native to People's Republic of China. Thus, we should expand our search into regions other than Hong Kong and mainland People's Republic of China. Another approach to search for the natural reservoir of SARS-CoV is to conduct infection experiments in different bat species. If we assume that the progenitor viruses come from bats, chances are high that the human/civet SARS-CoVs are still capable of infecting the original reservoir species.

Without knowing the natural reservoir of SARS-CoV, predicting the exact mechanism of transmission from reservoir host to intermediate host is difficult. However, the fecal-oral route represents the main mode of transmission among animals. Although mixing of live reservoir hosts (e.g., bats) and intermediate hosts (e.g., civets) would be an efficient means of transmission, the main source of cross-species transmission in the animal trading chain (including warehouses, transportation vehicles, markets) may come from contaminated feces, urine, blood, or aerosols. This may also be true for civet-to-human transmission. As shown in the case of the infected restaurant

0071

customer in 2004, the customer had no direct contact with civets and was sitting at a table ≈5 m from the civet cages (*25*).

Although at this stage we cannot rule out the possibility of direct transmission from the natural reservoir host to humans, molecular epidemiologic studies (*2*,*10*) and studies of the receptor-S protein interaction (*35*) indicate that the progenitor viruses are unlikely to be able to infect humans and that a rapid viral evolution in an intermediate host (such as civets) seems to be necessary to adapt the virus for human infection. Ability to efficiently use the receptor molecules (ACE2 for human and civet) seems to be a major limiting factor for animal-to-human and human-to-human transmission (*35*). This also explains why the SARS-CoV was able to cause the human pandemic but the closely related bat SARS-like–CoVs were not. For the SARS-like–CoVs to infect humans, substantial genetic changes in the S1 receptor-binding domain will be necessary. These changes may be achieved in 1 of 2 possible ways. They could be achieved by genetic recombination, as coronaviruses are known to be able to recombine. For example, bat SARS-like–CoVs and another yet unknown coronavirus could coinfect an intermediate host, and the bat viruses would gain the ACE2 binding site in the S1 domain by recombination. The alternative is continuous evolution independent of recombination. Coronaviruses in bats could have a spectrum sufficiently diverse to encompass the progenitor virus for SARS-CoVs. The progenitor virus's ability to bind human ACE2 may be acquired or improved by adaptation (i.e., point mutations) in ≥1 intermediate host before it could efficiently infect humans. The existence of at least 3 discontinuous highly variable genomic regions between SARS-CoV and SARS-like–CoV indicates that the second mechanism is more likely.

In conclusion, the discovery of bat SARS-like–CoVs and the great genetic diversity of coronaviruses in bats have shed new light on the origin and transmission of SARS-CoV. Although the exact natural reservoir host for the progenitor virus of SARS-CoV is still unknown, we believe that a continued search in different bat populations in People's Republic of China and neighboring countries, combined with experimental infection of different bat species with SARS-CoV, will eventually identify the native reservoir species. A positive outcome of these investigations will greatly enhance our understanding of spillover mechanisms, which will in turn facilitate development and implementation of effective prevention strategies. The discovery of SARS-like–CoVs in bats highlights the increasingly recognized importance of bats as reservoirs of emerging viruses (*36*). Moreover, the recent emergence of SARS-CoVs and other bat-associated viruses such as henipaviruses (*37*,*38*), Menangle, and Tioman viruses (*36*), and variants of rabies viruses and bat lyssaviruses (*38*,*39*) also supports the contention that viruses, especially RNA viruses, possess more risk than other pathogens for disease emergence in human and domestic mammals because of their higher mutation rates (*40*).

Acknowledgments

The work conducted by our multination collaborative team was jointly funded by a special grant for Animal Reservoirs of SARS-CoV, State Key Program for Basic Research grant no. 2005CB523004, and State High Technology Development Program grant no. 2005AA219070 from the Ministry of Science and Technology, People's Republic of China; a special fund from the president of the Chinese Academy of Sciences (no. 1009); the Sixth Framework Program, EPISARS, from the European Commission (no. 51163); the Australian Biosecurity Cooperative Research Centre for Emerging Infectious Diseases (Project 1.007R); an National Institutes of Health-National Science Foundation Ecology of Infectious Diseases award (no. R01-TW05869) from the John E. Fogarty International Center; and an award to the Consortium for Conservation Medicine from the V. Kann Rasmussen Foundation.

Dr Wang is a senior principal research scientist at the Commonwealth Scientific and Industrial Research Organisation, Australian Animal Health Laboratory. His research activities focus on emerging zoonotic viruses of bat origin, including Hendra, Nipah, and SARS viruses, and on development of rapid multiplex diagnostics for major viral diseases of livestock animals.

Bats Are Natural Reservoirs of SARS-Like Coronaviruses

Wendong Li,[1,2] Zhengli Shi,[2]* Meng Yu,[3] Wuze Ren,[2] Craig Smith,[4] Jonathan H. Epstein,[5] Hanzhong Wang,[2] Gary Crameri,[3] Zhihong Hu,[2] Huajun Zhang,[2] Jianhong Zhang,[2] Jennifer McEachern,[3] Hume Field,[4] Peter Daszak,[5] Bryan T. Eaton,[3] Shuyi Zhang,[1,6]* Lin-Fa Wang[3]*

Severe acute respiratory syndrome (SARS) emerged in 2002 to 2003 in southern China. The origin of its etiological agent, the SARS coronavirus (SARS-CoV), remains elusive. Here we report that species of bats are a natural host of coronaviruses closely related to those responsible for the SARS outbreak. These viruses, termed SARS-like coronaviruses (SL-CoVs), display greater genetic variation than SARS-CoV isolated from humans or from civets. The human and civet isolates of SARS-CoV nestle phylogenetically within the spectrum of SL-CoVs, indicating that the virus responsible for the SARS outbreak was a member of this coronavirus group.

Severe acute respiratory syndrome (SARS) was caused by a newly emerged coronavirus, now known as SARS coronavirus (SARS-CoV) (*1*, *2*). In spite of the early success of etiological studies and molecular characterization of this virus (*3*, *4*), efforts to identify the origin of SARS-CoV have been less successful. Without knowledge of the reservoir host distribution and transmission routes of SARS-CoV, it will be difficult to prevent and control future outbreaks of SARS.

Studies conducted previously on animals sampled from live animal markets in Guangdong, China, indicated that masked palm civets (*Paguma larvata*) and two other species had been infected by SARS-CoV (*5*). This led to a large-scale culling of civets to prevent further SARS outbreaks. However, subsequent studies have revealed no widespread infection in wild or farmed civets (*6*, *7*). Experimental infection of civets with two different human isolates of SARS-CoV resulted in overt clinical symptoms, rendering them unlikely to be the natural reservoir hosts (*8*). These data suggest that although *P. larvata* may have been the source of the human infection that precipitated the SARS outbreak, infection in this and other common species in animal markets was more likely a reflection of an "artificial" market cycle in naïve species than an indication of the natural reservoir of the virus.

Bats are reservoir hosts of several zoonotic viruses, including the Hendra and Nipah viruses, which have recently emerged in Australia and East Asia, respectively (*9*–*11*). Bats may be persistently infected with many viruses but rarely display clinical symptoms (*12*). These characteristics and the increasing presence of bats and bat products in food and traditional medicine markets in southern China and elsewhere in Asia (*13*) led us to survey bats in the search for the natural reservoir of SARS-CoV.

In this study, conducted from March to December of 2004, we sampled 408 bats representing nine species, six genera, and three families from four locations in China (Guangdong, Guangxi, Hubei, and Tianjin) after trapping them in their native habitat (Table 1). Blood, fecal, and throat swabs were collected; serum samples and cDNA from fecal or throat samples were independently analyzed, double-blind, with different methods in our laboratories in Wuhan and Geelong (*14*).

Among six genera of bat species surveyed (*Rousettus*, *Cynopterus*, *Myotis*, *Rhinolophus*, *Nyctalus*, and *Miniopterus*), three communal, cave-dwelling species from the genus *Rhinolophus* (horseshoe bats) in the family *Rhinolophidae* demonstrated a high SARS-CoV antibody prevalence: 13 out of 46 bats (28%) in *R. pearsoni* from Guangxi, 2 out of 6 bats (33%) in *R. pussilus* from Guangxi, and 5 out of 7 bats (71%) in *R. macrotis* from Hubei. The high seroprevalence and wide distribution of seropositive bats is expected for a wildlife reservoir host for a pathogen (*15*).

The serological findings were corroborated by poylmerase chain reaction (PCR) analyses with primer pairs derived from the nucleocapsid (N) and polymerase (P) genes (table S1). Five fecal samples tested positive, all of them from the genus *Rhinolophus*: three in *R. pearsoni* from Guangxi and one each in *R. macrotis* and *R. ferrumequinum*, respectively, from Hubei. No virus was isolated from an inoculation of Vero E6 cells with fecal swabs of PCR-positive samples.

A complete genome sequence was determined directly from PCR products from one of the fecal samples (sample Rp3) that contained relatively high levels of genetic material. The genome organization of this virus (Fig. 1), tentatively named SARS-like coronavirus isolate Rp3 (SL-CoV Rp3), was essentially identical to that of SARS-CoV, with the exception of three regions (Fig. 1, shaded boxes). The overall nucleotide sequence identity between SL-CoV Rp3 and SARS-CoV Tor2 was 92% and increased to ~94% when the three variable regions were excluded. The variable regions are located at the 5′ end of the S gene (equivalent to the S1 coding region of coronavirus S protein) and the region immediately upstream of the N gene. These regions have been identified as "high mutation" regions among different SARS-CoVs (*5*, *16*, *17*). The region upstream of the N gene is known to be prone to deletions of various sizes (*5*, *16*, *18*).

Predicted protein products from each gene or putative open reading frame (ORF) of SL-CoV Rp3 and SARS-CoV Tor2 were com-

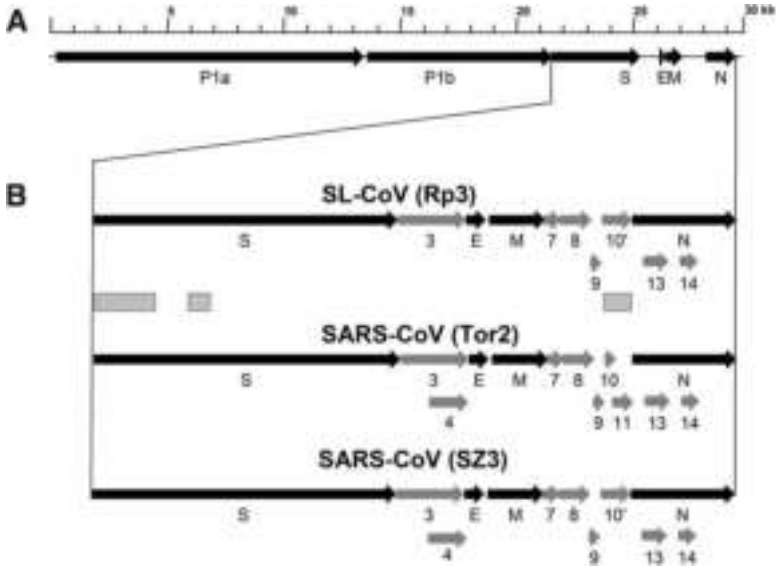

Fig. 1. Genome organization of, and comparison between, SL-CoV and SARS-CoV. (**A**) Overall genome organization of SL-CoV Rp3. (**B**) Expanded diagram of the 3′ region of the genome in comparison with SARS-CoV strains Tor2 and SZ3, following the same nomenclature used by Marra *et al*. (*4*). The genes (named by letters P, S, E, M, and N) present in all coronaviruses are shown in dark-colored arrows, whereas the SARS-CoV–specific ORFs are numbered and illustrated in light-colored arrows. ORF10′ follows the nomenclature by Guan *et al*. (*5*) to indicate that the single ORF present between ORF9 and N in SL-CoV is equivalent to the fusion of ORF10 and ORF11 in the same region in SARS-CoV Tor2. The shaded boxes mark the only three regions displaying significant sequence difference between the two viruses (table S2).

pared (table S2). The P, S, E, M, and N proteins, which are present in all coronaviruses, were similarly sized in the two viruses, with sequence identities ranging from 96% to 100%. The only exception was the S1 domain of the S protein, where sequence identity fell to 64%. The S1 domain is involved in receptor binding, whereas the S2 domain is responsible for the fusion of virus and host cell membranes (*19*). The sequence divergence in the S1 domain corroborated our serum neutralization studies, which indicated that although bat sera have a high level of cross-reactive antibodies (with enzyme-linked immunosorbent assay titers ranging from 1:100 to 1:6400), they failed to neutralize SARS-CoV when tested on Vero E6 cells. This finding suggests that S1 is the main target for antibody-mediated neutralization of this group of viruses, which is consistent with previous reports indicating that major SARS-CoV neutralization epitopes are located in the S1 region (*20*, *21*).

In addition to the five genes present in all coronavirus genomes, coronaviruses also have several ORFs between the P gene and the 3′ end of the genome that code for nonstructural proteins. The function of these nonstructural proteins is largely unknown. The location and sequence of ORFs are group- or virus-specific and hence can serve as important molecular markers for studying virus evolution and classification (*19*, *22*). SARS-CoV has a unique set of ORFs not shared by any of the known coronaviruses (*3*, *4*). Most of these ORFs were also present in SL-CoV, confirming the extremely close genetic relationship between SARS-CoV and SL-CoV (Fig. 1 and table S2).

Coronaviruses produce subgenomic mRNAs through a discontinuous transcription process not fully characterized (*19*). Conserved nucleotide sequences functioning as transcription regulatory sequences (TRSs) are required for the production of the subgenomic mRNAs. In SARS-CoV, such TRSs were identified at each of the predicted gene start sites (*3*, *4*). All of these TRSs were absolutely conserved between SARS-CoV Tor2 and SL-CoV Rp3 (table S3), further demonstrating that these two viruses are very closely related.

SL-CoV is completely different from a bat coronavirus (bat-CoV) recently identified by Poon *et al*. (*7*) from species of bats in the genus *Miniopterus* during a wildlife surveillance study in Hong Kong (Fig. 2). Because the complete genome sequence was not available for bat-CoV, only the trees covering the common sequences (i.e., parts of the P1b and S2 proteins) are shown. The phylogenetic analysis demonstrated that SL-CoV Rp3 and SARS-CoVs are clustered together but that bat-CoV is placed among the relatively distant group 1 viruses. Hereafter, SARS-CoVs and SL-CoVs will be collectively called the SARS cluster of coronaviruses.

In addition to the complete genome sequence of SL-CoV Rp3, partial genome sequences for the other four PCR-positive bat samples were also determined. Phylogenetic analysis based on the N protein sequences (Fig. 3A) revealed that the genetic variation among the SL-CoV sequences was much greater than that exhibited by SARS-CoVs (for simplicity, only three human and civet SARS-CoV isolates were used; the remainder are almost identical to those shown). This was especially obvious when SL-CoVs isolated from different bat species were compared. Moreover, the results suggested that SARS-CoVs nestle phylogenetically within the spectrum of SL-CoVs.

We also compared the "high mutation" regions in samples Rf1, Rm1, and Rp3. For the region upstream of the N gene, SL-CoVs from all three bat species contained a single ORF (ORF10′), similar to that found in SARS-CoV isolates from civets (*5*) and patients in the early phase of the outbreaks (*16*, *18*) but different from that in most human isolates, which

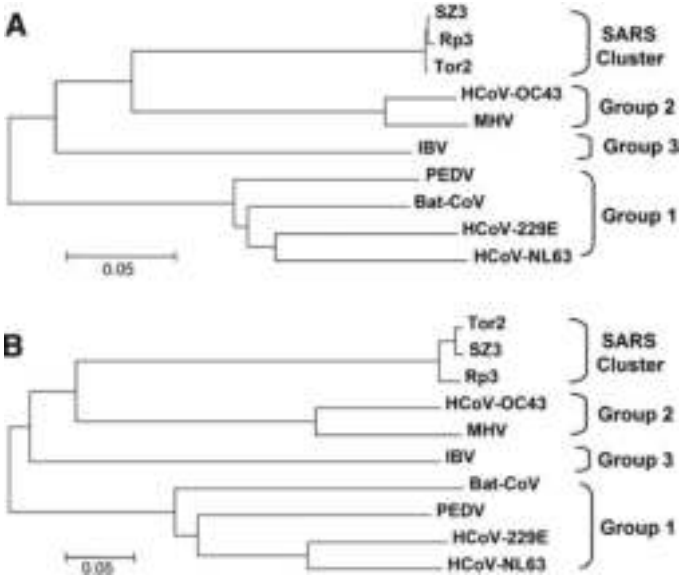

Fig. 2. Phylogenetic trees. (**A**) and (**B**) are trees based on deduced amino acid sequences of the same regions in P1b and S, respectively, as used by Poon *et al.* (*7*) for bat-CoV. Tor2 and SZ3, SARS-CoV strains Tor2 and SZ3; Rp3, SL-CoV Rp3; HCoV, human coronavirus; MHV, mouse hepatitis virus; PEDV, porcine epidemic diarrhea virus; IBV, avian infectious bronchitis virus.

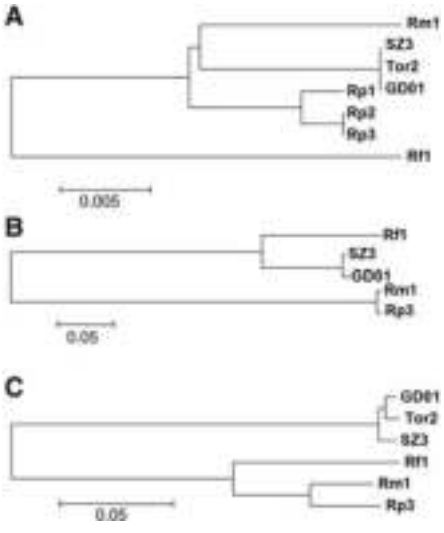

Fig. 3. Phylogenetic trees based on deduced amino acid sequences of (**A**) N, (**B**) ORF10′, and (**C**) S1 proteins. Tor2, SZ3, and GD01, different SARS-CoV strains; Rf1, Rm1, and Rp1-3, different SL-CoV sequences. The genetic distance scale shown for (A) is different from those for (B) and (C).

have a 29-nucleotide deletion in this region (*3*, *4*, *16*). ORF10′ in Rf1 codes for a protein having the same size (122 amino acids) as and more than 80% sequence identity to ORF10′ proteins of SARS-CoVs, but those in Rm1 and Rp3 code for a 121–amino acid protein with only 35% sequence identity (Fig. 3B and fig. S2). By contrast, analysis of the S1 protein regions (Fig. 3C and fig. S3) indicated that Rf1 was more closely related to SL-CoVs from two other bat species than to SARS-CoVs, suggesting that the SARS cluster of coronaviruses could recombine to increase genetic diversity and fitness, as is well documented for other coronaviruses (*19*). We were unable to sequence these regions for Rp1 or Rp2, owing to the poor quality of the fecal materials from these two animals. The limited amount of cDNA available was used up for N gene analysis and in initial sequencing trials with SARS-CoV–derived primers, which were largely unsuccessful. Judging from the close relationship of the N genes between Rp1, Rp2, and Rp3 (fig. S1), it is unlikely that Rp1 or Rp2 will have major sequence differences from Rp3 in the S1 or ORF10′ regions. This is not unexpected, considering that these three positive samples were obtained from the same bat species in the same location.

The genetic diversity of bat-derived sequences supports the notion that bats are a natural reservoir host of the SARS cluster of coronaviruses. A similar observation has been made for henipaviruses, another important group of emerging zoonotic viruses of bat origin, which show greater genetic diversity in bats than was observed among viruses isolated during the initial Nipah outbreaks in Malaysia (*23*–*26*). The overall nucleotide sequence identity of 92% between SL-CoVs and SARS-CoVs is very similar to that observed between Nipah viruses isolated from Malaysia and Bangladesh in 1999 and 2004, respectively (*25*) (fig. S4). SL-CoVs present a new challenge to the diagnosis and treatment of future disease outbreaks. The current tests and therapeutic strategies may not work effectively against all viruses in this group, owing to their great genetic variability in the S1 domain region of the S gene.

The genus *Rhinolophus* contains 69 species and has a wide distribution from Australia to Europe (*27*). They roost primarily in caves and feed mainly on moths and beetles. However, notwithstanding the predominant *Rhinolophus* findings in this study, it is highly likely that there are more SARS-related coronaviruses to be discovered in bats. Indeed, our positive serological findings in the cave-dwelling fruit bat *Rousettus leschenaulti* indicate that infection by a related virus could occur in fruit bats as well, albeit at a much lower frequency. A plausible mechanism for emergence from a natural bat reservoir can be readily envisaged. Fruit bats including *R. leschenaulti*, and less frequently insectivorous bats, are found in markets in southern China. An infectious consignment of bats serendipitously juxtaposed with a susceptible amplifying species, such as *P. larvata*, at some point in the wildlife supply chain could result in spillover and establishment of a market cycle while susceptible animals are available to maintain infection. Further studies in field epidemiology, laboratory infection, and receptor distribution and usage are being conducted to assess potential roles played by different bat species in SARS emergence.

These findings on coronaviruses, together with data on henipaviruses (*23*–*25*, *28*), suggest that genetic diversity exists among zoonotic viruses in bats, increasing the possibility of variants crossing the species barrier and causing outbreaks of disease in human populations. It is therefore essential that we enhance our knowledge and understanding of reservoir host distribution, animal-animal and human-animal interaction (particularly within the wet-market system), and the genetic diversity of bat-borne viruses to prevent future outbreaks.

Neurogenesis in the Hypothalamus of Adult Mice: Potential Role in Energy Balance

Maia V. Kokoeva, Huali Yin, Jeffrey S. Flier*

Ciliary neurotrophic factor (CNTF) induces weight loss in obese rodents and humans, and for reasons that are not understood, its effects persist after the cessation of treatment. Here we demonstrate that centrally administered CNTF induces cell proliferation in feeding centers of the murine hypothalamus. Many of the newborn cells express neuronal markers and show functional phenotypes relevant for energy-balance control, including a capacity for leptin-induced phosphorylation of signal transducer and activator of transcription 3 (STAT3). Co-administration of the mitotic blocker cytosine-β-D-arabinofuranoside (Ara-C) eliminates the proliferation of neural cells and abrogates the long-term, but not the short-term, effect of CNTF on body weight. These findings link the sustained effect of CNTF on energy balance to hypothalamic neurogenesis and suggest that regulated hypothalamic neurogenesis in adult mice may play a previously unappreciated role in physiology and disease.

The obesity epidemic has prompted major efforts to develop safe and effective therapies (*1*, *2*). However, approved drugs for obesity have limited efficacy and act only acutely, with patients rapidly regaining weight after terminating treatment (*3*). Only the neurocytokine ciliary neurotrophic factor (CNTF) and Axokine, an analog of CNTF developed as a drug candidate for the treatment of obesity, appear to deviate from this paradigm. Rodents and patients treated with Axokine were reported to maintain lowered body weights weeks to months after the cessation of treatment (*4*, *5*). This feature of Axokine/CNTF action is unexplained and suggests that CNTF induces long-lasting changes in one or more elements of the energy-balance circuitry.

In rodents, CNTF is most potent when administered directly into the cerebrospinal fluid (*6*) and activates signaling cascades in hypothalamic nuclei involved in feeding control (*5*, *7*, *8*). For instance, CNTF activates phosphorylation of signal transducer and activator of transcription 3 (STAT3) in a population of hypothalamic neurons that substantially overlaps with those activated by leptin (*5*). However, in contrast to CNTF, leptin-treated animals do not maintain their lowered body weight after the cessation of treatment. We thus sought a CNTF-specific mechanism to explain this long-term effect.

CNTF supports the survival of neurons in vitro and in vivo (*9*) and has also been implicated in the maintenance of adult neural stem cells (*10*). Furthermore, other trophic factors, such as epidermal growth factor and fibroblast growth factor 2, are known to act as mitogens on adult neuronal progenitors (*11*, *12*), and they promote the functional regeneration of hippocampal pyramidal neurons (*13*). Neurogenesis in the adult brain is most clearly defined in the subventricular zone (SVZ) of the lateral ventricles and the subgranular zone (SGZ) of the hippocampal formation (*14*). However, recent reports indicate that the neuroproliferative potency in the adult extends to other brain structures, including the hypothalamus (*15*–*17*). On the basis of these findings, we hypothesized that the long-term effect of CNTF on body-weight regulation might involve neurogenesis in the hypothalamus, which is the brain region most relevant for energy-balance regulation.

To assess the mitogenic potency of CNTF in the adult nervous system in vivo, we delivered the cell-proliferation marker bromodeoxyuridine (BrdU) alone (vehicle treatment) or together with CNTF directly into the cerebrospinal fluid of mouse brains (*18*). CNTF and BrdU were continuously infused for 7 days into the right lateral ventricle using osmotic minipumps. Mice were switched to a high-fat diet two months before surgery and were kept on this diet throughout the experiments. In accordance with previous results (*5*), CNTF-treated mice showed a marked reduction in body weights (Fig. 1A), which persisted after termination of CNTF delivery. Mice were killed 22 days after surgery, and brain sections were immunostained with an antibody against BrdU. Because BrdU incorporates into DNA of dividing cells, BrdU-positive ($BrdU^+$) cells are thought to represent newborn cells. Figure 1B shows coronal sections of vehicle- and CNTF-infused animals at the level of the arcuate, ventromedial, and dorsomedial nuclei, well-known hypothalamic centers for energy-balance regulation (*19*). In vehicle-infused animals, few $BrdU^+$ cells were detected in the parenchyma surrounding the third ventricle (Fig. 1B, left). Administration with CNTF led to a dramatic increase of BrdU+ cells (Fig. 1B, right). Note the higher density of $BrdU^+$ cells at the base of the third ventricle, which is part of the arcuate nucleus/median eminence.

The pattern of CNTF receptor (CNTFR) mRNA expression is consistent with this observation. In situ hybridization using a riboprobe against CNTFR mRNA revealed strong staining in the walls of the basal third ventricle and surrounding arcuate nucleus parenchyma (Fig. 1C). Because this section originated from an animal treated with both CNTF and BrdU, we colabeled with antibodies to BrdU. Many $BrdU^+$ cells were positive for CNTFR expression, indicating that CNTF, at least in part, directly promotes cell division by binding to CNTFR on putative neural progenitor cells (Fig. 1D, inset). By counting all newly generated cells in the caudal hypothalamus, CNTF treatment led to a marked increase of $BrdU^+$ cells over vehicle-infused animals (Fig. 1E). The total number of $BrdU^+$ cells in CNTF-treated animals remained constant for at least 2 weeks after the infusion period. Subsequently, the numbers decreased but plateaued at a high level. Vehicle-infused animals showed a similar fractional decrease over time. Thus it appears that the majority of hypothalamic $BrdU^+$ cells do not die or migrate to distant areas as reported for newborn neurons of the SVZ, which follow the rostral migratory stream toward the olfactory bulb (*20*).

To investigate the origin of adult-born cells in the hypothalamus, we examined CNTF and vehicle-infused brains every 12 hours starting 48 hours after surgery, a time when the infused CNTF/BrdU should just reach the ventricular system (*18*). Hypothalamic BrdU incorporation was first detected 60 to 72 hours

Evolutionary origins of the SARS-CoV-2 sarbecovirus lineage responsible for the COVID-19 pandemic

Maciej F. Boni[1,8]✉, Philippe Lemey[2,8]✉, Xiaowei Jiang[3], Tommy Tsan-Yuk Lam[4], Blair W. Perry[5], Todd A. Castoe[5], Andrew Rambaut[6]✉ and David L. Robertson[7]✉

There are outstanding evolutionary questions on the recent emergence of human coronavirus SARS-CoV-2 including the role of reservoir species, the role of recombination and its time of divergence from animal viruses. We find that the sarbecoviruses—the viral subgenus containing SARS-CoV and SARS-CoV-2—undergo frequent recombination and exhibit spatially structured genetic diversity on a regional scale in China. SARS-CoV-2 itself is not a recombinant of any sarbecoviruses detected to date, and its receptor-binding motif, important for specificity to human ACE2 receptors, appears to be an ancestral trait shared with bat viruses and not one acquired recently via recombination. To employ phylogenetic dating methods, recombinant regions of a 68-genome sarbecovirus alignment were removed with three independent methods. Bayesian evolutionary rate and divergence date estimates were shown to be consistent for these three approaches and for two different prior specifications of evolutionary rates based on HCoV-OC43 and MERS-CoV. Divergence dates between SARS-CoV-2 and the bat sarbecovirus reservoir were estimated as 1948 (95% highest posterior density (HPD): 1879–1999), 1969 (95% HPD: 1930–2000) and 1982 (95% HPD: 1948–2009), indicating that the lineage giving rise to SARS-CoV-2 has been circulating unnoticed in bats for decades.

In December 2019, a cluster of pneumonia cases epidemiologically linked to an open-air live animal market in the city of Wuhan (Hubei Province), China[1,2] led local health officials to issue an epidemiological alert to the Chinese Center for Disease Control and Prevention and the World Health Organization's (WHO) China Country Office. In early January, the aetiological agent of the pneumonia cases was found to be a coronavirus[3], subsequently named SARS-CoV-2 by an International Committee on Taxonomy of Viruses (ICTV) Study Group[4] and also named hCoV-19 by Wu et al.[5]. The first available sequence data[6] placed this novel human pathogen in the *Sarbecovirus* subgenus of *Coronaviridae*[7], the same subgenus as the SARS virus that caused a global outbreak of >8,000 cases in 2002–2003. By mid-January 2020, the virus was spreading widely within Hubei province and by early March SARS-CoV-2 was declared a pandemic[8].

In outbreaks of zoonotic pathogens, identification of the infection source is crucial because this may allow health authorities to separate human populations from the wildlife or domestic animal reservoirs posing the zoonotic risk[9,10]. If stopping an outbreak in its early stages is not possible—as was the case for the COVID-19 epidemic in Hubei—identification of origins and point sources is nevertheless important for containment purposes in other provinces and prevention of future outbreaks. When the first genome sequence of SARS-CoV-2, Wuhan-Hu-1, was released on 10 January 2020 (GMT) on Virological.org by a consortium led by Zhang[6], it enabled immediate analyses of its ancestry. Across a large region of the virus genome, corresponding approximately to ORF1b, it did not cluster with any of the known bat coronaviruses indicating that recombination probably played a role in the evolutionary history of these viruses[5,7]. Subsequently a bat sarbecovirus—RaTG13, sampled from a *Rhinolophus affinis* horseshoe bat in 2013 in Yunnan Province—was reported that clusters with SARS-CoV-2 in almost all genomic regions with approximately 96% genome sequence identity[2]. Zhou et al.[2] concluded from the genetic proximity of SARS-CoV-2 to RaTG13 that a bat origin for the current COVID-19 outbreak is probable. Concurrent evidence also proposed pangolins as a potential intermediate species for SARS-CoV-2 emergence and suggested them as a potential reservoir species[11–13].

Unlike other viruses that have emerged in the past two decades, coronaviruses are highly recombinogenic[14–16]. Influenza viruses reassort[17] but they do not undergo homologous recombination within RNA segments[18,19], meaning that origins questions for influenza outbreaks can always be reduced to origins questions for each of influenza's eight RNA segments. For coronaviruses, however, recombination means that small genomic subregions can have independent origins, identifiable if sufficient sampling has been done in the animal reservoirs that support the endemic circulation, co-infection and recombination that appear to be common. Here, we analyse the evolutionary history of SARS-CoV-2 using available genomic data on sarbecoviruses. We demonstrate that the sarbecoviruses circulating in horseshoe bats have complex recombination histories as reported by others[15,20–26]. Despite the SARS-CoV-2 lineage's acquisition of residues in its Spike (S) protein's receptor-binding domain (RBD) permitting the use of human

ACE2 (ref. [27]) receptors and its RBD being genetically closer to a pangolin virus than to RaTG13 (refs. [11–13,22,28])—a signal that suggests recombination—the divergence patterns in the S protein do not show evidence of recombination between the lineage leading to SARS-CoV-2 and known sarbecoviruses. Our results indicate the presence of a single lineage circulating in bats with properties that allowed it to infect human cells, as previously described for bat sarbecoviruses related to the first SARS-CoV lineage[29–31].

To gauge the length of time this lineage has circulated in bats, we estimate the time to the most recent common ancestor (TMRCA) of SARS-CoV-2 and RaTG13. We use three bioinformatic approaches to remove the effects of recombination, and we combine these approaches to identify putative non-recombinant regions that can be used for reliable phylogenetic reconstruction and dating. Collectively our analyses point to bats being the primary reservoir for the SARS-CoV-2 lineage. While it is possible that pangolins, or another hitherto undiscovered species, may have acted as an intermediate host facilitating transmission to humans, current evidence is consistent with the virus having evolved in bats resulting in bat sarbecoviruses that can replicate in the upper respiratory tract of both humans and pangolins[25,32].

Results

Recombination analysis and identification of breakpoint-free genome regions. Among the 68 sequences in the aligned sarbecovirus sequence set, 67 show evidence of mosaicism (all Dunn–Sidak-corrected $P < 4 \times 10^{-4}$ and 3SEQ[14]), indicating involvement in homologous recombination either directly with identifiable parentals or in their deeper shared evolutionary history—that is, due to shared ancestral recombination events. This is evidence for numerous recombination events occurring in the evolutionary history of the sarbecoviruses[22,33]; specifying all past events in their correct temporal order[34] is challenging and not shown here. Figure 1 (top) shows the distribution of all identified breakpoints (using 3SEQ's exhaustive triplet search) by the number of candidate recombinant sequences supporting them. The histogram allows for the identification of non-recombining regions (NRRs) by revealing regions with no breakpoints. Sorting these breakpoint-free regions (BFRs) by length results in two segments >5 kb: an ORF1a subregion spanning nucleotides (nt) 3,625–9,150 and the first half of ORF1b spanning nt 13,291–19,628 (sequence numbering given in Source Data, https://github.com/plemey/SARSCoV2origins). Eight other BFRs <500 nt were identified, and the regions were named BFR A–J in order of length. Of the nine breakpoints defining these ten BFRs, four showed phylogenetic incongruence (PI) signals with bootstrap support >80%, adopting previously published criteria on using a combination of mosaic and PI signals to show evidence of past recombination events[19]. All four of these breakpoints were also identified with the tree-based recombination detection method GARD[35].

The extent of sarbecovirus recombination history can be illustrated by five phylogenetic trees inferred from BFRs or concatenated adjacent BFRs (Fig. 1c). BFRs were concatenated if no phylogenetic incongruence signal could be identified between them. When viewing the last 7 kb of the genome, a clade of viruses from northern China appears to cluster with sequences from southern Chinese provinces but, when inspecting trees from different parts of ORF1ab, the N. China clade is phylogenetically separated from the S. China clade. Individual sequences such as RpShaanxi2011, Guangxi GX2013 and two sequences from Zhejiang Province (CoVZXC21/CoVZC45), as previously shown[22,25], have strong phylogenetic recombination signals because they fall on different evolutionary lineages (with bootstrap support >80%) depending on what region of the genome is being examined.

Despite the high frequency of recombination among bat viruses, the block-like nature of the recombination patterns across the genome permits retrieval of a clean subalignment for phylogenetic analysis. Conservatively, we combined the three BFRs >2 kb identified above into non-recombining region 1 (NRR1). Removal of five sequences that appear to be recombinants and two small subregions of BFR A was necessary to ensure that there were no phylogenetic incongruence signals among or within the three BFRs. Alternatively, combining 3SEQ-inferred breakpoints, GARD-inferred breakpoints and the necessity of PI signals for inferring recombination, we can use the 9.9-kb region spanning nucleotides 11,885–21,753 (NRR2) as a putative non-recombining region; this approach is breakpoint-conservative because it is conservative in identifying breakpoints but not conservative in identifying non-recombining regions. Using a third consensus-based approach for identifying recombinant regions in individual sequences—with six different recombination detection methods in RDP5 (ref. [36])—gives a putative recombination-free alignment that we call non-recombinant alignment 3 (NRA3) (see Methods).

All three approaches to removal of recombinant genomic segments point to a single ancestral lineage for SARS-CoV-2 and RaTG13. Two other bat viruses (CoVZXC21 and CoVZC45) from Zhejiang Province fall on this lineage as recombinants of the RaTG13/SARS-CoV-2 lineage and the clade of Hong Kong bat viruses sampled between 2005 and 2007 (Fig. 1c). Specifically, progenitors of the RaTG13/SARS-CoV-2 lineage appear to have recombined with the Hong Kong clade (with inferred breakpoints at 11.9 and 20.8 kb) to form the CoVZXC21/CoVZC45-lineage. Sibling lineages to RaTG13/SARS-CoV-2 include a pangolin sequence sampled in Guangdong Province in March 2019 and a clade of pangolin sequences from Guangxi Province sampled in 2017.

Because the SARS-CoV-2 S protein has been implicated in past recombination events or possibly convergent evolution[12], we specifically investigated several subregions of the S protein—the N-terminal domain of S1, the C-terminal domain of S1, the variable-loop region of the C-terminal domain, and S2. The variable-loop region in SARS-CoV-2 shows closer identity to the 2019 pangolin coronavirus sequence than to the RaTG13 bat virus, supported by phylogenetic inference (Fig. 2). On first examination this would suggest that that SARS-CoV-2 is a recombinant of an ancestor of Pangolin-2019 and RaTG13, as proposed by others[11,22]. However, on closer inspection, the relative divergences in the phylogenetic tree (Fig. 2, bottom) show that SARS-CoV-2 is unlikely to have acquired the variable loop from an ancestor of Pangolin-2019 because these two sequences are approximately 10–15% divergent throughout the entire S protein (excluding the N-terminal domain). It is RaTG13 that is more divergent in the variable-loop region (Extended Data Fig. 1) and thus likely to be the product of recombination, acquiring a divergent variable loop from a hitherto unsampled bat sarbecovirus[28]. This is notable because the variable-loop region contains the six key contact residues in the RBD that give SARS-CoV-2 its ACE2-binding specificity[27,37]. These residues are also in the Pangolin Guangdong 2019 sequence. The most parsimonious explanation for these shared ACE2-specific residues is that they were present in the common ancestors of SARS-CoV-2, RaTG13 and Pangolin Guangdong 2019, and were lost through recombination in the lineage leading to RaTG13. This provides compelling support for the SARS-CoV-2 lineage being the consequence of a direct or nearly-direct zoonotic jump from bats, because the key ACE2-binding residues were present in viruses circulating in bats.

Ancestry in non-recombinant regions. Using the most conservative approach to identification of a non-recombinant genomic region (NRR1), SARS-CoV-2 forms a sister lineage with RaTG13, with genetically related cousin lineages of coronavirus sampled in pangolins in Guangdong and Guangxi provinces (Fig. 3). Given that these pangolin viruses are ancestral to the progenitor of the

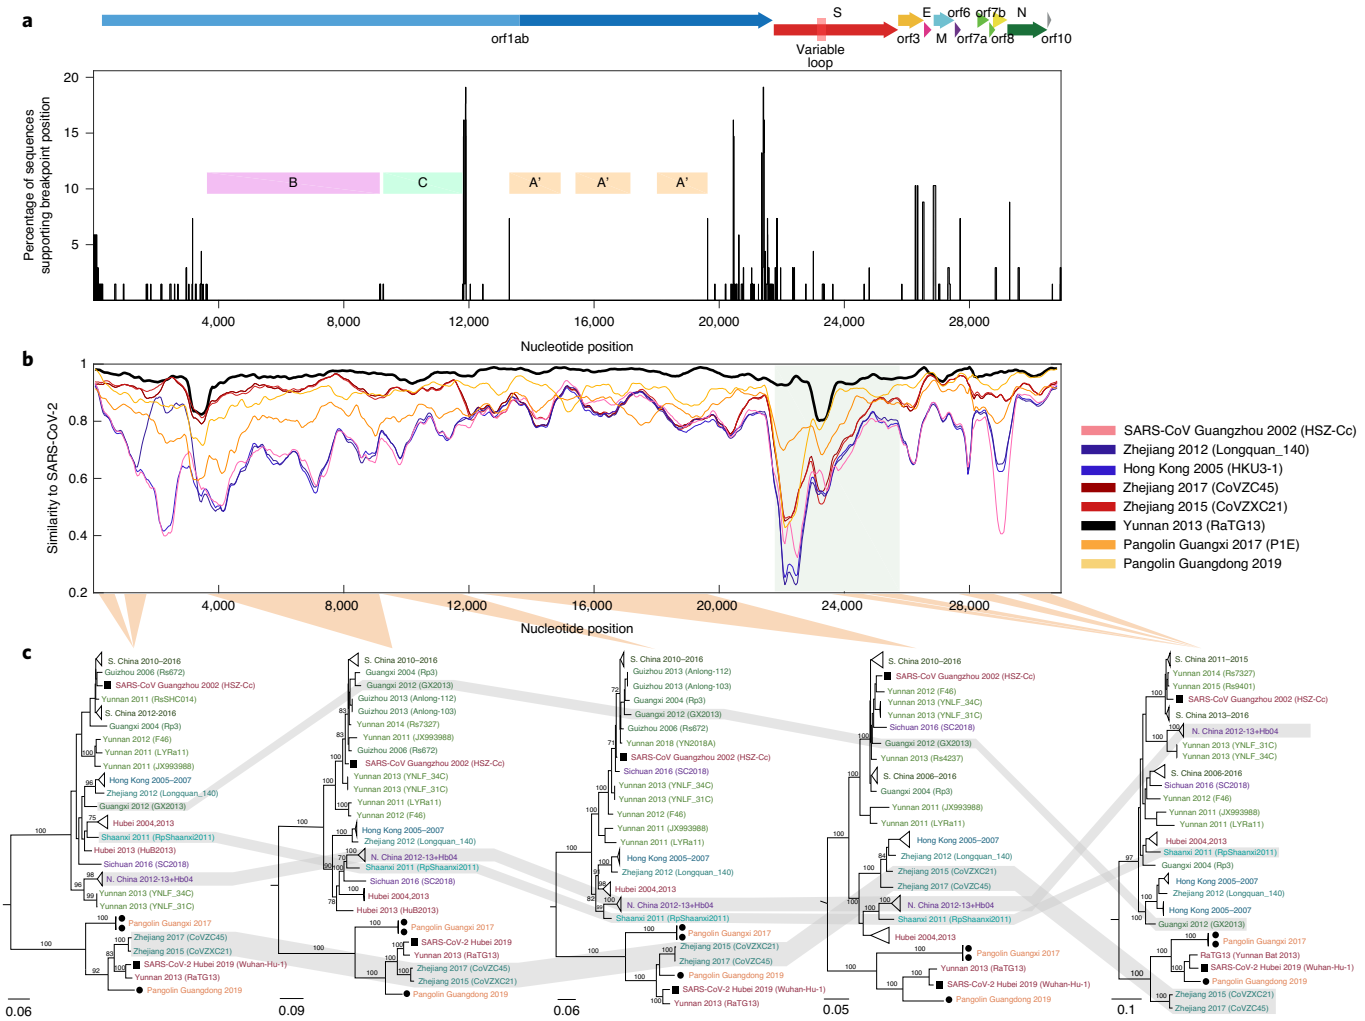

Fig. 1 | Breakpoints identified by 3SEQ. a, Breakpoints identified by 3SEQ illustrated by percentage of sequences (out of 68) that support a particular breakpoint position. Note that breakpoints can be shared between sequences if they are descendants of the same recombination events. Pink, green and orange bars show BFRs, with region A (nt 13,291–19,628) showing two trimmed segments yielding region A′ (nt 13,291–14,932, 15,405–17,162, 18,009–19,628). Regions B and C span nt 3,625–9,150 and 9,261–11,795, respectively. Concatenated region A′BC is NRR1. Open reading frames are shown above the breakpoint plot, with the variable-loop region indicated in the S protein. **b**, Similarity plot between SARS-CoV-2 and several selected sequences including RaTG13 (black), SARS-CoV (pink) and two pangolin sequences (orange). The shaded region corresponds to the S protein. **c**, Maximum likelihood phylogenetic trees rooted on a 2007 virus sampled in Kenya (BtKy72; root truncated from images), shown for five BFRs of the sarbecovirus alignment. Nucleotide positions for phylogenetic inference are 147–695, 962–1,686 (first tree), 3,625–9,150 (second tree, also BFR B), 9,261–11,795 (third tree, also BFR C), 12,443–19,638 (fourth tree) and 23,631–24,633, 24,795–25,847, 27,702–28,843 and 29,574–30,650 (fifth tree). Relevant bootstrap values are shown on branches, and grey-shaded regions show sequences exhibiting phylogenetic incongruence along the genome. S. China corresponds to Guangxi, Yunnan, Guizhou and Guangdong provinces. N. China corresponds to Jilin, Shanxi, Hebei and Henan provinces, and the N. China clade also includes one sequence sampled in Hubei Province in 2004.

RaTG13/SARS-CoV-2 lineage, it is more likely that they are also acquiring viruses from bats. While pangolins could be acting as intermediate hosts for bat viruses to get into humans—they develop severe respiratory disease[38] and commonly come into contact with people through trafficking—there is no evidence that pangolin infection is a requirement for bat viruses to cross into humans.

Phylogenies of subregions of NRR1 depict an appreciable degree of spatial structuring of the bat sarbecovirus population across different regions (Fig. 3). One geographic clade includes viruses from provinces in southern China (Guangxi, Yunnan, Guizhou and Guangdong), with its major sister clade consisting of viruses from provinces in northern China (Shanxi, Henan, Hebei and Jilin) as well as Hubei Province in central China and Shaanxi Province in northwestern China. Several of the recombinant sequences in these trees show that recombination events do occur across geographically divergent clades. The Sichuan (SC2018) virus appears to be a recombinant of northern/central and southern viruses, while the two Zhejiang viruses (CoVZXC21 and CoVZC45) appear to carry a recombinant region from southern or central China.

TMRCA for NRRs of SARS-CoV-2 lineage. To avoid artefacts due to recombination, we focused on NRR1 and NRR2 and the recombination-masked alignment NRA3 to infer time-measured evolutionary histories. Visual exploration using TempEst[39] indicates that there is no evidence for temporal signal in these datasets (Extended Data Fig. 2). This is not surprising for diverse viral populations with relatively deep evolutionary histories. In such cases, even moderate rate variation among long, deep phylogenetic branches will substantially impact expected root-to-tip divergences over a sampling time range that represents only a small fraction of

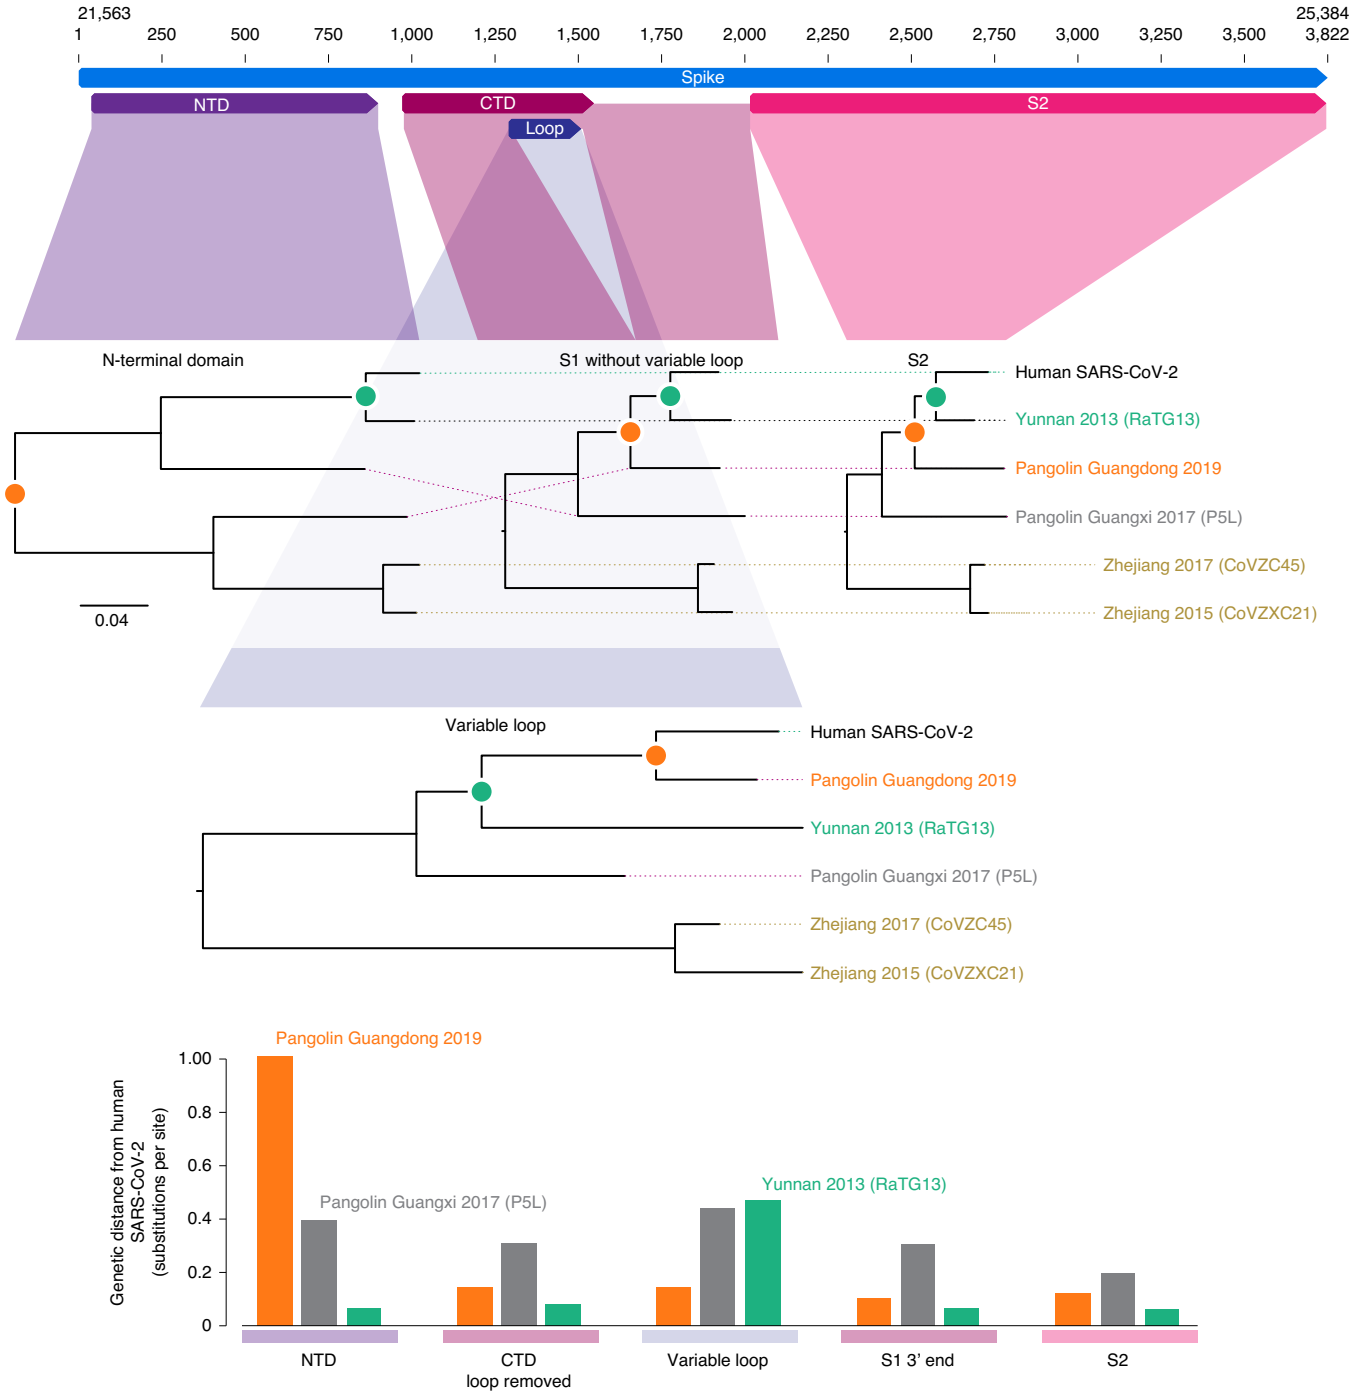

Fig. 2 | Phylogenetic relationships among SARS-CoV-2 and closely related sequences for subregions of the S protein. SARS-CoV-2 and RaTG13 are the most closely related (their most recent common ancestor nodes denoted by green circles), except in the 222-nt variable-loop region of the C-terminal domain (bar graphs at bottom). In the variable-loop region, RaTG13 diverges considerably with the TMRCA, now outside that of SARS-CoV-2 and the Pangolin Guangdong 2019 ancestor, suggesting that RaTG13 has acquired this region from a more divergent and undetected bat lineage. The genetic distances between SARS-CoV-2 and RaTG13 (bottom) demonstrate that their relationship is consistent across all regions except for the variable loop. The genetic distances between SARS-CoV-2 and Pangolin Guangdong 2019 are consistent across all regions except the N-terminal domain, implying that a recombination event between these two sequences in this region is unlikely. Uncertainty measures are shown in Extended Data Fig. 1. NTD, N-terminal domain; CTD, C-terminal domain.

the evolutionary history[40]. However, formal testing using marginal likelihood estimation[41] does provide some evidence of a temporal signal, albeit with limited log Bayes factor support of 3 (NRR1), 10 (NRR2) and 3 (NRA3); see Supplementary Table 1.

In the absence of a strong temporal signal, we sought to identify a suitable prior rate distribution to calibrate the time-measured trees by examining several coronaviruses sampled over time, including HCoV-OC43, MERS-CoV, and SARS-CoV virus genomes. These datasets were subjected to the same recombination masking approach as NRA3 and were characterized by a strong temporal signal (Fig. 4), but also by markedly different evolutionary rates. Specifically, using a formal Bayesian approach[42] (see Methods), we

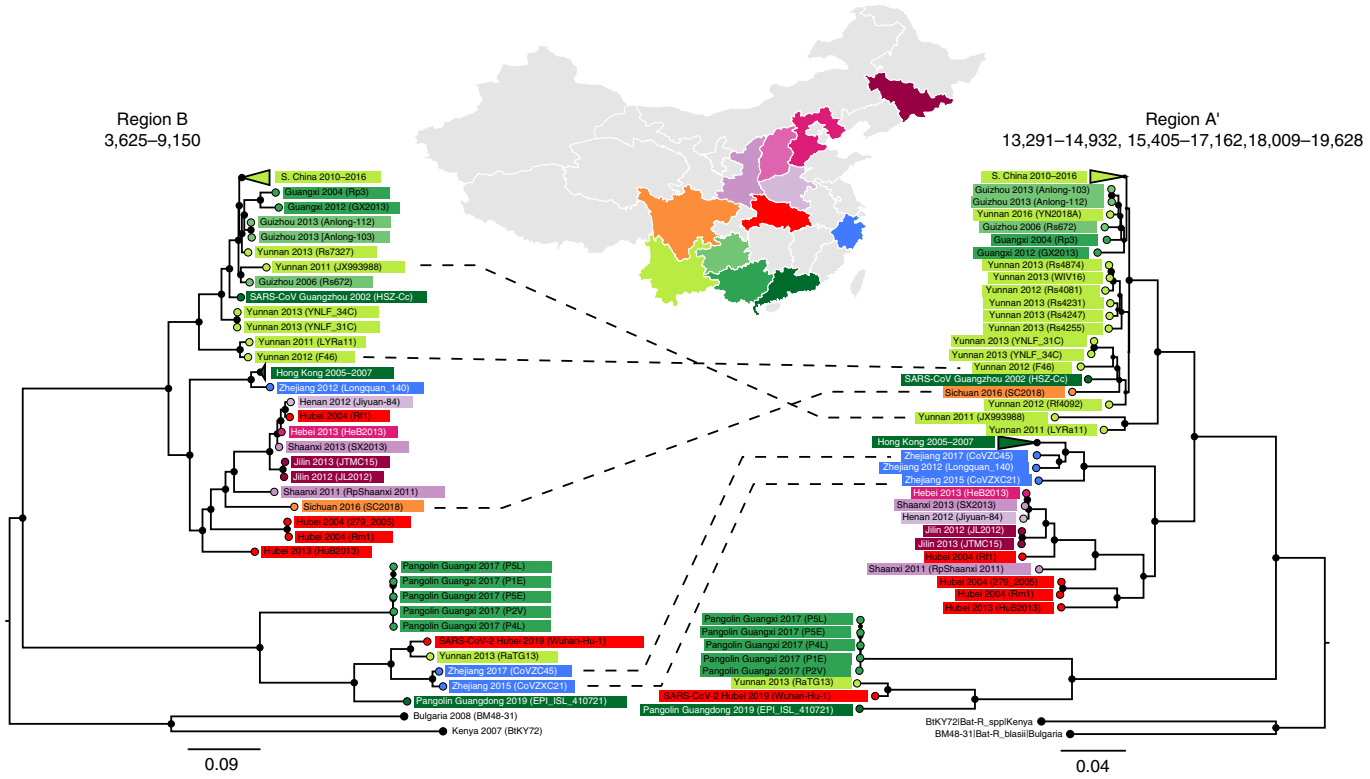

Fig. 3 | Maximum likelihood trees of the sarbecoviruses using the two longest BFRs, rooted on the Kenya/Bulgaria lineage. Region A has been shortened to A′ (5,017 nt) based on potential recombination signals within the region. Region B is 5,525 nt long. Sequences are colour-coded by province according to the map. Five example sequences with incongruent phylogenetic positions in the two trees are indicated by dashed lines.

estimate a fast evolutionary rate (0.00169 substitutions per site yr^{-1}, 95% highest posterior density (HPD) interval (0.00131,0.00205)) for SARS viruses sampled over a limited timescale (1 year), a slower rate (0.00078 (0.00063,0.00092) substitutions per site yr^{-1}) for MERS-CoV on a timescale of about 4 years and the slowest rate (0.00024 (0.00019,0.00029) substitutions per site yr^{-1}) for HCoV-OC43 over almost five decades. These differences reflect the fact that rate estimates can vary considerably with the timescale of measurement, a frequently observed phenomenon in viruses known as time-dependent evolutionary rates[41,43,44]. Over relatively shallow timescales, such differences can primarily be explained by varying selective pressure, with mildly deleterious variants being eliminated more strongly by purifying selection over longer timescales[44–46]. Consistent with this, we estimate a concomitantly decreasing non-synonymous-to-synonymous substitution rate ratio over longer evolutionary timescales: 1.41 (1.20,1.68), 0.35 (0.30,0.41) and 0.133 (0.129,0.136) for SARS, MERS-CoV and HCoV-OC43, respectively. In light of these time-dependent evolutionary rate dynamics, a slower rate is appropriate for calibration of the sarbecovirus evolutionary history. We compare both MERS-CoV- and HCoV-OC43-centred prior distributions (Extended Data Fig. 3) to examine the sensitivity of date estimates to this prior specification.

We infer time-measured evolutionary histories using a Bayesian phylogenetic approach while incorporating rate priors based on mean MERS-CoV and HCoV-OC43 rates and with standard deviations that allow for more uncertainty than the empirical estimates for both viruses (see Methods). Using both prior distributions, this results in six highly similar posterior rate estimates for NRR1, NRR2 and NRA3, centred around 0.00055 substitutions per site yr^{-1}. The fact that these estimates lie between the rates for MERS-CoV and HCoV-OC43 is consistent with the intermediate sampling time range of about 18 years (Fig. 5). The consistency of the posterior rates for the different prior means also implies that the data do contribute to the evolutionary rate estimate, despite the fact that a temporal signal was visually not apparent (Extended Data Fig. 2). Below, we report divergence time estimates based on the HCoV-OC43-centred rate prior for NRR1, NRR2 and NRA3 and summarize corresponding estimates for the MERS-CoV-centred rate priors in Extended Data Fig. 4. Divergence time estimates based on the HCoV-OC43-centred rate prior for the separate BFRs (Supplementary Table 3) show consistency in TMRCA estimates across the genome.

The divergence time estimates for SARS-CoV-2 and SARS-CoV from their respective most closely related bat lineages are reasonably consistent among the three approaches we use to eliminate the effects of recombination in the alignment. Using the most conservative approach (NRR1), the divergence time estimate for SARS-CoV-2 and RaTG13 is 1969 (95% HPD: 1930–2000), while that between SARS-CoV and its most closely related bat sequence is 1962 (95% HPD: 1932–1988); see Fig. 5. These are in general agreement with estimates using NRR2 and NRA3, which result in divergence times of 1982 (1948–2009) and 1948 (1879–1999), respectively, for SARS-CoV-2, and estimates of 1952 (1906–1989) and 1970 (1932–1996), respectively, for the divergence time of SARS-CoV from its closest known bat relative. The SARS-CoV divergence times are somewhat earlier than dates previously estimated[15] because previous estimates were obtained using a collection of SARS-CoV genomes from human and civet hosts (as well as a few closely related bat genomes), which implies that evolutionary rates were predominantly informed by the short-term SARS outbreak scale and probably biased upwards. Indeed, the rates reported by these studies are in line with the short-term SARS rates that we estimate (Fig. 4). The estimated divergence times for the pangolin virus most closely related to the SARS-CoV-2/RaTG13 lineage

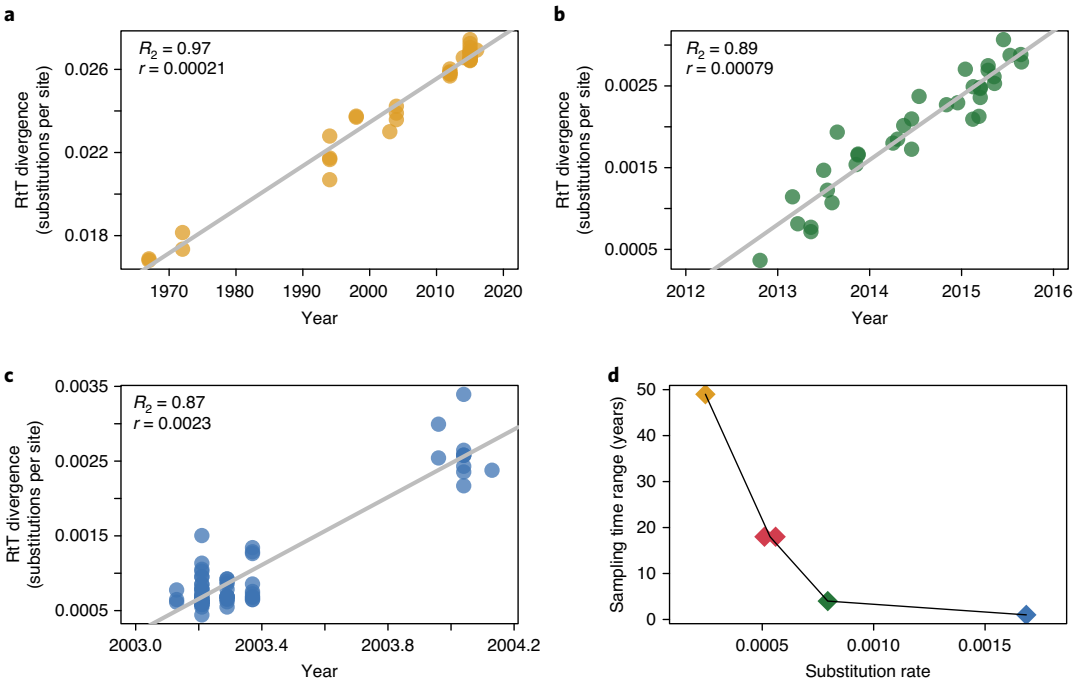

Fig. 4 | Temporal signal and mean evolutionary rate estimates for coronaviruses HCoV-OC43, MERS and SARS. a–c, Root-to-tip (RtT) divergence as a function of sampling time for the three coronavirus evolutionary histories unfolding over different timescales (HCoV-OC43 (n = 37; **a**) MERS (n = 35; **b**) and SARS (n = 69; **c**)). Decimal years are shown on the x axis for the 1.2 years of SARS sampling in **c**. **d**, Mean evolutionary rate estimates plotted against sampling time range for the same three datasets (represented by the same colour as the data points in their respective RtT divergence plots), as well as for the comparable NRA3 using the two different priors for the rate in the Bayesian inference (red points).

range from 1851 (1730–1958) to 1877 (1746–1986), indicating that these pangolin lineages were acquired from bat viruses divergent to those that gave rise to SARS-CoV-2. Current sampling of pangolins does not implicate them as an intermediate host.

Discussion

Identifying the origins of an emerging pathogen can be critical during the early stages of an outbreak, because it may allow for containment measures to be precisely targeted at a stage when the number of daily new infections is still low. Early detection via genomics was not possible during Southeast Asia's initial outbreaks of avian influenza H5N1 (1997 and 2003–2004) or the first SARS outbreak (2002–2003). By 2009, however, rapid genomic analysis had become a routine component of outbreak response. The 2009 influenza pandemic and subsequent outbreaks of MERS-CoV (2012), H7N9 avian influenza (2013), Ebola virus (2014) and Zika virus (2015) were met with rapid sequencing and genomic characterization. For the current pandemic, the 'novel pathogen identification' component of outbreak response delivered on its promise, with viral identification and rapid genomic analysis providing a genome sequence and confirmation, within weeks, that the December 2019 outbreak first detected in Wuhan, China was caused by a coronavirus[3]. Unfortunately, a response that would achieve containment was not possible. Given what was known about the origins of SARS, as well as identification of SARS-like viruses circulating in bats that had binding sites adapted to human receptors[29–31], appropriate measures should have been in place for immediate control of outbreaks of novel coronaviruses. The key to successful surveillance is knowing which viruses to look for and prioritizing those that can readily infect humans[47].

The difficulty in inferring reliable evolutionary histories for coronaviruses is that their high recombination rate[48,49] violates the assumption of standard phylogenetic approaches because different parts of the genome have different histories. To begin characterizing any ancestral relationships for SARS-CoV-2, NRRs of the genome must be identified so that reliable phylogenetic reconstruction and dating can be performed. Evolutionary rate estimation can be profoundly affected by the presence of recombination[50]. Because there is no single accepted method of inferring breakpoints and identifying clean subregions with high certainty, we implemented several approaches to identifying three classic statistical signals of recombination: mosaicism, phylogenetic incongruence and excessive homoplasy[51]. Our most conservative approach attempted to ensure that putative NRRs had no mosaic or phylogenetic incongruence signals. A second breakpoint-conservative approach was conservative with respect to breakpoint identification, but this means that it is accepting of false-negative outcomes in breakpoint inference, resulting in less certainty that a putative NRR truly contains no breakpoints. A third approach attempted to minimize the number of regions removed while also minimizing signals of mosaicism and homoplasy. The origins we present in Fig. 5 (NRR1) are conservative in the sense that NRR1 is more likely to be non-recombinant than NRR2 or NRA3. Because the estimated rates and divergence dates were highly similar in the three datasets analysed, we conclude that our estimates are robust to the method of identifying a genome's NRRs.

Due to the absence of temporal signal in the sarbecovirus datasets, we used informative prior distributions on the evolutionary rate to estimate divergence dates. Calibration of priors can be performed using other coronaviruses (SARS-CoV, MERS-CoV and HCoV-OC43), but estimated rates vary with the timescale of sample collection. In the presence of time-dependent rate variation, a widely observed phenomenon for viruses[43,44,52], slower prior rates appear more appropriate for sarbecoviruses that currently encompass a sampling time range of about 18 years. Our approach resulted in similar posterior rates using two different prior means, implying

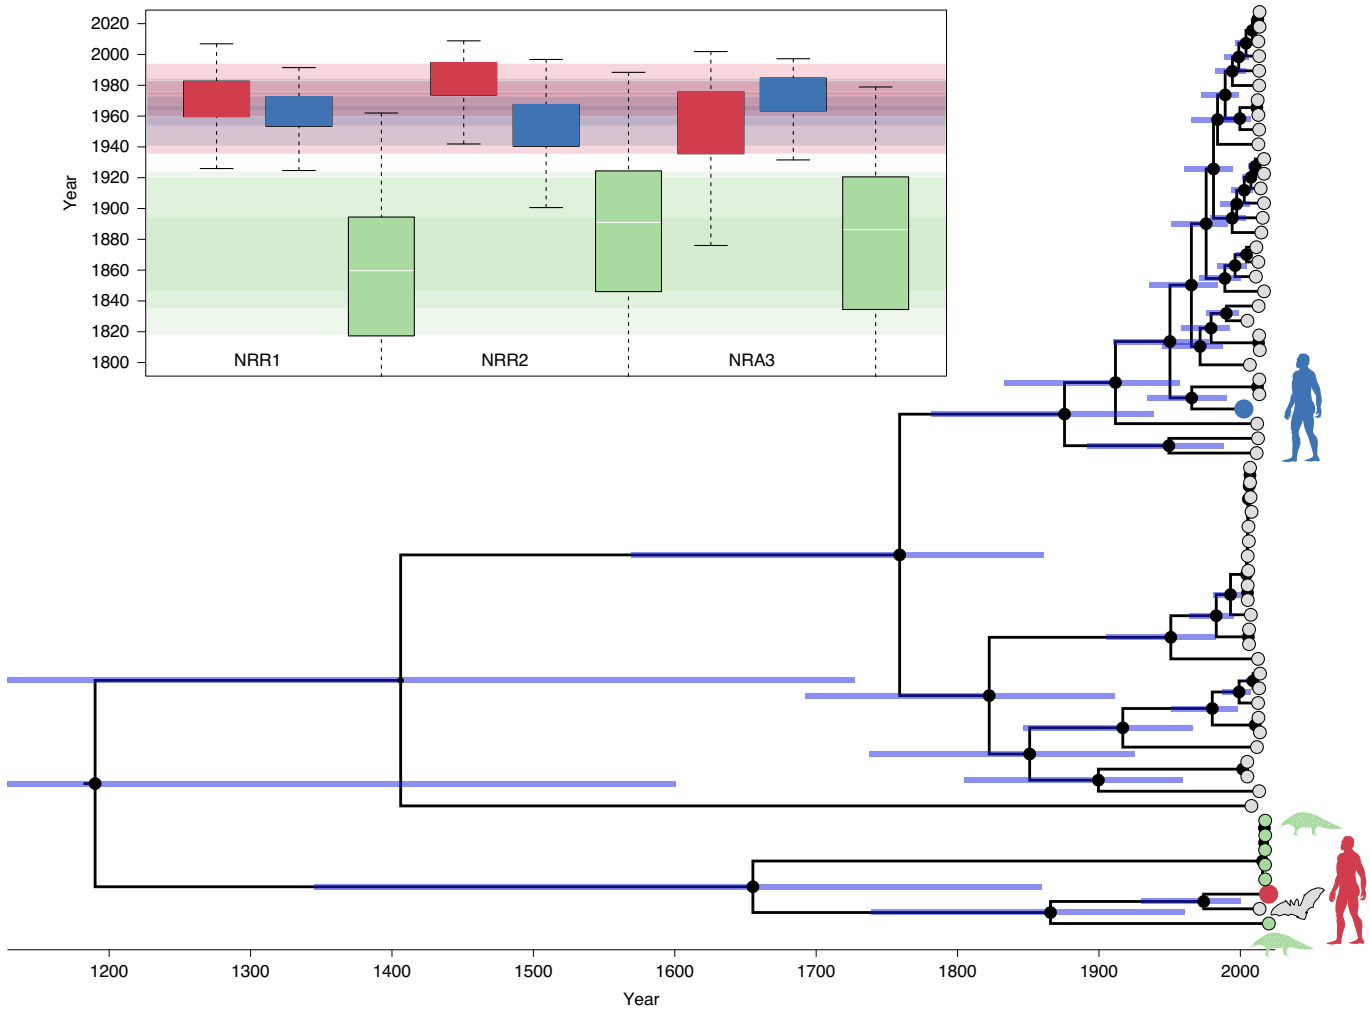

Fig. 5 | Time-measured phylogenetic estimates and divergence times for sarbecovirus lineages using an HCoV-OC43-centred rate prior. The time-calibrated phylogeny represents a maximum clade credibility tree inferred for NRR1. Grey tips correspond to bat viruses, green to pangolin, blue to SARS-CoV and red to SARS-CoV-2. The sizes of the black internal node circles are proportional to the posterior node support. 95% credible interval bars are shown for all internal node ages. The inset represents divergence time estimates based on NRR1, NRR2 and NRA3. The boxplots show divergence time estimates (posterior medians) for SARS-CoV-2 (red) and the 2002–2003 SARS-CoV virus (blue) from their most closely related bat virus. Green boxplots show the TMRCA estimate for the RaTG13/SARS-CoV-2 lineage and its most closely related pangolin lineage (Guangdong 2019). Boxplots show interquartile ranges, white lines are medians and box whiskers show the full range of posterior distribution. Transparent bands of interquartile range width and with the same colours are superimposed to highlight the overlap between estimates. In Extended Data Fig. 4 we compare these divergence time estimates to those obtained using the MERS-CoV-centred rate priors for NRR1, NRR2 and NRA3.

that the sarbecovirus data do inform the rate estimate even though a root-to-tip temporal signal was not apparent.

The relatively fast evolutionary rate means that it is most appropriate to estimate shallow nodes in the sarbecovirus evolutionary history. Accurate estimation of ages for deeper nodes would require adequate accommodation of time-dependent rate variation. While such models have recently been made available, we lack the information to calibrate the rate decline over time (for example, through internal node calibrations[44]). As a proxy, it would be possible to model the long-term purifying selection dynamics as a major source of time-dependent rates[43,44,52], but this is beyond the scope of the current study. The assumption of long-term purifying selection would imply that coronaviruses are in endemic equilibrium with their natural host species, horseshoe bats, to which they are presumably well adapted. While there is evidence of positive selection in the sarbecovirus lineage leading to RaTG13/SARS-CoV-2 (ref. [53]), this is inferred to have occurred before the divergence of RaTG13 and SARS-CoV-2 and thus should not influence our inferences.

Of importance for future spillover events is the appreciation that SARS-CoV-2 has emerged from the same horseshoe bat subgenus that harbours SARS-like coronaviruses. Another similarity between SARS-CoV and SARS-CoV-2 is their divergence time (40–70 years ago) from currently known extant bat virus lineages (Fig. 5). This long divergence period suggests there are unsampled virus lineages circulating in horseshoe bats that have zoonotic potential due to the ancestral position of the human-adapted contact residues in the SARS-CoV-2 RBD. Without better sampling, however, it is impossible to estimate whether or how many of these additional lineages exist. While there is involvement of other mammalian species—specifically pangolins for SARS-CoV-2—as a plausible conduit for transmission to humans, there is no evidence that pangolins are facilitating adaptation to humans. A hypothesis of snakes as intermediate hosts of SARS-CoV-2 was posited during the early epidemic phase[54], but we found no evidence of this[55,56]; see Extended Data Fig. 5.

With horseshoe bats currently the most plausible origin of SARS-CoV-2, it is important to consider that sarbecoviruses cir-

culate in a variety of horseshoe bat species with widely overlapping species ranges[57]. Nevertheless, the viral population is largely spatially structured according to provinces in the south and southeast on one lineage, and provinces in the centre, east and northeast on another (Fig. 3). This boundary appears to be rarely crossed. Two exceptions can be seen in the relatively close relationship of Hong Kong viruses to those from Zhejiang Province (with two of the latter, CoVZC45 and CoVZXC21, identified as recombinants) and a recombinant virus from Sichuan for which part of the genome (region B of SC2018 in Fig. 3) clusters with viruses from provinces in the centre, east and northeast of China. SARS-CoV-2 and RaTG13 are also exceptions because they were sampled from Hubei and Yunnan, respectively. The fact that they are geographically relatively distant is in agreement with their somewhat distant TMRCA, because the spatial structure suggests that migration between their locations may be uncommon. From this perspective, it may be useful to perform surveillance for more closely related viruses to SARS-CoV-2 along the gradient from Yunnan to Hubei.

It is clear from our analysis that viruses closely related to SARS-CoV-2 have been circulating in horseshoe bats for many decades. The unsampled diversity descended from the SARS-CoV-2/RaTG13 common ancestor forms a clade of bat sarbecoviruses with generalist properties—with respect to their ability to infect a range of mammalian cells—that facilitated its jump to humans and may do so again. Although the human ACE2-compatible RBD was very likely to have been present in a bat sarbecovirus lineage that ultimately led to SARS-CoV-2, this RBD sequence has hitherto been found in only a few pangolin viruses. Furthermore, the other key feature thought to be instrumental in the ability of SARS-CoV-2 to infect humans—a polybasic cleavage site insertion in the S protein—has not yet been seen in another close bat relative of the SARS-CoV-2 virus.

The existing diversity and dynamic process of recombination amongst lineages in the bat reservoir demonstrate how difficult it will be to identify viruses with potential to cause major human outbreaks before they emerge. This underscores the need for a global network of real-time human disease surveillance systems, such as that which identified the unusual cluster of pneumonia in Wuhan in December 2019, with the capacity to rapidly deploy genomic tools and functional studies for pathogen identification and characterization.

Methods

Dataset compilation. *Sarbecovirus data.* Complete genome sequence data were downloaded from GenBank and ViPR; accession numbers of all 68 sequences are available in Supplementary Table 4. Sequences were aligned by MAFFT[58] v.7.310, with a final alignment length of 30,927, and used in the analyses below.

HCoV-OC43. We compiled a dataset including 27 human coronavirus OC43 virus genomes and ten related animal virus genomes (six bovine, three white-tailed deer and one canine virus). The canine viral genome was excluded from the Bayesian phylogenetic analyses because temporal signal analyses (see below) indicated that it was an outlier.

MERS-CoV. We extracted a similar number ($n = 35$) of genomes from a MERS-CoV dataset analysed by Dudas et al.[59] using the phylogenetic diversity analyser tool[60] (v.0.5).

SARS-CoV. We compiled a set of 69 SARS-CoV genomes including 58 sampled from humans and 11 sampled from civets and raccoon dogs. This dataset comprises an updated version of that used in Hon et al.[15] and includes a cluster of genomes sampled in late 2003 and early 2004, but the evolutionary rate estimate without this cluster (0.00175 substitutions per site yr^{-1} (0.00117,0.00229)) is consistent with the complete dataset (0.00169 substitutions per site yr^{-1}, (0.00131,0.00205)).

Sarbecovirus, HCoV-OC43 and SARS-CoV data were assembled from GenBank to be as complete as possible, with sampling year as an inclusion criterion. MERS-CoV data were subsampled to match sample sizes with SARS-CoV and HCoV-OC43.

Recombination analysis. Because coronaviruses are known to be highly recombinant, we used three different approaches to identify non-recombinant regions for use in our Bayesian time-calibrated phylogenetic inference.

First, we took an approach that relies on identification of mosaic regions (via 3SEQ[14] v.1.7) that are also supported by PI signals[19]. Because 3SEQ is the most statistically powerful of the mosaic methods[61], we used it to identify the best-supported breakpoint history for each potential child (recombinant) sequence in the dataset. A single 3SEQ run on the genome alignment resulted in 67 out of 68 sequences supporting some recombination in the past, with multiple candidate breakpoint ranges listed for each putative recombinant. Next, we (1) collected all breakpoints into a single set, (2) complemented this set to generate a set of non-breakpoints, (3) grouped non-breakpoints into contiguous BFRs and (4) sorted these regions by length. A phylogenetic tree—using RAxML v8.2.8 (ref. [62,63]), the GTR + Γ model and 100 bootstrap replicates—was inferred for each BFR >500 nt.

We considered (1) the possibility that BFRs could be combined into larger non-recombinant regions and (2) the possibility of further recombination within each BFR.

We named the length-sorted BFRs as: BFR A (nt positions 13,291–19,628, length = 6,338 nt), BFR B (nt positions 3,625–9,150, length = 5,526 nt), BFR C (nt positions 9,261–11,795, length = 2,535 nt), BFR D (nt positions 27,702–28,843, length = 1,142 nt) and six further regions (E–J). Phylogenetic trees and exact breakpoints for all ten BFRs are shown in Supplementary Figs. 1–10. Regions A–C had similar phylogenetic relationships among the southern China bat viruses (Yunnan, Guangxi and Guizhou provinces), the Hong Kong viruses, northern Chinese viruses (Jilin, Shanxi, Hebei and Henan provinces, including Shaanxi), pangolin viruses and the SARS-CoV-2 lineage. Because these subclades had different phylogenetic relationships in region D (Supplementary Fig. 4), that region and shorter BFRs were not included in combined putative non-recombinant regions.

Regions A–C were further examined for mosaic signals by 3SEQ, and all showed signs of mosaicism. In region A, we removed subregion A1 (nt positions 3,872–4,716 within region A) and subregion A4 (nt 1,642–2,113) because both showed PI signals with other subregions of region A. After removal of A1 and A4, we named the new region A′. In addition, sequences NC_014470 (Bulgaria 2008), CoVZXC21, CoVZC45 and DQ412042 (Hubei-Yichang) needed to be removed to maintain a clean non-recombinant signal in A′. Region B showed no PI signals within the region, except one including sequence SC2018 (Sichuan), and thus this sequence was also removed from the set. Region C showed no PI signals within it. Combining regions A′, B and C and removing the five named sequences gives us putative NRR1, as an alignment of 63 sequences. We say that this approach is conservative because sequences and subregions generating recombination signals have been removed, and BFRs were concatenated only when no PI signals could be detected between them. The construction of NRR1 is the most conservative as it is least likely to contain any remaining recombination signals.

In our second stage, we wanted to construct non-recombinant regions where our approach to breakpoint identification was as conservative as possible. We call this approach breakpoint-conservative, but note that this has the opposite effect to the construction of NRR1 in that this approach is the most likely to allow breakpoints to remain inside putative non-recombining regions. In other words, a true breakpoint is less likely to be called as such (this is breakpoint-conservative), and thus the construction of a non-recombining region may contain true recombination breakpoints (with insufficient evidence to call them as such). In this approach, we considered a breakpoint as supported only if it had three types of statistical support: from (1) mosaic signals identified by 3SEQ, (2) PI signals identified by building trees around 3SEQ's breakpoints and (3) the GARD algorithm[35], which identifies breakpoints by identifying PI signals across proposed breakpoints. Because 3SEQ identified ten BFRs >500 nt, we used GARD's (v.2.5.0) inference on 10, 11 and 12 breakpoints. A reduced sequence set of 25 sequences chosen to capture the breadth of diversity in the sarbecoviruses (obvious recombinants not involving the SARS-CoV-2 lineage were also excluded) was used because GARD is computationally intensive. GARD identified eight breakpoints that were also within 50 nt of those identified by 3SEQ. PI signals were identified (with bootstrap support >80%) for seven of these eight breakpoints: positions 1,684, 3,046, 9,237, 11,885, 21,753, 22,773 and 24,628. Using these breakpoints, the longest putative non-recombining segment (nt 1,885–21,753) is 9.9 kb long, and we call this region NRR2.

Our third approach involved identifying breakpoints and masking minor recombinant regions (with gaps, which are treated as unobserved characters in probabilistic phylogenetic approaches). Specifically, we used a combination of six methods implemented in v.5.5 of RDP5 (ref. [36]) (RDP, GENECONV, MaxChi, Bootscan, SisScan and 3SEQ) and considered recombination signals detected by more than two methods for breakpoint identification. Except for specifying that sequences are linear, all settings were kept to their defaults. Based on the identified breakpoints in each genome, only the major non-recombinant region is kept in each genome while other regions are masked. To evaluate the performance procedure, we confirmed that the recombination masking resulted in (1) a markedly different outcome of the PHI test[64], (2) removal of well-supported (bootstrap value >95%) incompatible splits in Neighbor-Net[65] and (3) a

near-complete reduction of mosaic signal as identified by 3SEQ. If the latter still identified non-negligible recombination signal, we removed additional genomes that were identified as major contributors to the remaining signal. This produced non-recombining alignment NRA3, which included 63 of the 68 genomes.

Bayesian divergence time estimation. We focused on these three non-recombining regions/alignments for divergence time estimation; this avoids inappropriate modelling of evolutionary processes with recombination on strictly bifurcating trees, which can result in different artefacts such as homoplasies that inflate branch lengths and lead to apparently longer evolutionary divergence times. To examine temporal signal in the sequenced data, we plotted root-to-tip divergence against sampling time using TempEst[39] v.1.5.3 based on a maximum likelihood tree. The latter was reconstructed using IQTREE[66] v.2.0 under a general time-reversible (GTR) model with a discrete gamma distribution to model inter-site rate variation.

Time-measured phylogenetic reconstruction was performed using a Bayesian approach implemented in BEAST[42] v.1.10.4. When the genomic data included both coding and non-coding regions we used a single GTR + Γ substitution model; for concatenated coding genes we partitioned the alignment by codon position and specified an independent GTR + Γ model for each partition with a separate gamma model to accommodate inter-site rate variation. We used an uncorrelated relaxed clock model with log-normal distribution for all datasets, except for the low-diversity SARS data for which we specified a strict molecular clock model. For the HCoV-OC43, MERS-CoV and SARS datasets we specified flexible skygrid coalescent tree priors. In the absence of any reasonable prior knowledge on the TMRCA of the sarbecovirus datasets (which is required for grid specification in a skygrid model), we specified a simpler constant size population prior. As informative rate priors for the analysis of the sarbecovirus datasets, we used two different normal prior distributions: one with a mean of 0.00078 and s.d. = 0.00075 and one with a mean of 0.00024 and s.d. = 0.00025. These means are based on the mean rates estimated for MERS-CoV and HCoV-OC43, respectively, while the standard deviations are set ten times higher than empirical values to allow greater prior uncertainty and avoid strong bias (Extended Data Fig. 3). In our analyses of the sarbecovirus datasets, we incorporated the uncertainty of the sampling dates when exact dates were not available. To estimate non-synonymous over synonymous rate ratios for the concatenated coding genes, we used the empirical Bayes Renaissance counting'procedure[67]. Temporal signal was tested using a recently developed marginal likelihood estimation procedure[41] (Supplementary Table 1).

Posterior distributions were approximated through Markov chain Monte Carlo sampling, which were run sufficiently long to ensure effective sampling sizes >100. BEAST inferences made use of the BEAGLE v.3 library[68] for efficient likelihood computations. We used TreeAnnotator to summarize posterior tree distributions and annotated the estimated values to a maximum clade credibility tree, which was visualized using FigTree.

Reporting Summary. Further information on research design is available in the Nature Research Reporting Summary linked to this article.

Data availability

All sequence data analysed in this manuscript are available at https://github.com/plemey/SARSCoV2origins. Note that six of these sequences fall under the terms of use of the GISAID platform.

Code availability

All custom code used in the manuscript is available at https://github.com/plemey/SARSCoV2origins.

Author contributions

All authors contributed to analyses and interpretations. D.L.R. and X.J. performed recombination and phylogenetic analysis and annotated virus names with geographical and sampling dates. A.R. performed S recombination analysis. B.W.P. and T.A.C. performed codon usage analysis. M.F.B. performed recombination analysis for non-recombining regions 1 and 2, breakpoint analysis and phylogenetic inference on recombinant segments. P.L. performed recombination analysis for non-recombining alignment 3, calibration of rate of evolution and phylogenetic reconstruction and dating. T.T.-Y.L. collected SARS-CoV data and assisted in analyses of SARS-CoV and SARS-CoV-2 data. M.F.B., P.L. and D.L.R. wrote the first draft of the manuscript, and all authors contributed to manuscript editing.

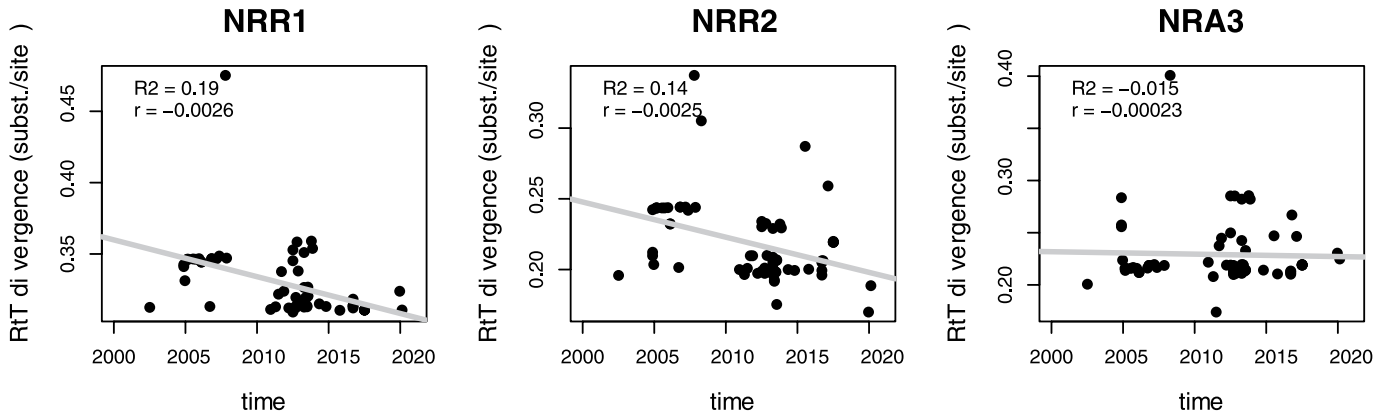
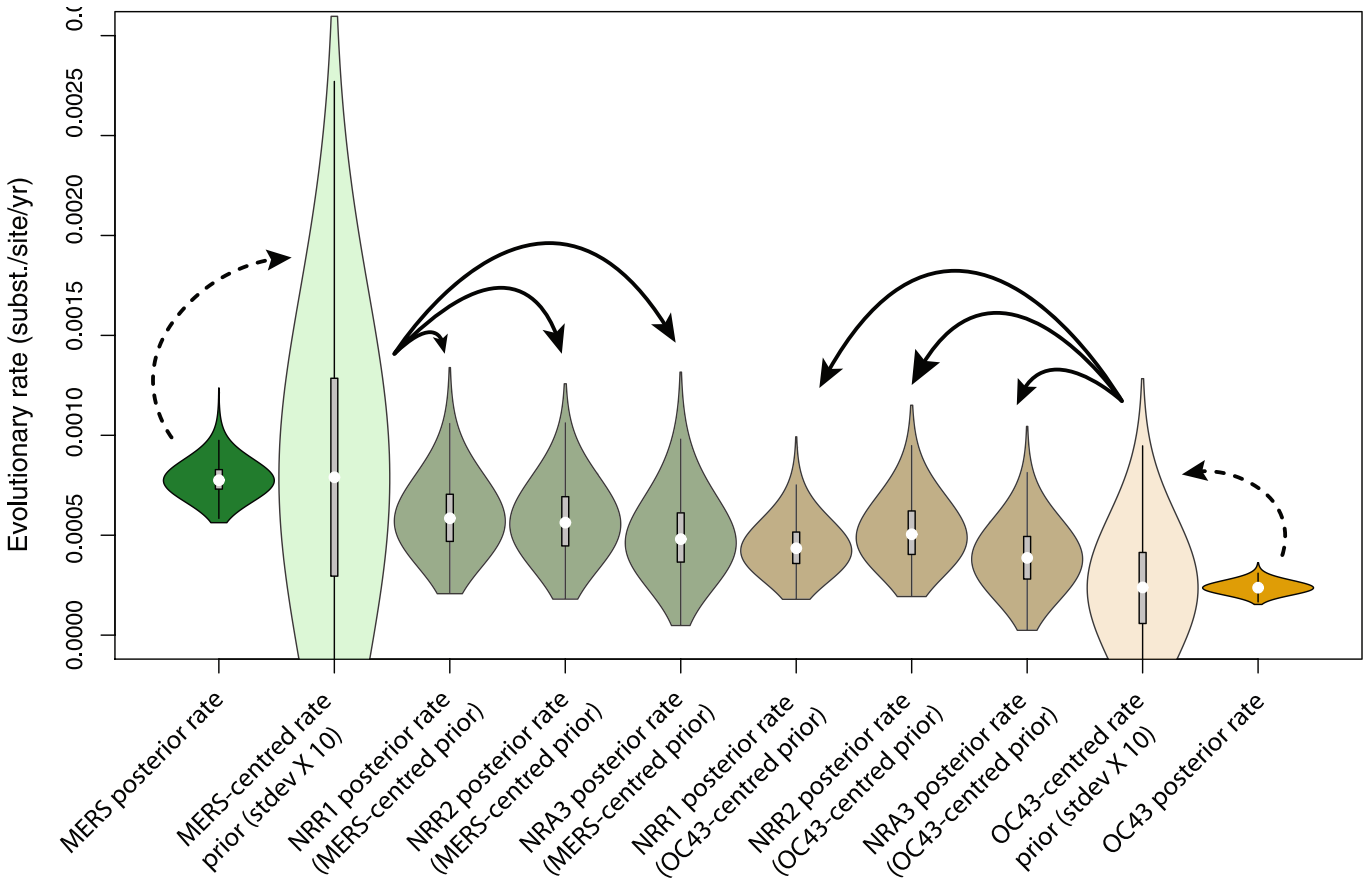
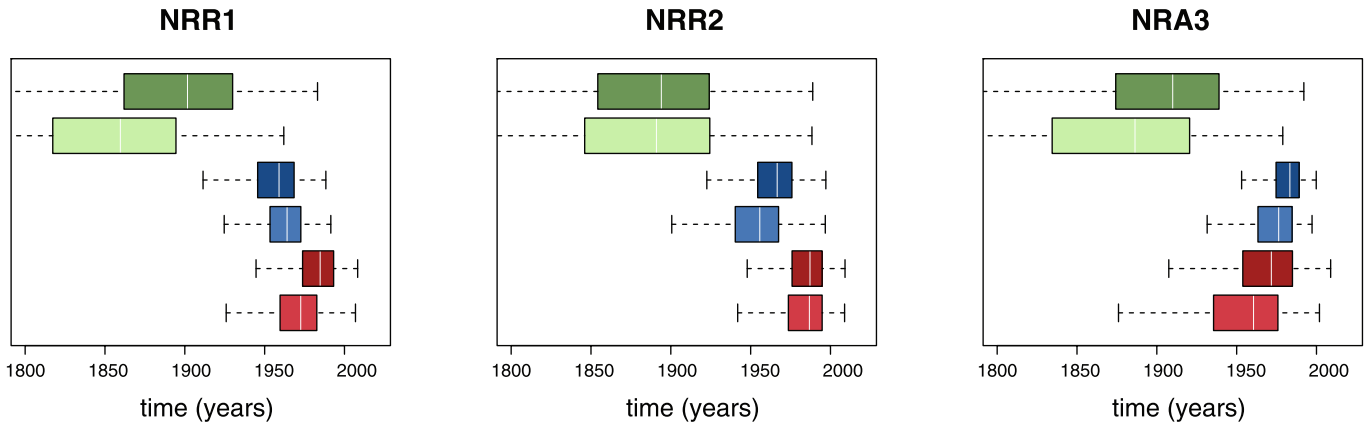
Extended Data Fig. 1 | Phylogenetic relationships in the C-terminal domain (CTD). Posterior means (horizontal bars) of patristic distances between SARS-CoV-2 and its closest bat and pangolin sequences, for the spike protein's variable loop region and CTD region excluding the variable loop. Boxes show 95% HPD credible intervals. Means and 95% HPD intervals are 0.080 [0.058–0.101] and 0.530 [0.304–0.780] for the patristic distances between SARS-CoV-2 and RaTG13 (green) and 0.143 [0.109–0.180] and 0.154 [0.093–0.231] for the patristic distances between SARS-CoV-2 and Pangolin 2019 (orange). Gray inset shows majority rule consensus trees with mean posterior branch lengths for the two regions, with posterior probabilities on the key nodes showing the relationships among SARS-CoV-2, RaTG13, and Pangolin 2019.



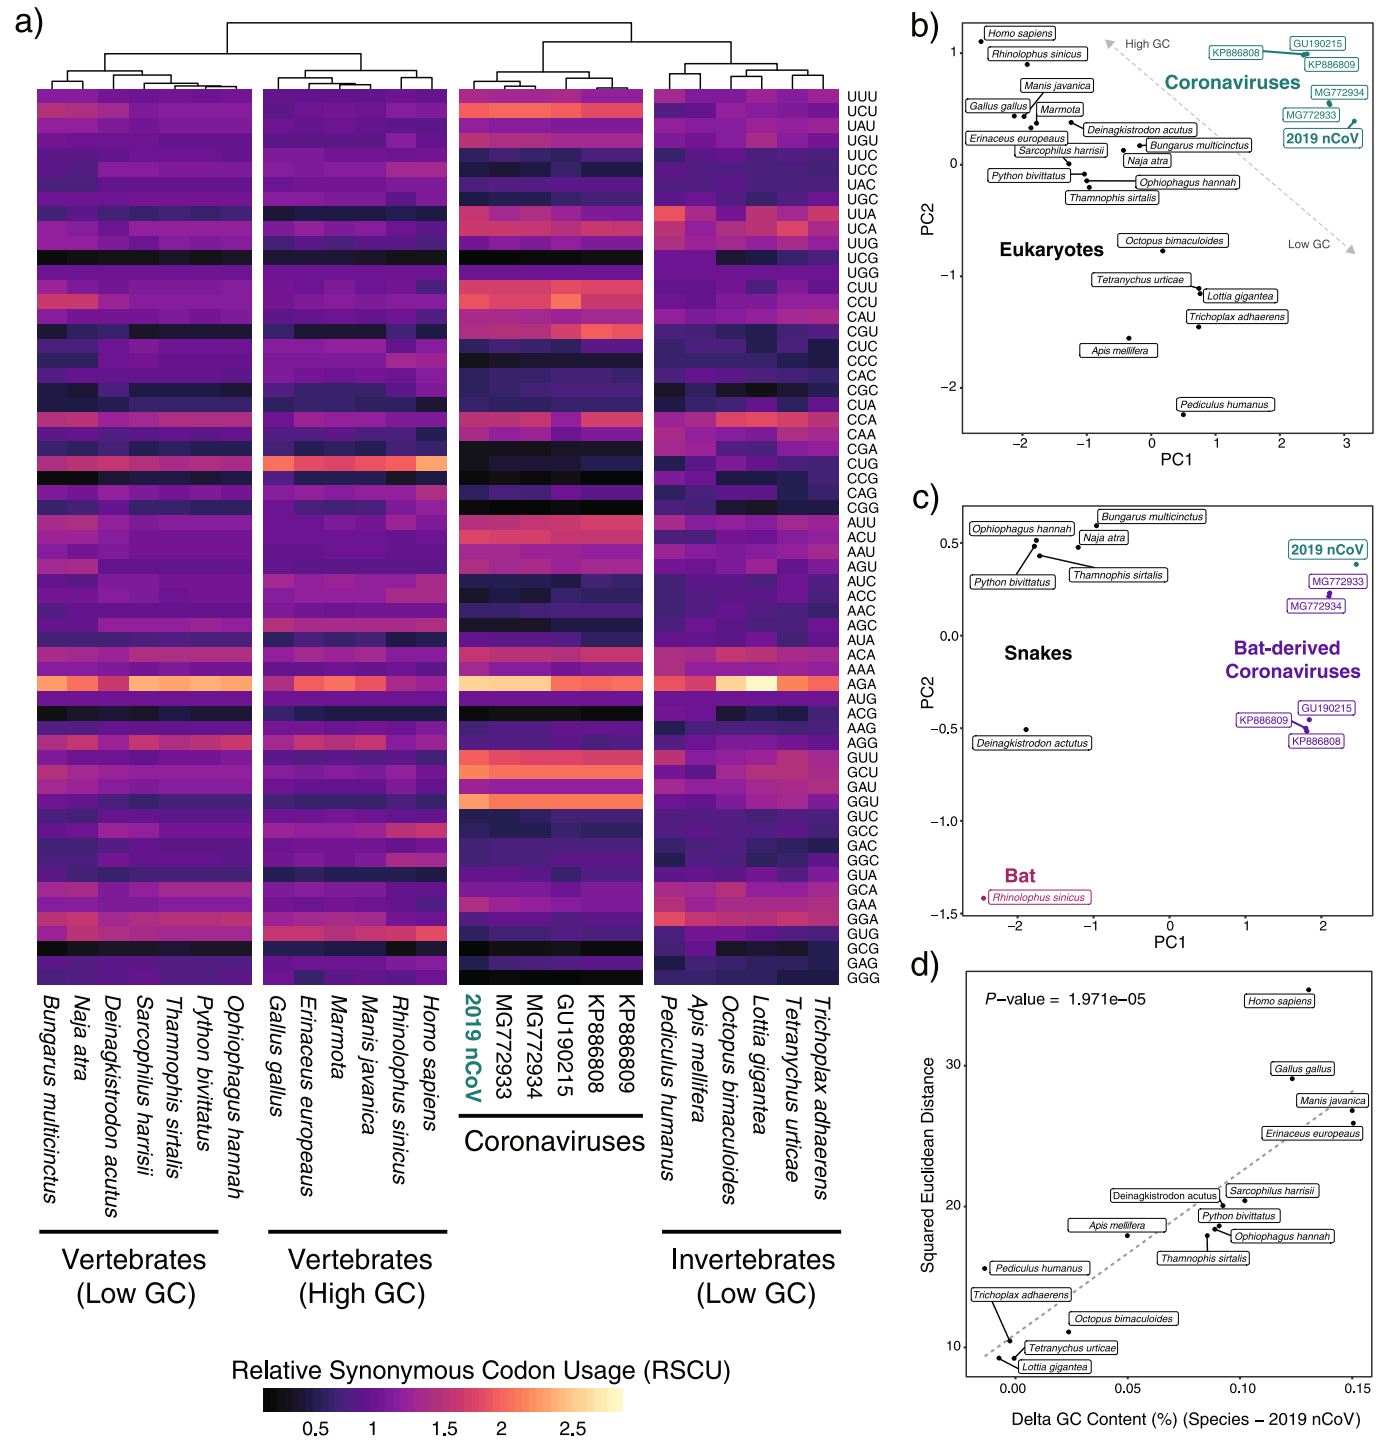
Extended Data Fig. 2 | Lack of root-to-tip temporal signal in SARS-CoV-2. Root-to-tip divergence as a function of sampling time for non-recombinant regions **NRR1** and **NRR2** and recombination-masked alignment set **NRA3**. The plots are based on maximum likelihood tree reconstructions with a root position that maximises the residual mean squared for the regression of root-to-tip divergence and sampling time.



Extended Data Fig. 3 | Priors and posteriors for evolutionary rate of SARS-CoV-2. Posterior rate distributions for MERS-CoV (far left) and HCoV-OC43 (far right) using BEAST on $n = 27$ sequences spread over 4 years (MERS-CoV) and $n = 27$ sequences spread over 49 years (HCoV-OC43). As illustrated by the dashed arrows, these two posteriors motivate our specification of prior distributions with standard deviations inflated 10-fold (light color). These rate priors are subsequently used in the Bayesian inference of posterior rates for **NRR1, NRR2**, and **NRA3** as indicated by the solid arrows.



Extended Data Fig. 4 | TMRCAs for SARS-CoV and SARS-CoV-2. Divergence time estimates based on the three regions/alignments where the effects of recombination have been removed. The red and blue boxplots represent the divergence time estimates for SARS-CoV-2 (red) and the 2002-2003 SARS-CoV (blue) from their most closely related bat virus, with the light- and dark-colored versions based on the HCoV-OC43 and MERS-CoV centered priors, respectively. Green boxplots show the TMRCA estimate for the RaTG13/SARS-CoV-2 lineage and its most closely related pangolin lineage (Guangdong 2019), with the light and dark coloured version based on the HCoV-OC43 and MERS-CoV centred priors, respectively. TMRCA estimates for SARS-CoV-2 and SARS-CoV from their respective most closely related bat lineages are reasonably consistent for the different data sets and different rate priors in our analyses. Posterior means with 95% HPDs are shown in Supplementary Information Table 2.



Extended Data Fig. 5 | Comparisons of GC content across taxa. Conducting analogous analyses of codon usage bias as Ji et al. (2020) with additional (and higher quality) snake coding sequence data and several miscellaneous eukaryotes with low genomic GC content failed to find any meaningful clustering of the SARS-CoV-2 with snake genomes (**a**). Instead, similarity in codon usage metrics between the SARS-CoV-2 and eukaryotes analyzed was correlated with coding sequence GC content of the eukaryote, with more similar codon usage being identified in eukaryotes with low GC content similar to that of the coronavirus (**b**).

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see Authors & Referees and the Editorial Policy Checklist.

Statistics

For all statistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.

n/a	Confirmed
☒	☐ The exact sample size (*n*) for each experimental group/condition, given as a discrete number and unit of measurement
☒	☐ A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
☐	☒ The statistical test(s) used AND whether they are one- or two-sided *Only common tests should be described solely by name; describe more complex techniques in the Methods section.*
☒	☐ A description of all covariates tested
☐	☒ A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
☐	☒ A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
☒	☐ For null hypothesis testing, the test statistic (e.g. *F*, *t*, *r*) with confidence intervals, effect sizes, degrees of freedom and *P* value noted *Give P values as exact values whenever suitable.*
☐	☒ For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
☒	☐ For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
☒	☐ Estimates of effect sizes (e.g. Cohen's *d*, Pearson's *r*), indicating how they were calculated

Our web collection on statistics for biologists contains articles on many of the points above.

Software and code

Policy information about availability of computer code

Data collection	All in Methods section of paper.
Data analysis	Software used: RAxML (v8.2.8), 3SEQ (v1.7), RDP5 (v5), GARD (v2.5.0), BEAST (v1.10.4), BEAGLE (v3), MAFFT (v7.310), Neighbor-Nets (SplitsTree v4.15.1), PHI-Test (SplitsTree v4.15.1), IQTREE (v2.0), TempEst (v1.5.3), Tree Annotator (v1.10.4), FigTree(v1.4.2), Phylogenetic Diversity Analyzer Tool (v0.5), BBMap (v38.75), pheatmap (v1.0.12). All custom code available at https://github.com/plemey/SARSCoV2origins

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors/reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research guidelines for submitting code & software for further information.

Data

Policy information about availability of data

All manuscripts must include a data availability statement. This statement should provide the following information, where applicable:

- All sequence data are available in GenBank and GISAID, with accession numbers listed in Supplementary Table S4.

All sequence data analyzed in this manuscript are available at https://github.com/plemey/SARSCoV2origins. Note that one of the sequences requires GISAID permissions from original authors, but will be made available either individually or publicly depending on original depositor's request.

Field-specific reporting

Please select the one below that is the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

Ecological, evolutionary & environmental sciences study design

All studies must disclose on these points even when the disclosure is negative.

Study description	Sarbecovirus genomes were downloaded from publicly available sources. Non-recombinant regions were identified. Evolutionary rate calibration for coronaviruses was performed using publicly available data sets for SARS, MERS, and OC43. An evolutionary rate was inferred for three putative non-recombinant regions of the sarbecoviruses. Time to the most common ancestor between SARS-CoV-2 and its closest bat-virus relative were computed.
Research sample	All available genomes (n=68) for sarbecoviruses -- including the SARS-CoV-2 genome; 27 genomes of human coronavirus OC43; 35 genomes of MERC-CoV; 69 genomes of SARS-CoV.
Sampling strategy	No sample size calculation was done as it was possible to use all samples (all available sequences) in the analysis.
Data collection	Publicly available sequence data were downloaded from GenBank and GISAID.
Timing and spatial scale	Sarbecovirus genomes were collected over an 18-year period (2002-2020), OC43 sequences from 1968 to 2016, MERS sequences from 2012 to 2015, and SARS-CoV sequences from 2002-2004.
Data exclusions	Sequences without 'sampling year' were excluded. This exclusion criterion was not formally pre-established, but this exclusion is both common and necessary when estimating evolutionary rates from sequence data. It goes without saying that sequences without dates must be excluded.
Reproducibility	N/A;
Randomization	N/A
Blinding	N/A

Paul, C.M. Carlson, H.P. McLaughlin, N. Thornburg, S. Tong, A. Tamin, Y. Tao, A. Uehara, J. Harcourt, S. Clark, C. Brostrom-Smith, L.C. Page, M. Kay, J. Lewis, P. Montgomery, N.D. Stone, T.A. Clark, M.A. Honein, J.S. Duchin, and J.A. Jernigan, for the Public Health–Seattle and King County and CDC COVID-19 Investigation Team*

ABSTRACT

BACKGROUND

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection can spread rapidly within skilled nursing facilities. After identification of a case of Covid-19 in a skilled nursing facility, we assessed transmission and evaluated the adequacy of symptom-based screening to identify infections in residents.

METHODS

We conducted two serial point-prevalence surveys, 1 week apart, in which assenting residents of the facility underwent nasopharyngeal and oropharyngeal testing for SARS-CoV-2, including real-time reverse-transcriptase polymerase chain reaction (rRT-PCR), viral culture, and sequencing. Symptoms that had been present during the preceding 14 days were recorded. Asymptomatic residents who tested positive were reassessed 7 days later. Residents with SARS-CoV-2 infection were categorized as symptomatic with typical symptoms (fever, cough, or shortness of breath), symptomatic with only atypical symptoms, presymptomatic, or asymptomatic.

RESULTS

Twenty-three days after the first positive test result in a resident at this skilled nursing facility, 57 of 89 residents (64%) tested positive for SARS-CoV-2. Among 76 residents who participated in point-prevalence surveys, 48 (63%) tested positive. Of these 48 residents, 27 (56%) were asymptomatic at the time of testing; 24 subsequently developed symptoms (median time to onset, 4 days). Samples from these 24 presymptomatic residents had a median rRT-PCR cycle threshold value of 23.1, and viable virus was recovered from 17 residents. As of April 3, of the 57 residents with SARS-CoV-2 infection, 11 had been hospitalized (3 in the intensive care unit) and 15 had died (mortality, 26%). Of the 34 residents whose specimens were sequenced, 27 (79%) had sequences that fit into two clusters with a difference of one nucleotide.

CONCLUSIONS

Rapid and widespread transmission of SARS-CoV-2 was demonstrated in this skilled nursing facility. More than half of residents with positive test results were asymptomatic at the time of testing and most likely contributed to transmission. Infection-control strategies focused solely on symptomatic residents were not sufficient to prevent transmission after SARS-CoV-2 introduction into this facility.

The first reported case of coronavirus disease 2019 (Covid-19) in the United States was diagnosed in a resident of Snohomish County, Washington, on January 20, 2020.[1] In late February, an outbreak was identified in a skilled nursing facility in neighboring King County; morbidity and mortality among residents were high, straining the regional health care system.[2,3]

We report another outbreak of Covid-19 in a separate skilled nursing facility in the same county. In the course of this outbreak investigation, Public Health–Seattle and King County (PHSKC) and the Centers for Disease Control and Prevention (CDC) identified residents with asymptomatic SARS-CoV-2 infection, which prompted further investigation. We performed serial point-prevalence surveys to assess the extent of transmission and to evaluate the adequacy of symptom-based screening of residents to identify infections. Initial findings of this investigation were previously reported.[4]

Description of the Outbreak

On February 29, 2020, in response to increased local awareness of Covid-19 in King County, Washington, administrative leadership at Facility A instituted enhanced infection-control measures. Nursing staff assessed residents twice daily for possible signs and symptoms of Covid-19, including fever (oral or temporal temperature measurement), cough, shortness of breath, and other symptoms. Health care personnel were assessed at the start of each shift with oral temperature measurement and screening for symptoms, including cough, shortness of breath, sore throat, or any other respiratory symptoms.

On March 1, one member of the health care staff tested positive for SARS-CoV-2 after having worked in a single unit (Unit 1) while symptomatic on February 26, the first day of symptoms, and on February 28. On March 5, the facility was informed that a hospitalized resident of Unit 1 (in whom symptoms had developed on March 2 and testing was done on March 3) had been diagnosed with Covid-19. Subsequently, all visitors were restricted and communal activities were canceled. PHSKC and the CDC initiated an outbreak investigation, and on March 6, provided on-site infection prevention and control recommendations, including the recommendation that all health care staff entering symptomatic residents' rooms wear eye protection, a gown, gloves, and a face mask (N95 respirators were not routinely available).[5] On March 8, the CDC and PHSKC offered testing to all residents in Unit 1; 13 of 15 residents present were tested for SARS-CoV-2 (2 residents declined). A total of 6 residents tested positive; of these, 4 had symptoms (e.g., fever, cough, shortness of breath, or sore throat) and 2 had been asymptomatic during the preceding 14 days. On March 9, the facility implemented Covid-19 transmission-based precautions for all residents of Unit 1, regardless of symptoms or infection status.

Methods

Study Population

Facility A is a 116-bed skilled nursing facility divided into four separate units with an equal mix of short- and long-term residents in each unit. There were 89 residents present at Facility A on March 3, the date of the first positive test in a resident. Facility A provided a list of full-time health care personnel by occupation. Results of positive SARS-CoV-2 tests obtained during postmortem examination or by outside health care providers during clinical evaluation of symptomatic residents and staff were provided to the CDC and PHSKC through March 26. All symptomatic health care personnel were advised to be tested by their health care provider; asymptomatic staff members were not tested as part of this investigation.

Point-Prevalence Surveys

On two occasions, residents in the facility were offered SARS-CoV-2 testing as part of a facility-wide point-prevalence survey. The first survey was performed for all assenting residents, including those who had previously tested positive, on March 13 (10 days after the first resident had tested positive for SARS-CoV-2). Nasopharyngeal and oropharyngeal swabs were collected in accordance with CDC guidelines.[6] A second survey was conducted 7 days later (March 19–20) for residents who had had either a negative test result or a positive result with atypical or no symptoms reported in the first survey.

Symptom Assessment

On the day of point-prevalence surveys, a standardized symptom-assessment form was completed by nurses for each resident tested. Symptoms present during the preceding 14 days were recorded on

The New England Journal of Medicine
Downloaded from nejm.org on January 16, 2021. For personal use only. No other uses without permission.
Copyright © 2020 Massachusetts Medical Society. All rights reserved.

the basis of interview and review of medical records. Asymptomatic residents with a positive test result were reassessed for symptoms 7 days later. For additional details on symptom assessment, see the Supplementary Appendix, available with the full text of this article at NEJM.org.

Residents were classified as symptomatic if they had had at least one new or worsened typical or atypical symptom of Covid-19 in the preceding 14 days. Residents with subjective fever or temperature greater than 100.0°F (37.8°C), cough, or shortness of breath were classified as symptomatic with typical symptoms.[7] Residents were classified as symptomatic with atypical symptoms if their symptoms included only chills, malaise, increased confusion, rhinorrhea, nasal congestion, sore throat, myalgia, dizziness, headache, nausea, or diarrhea.

Asymptomatic residents were those who had no symptoms or only stable chronic symptoms (e.g., chronic cough without worsening). Presymptomatic residents were those who were asymptomatic at the time of testing but developed symptoms within 7 days after testing. Residents who did not develop symptoms in the 7 days after testing remained classified as asymptomatic.

LABORATORY TESTING

The Washington State Public Health Laboratory performed one-step real-time reverse transcriptase–polymerase chain reaction (rRT-PCR) on all samples, using the SARS-CoV-2 CDC assay protocol; cycle threshold (Ct) values were reported for two genetic markers: the N1 and N2 viral nucleocapsid protein gene regions.[8,9] Values below 40 cycles indicate a positive result for SARS-CoV-2.

All rRT-PCR–positive specimens from point-prevalence surveys were shipped to the CDC for viral culture using Vero-CCL-81 cells. Cells showing cytopathic effect were used for SARS-CoV-2 rRT-PCR to confirm isolation and viral growth in culture. Nucleic acid was extracted from rRT-PCR–positive specimens and amplified for subsequent sequencing (Oxford Nanopore MinION), with phylogenetic trees inferred with the neighbor-joining method.[10] Additional details on culture and sequencing methods are provided in the Supplementary Appendix.

ANALYSES

The daily proportions of residents with any known positive test for SARS-CoV-2 (including those tested as part of clinical management) were described according to their unit in the facility. The daily growth rate for the facility was estimated through regression analysis, using the log-transformed daily cumulative counts of all residents who were positive for SARS-CoV-2 from March 3 through March 20; doubling time was estimated by dividing the natural logarithm of 2 by the growth rate. Similarly, doubling time was estimated for all residents of King County, using case count data reported through the PHSKC Covid-19 data dashboard.[11]

All analyses were completed with SAS software, version 9.4 (SAS Institute). Data were collected as part of public health response and were deemed non–human subjects research by the CDC.

RESULTS

RESIDENTS

Of the 89 residents who lived in Facility A when the first resident with confirmed Covid-19 was tested, 57 (64%) had tested positive for SARS-CoV-2 either during the point-prevalence surveys, clinical evaluation, or postmortem examination as of March 26. Seventy-six residents participated in the first point-prevalence survey on March 13 (Fig. 1). Of these 76 residents, 48 (63%) tested positive in either the initial or subsequent point-prevalence surveys. Demographic characteristics, coexisting conditions, and symptoms of surveyed residents were similar, regardless of test result (Table 1).

Of the 48 residents who tested positive from the surveys, 17 (35%) reported typical symptoms, 4 (8%) reported only atypical symptoms, and 27 (56%) reported no new symptoms or changes in chronic symptoms at the time of testing (Table 1 and Table S1). Among the 27 residents classified as asymptomatic, 15 reported no symptoms and 12 reported only stable chronic symptoms. Fifteen (56%) residents who were asymptomatic at the time of testing had documented cognitive impairment; similar proportions were reported in symptomatic residents (Table S2).

In the 7 days after their positive test, 24 of the 27 asymptomatic residents (89%) had onset of symptoms and were recategorized as presymptomatic. The median time to symptom onset was 4 days (interquartile range, 3 to 5). The most common new symptoms were fever (71%), cough (54%), and malaise (42%) (Table S3).

Figure 1 (facing page). Residents in Facility A on March 3 through Two Point-Prevalence Surveys.

Shown are all 89 residents who lived in skilled nursing facility A from March 3, when the first resident tested positive for SARS-CoV-2. By March 13, the date of the first point-prevalence survey, 82 residents remained in the facility, and 76 were tested. By the second point-prevalence survey, 48 of the 76 residents tested in the point-prevalence surveys had been identified as positive. Overall, 57 residents were positive as of March 26. Cycle threshold values were available for 47 residents who tested positive in the point-prevalence surveys on March 13 and March 19–20.

CYCLE THRESHOLD AND VIRAL CULTURE

rRT-PCR Ct values for the N1 genetic markers for 47 residents ranged from 13.7 to 37.9; median Ct values for the four symptom status groups were similar (asymptomatic residents, 25.5; presymptomatic residents, 23.1; residents with atypical symptoms, 24.2; and residents with typical symptoms, 24.8) (Fig. 2). SARS-CoV-2 growth was identified from 31 of 46 rRT-PCR–positive specimens (Fig. 2). Viral growth was observed for specimens obtained from 10 of 16 residents with typical symptoms, 3 of 4 with atypical symptoms, 17 of

Table 1. Demographic Characteristics and Reported Symptoms in Residents of Facility A at the Time of Testing.*

Characteristics	SARS-CoV-2 Test Results	
	Positive† (N=48)	Negative‡ (N=28)
Overall		
Positive result during initial facility-wide cohort testing — no. (%)	23 (48)	—
Mean age (±SD) — yr	78.6±9.5	73.8±11.5
Length of stay at Facility A <90 days before testing — no. (%)	23 (48)	14 (50)
Coexisting conditions — no. (%)		
Any coexisting condition	47 (98)	28 (100)
Chronic lung disease	18 (38)	8 (29)

Cerebrovascular accident	19 (40)	8 (29)
Renal disease	18 (38)	9 (32)
Received hemodialysis	3 (6)	1 (4)
Cognitive impairment	28 (58)	13 (46)
Obesity	11 (23)	6 (21)
Symptoms during the past 14 days — no. (%)		
In symptomatic residents§	21 (44)	11 (39)
At least one typical Covid-19 symptom	17 (35)	8 (29)
Only atypical Covid-19 symptoms	4 (8)	3 (11)
In asymptomatic residents	27 (56)	18 (64)
No symptoms	15 (31)	14 (50)
Only stable, chronic symptoms	12 (25)	3 (11)

* Results include all residents who were present in the facility on March 13 and assented to screening. Facility-wide cohort symptom screens and point-prevalence surveys were performed on March 13 and March 19–20, 2020.

† Residents categorized as positive include those with at least one positive test from facility-wide point-prevalence surveys on March 13 or March 19–20 and one resident who tested negative on March 13 but tested positive before March 13.

‡ Residents categorized as negative include 3 residents who had only one negative swab on March 13 and were not retested.

§ Typical symptoms include fever, cough, and shortness of breath. Atypical symptoms include chills, malaise, sore throat, increased confusion, rhinorrhea or nasal congestion, myalgia, dizziness, headache, nausea, and diarrhea.

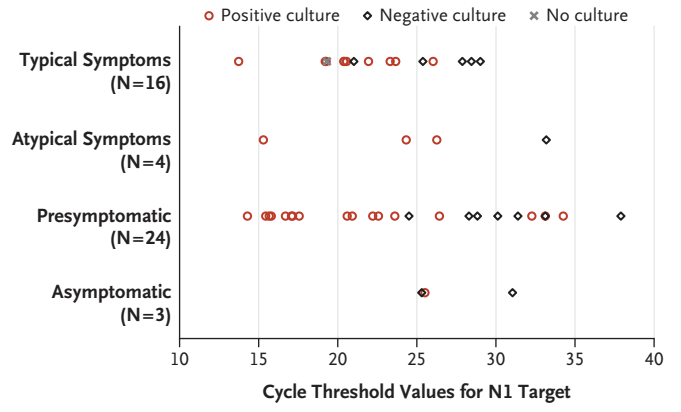

Figure 2. Cycle Threshold Values and Results of Viral Culture for Residents with Positive SARS-CoV-2 Tests According to Their Symptom Status.

Shown are N1 target cycle threshold values and viral culture results for 47 residents' first positive test for SARS-CoV-2 stratified by the resident's symptom status at the time of the test. One positive test was not assessed for culture growth. Typical symptoms include fever, cough, and shortness of breath; atypical symptoms include chills, malaise, increased confusion, rhinorrhea or nasal congestion, myalgia, dizziness, headache, nausea, and diarrhea.

24 who were presymptomatic, and 1 of 3 who remained asymptomatic.

We observed no correlation between Ct values and the number of days from the first evidence of typical symptoms. Ct values consistent with a high viral load were identified among residents who tested positive before typical symptom onset (median Ct value among 26 observations, 24.0; interquartile range, 20.4 to 28.5) and those who tested positive 7 or more days after typical symptom onset (median Ct value among 8 observations, 25.0; interquartile range, 21.3 to 28.2) (Fig. 3, and Fig. S1). Viable virus was isolated from specimens collected 6 days before to 9 days after the first evidence of typical symptoms.

PREVALENCE AND TRANSMISSION IN THE FACILITY

We estimated the doubling time among residents to be 3.4 days (95% confidence interval [CI], 2.5 to 5.3) (Table S4). The doubling time for the surrounding King County was 5.5 days (95% CI, 4.8 to 6.7). As of April 3, a total of 11 of the 57 residents with SARS-CoV-2 infection identified by March 26 had been admitted to the hospital (including 3 in intensive care) and 15 had died (mortality, 26%). The unit where presumed introduction of infection took place and where the first resident with SARS-CoV-2 infection lived (Unit 1) had the highest prevalence in the facility at the end of the first point-prevalence survey. Although other units identified SARS-CoV-2 infection in residents later, their prevalence also continued to increase (Fig. 4, and Fig. S4).

By the time of the first point-prevalence survey, 11 of 138 full-time staff members (8%) had had a positive test for SARS-CoV-2. By March 26,

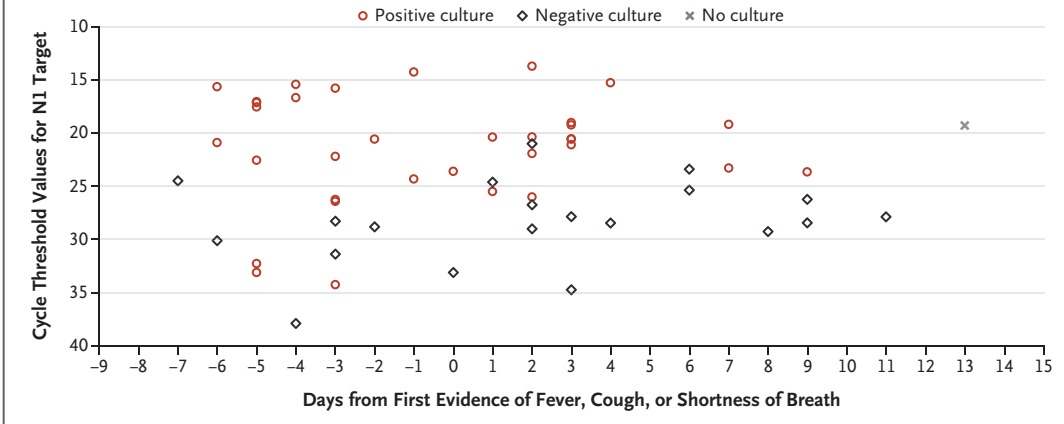

Figure 3. Cycle Threshold Values Relative to First Evidence of Fever, Cough, or Shortness of Breath.

Shown are N1 target cycle threshold values and viral culture results for each resident's positive tests for SARS-CoV-2 shown by day since the first evidence of fever, cough, or shortness of breath (N=55). Dates of onset of typical symptoms were known for 43 residents; 12 residents with two specimens that were positive for SARS-CoV-2 are also included. One positive test was not assessed for culture growth. The relationship between the first test and the second test for residents who had two positive tests is shown in Figure S2.

0101

a total of 55 of the 138 (40%) had reported symptoms, 51 (37%) had been tested, and 26 (19%) had received a positive test result. Of the 26 staff members with positive tests, 17 were nursing staff and 9 had occupations that provided services across multiple units during their shift (therapists, environmental services, dietary services). No staff members with Covid-19 were hospitalized.

Thirty-nine specimens from 34 residents were sequenced. All sequences were identical or highly similar to sequences reported in previous analyses of Covid-19 cases in Washington (Fig. S3). Of the 34 residents whose specimens were sequenced, 27 (79%) had sequences that fit into two clusters with one nucleotide difference (Fig. S4 and Table S5).

DISCUSSION

Twenty-three days after identifying the first resident with SARS-CoV-2 infection, Facility A had a 64% prevalence of Covid-19 among residents, with a case fatality rate of 26% despite early adoption of infection-control measures. In addition, Covid-19 was diagnosed in 26 members of the staff (19%). These findings are strikingly similar to descriptions of the first Covid-19 outbreak in a U.S. skilled nursing facility, which occurred in the same county at nearly the same time.[2] In the investigation reported here, more than half of the residents with positive tests were asymptomatic at the time of testing. Transmission from asymptomatic residents infected with SARS-CoV-2 most likely contributed to the rapid and extensive spread of infection to other residents and staff. Symptom-based infection-control strategies were not sufficient to prevent transmission after the introduction of SARS-CoV-2 into this skilled nursing facility.

Although we are unable to quantify the contributions of asymptomatic and presymptomatic residents to transmission of SARS-CoV-2 in this facility, evidence suggests that these residents had the potential for substantial viral shedding.

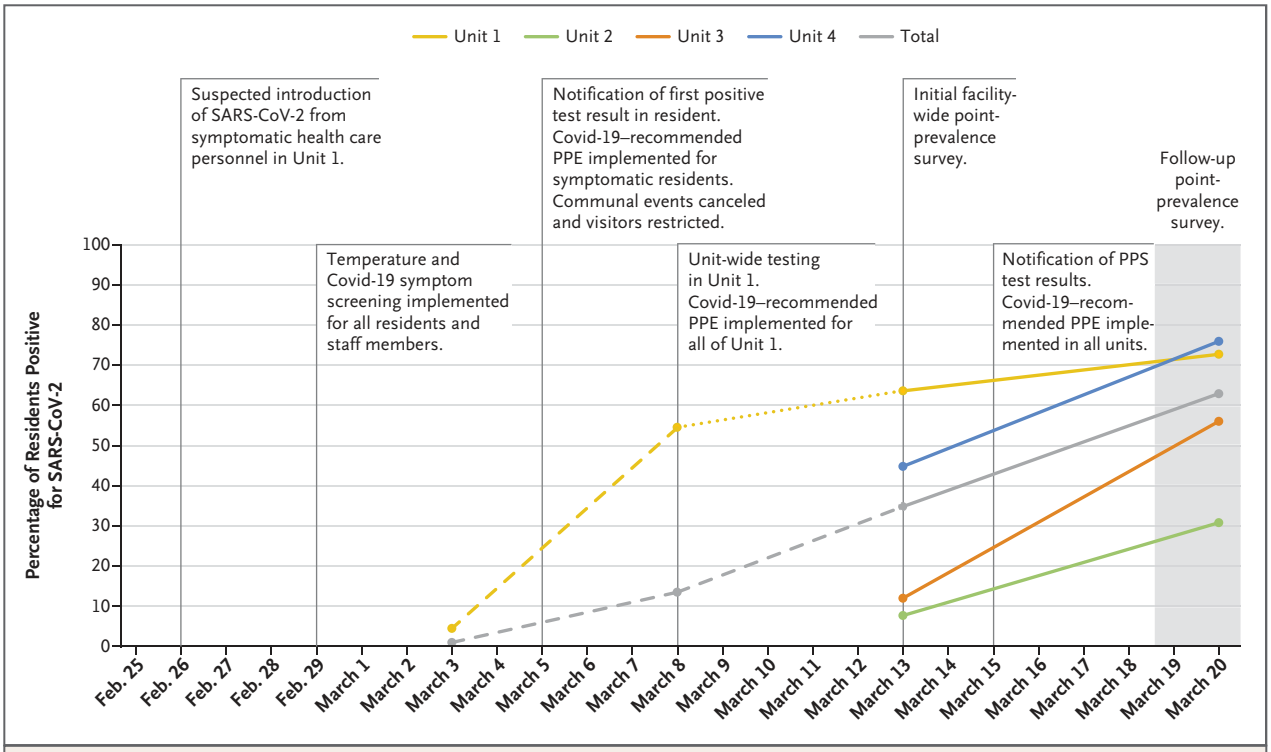

Figure 4. Timeline Showing Prevalence, Notable Events, and Implementation of Infection Prevention and Control Measures at Facility A.
Dashed lines indicate the prevalence of Covid-19 based on test results obtained during clinical evaluation of symptomatic residents before a unit-wide or facility-wide point-prevalence survey (PPS); the dotted line indicates the prevalence based on results from a unit-specific point-prevalence survey; and solid lines indicate the prevalence based on results from clinical evaluation and a facility-wide point-prevalence survey. PPE denotes personal protective equipment.

Ct values indicating large quantities of viral RNA were identified, and viable SARS-CoV-2 was isolated from specimens of asymptomatic and presymptomatic residents. Evidence of transmission from presymptomatic persons has been shown in epidemiologic investigations of SARS-CoV-2.[12-14]

We estimated that the doubling time in this facility was 3.4 days, which is faster than that of the surrounding community, 5.5 days. The accelerated doubling time was likely to have been due to inadequately controlled intrafacility transmission, which sequencing and spatiotemporal data suggest was the primary driver of new infections. Shedding of high viral titers from the respiratory tract, including shedding before the onset of symptoms, might have led to droplet and possibly aerosol transmission. Residents and staff members with undetected SARS-CoV-2 infection are likely to have contributed to transmission through interactions between and among residents and staff. The contribution of indirect contact transmission in this outbreak is not known. However, contaminated environmental surfaces and shared medical devices could also have played a role. Most of the early transmission appeared to have occurred in Unit 1, where the initial introduction of SARS-CoV-2 took place, several days before other units were involved. Early recognition of initial SARS-CoV-2 introduction combined with early interventions in all units might prevent spread within a facility.

The CDC and PHSKC confirmed Covid-19 infection in 26 symptomatic staff members associated with this skilled nursing facility as of March 26; these staff members most likely contributed to intrafacility transmission. A concurrent study of King County health care personnel with Covid-19 showed that 65% worked while symptomatic and that 17% of symptomatic health care personnel initially had mild, nonspecific symptoms and no fever, cough, shortness of breath, or sore throat.[15] The potential for viral shedding from staff members with SARS-CoV-2 infection during either the presymptomatic or the mildly symptomatic phase of the illness reinforces current recommendations for expanded symptom screening for health care personnel and universal use of face masks for all health care staff in long-term care facilities.[5]

Current interventions for preventing SARS-CoV-2 transmission in health care settings rely primarily on the presence of signs and symptoms to identify and isolate residents and staff who might have Covid-19. The data presented here suggest that sole reliance on symptom-based strategies may not be effective to prevent introduction of SARS-CoV-2 and further transmission in skilled nursing facilities. Impaired immune responses associated with aging and the high prevalence of underlying conditions, such as cognitive impairment and chronic cough, make it difficult to recognize early signs and symptoms of respiratory viral infections in this population.[16] Studies have shown that in the elderly, including those living in skilled nursing facilities, influenza often manifests with few or atypical symptoms, delaying diagnosis and contributing to transmission.[17,18] Furthermore, symptom-based cohorting strategies could inadvertently increase the risk of SARS-CoV-2 exposure for uninfected residents, given that typical symptoms were common in those who tested negative.

Our investigation demonstrated a poor correlation between symptom onset and viral shedding that was potentially due to the difficulty of ascertaining precise dates of symptom onset or to differences in viral shedding in this population. Studies in other populations show that SARS-CoV-2 shedding is highest early in the illness.[19,20] Our investigation shows that some facility residents shed virus for more than 7 days after symptom onset, a finding seen in some other populations.[21] These data support current recommendations preferring a test-based strategy to discontinue transmission-based precautions for residents of skilled nursing facilities.[22] If a non–test-based strategy is used, these data support extending the duration of transmission-based precautions.[22]

Because asymptomatic or presymptomatic residents might play an important role in transmission in this high-risk population, additional prevention measures merit consideration, including using testing to guide the use of transmission-based precautions, isolation, and cohorting strategies. The ability to test large numbers of residents and staff with rapid turn-around times may expedite cohorting of residents and staff in locations designated for the care of those with SARS-CoV-2 infection either in different locations within individual facilities or in separate facilities.

This investigation has several limitations. First, challenges in symptom ascertainment may

The New England Journal of Medicine
Downloaded from nejm.org on January 16, 2021. For personal use only. No other uses without permission.
Copyright © 2020 Massachusetts Medical Society. All rights reserved.

have resulted in misclassification of symptom grouping for some residents. However, multiple sources of symptom data were used to minimize such misclassification. The accuracy of symptom ascertainment for this investigation is likely to be equivalent to, if not exceed, symptom screening in most skilled nursing facilities, and thus, these findings should be generalizable to this setting. Second, because this analysis was conducted among residents of a skilled nursing facility, it is not known whether the findings apply to the general population, including younger persons, those without underlying medical conditions, or similarly aged populations in the general community or in other long-term care settings. Third, asymptomatic staff members were not tested; therefore, we are unable to document their role in transmission in this facility.

SARS-CoV-2 can spread rapidly after introduction into skilled nursing facilities, resulting in substantial morbidity and mortality and increasing the burden on regional health care systems. Unrecognized asymptomatic and presymptomatic infections most likely contribute to transmission in these settings. During the current Covid-19 pandemic, skilled nursing facilities and all long-term care facilities should take proactive steps to prevent introduction of SARS-CoV-2. These steps include restricting visitors and nonessential personnel from entering the building, requiring universal use of face masks by all staff for source control while in the facility, and implementing strict screening of staff. Our data suggest that symptom-based strategies for identifying residents with SARS-CoV-2 are insufficient for preventing transmission in skilled nursing facilities. Once SARS-CoV-2 has been introduced, additional strategies should be implemented to prevent further transmission, including use of recommended personal protective equipment, when available, during all resident care activities regardless of symptoms.[5] Consideration should be given to test-based strategies for identifying residents and staff with SARS-CoV-2 infection for the purpose of excluding infected staff and cohorting residents, either in designated units within a facility or in a separate facility designated for residents with Covid-19.

The findings and conclusion in this report are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention.

ORIGINAL ARTICLE

An Outbreak of Covid-19 on an Aircraft Carrier

Matthew R. Kasper, Ph.D., Jesse R. Geibe, M.D., Christine L. Sears, M.D., Asha J. Riegodedios, M.S.P.H., Tina Luse, M.P.H., Annette M. Von Thun, M.D., Michael B. McGinnis, M.D., Niels Olson, M.D., Daniel Houskamp, M.D., Robert Fenequito, M.D., Timothy H. Burgess, M.D., Adam W. Armstrong, M.D., Gerald DeLong, Ph.D., Robert J. Hawkins, Ph.D., and Bruce L. Gillingham, M.D.

ABSTRACT

BACKGROUND

An outbreak of coronavirus disease 2019 (Covid-19) occurred on the U.S.S. *Theodore Roosevelt*, a nuclear-powered aircraft carrier with a crew of 4779 personnel.

METHODS

We obtained clinical and demographic data for all crew members, including results of testing by real-time reverse-transcriptase polymerase chain reaction (rRT-PCR). All crew members were followed up for a minimum of 10 weeks, regardless of test results or the absence of symptoms.

RESULTS

The crew was predominantly young (mean age, 27 years) and was in general good health, meeting U.S. Navy standards for sea duty. Over the course of the outbreak, 1271 crew members (26.6% of the crew) tested positive for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection by rRT-PCR testing, and more than 1000 infections were identified within 5 weeks after the first laboratory-confirmed infection. An additional 60 crew members had suspected Covid-19 (i.e., illness that met Council of State and Territorial Epidemiologists clinical criteria for Covid-19 without a positive test result). Among the crew members with laboratory-confirmed infection, 76.9% (978 of 1271) had no symptoms at the time that they tested positive and 55.0% had symptoms develop at any time during the clinical course. Among the 1331 crew members with suspected or confirmed Covid-19, 23 (1.7%) were hospitalized, 4 (0.3%) received intensive care, and 1 died. Crew members who worked in confined spaces appeared more likely to become infected.

CONCLUSIONS

SARS-CoV-2 spread quickly among the crew of the U.S.S. *Theodore Roosevelt*. Transmission was facilitated by close-quarters conditions and by asymptomatic and presymptomatic infected crew members. Nearly half of those who tested positive for the virus never had symptoms.

0106

The U.S.S. *THEODORE ROOSEVELT* was conducting operations in the western Pacific Ocean when an outbreak of infection with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) occurred on board. On identification of the outbreak, the ship was diverted to U.S. Naval Base Guam. The base hospital, a 42-bed inpatient facility, provides medical care for U.S. military beneficiaries and others in the region. Although the initial response was handled by the medical staffs of the ship and Naval Hospital Guam, it was quickly augmented by a joint medical task force.

This report provides key findings from the U.S. Navy response and epidemiologic investigation of the outbreak. Over the course of the response, every member of the crew of the U.S.S. *Theodore Roosevelt* was evaluated, tested, placed in isolation or quarantine, and monitored on a daily basis to ensure their well-being. Our findings offer insights into the epidemiology and outcomes of SARS-CoV-2 infection in healthy, fit, military-aged adults who are housed in close quarters.

METHODS

INITIAL RESPONSE TO THE OUTBREAK AND FOLLOW-UP

The ship had been at sea for 13 days when three crew members presented to the medical department with symptoms suggestive of coronavirus disease 2019 (Covid-19). All three underwent testing by real-time reverse-transcriptase polymerase chain reaction (rRT-PCR) and were found to be positive for SARS-CoV-2. Over the next 24 hours, additional symptomatic crew members and approximately 400 close contacts were identified by contact tracing. Four days after the first positive test result was reported, the ship reached Naval Base Guam. Crew members with confirmed cases of Covid-19 were placed in isolation on Naval Base Guam or in the base hospital. Persons with one or more negative Covid-19 tests and no symptoms were quarantined in hotels off base or on Naval Base Guam. In addition, essential personnel who were uninfected stayed aboard the ship in port.

All members of the crew underwent screening for signs and symptoms of Covid-19 and testing by rRT-PCR. Those who tested positive for SARS-CoV-2 were placed in isolation and received twice-daily symptom, temperature, and pulse oximetry checks. Those who tested negative were placed in quarantine. Ultimately, 4079 SARS-CoV-2–negative crew members who did not have symptoms were quarantined in 11 hotels in Guam. All were placed in single-occupancy rooms.

A surveillance model was implemented that relied on in-person health screenings. These screenings were supplemented by self-reporting with the use of a symptom checker developed by Defense Digital Service. Health screenings and symptom-checker data were collated and analyzed each morning by 9 a.m. and again in the evening by 9 p.m. Crew members who had progressive symptoms or were deemed to have conditions potentially placing them at higher risk for poorer outcomes were followed up with additional screening. Any crew members who were determined by on-site medical providers to need closer observation or treatment were transported to Naval Hospital Guam for care. In addition to Covid-19–related health surveillance, crew members received primary care, pharmacy, and psychiatric services to ensure a complete scope of medical coverage.

On completion of prespecified periods of isolation or quarantine, all personnel were required to undergo repeat rRT-PCR testing. To be eligible for exit testing, a crew member had to remain in isolation or quarantine for a minimum of 14 days. Those in isolation were also required to be symptom-free for 3 days before exit testing. Any crew member in quarantine in whom symptoms developed was tested and moved to isolation for at least 14 additional days. All crew members were followed up for a minimum of 10 weeks, regardless of their Covid-19 status.

LABORATORY TESTING

Nasopharyngeal swab specimens were obtained from all members of the crew with the use of viral transport medium swab kits. The presence of SARS-CoV-2 infection was determined by rRT-PCR testing with the Thermo Fisher ABI 7500 or the Bio-Rad CFX96 Touch Real-Time PCR Detection System. Samples were processed with either the Qiagen QIAamp Viral RNA Mini Kit or the Roche MagNA Pure 96 instrument for automated nucleic acid extraction, and testing was performed with the Seegene Allplex 2019-nCOV assay test kit or the Centers for Disease Control

and Prevention (CDC) emergency-use-authorization assay.[1] These assays included the detection of two targets in the nucleocapsid gene, N1 and N2. Surveillance testing for influenza-like illness was conducted with the Biofire Respiratory 2 Panel.

COLLECTION OF OUTBREAK DATA

The Navy and Marine Corps Public Health Center was tasked with providing public health support for the outbreak investigation and conducting data analysis in alignment with its core public health mission. Data were collected as part of a coordinated public health outbreak investigation conducted by the Navy to bring the outbreak under control, ensure the well-being of the crew, assess the spread and effects of SARS-CoV-2, and implement measures to return the crew to work safely. Under Navy public health support criteria, the intent of the outbreak investigation was to mitigate spread, inform decision making, gather information for use in other outbreaks, and decrease the effect on the health of the crew. This project was deemed to be nonresearch with respect to the use of human subject information and was exempt from review by the institutional review board as an emergency public health outbreak investigation.

A roster of Electronic Data Interchange Personal Identifiers for the shipboard population was matched to Defense Manpower Data Center personnel rosters from February 2020 to identify demographic information for each crew member and to confirm personal identifiers. Civilian personnel and anyone with an Electronic Data Interchange Personal Identifier that did not match with Defense Manpower Data Center were excluded from analysis. The Defense Enrollment Eligibility Reporting System was used to identify race and ethnic group for all crew members. Ages of crew members at time of the outbreak were calculated from the date of birth to March 3, 2020.

Medical surveillance data collected by the ship medical department, Naval Hospital Guam, and the joint medical task force were collated with the roster to create a data set that included dates of symptom onset, daily clinical signs and symptoms, and test results. Data from the Defense Digital Service MySymptoms symptom-tracker application were also collated into the final data set. For the purpose of this analysis, fever is defined as subjective fever reported by the crew member or a measured temperature of 100.0°F or higher. All other symptoms were reported by the crew members. Data on health-related factors were obtained from a number of existing clinical Military Health System data sources, including the Armed Forces Health Longitudinal Technology Application and Military Health System Genesis.

A confirmed case of Covid-19 was defined as one in which a nasopharyngeal swab specimen was positive for SARS-CoV-2 by rRT-PCR. A suspected case of Covid-19 was defined as one that met Council of State and Territorial Epidemiologists clinical criteria for Covid-19 without a positive test result. Confirmed cases were further classified as symptomatic (with symptom onset before the first positive laboratory test), presymptomatic (with the first positive laboratory test before subsequent symptom onset), and asymptomatic (positive laboratory test but clinical criteria never met). Patients with confirmed or suspected infection were classified as having been hospitalized for Covid-19 if the admission diagnosis suggested a Covid-19–related illness.

STATISTICAL ANALYSIS

Data collation and analysis were performed with the use of SAS software, version 9.4 (SAS Institute). Baseline characteristics among crew members who were infected and those who were not infected were compared and univariate odds ratios with 95% confidence intervals were calculated with OpenEpi (www.openepi.com). For denominators of less than 20, odds ratios were not calculated. All reported odds ratios are not adjusted for multiple comparisons.

RESULTS

TIMELINE OF THE OUTBREAK

Between March 23 and May 18, 2020, a total of 1271 crew members (26.6% of the crew) tested positive for SARS-CoV-2. An additional 60 crew members had suspected Covid-19 (Fig. 1). Of the 1271 crew members with laboratory-confirmed Covid-19, 572 (43.0%) remained asymptomatic throughout the outbreak, 293 (22.0%) were symptomatic at the time that they tested positive, and an additional 406 (30.5%) were presymptomatic at the time that they tested positive. In all, 978 (76.9%) of the 1271 crew members with labora-

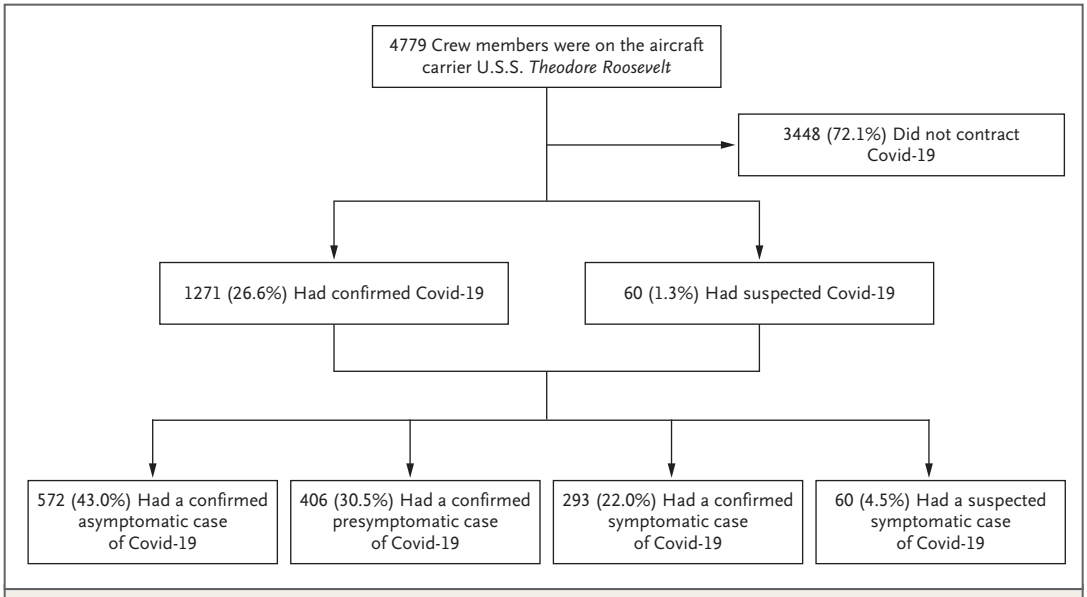

Figure 1. Distribution of Personnel According to Case Status.

A confirmed case of coronavirus disease 2019 (Covid-19) was defined as one in which a nasopharyngeal swab specimen was positive for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) by real-time reverse-transcriptase polymerase chain reaction. A suspected case was defined as one that met Council of State and Territorial Epidemiologists clinical criteria for Covid-19 without a positive test result. Confirmed cases were further classified as symptomatic (with symptom onset before the first positive laboratory test), presymptomatic (with the first positive laboratory test before subsequent symptom onset), and asymptomatic (positive laboratory test but clinical criteria never met).

tory-confirmed Covid-19 did not have symptoms at the time that they tested positive, and 699 (55.0%) had symptoms develop at any time during the clinical course.

Testing for influenza-like illnesses had been conducted on a limited number of specimens before and after the start of the outbreak. Testing of specimens obtained from 5 crew members during the week before the outbreak identified 3 crew members who were positive for human rhinovirus or enterovirus, 1 who was positive for respiratory syncytial virus (RSV), and 1 with no pathogens detected. After the outbreak was identified on March 23, specimens from 16 crew members were tested: 10 crew members had no pathogens detected, 3 were positive for human rhinovirus or enterovirus, 2 were positive for coronavirus OC43 (not SARS-CoV-2), and 1 was positive for both human rhinovirus or enterovirus and RSV.

The outbreak epidemic curve is shown in Figure 2. In retrospect, crew members with symptomatic confirmed or suspected Covid-19 had symptoms as early as March 11, 2020, and continued to receive diagnoses up to the end of the analysis period. Epidemic curves according to sex and crew type show parallel infection rates for men and women. Although the ship docked in Guam on March 27, 2020, the outbreak continued for at least an additional 6 weeks.

CHARACTERISTICS OF THE CREW MEMBERS

The crew was predominantly young (mean age, 27 years) and male (78.3%) and was racially and ethnically diverse. At the time of deployment, all crew members were in general good health and met the U.S. Navy standards for sea duty. Ultimately, Covid-19 cases were evenly distributed across sexes, races and ethnic groups, and crew types (Table 1). Enlisted personnel (90% of the shipboard population) appeared more likely than officers to have confirmed or suspected Covid-19.

Data were analyzed to identify higher-risk work spaces. Those working in tighter spaces (e.g., reactor, engineering, supply, and weapons

Personnel, supplies, and mail are delivered to an aircraft carrier during carrier onboard delivery (COD).

departments) appeared more likely to have confirmed or suspected Covid-19 than those working in a combination of open-air and confined conditions (e.g., air and deck crew). Members of the medical department, who wore personal protective equipment when evaluating crew members, had a somewhat lower attack rate (16.7% [8 cases among 48 personnel) than the overall crew, despite being at highest risk as a result of exposure to patients with Covid-19 in a small space.

SYMPTOMS AND CARE

Among the crew members who had symptomatic Covid-19 (confirmed or suspected), headache was the most common symptom reported at any point during illness (occurring in 68.0%), followed by cough (59.5%), nasal or sinus congestion (43.8%), and altered sense of taste or smell (42.3%) (Fig. 3). The predominant symptoms reported at the onset of illness were cough (32.8%), headache (31.0%), and altered sense of taste or smell (24.1%). Shortness of breath at any point during illness was reported by 20.3% of the crew members with symptomatic cases, and 7.0% noted shortness of breath as an initial presenting symptom. In addition, 26.2% of the crew members with symptomatic Covid-19 reported chest pain or chest pressure at some point during their illness. Fever was reported as an initial presenting symptom by 5.3% of the crew members with symptomatic Covid-19, and fever at any point during illness was reported by 13.2%. Measured temperature readings showed that 2.8% of the crew members who had Covid-19 had a recorded temperature of 100.0°F or above, as compared with 0.3% of the crew members who did not have Covid-19. Among the crew members with Covid-19 for whom pulse oximetry data were available, approximately 0.5% had readings below 95% while breathing ambient air, with 0.08% below 94% and none below 90%.

Of the 1271 crew members who tested positive for SARS-CoV-2 plus the 60 who had suspected Covid-19, 23 (1.7%) received hospital care, for a mean of 16 days after symptom onset. Four crew members (0.3% of those with suspected or laboratory-confirmed Covid-19) were admitted to the intensive care unit, 1 of whom died from Covid-19–related cardiovascular complications. Before hospitalization, crew mem-

* Percentages may not total 100 because of rounding. Covid-19 denotes coronavirus disease 2019.
† The Defense Enrollment Eligibility Reporting System was used to identify race and ethnic group for all crew members.
‡ Augmented crew reside on the ship only at certain times when a ship is under way and provide specialized capability such as air squadrons, submarine groups, destroyer squadrons, and helicopter maritime strike squadrons.
§ Crew members in the departments of reactor, engineering, supply, weapons and in the combat support division tend to work in more confined spaces than those in the air and deck departments. Crew members in the air and deck departments tend to work in a combination of open-air and confined conditions. Medical personnel work in confined spaces but wear personal protective equipment when caring for crew members.
¶ Underweight was defined as a body-mass index (BMI, the weight in kilograms divided by the square of the height in meters) of less than 18.5; normal or healthy weight, 18.5 to 24.9; overweight, 25.0 to 29.9; and obese, 30 or higher.
‖ Conditions were identified from October 1, 2017, through March 1, 2020, with the use of the following data sources: Theater Medical Data Store, Comprehensive Ambulatory/Professional Encounter Record, Standard Inpatient Data Record, Armed Forces Health Longitudinal Technology Application Clinical Data Repository, Military Health System (MHS) GENESIS, TRICARE Encounter Data, and Periodic Health Assessment.

bers with Covid-19 who became hospitalized were more likely to report cough (68%), body aches (58%), and fever (32%) than those who did not. One third of hospitalized patients reported fever before their hospitalization, as compared with 12% of nonhospitalized crew members with Covid-19. During the outbreak, as a precautionary measure, admission criteria were revised to permit hospitalization of crew members with less severe symptoms.

DISCUSSION

The epidemiology of SARS-CoV-2 infection in young, healthy populations has not been studied extensively.[2] The outbreak of Covid-19 on the U.S.S. *Theodore Roosevelt* provided an unusual opportunity to assess an outbreak in a predominantly young, healthy, working-age population. Approximately 69% of crew members were younger than 30 years of age, and no crew member was older than 65 years. All were up to date with their immunizations. Over the course of the outbreak and the subsequent response by the U.S. Navy, every crew member underwent evaluation, testing, and follow-up. This level of controlled evaluation and documentation is difficult to achieve in civilian populations.

On ships at sea, respiratory viruses such as influenza and enteric pathogens such as norovirus can spread quickly.[3,4] In the early weeks of the pandemic, several outbreaks of Covid-19 occurred on cruise ships, most notably on the *Diamond Princess*.[5,6] The medical department of a ship can be overwhelmed quickly by a major outbreak of disease, as is similarly seen with health care fa-

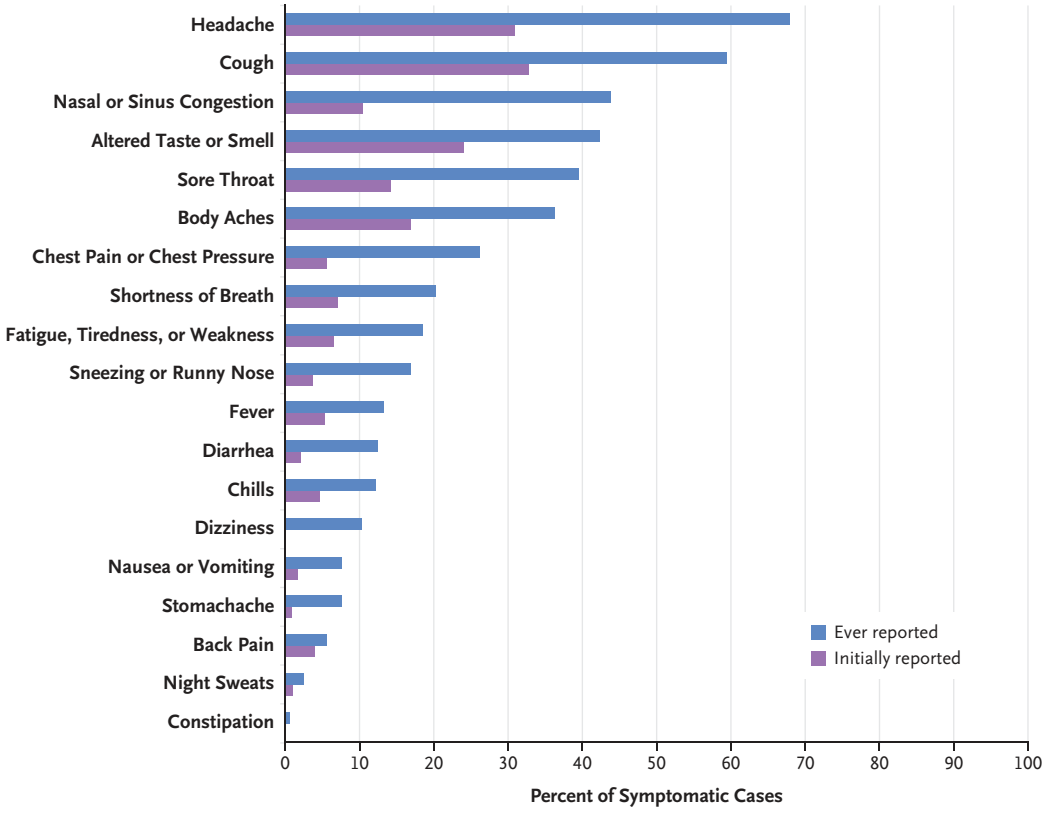

Figure 3. Distribution of Symptomatic Confirmed or Suspected Covid-19 Cases According to Symptoms.

cilities in civilian communities.[7] The shipboard environment on naval vessels is generally more confined. Typically, enlisted crew members sleep in open bays packed with dozens of tightly spaced bunks, work in densely populated areas, and congregate in gathering points such as the gyms and galleys (Figs. S1 and S2 in the Supplementary Appendix, available with the full text of this article at NEJM.org). These conditions probably facilitated the transmission of SARS-CoV-2, as evidenced by the higher likelihood of Covid-19 among enlisted crew members than among officers (Table 1).

Not surprisingly, crew members working in the engine room and other confined areas of the ship faced a higher risk of being infected than their shipmates on deck. A study conducted by the Navy and Marine Corps Public Health Center and the CDC, involving 384 volunteer U.S.S. *Theodore Roosevelt* crew members, showed similar results: those working in confined spaces had higher odds of contracting Covid-19.[8] A majority of infected crew members did not note symptoms at the time that Covid-19 was diagnosed by rRT-PCR testing. In addition, crew members with unusual or atypical symptoms may not have considered themselves to be infected with SARS-CoV-2.[9] These observations suggest that nonsymptomatic or mildly symptomatic crew members played an important role in the rapid spread of the outbreak, much as young adults with asymptomatic infection appear to contribute to spread in civilian populations.[10,11]

Although cases of serious illness occur in younger persons, they are less frequent and typically less severe than those in older persons.[9,11] In the case of the U.S.S. *Theodore Roosevelt*, few crew members were hospitalized. Certain coexisting conditions, such as hypertension, obesity, and diabetes, are associated with higher mortality.[12-14] In our findings, we noted a number of coexisting conditions among hospitalized crew members,

including uncomplicated, mild, and medically managed asthma, lung disease (e.g., bronchitis), hypertension, and liver disease–related conditions.

Although we were able to confirm the outcomes in all infected crew members, data collection was limited by the quality of records, particularly those generated in the early days of the outbreak. Future studies involving longitudinal cohorts may provide greater insight into the epidemiology of SARS-CoV-2 infection in young adults. Our observations within a military population may not be fully generalizable to civilians. The CDC case definition for Covid-19, along with clinical criteria, changed over time (e.g., the outbreak began in March 2020, and the CDC-published case definition for Covid-19 changed in April 2020). Multiplex testing by polymerase chain reaction identified other causes of influenza-like illness on board the ship. Any effect that the case definition or other respiratory pathogens may have had on classifying a case of Covid-19 is limited, because the majority of cases were confirmed by rRT-PCR testing. Finally, the crew of the U.S.S. *Theodore Roosevelt*, like all members of the U.S. military forces, have equal access to health care. This is not true for all civilians in the United States.

Since this outbreak occurred, the U.S. Navy has incorporated lessons learned to enhance the safety and readiness of its crews. To minimize the risk of deploying with asymptomatic carriers of SARS-CoV-2 on board, the Navy has initiated several procedures to create and sustain Covid-19–free environments on its ships. Before deployment, all members of a ship's crew are placed in "restriction of movement" and insulated from community exposure for 14 days. To identify asymptomatic or presymptomatic carriers, the Navy added rRT-PCR testing at the end of the "restriction of movement" period. Navy ships have sharply reduced shore leaves at foreign ports to prevent crew members from bringing the virus on board. Since these policies (along with preventive measures of mask use, social distancing to the extent possible, small-group cohorting, strict hand hygiene, and regular cleaning of common spaces) were put in place, the Navy has deployed multiple ships without sustaining another serious outbreak. The concept of creating virus-free "bubbles" is a strategy the Navy has used and has been mirrored by the National Basketball Association and Major League Soccer to enable competition while minimizing the risk of player exposure. It is unlikely that this strategy is practical for all employers, much less the general population; however, creating bubbles or cohorts for select populations may be achievable.

Organizations seeking to safeguard their employees, customers, patients, or students may benefit from assuming that Covid-19 will be introduced into their populations and rigorously enforcing measures to minimize viral transmission by all, since persons may be unaware that they are infected.

CLINICAL PRACTICE

Caren G. Solomon, M.D., M.P.H., *Editor*

Severe Covid-19

David A. Berlin, M.D., Roy M. Gulick, M.D., M.P.H., and Fernando J. Martinez, M.D.

This Journal *feature begins with a case vignette highlighting a common clinical problem. Evidence supporting various strategies is then presented, followed by a review of formal guidelines, when they exist. The article ends with the authors' clinical recommendations.*

A 50-year-old, previously healthy man presents to the emergency department with 2 days of worsening dyspnea. He had fever, cough, and fatigue during the week before presentation. He appears acutely ill. The body temperature is 39.5°C (103°F), heart rate 110 beats per minute, respiratory rate 24 breaths per minute, and blood pressure 130/60 mm Hg. The oxygen saturation is 87% while the patient is breathing ambient air. The white-cell count is 7300 per microliter with lymphopenia. Chest radiography shows patchy bilateral opacities in the lung parenchyma. A reverse-transcriptase–polymerase-chain-reaction assay detects the presence of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) RNA in a nasopharyngeal swab. How would you evaluate and manage this case?

THE CLINICAL PROBLEM

The most common initial symptoms of coronavirus disease 2019 (Covid-19) are cough, fever, fatigue, headache, myalgias, and diarrhea.[1] Severe illness usually begins approximately 1 week after the onset of symptoms. Dyspnea is the most common symptom of severe disease and is often accompanied by hypoxemia[2,3] (Fig. 1). Progressive respiratory failure develops in many patients with severe Covid-19 soon after the onset of dyspnea and hypoxemia. These patients commonly meet the criteria for the acute respiratory distress syndrome (ARDS), which is defined as the acute onset of bilateral infiltrates, severe hypoxemia, and lung edema that is not fully explained by cardiac failure or fluid overload.[4] The majority of patients with severe Covid-19 have lymphopenia,[5] and some have thromboembolic complications[6] as well as disorders of the central or peripheral nervous system.[7] Severe Covid-19 may also lead to acute cardiac, kidney, and liver injury, in addition to cardiac arrhythmias, rhabdomyolysis, coagulopathy, and shock.[8,9] These organ failures may be associated with clinical and laboratory signs of inflammation, including high fevers, thrombocytopenia, hyperferritinemia, and elevations in C-reactive protein and interleukin-6.[10]

The diagnosis of Covid-19 can be established on the basis of a suggestive clinical history and the detection of SARS-CoV-2 RNA in respiratory secretions. Chest radiography should be performed and commonly shows bilateral consolidations or ground-glass opacities[11] (Fig. 2).

For epidemiologic purposes, severe Covid-19 in adults is defined as dyspnea, a respiratory rate of 30 or more breaths per minute, a blood oxygen saturation of 93% or less, a ratio of the partial pressure of arterial oxygen to the fraction of inspired oxygen (Pao_2:Fio_2) of less than 300 mm Hg, or infiltrates in more than 50%

KEY CLINICAL POINTS

EVALUATION AND MANAGEMENT OF SEVERE COVID-19

- Patients with severe coronavirus disease 2019 (Covid-19) may become critically ill with acute respiratory distress syndrome that typically begins approximately 1 week after the onset of symptoms.
- Deciding when a patient with severe Covid-19 should receive endotracheal intubation is an essential component of care.
- After intubation, patients should receive lung-protective ventilation with plateau pressure less than or equal to 30 cm of water and with tidal volumes based on the patient's height.
- Prone positioning is a potential treatment strategy for refractory hypoxemia.
- Thrombosis and renal failure are well-recognized complications of severe Covid-19.
- Dexamethasone has been shown to reduce mortality among hospitalized patients with Covid-19 who require oxygen, particularly those receiving mechanical ventilation.
- Remdesivir was recently approved by the Food and Drug Administration for the treatment of Covid-19 in hospitalized patients, on the basis of randomized trials showing that the drug reduces time to clinical recovery; however, more data are needed to inform its role in treating severe Covid-19.

of the lung field.[12] In a large cohort of symptomatic patients with Covid-19 described early in the pandemic, 81% had mild disease, 14% had severe disease, and 5% became critically ill with organ failure; the mortality in the critically ill group was 49%.[12]

Healthy persons of any age may become critically ill with Covid-19. However, age is the most important risk factor for death or critical illness, and the risk increases with each additional decade.[13] People with chronic health conditions such as cardiovascular disease, diabetes mellitus, immunosuppression, and obesity are more likely to become critically ill from Covid-19. Severe disease is more common among men than among women. The risk is also increased among certain racial and ethnic groups such as Black and Hispanic persons in the United States.[14] The social determinants of health probably have a strong influence on the risk of severe disease.[13] A hallmark of the Covid-19 pandemic is the sudden appearance of an unprecedented number of critically ill patients in a small geographic area.[12] This can overwhelm local health care resources, resulting in shortages of trained staff, ventilators, renal-replacement therapy, and intensive care unit beds.

STRATEGIES

INITIAL STEPS

Patients with severe Covid-19 should be hospitalized for careful monitoring. Given the high risk of nosocomial spread,[3] strict infection-control procedures are needed at all times. If able, the patient should wear a surgical mask to limit the dispersion of infectious droplets.[15] Clinicians should don appropriate personal protective equipment (PPE) as defined by their local infection-prevention program, using particular caution when performing procedures that may increase the generation or dispersion of infectious aerosols. These include endotracheal intubation, extubation, bronchoscopy, airway suctioning, nebulization of medication, the use of high-flow nasal cannulae, noninvasive ventilation, and manual ventilation with a bag-mask device.[16] Current guidelines recommend that clinicians wear gowns, gloves, N95 masks, and eye protection at the least and place patients in negative-pressure rooms whenever possible during aerosol-generating procedures.[17]

Patients with severe Covid-19 have a substantial risk of prolonged critical illness and death. Therefore, at the earliest opportunity, clinicians should partner with patients by reviewing advanced directives, identifying surrogate medical decision makers, and establishing appropriate goals of care. Because infection-control measures during the pandemic may prevent families from visiting seriously ill patients, care teams should develop plans to communicate with patients' families and surrogate decision makers.

BASICS OF RESPIRATORY CARE

Patients should be monitored carefully by direct observation and pulse oximetry. Oxygen should be supplemented by the use of a nasal cannula or Venturi mask to keep the oxygen saturation of hemoglobin between 90 and 96%.[17] Deciding whether or not to intubate is a critical aspect of caring for seriously ill patients with Covid-19. Clinicians must weigh the risks of premature

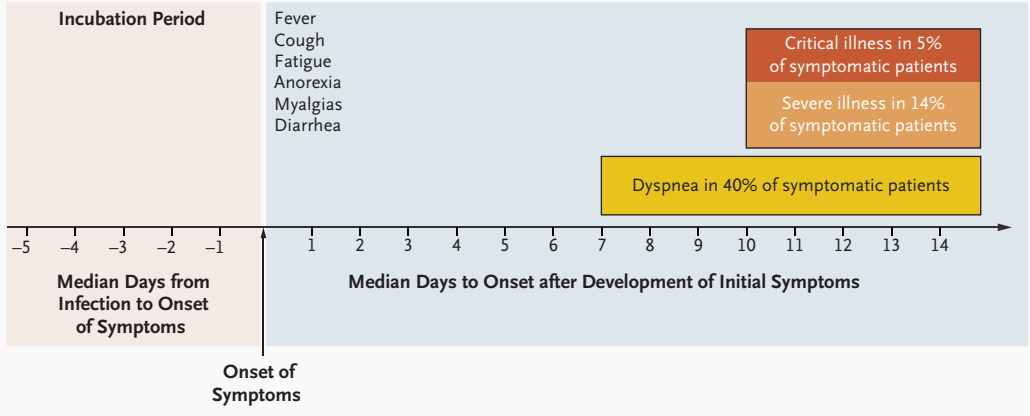

Figure 1. Timeline of Symptoms of Severe Coronavirus Disease 2019 (Covid-19).

The left border of the colored boxes shows the median time to onset of symptoms and complications. There is wide variation in the duration of symptoms and complications. Adapted from Zhou et al.[2] and the Centers for Disease Control and Prevention.[1]

intubation against the risk of sudden respiratory arrest with a chaotic emergency intubation, which exposes staff to a greater risk of infection. Signs of excessive effort in breathing, hypoxemia that is refractory to oxygen supplementation, and encephalopathy herald impending respiratory arrest and the need for urgent endotracheal intubation and mechanical ventilation. There is no single number or algorithm that determines the need for intubation, and clinicians must consider a variety of factors (Fig. 3A).

If the patient does not require intubation but remains hypoxemic, a high-flow nasal cannula can improve oxygenation and may prevent intubation in selected patients.[17,18] The use of noninvasive positive-pressure ventilation should probably be restricted to patients with Covid-19 who have respiratory insufficiency due to chronic obstructive pulmonary disease, cardiogenic pulmonary edema, or obstructive sleep apnea rather than ARDS. Patients treated with a high-flow nasal cannula or noninvasive ventilation require careful monitoring for deterioration that would indicate the need for invasive mechanical ventilation.[18]

Having awake patients turn to the prone position while they breathe high concentrations of supplemental oxygen may improve oxygenation in patients with severe Covid-19. This approach is supported by data from prospective cohorts describing its use in nonintubated patients with severe hypoxemia.[19] However, whether prone positioning can prevent intubation in patients with severe Covid-19 is unclear. Because it is difficult to provide rescue ventilation to patients who are prone, this position should be avoided in patients whose condition is rapidly deteriorating.

ENDOTRACHEAL INTUBATION

A skilled operator should perform endotracheal intubation in patients with severe Covid-19. The use of unfamiliar PPE, the risk of infection to staff, and the presence of severe hypoxemia in patients all increase the difficulty of intubation. If possible, intubation should be performed after preoxygenation and rapid-sequence induction of sedation and neuromuscular blockade. An antiviral filter should be placed in line with the airway circuit at all times. Video laryngoscopy may allow the operator to have a good view of the airway from a greater distance.[20] However, operators should choose the technique that is most likely to be successful on the first attempt. Continuous-wave capnography is the best method to confirm tracheal intubation.[20] Patients with severe Covid-19 often become hypotensive soon after intubation owing to positive-pressure ventilation and systemic vasodilation from sedatives.[20] Therefore, intravenous fluids and vasopressors should be immediately available at the time of intubation, and careful hemodynamic monitoring is essential.[20]

VENTILATOR MANAGEMENT

It is unclear whether Covid-19 is associated with a distinct form of ARDS that would benefit from

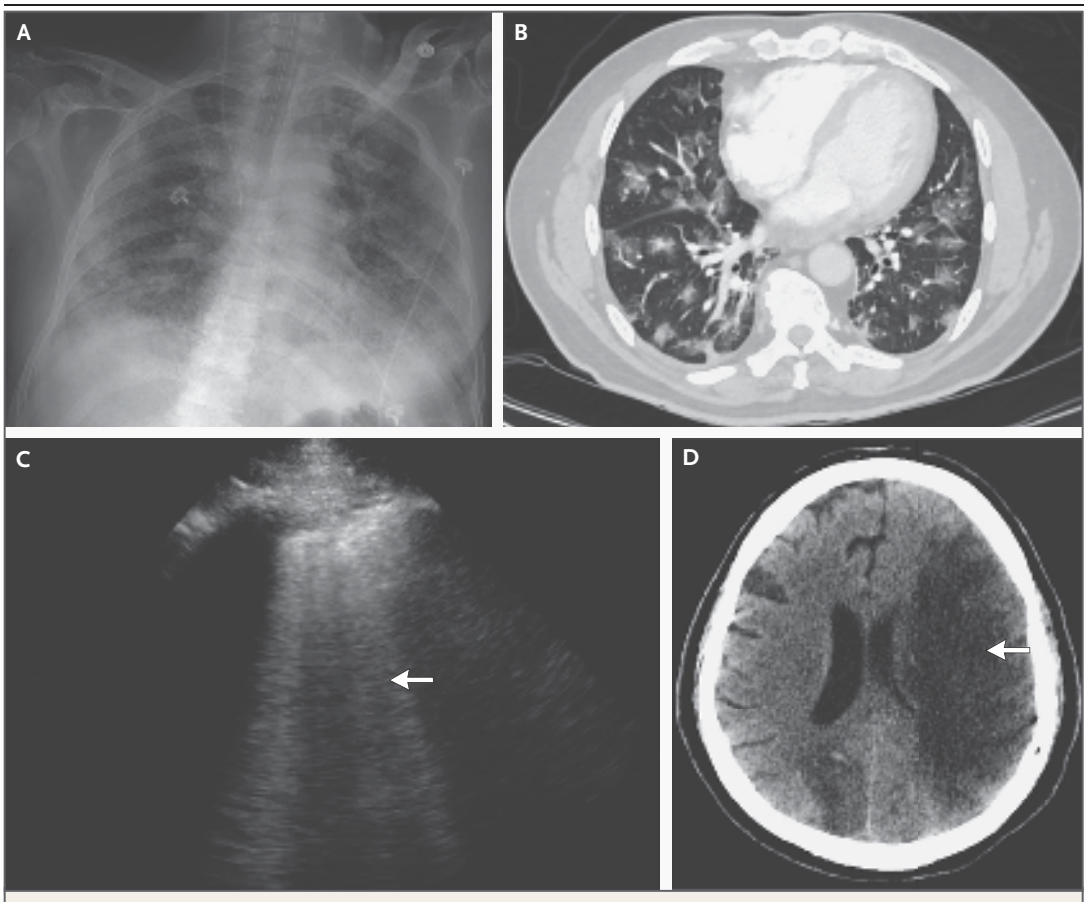

Figure 2. Radiographic and Ultrasonographic Findings of Severe Covid-19.

Chest radiography (Panel A) shows bilateral ground-glass opacities and consolidations. Computed tomography (CT) of the chest (Panel B) shows bilateral ground-glass opacities. Thoracic ultrasonography (Panel C) shows B lines (arrow); this image is courtesy of Dr. Christopher Parkhurst. CT of the head (Panel D) shows left-greater-than-right cerebral infarcts (arrow).

a new strategy of mechanical ventilation. However, most autopsies performed on patients with severe Covid-19 reveal the presence of diffuse alveolar damage, which is the hallmark of ARDS.[21] Moreover, respiratory-system compliance and gas exchange in patients with respiratory failure from severe Covid-19 are similar to those in populations enrolled in previous therapeutic trials for ARDS.[22] Therefore, clinicians should follow the treatment paradigm developed during the past two decades for ARDS (Fig. 3B).[17,18] This strategy aims to prevent ventilator-induced lung injury by avoiding alveolar overdistention, hyperoxia, and cyclical alveolar collapse.

To prevent alveolar overdistention, clinicians should limit both the tidal volume delivered by the ventilator and the maximum pressure in the alveoli at the end of inspiration. To do this, clinicians should set the ventilator to deliver a tidal volume of 6 ml per kilogram of predicted body weight; this approach is termed "lung-protective ventilation." A tidal volume up to 8 ml per kilogram of predicted body weight is allowed if the patient becomes distressed and attempts to take larger tidal volumes. A few times each day, clinicians should initiate a half-second end-inspiratory pause, which allows the pressure in the airway circuit to equilibrate between the patient and the ventilator. The pressure in the airway circuit at the end of the pause — "the plateau pressure" — approximates the alveolar pressure (relative

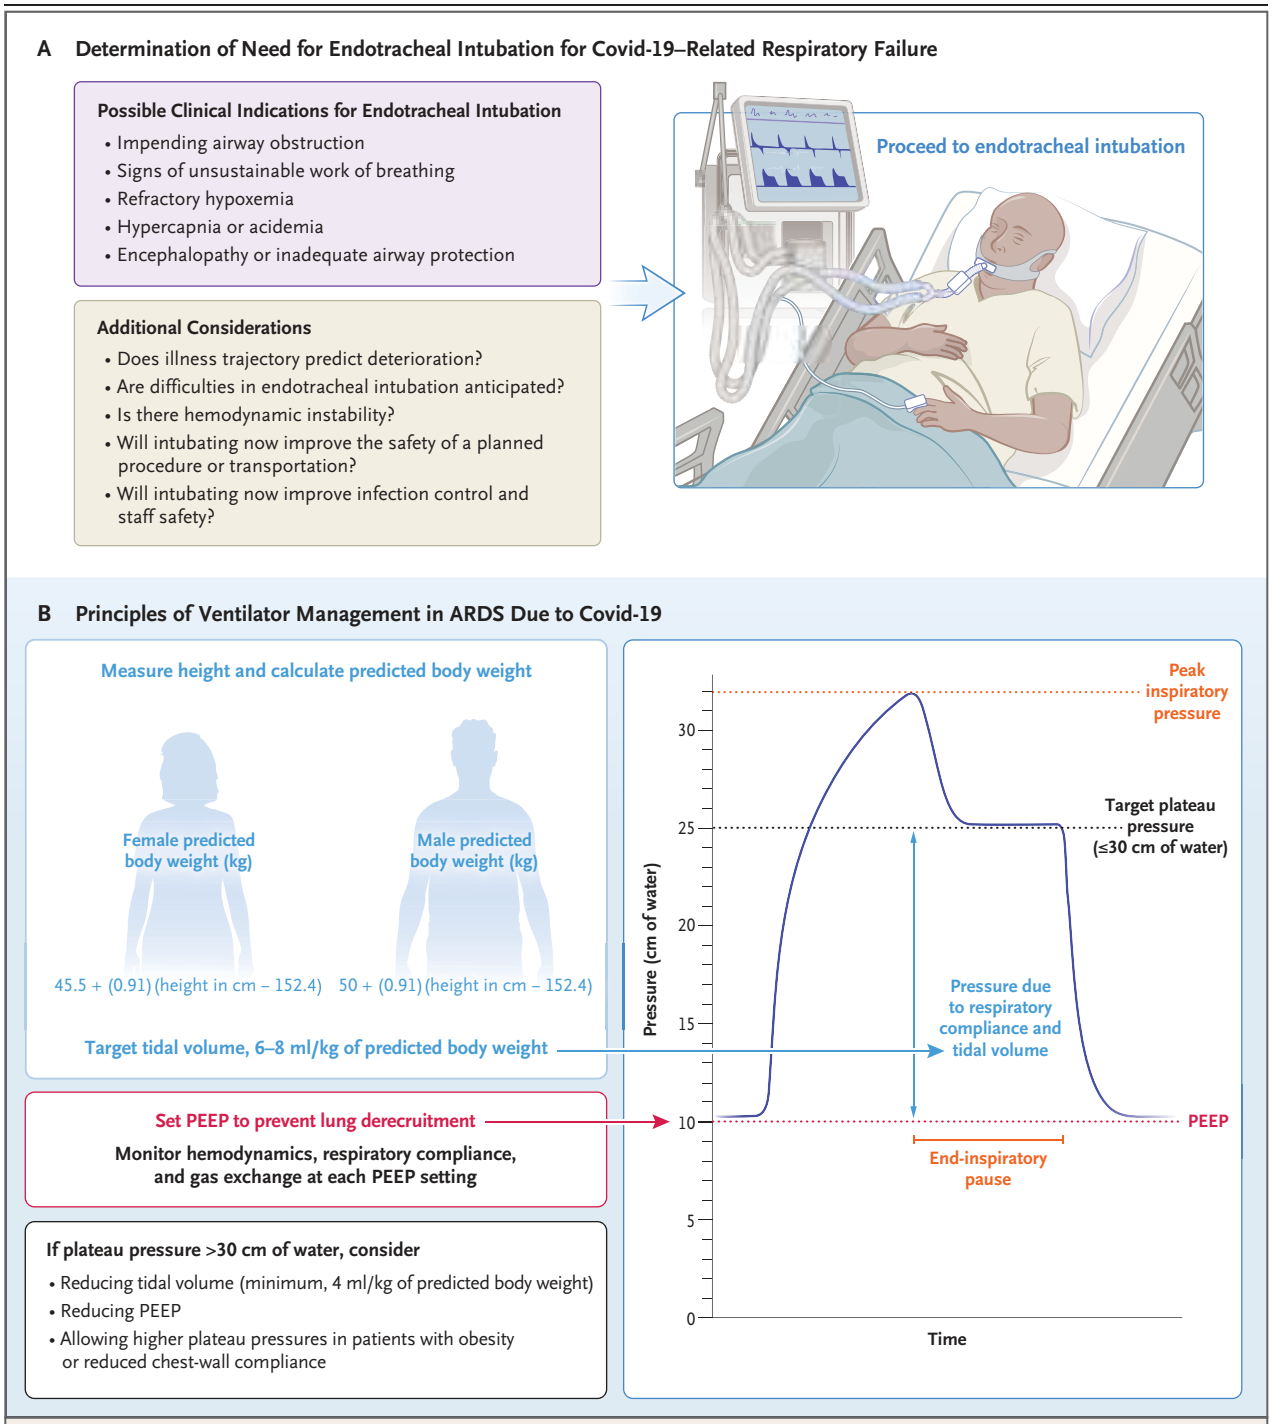

Figure 3. Invasive Mechanical Ventilation for Covid-19–Related Respiratory Failure.

As shown in Panel A, a life-threatening problem in the purple box or a combination of less severe problems in the purple and tan boxes determines the need for endotracheal intubation. In Panel B, "lung derecruitment" refers to the collapse of alveoli. All pressures are measured in the ventilator circuit and referenced to atmospheric pressure. ARDS denotes acute respiratory distress syndrome, and PEEP positive end-expiratory pressure.

Copyright © 2020 Massachusetts Medical Society. All rights reserved.

to atmospheric pressure). To prevent alveolar overdistention, the plateau pressure should not exceed 30 cm of water.[23] A higher plateau pressure without the development of ventilator-induced lung injury may be possible in patients with central obesity or noncompliant chest walls.

For patients with Covid-19–related ARDS, setting sufficient positive end-expiratory pressure (PEEP) on the ventilator may prevent alveolar collapse and facilitate the recruitment of unstable lung regions. As a result, PEEP can improve respiratory-system compliance and allow for a reduction in the F_{IO_2}. However, PEEP can reduce venous return to the heart and cause hemodynamic instability. Moreover, excessive PEEP can lead to alveolar overdistention and reduce respiratory-system compliance. No particular method of determining the appropriate level of PEEP has been shown to be superior to other methods.[17]

Sedatives and analgesics should be targeted to prevent pain, distress, and dyspnea. They can also be used to blunt the patient's respiratory drive, which improves patient synchrony with mechanical ventilation. Sedation is especially important in febrile patients with high metabolic rates who are treated with lung-protective ventilation. Neuromuscular blocking agents can be used in deeply sedated patients who continue to use their accessory muscles of ventilation and have refractory hypoxemia.[17] These agents can reduce the work of breathing, which reduces oxygen consumption and carbon dioxide production.[24] Moreover, sedatives and neuromuscular blocking agents may help reduce the risk of lung injury that may occur when patients generate strong spontaneous respiratory efforts.

REFRACTORY HYPOXEMIA

Clinicians should consider prone positioning during mechanical ventilation in patients with refractory hypoxemia (P_{aO_2}:F_{IO_2} of <150 mm Hg during respiration and F_{IO_2} of 0.6 despite appropriate PEEP). In randomized trials involving intubated patients with ARDS (not associated with Covid-19), placing the patient in the prone position for 16 hours per day has improved oxygenation and reduced mortality.[18,25] However, prone positioning of patients requires a team of at least three trained clinicians, all of whom require full PPE.[17] Inhaled pulmonary vasodilators (e.g., inhaled nitric oxide) can also improve oxygenation in refractory respiratory failure, although they do not improve survival in ARDS not associated with Covid-19.[17] Extracorporeal membrane oxygenation (ECMO) is a potential rescue strategy in patients with refractory respiratory failure. Clinicians should carefully balance possible benefits with risks (e.g., bleeding) as well as the resources available during the pandemic.[26]

THERAPY

A large, randomized clinical trial involving more than 6400 hospitalized patients with Covid-19 showed that dexamethasone significantly reduced 30-day mortality (17% reduction); benefit was limited to patients who required oxygen supplementation and appeared greater in patients receiving mechanical ventilation.[27] Consequently, dexamethasone (or potentially other glucocorticoids) is now considered the standard of care for patients with severe Covid-19.

Data from a randomized, placebo-controlled trial involving more than 1000 patients with severe Covid-19 showed that the antiviral agent remdesivir reduced time to clinical recovery; the benefit appeared greatest in patients who were receiving supplemental oxygen but were not intubated.[28] The 29-day mortality in that trial was 11.4% with remdesivir and 15.2% with placebo (hazard ratio for death, 0.73; 95% confidence interval, 0.52 to 1.03). These data support the Food and Drug Administration (FDA) approval of remdesivir for the treatment of hospitalized patients with Covid-19 in October 2020. Recent preliminary results of a large, multinational, open-label, randomized trial did not show a reduction in in-hospital mortality with use of remdesivir.[29] The combination of dexamethasone and remdesivir is increasingly used clinically, but its benefit has not been shown in randomized clinical trials. Tocilizumab, an interleukin-6 inhibitor, did not significantly reduce disease progression[30] or death in small randomized trials involving patients with severe Covid-19.[31,32]

SUPPORTIVE CARE

Patients with Covid-19 often present with volume depletion and receive isotonic-fluid resuscitation. Volume repletion helps maintain blood pressure and cardiac output during intubation and positive-pressure ventilation. After the first few days of mechanical ventilation, the goal should be to avoid hypervolemia.[33] Fever and tachypnea in patients with severe Covid-19 often

The New England Journal of Medicine

increase insensible water loss, and careful attention must be paid to water balance. If the patient is hypotensive, the dose of vasopressor can be adjusted to maintain a mean arterial pressure of 60 to 65 mm Hg.[17] Norepinephrine is the preferred vasopressor. The presence of unexplained hemodynamic instability should prompt consideration of myocardial ischemia, myocarditis, or pulmonary embolism.

In case series, approximately 5% of patients with severe Covid-19 have received renal-replacement therapy[34]; the pathophysiology of the renal failure is currently unclear but is probably multifactorial. Because blood clotting in the circuit is common in patients with severe Covid-19,[6] the efficacy of continuous renal-replacement therapy is uncertain.

Abnormalities of the clotting cascade, such as thrombocytopenia and elevation of D-dimer levels, are common in patients with severe Covid-19 and are associated with increased mortality.[3] If there are no contraindications, patients should receive standard thromboprophylaxis (e.g., subcutaneous low-molecular-weight heparin).[35] Some case series of patients with severe Covid-19 have shown clinically significant thrombosis despite the use of thromboprophylaxis.[6] However, the benefits and risks of the routine use of more intense prophylactic anticoagulation in patients are unknown.[35]

Patients hospitalized with severe Covid-19 are often treated empirically with antibiotics.[3,9] However, bacterial coinfection is rare when immunocompetent patients first present to the hospital.[36] Antibiotics can be discontinued after a short course if signs of bacterial coinfection, such as leukocytosis and focal pulmonary infiltrates, are absent.[18] Although Covid-19 itself can cause prolonged fever,[2] clinicians should be vigilant for nosocomial infections.

Performing cardiopulmonary resuscitation in patients with Covid-19 may expose health care workers to infectious droplets and aerosols. Therefore, all the members of the resuscitation team should wear appropriate PPE before performing rescue ventilation, chest compressions, or defibrillation.[37]

Patients with Covid-19 who are receiving mechanical ventilation should receive appropriate nutrition and care to prevent constipation and injury to the skin and corneas. If the condition of a patient has stabilized, clinicians should attempt to withhold continuous sedation each day.[38] Daily awakening may be challenging because an increase in the work of breathing and the loss of synchrony with mechanical ventilation may result in distress and hypoxemia.

During the Covid-19 pandemic, an overwhelming surge of patients presenting to a hospital may temporarily require the rationing of health care resources. Local guidelines and medical ethics consultation can help clinicians navigate these difficult decisions with patients and their families.

AREAS OF UNCERTAINTY

Despite FDA approval of remdesivir for hospitalized patients with Covid-19, more data are needed to inform the role of this drug in severe Covid-19. Numerous randomized trials of many other candidate therapies, including antivirals, antibodies, and immunomodulating agents, are ongoing (Table 1).

Despite observational studies suggesting benefit of interleukin-6 inhibitors,[53,54] small, randomized clinical trials failed to show consistent benefit.[30-32] Other immunomodulating agents currently being evaluated for severe Covid-19 include passive immunotherapy with convalescent plasma, monoclonal antibodies, immunoglobulins, and interleukin-1 pathway inhibitors.[55] Pending final results of randomized trials, the risks and benefits of these approaches are also unknown. Candidate therapies for Covid-19 warrant evaluation separately in patients with established severe disease and in those with milder illness to determine whether they reduce the risk of progression to severe disease.

GUIDELINES

The recommendations in this article are largely concordant with the guidelines for severe Covid-19 from the American Thoracic Society, the Infectious Diseases Society of America, the National Institutes of Health, and the Surviving Sepsis Campaign.[17,18,56,57]

CONCLUSIONS AND RECOMMENDATIONS

For the patient described in the vignette, an important aspect of care is careful monitoring of

Table 1. Selected Candidate Therapies for Coronavirus Disease 2019 (Covid-19).*

Class	Availability	Rationale	Clinical Data
Antiviral agents			
Hydroxychloroquine	FDA-approved for lupus, malaria, rheumatoid arthritis; FDA emergency-use authorization for certain hospitalized patients with Covid-19 was revoked	In vitro activity against SARS-CoV-2[39]	Randomized, controlled trials showed no benefit in hospitalized patients[40,41]
Lopinavir–ritonavir	FDA-approved for HIV infection	In vitro activity against SARS-CoV-2[42]	Randomized, controlled trials showed no benefit in hospitalized patients[43,44]
Remdesivir	FDA-approved for hospitalized patients with Covid-19	In vitro activity against SARS-CoV-2[42,45]	Randomized, placebo-controlled trials showed faster time to recovery with remdesivir in hospitalized patients[28,46]; preliminary results from a large, multinational, open-label randomized trial showed no mortality benefit[29]
Antibodies			
Convalescent plasma	Investigational; FDA emergency-use authorization for hospitalized patients with Covid-19	Use in other viral illnesses, including H1N1 influenza, SARS, and MERS	Small, uncontrolled cohort studies suggested benefit[47,48]; small randomized, controlled trials did not suggest benefit[49,50]; large uncontrolled study showed preliminary safety[51]; additional randomized, controlled trials in progress
Monoclonal antibodies	Investigational; FDA emergency-use authorization for nonhospitalized patients with Covid-19	Use in other viral illnesses, including Ebola and HIV	One randomized clinical trial showed that a single dose of bamlanivimab (LY-CoV555) reduced viral load in outpatients with Covid-19[52]; role in inpatients unclear
Immune-based agents			
BTK inhibitors (acalabrutinib, ibrutinib, rilzabrutinib)	FDA-approved for some hematologic cancers	Immunomodulation-targeting cytokines	Clinical trials in progress
Dexamethasone (and other glucocorticoids)	FDA-approved for multiple indications	Broad immunomodulation	Large randomized, controlled trial showed mortality benefit with dexamethasone in hospitalized patients requiring oxygen[27]
Interleukin-1 inhibitors (anakinra, canakinumab)	FDA-approved for some autoimmune diseases	Immunomodulation; activity in macrophage activation syndrome	Clinical trials in progress
Interleukin-6 inhibitors (sarilumab, siltuximab, tocilizumab)	FDA-approved for some autoimmune diseases and cytokine release syndrome (tocilizumab)	Immunomodulation; activity in cytokine release syndrome	Small randomized, controlled trials have not shown benefit[30-32]; additional clinical trials in progress
JAK inhibitors (baricitinib, ruxolitinib)	FDA-approved for rheumatoid arthritis (baricitinib) and myelofibrosis and polycythemia vera (ruxolitinib); FDA emergency-use authorization for baricitinib in combination with remdesivir for hospitalized patients with Covid-19 requiring oxygen	Broad immunomodulation	Clinical trials in progress

* Selected references are provided for rationale and clinical data. ARDS denotes acute respiratory distress syndrome, BTK Bruton's tyrosine kinase, FDA Food and Drug Administration, HIV human immunodeficiency virus, IND investigational new drug, JAK Janus kinase, MERS Middle East respiratory syndrome, SARS severe acute respiratory syndrome, and SARS-CoV-2 severe acute respiratory syndrome coronavirus 2.

his respiratory status to determine whether endotracheal intubation is appropriate. If mechanical ventilation is initiated, the clinician should adhere to a lung-protective ventilation strategy by limiting the plateau pressure and tidal volumes. Deep sedation with neuromuscular blocking agents and prone positioning should be considered if refractory hypoxemia develops. Prophylactic anticoagulants should be administered to prevent thrombosis. Dexamethasone should be started, because data from a randomized clinical trial show a reduction in mortality. Although more data are needed to inform benefits of treatment with both remdesivir and dexamethasone, we would also give remdesivir given its antiviral mechanism of action and data from randomized clinical trials showing that it shortens time to clinical recovery. Rigorous adherence to infection-control practices is essential at all times. Given the high risk of complications from severe Covid-19, clinicians should work with patients and families to establish appropriate goals of care at the earliest possible time.

Given the uncertainties regarding effective treatment, clinicians should discuss available clinical trials with patients. In addition, clinicians should discuss the value of autopsies with the families of patients who do not survive.

COVID-19 daily epidemiology update

Updated: April 19, 2021, 7 pm EST

Summary of COVID-19 cases across Canada and over time. Contains detailed data about the spread of the virus over time and in different regions of the country. Includes breakdowns by age and sex or gender. Provides an overview of hospitalizations and deaths, testing, variants of concern and exposures.

Key updates as of April 19, 2021, 7 pm EST

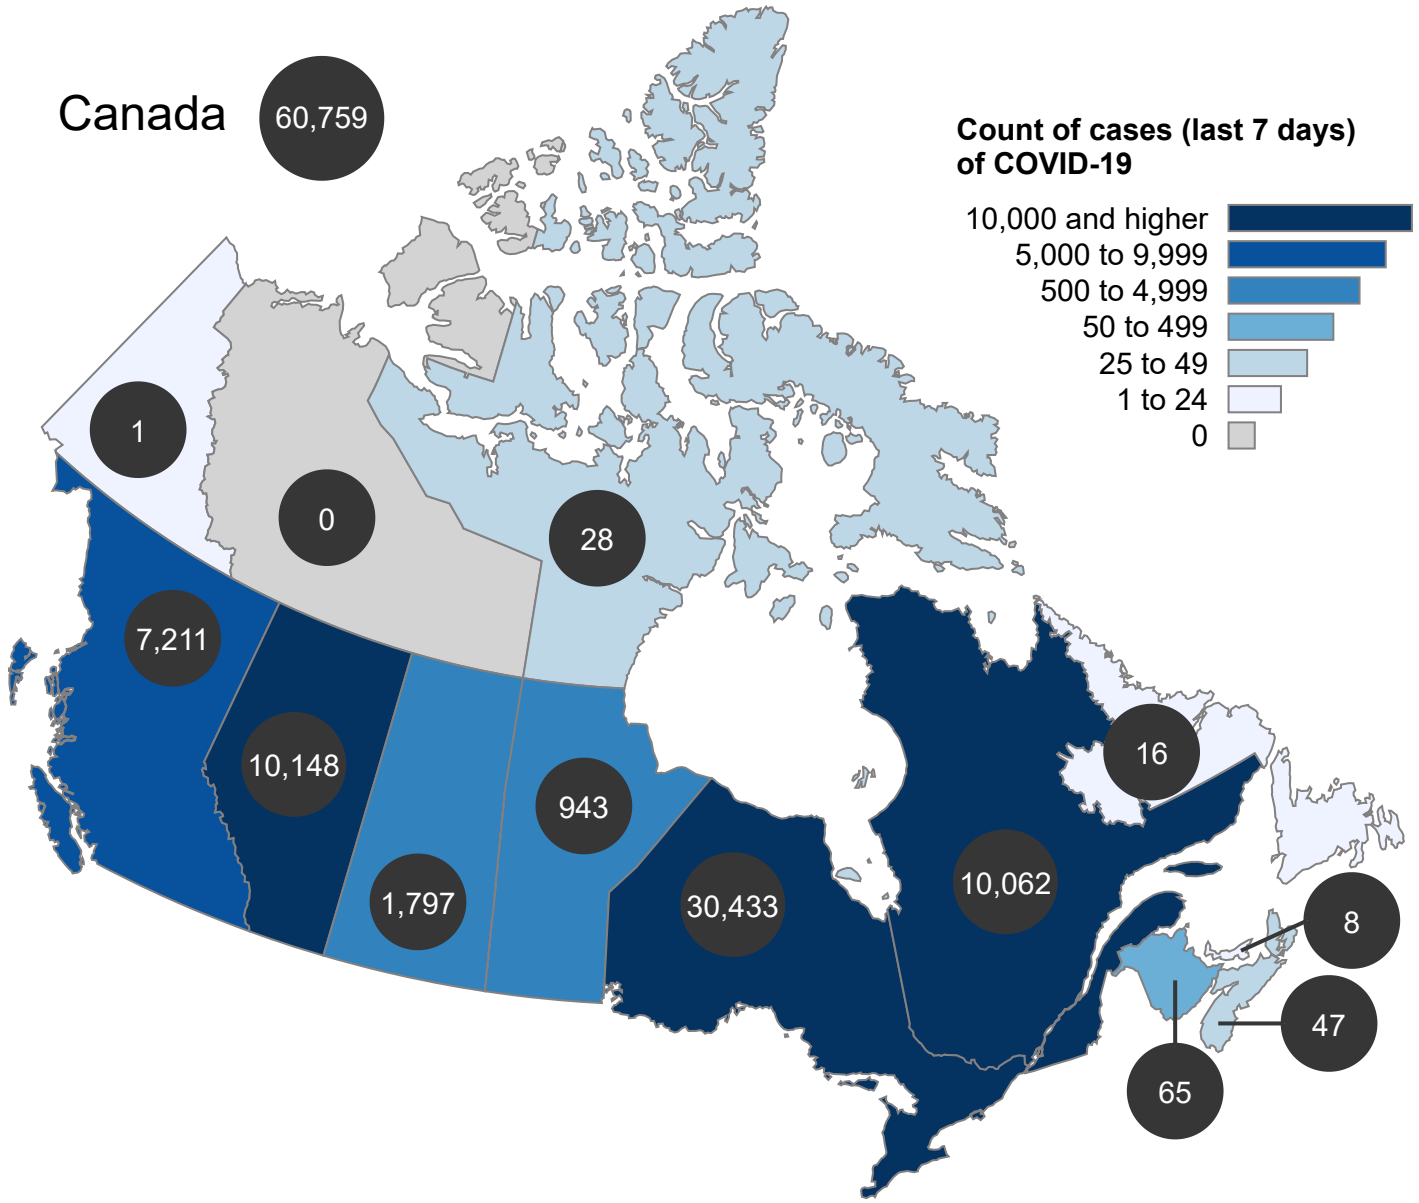
Cases today	Total cases	Active cases	Total resolved	Deaths today	Total deaths
8,317	1,131,773	88,327	1,019,779	45	23,667

Tests performed today	Total tests performed	Percent positive (total)	Tests performed per million population
105,799	30,041,115	3.9%	790,447

- We update these sections daily at 7:00 PM EST: Key updates, Current situation and National overview.
- We update these sections every Friday: Epidemic curve, Demographics, How people were exposed, and Severe illness and outcomes.
- Most cases (67.1%) and deaths (78.4%) were reported by Ontario and Quebec.
- Of the 13 jurisdictions reporting updates, no new cases were reported in 2 provinces or territories in the past 24 hours.
- Of the 13 jurisdictions reporting updates, no new deaths were reported in 9 provinces or territories in the past 24 hours.

Current situation

Figure 1a. Count of cases (last 7 days) of COVID-19, by province/territory as of April 19, 2021



The count of cases (last 7 days) of COVID-19 in **Canada** was **60,759** as of April 19, 2021.

This information is based on data from our provincial and territorial partners. It's current as of April 19, 2021, 7 pm EST. For the most up to date data for any province, territory or city, please visit their web site.

Areas in Canada with cases of COVID-19 as of April 19, 2021

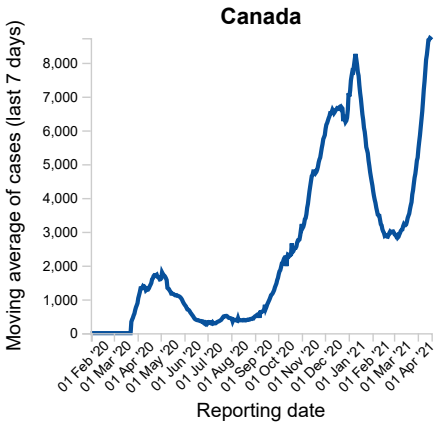
† Rate per 1,000,000 population

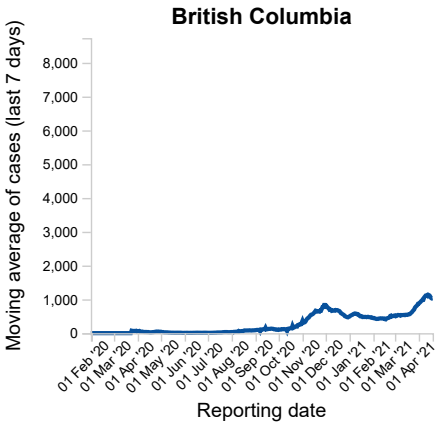
* Rate per 100,000 population

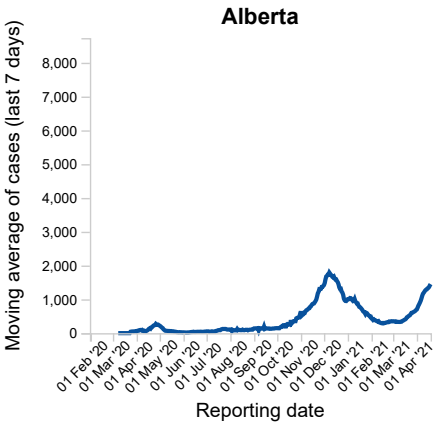
†† Recovered refers to cases that are resolved. These are people who have molecular test proof to show they had a positive COVID-19 test taken between 14 to 90 days before travel.

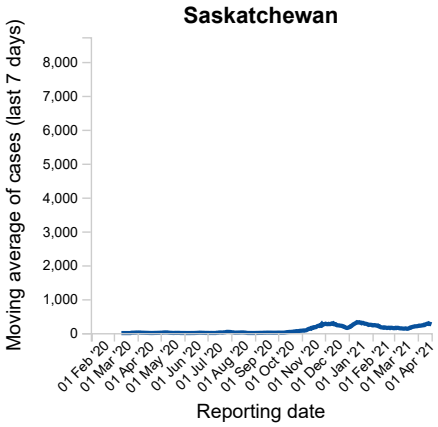
Figure 1b. Moving average of cases (last 7 days) of COVID-19 in Canada as of April 19, 2021, 7 pm EST

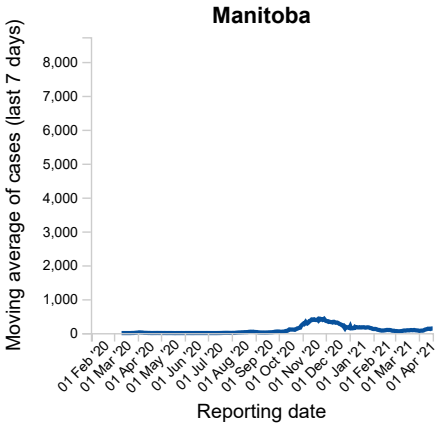
The figures below show cases over time. The range of dates (January 31st, 2020 - present date) is the same for each figure. This allows you to compare the provinces and territories on the same timescale.

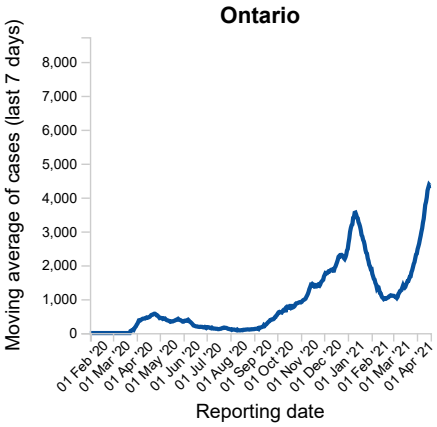


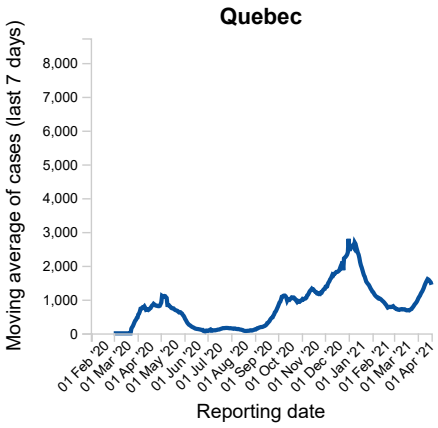


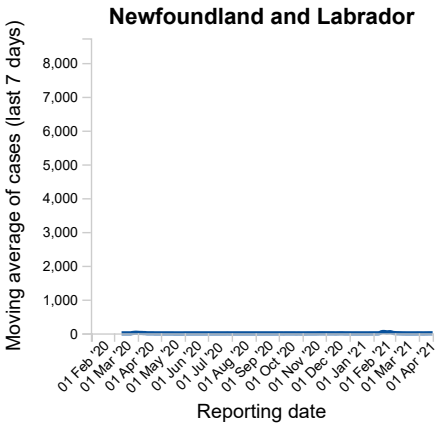


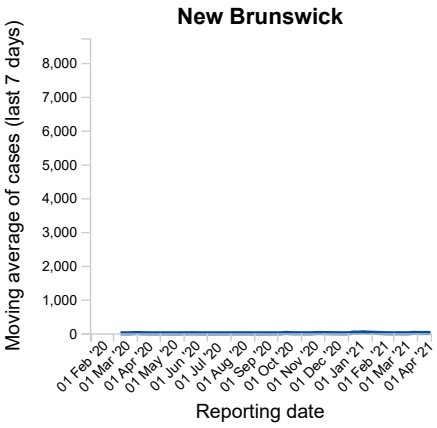


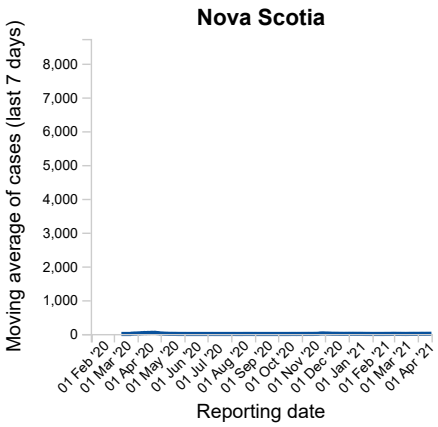


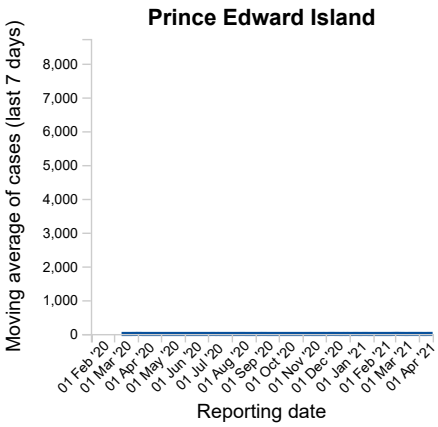


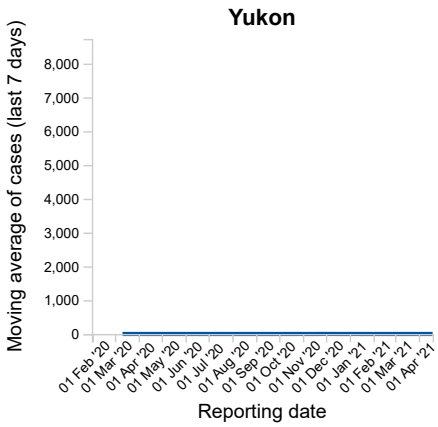


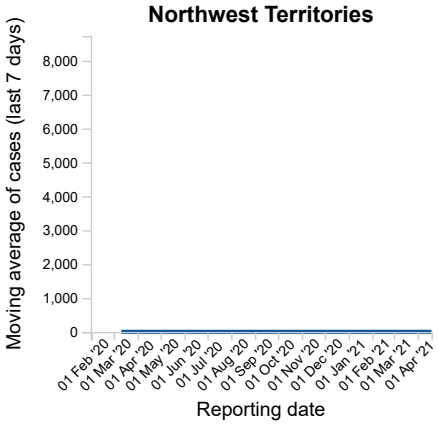


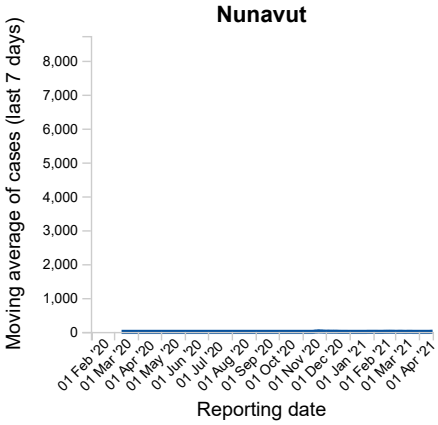












Downloadable data (in .csv format).

Note: Out of the total number of people tested, 76 were repatriated travellers, of which 13 were cases.

National overview

There have been over **30,041,115** COVID-19 tests performed in Canada or **790,447 tests per 1 million people**. Of these, **3.9%** were positive. For information about testing trends, please see the Detailed weekly epidemiological report (PDF).

Table 1. Daily* change in the number of cases, deaths and tests performed, by province or territory, as of April 19, 2021, 7 pm EST

Location	New cases	New deaths	Tests performed
Canada	**8,317**	**45**	**105,799**
British Columbia	1,000	8	10,656
Alberta	1,391	3	N/A

Manitoba	108	0	2,410
Ontario	4,447	19	53,776
Quebec	1,092	15	31,678
Newfoundland and Labrador	3	0	728
New Brunswick	9	0	1,029
Nova Scotia	15	0	2,052
Prince Edward Island	3	0	255
Yukon	0	0	11
Northwest Territories	0	0	18
Nunavut	6	0	88

* The new cases, deaths and tests reflect the difference between a province or territory's current report and their last report. Some provinces and territories do not update daily.

N/A means that no daily update was provided by the province or territory.

Variants of Concern (VOC) in Canada

All viruses, including COVID-19, change, or mutate, over time. Not all mutations are of concern. However, some changes result in variants of concern (VOC). A VOC has changes that are significant to public health. For example, they might:

- spread more easily
- cause more severe illness
- require different treatments, or
- not respond the same to current vaccines

We update VOC (Variants of concern) information daily from Sunday to Thursday at 7:00 PM EST, using publicly reported information fro the provinces and territories.

Table 2. Cumulative number of cases involving variants of concern (VOC) publicly reported, as of April 19, 2021 7:00 PM EST

Location	B.1.1.7 variant	B.1.351 variant	P.1 variant
Canada	**63,543**	**415**	**2,201**
British Columbia	3,858	71	1,810

Northwest Territories	1	0	0
Nunavut	0	0	0

Note: The table reports publicly available information from the provinces and territories. In case of discrepancies, the provincial or territorial data should be considered current and correct.

Detailed case information

The tables and figures below reflect detailed case information provided to the Public Health Agency of Canada (PHAC) by health authorities in the provinces and territories. This data is updated every week. It may change as we get more information about cases.

Updated: April 16, 2021, 9 am EST

Epidemic curve

As of April 16, 2021, 9 am EST, PHAC has received detailed case report data on 1,093,690 cases. Both exposure and symptom onset date were available for 1,078,119 (98.6%) cases [1].

The shaded area on the far right of Figure 2 represents lag time. This is the period of time (1 to 2 weeks) before the latest cases are reported to PHAC. This delay is a result of the time required to seek health care, get tested and receive results. It also takes time for public health authorities to gather information on cases. We update this information as it becomes available.

Figure 2. COVID-19 cases (n=1,078,119 [1]) in Canada by date of illness onset [2] as of April 16, 2021, 7 pm EST (total cases)

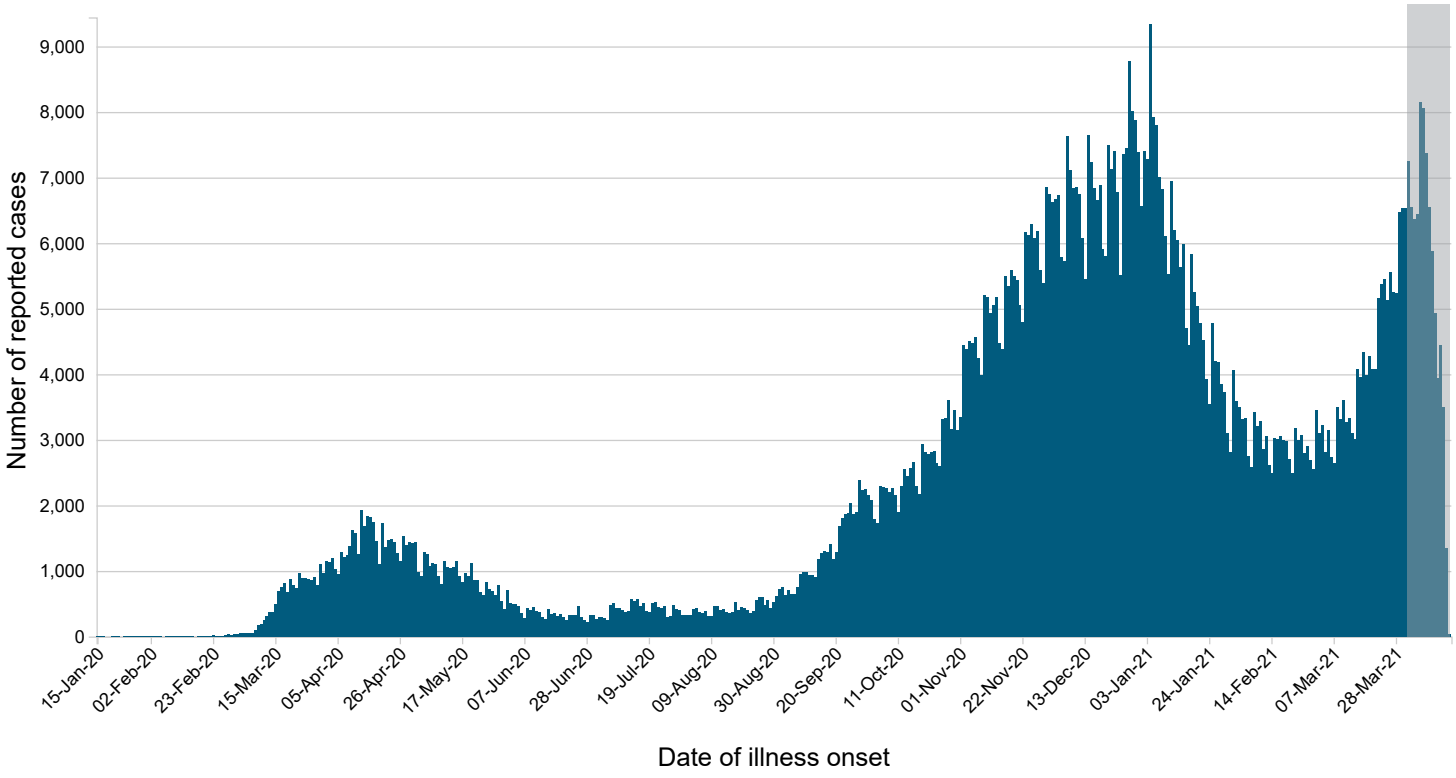

Figure 2. COVID-19 cases (n=1,078,119 [1]) in Canada by date of illness onset [2] as of April 16, 2021, 7 pm EST (by exposure)

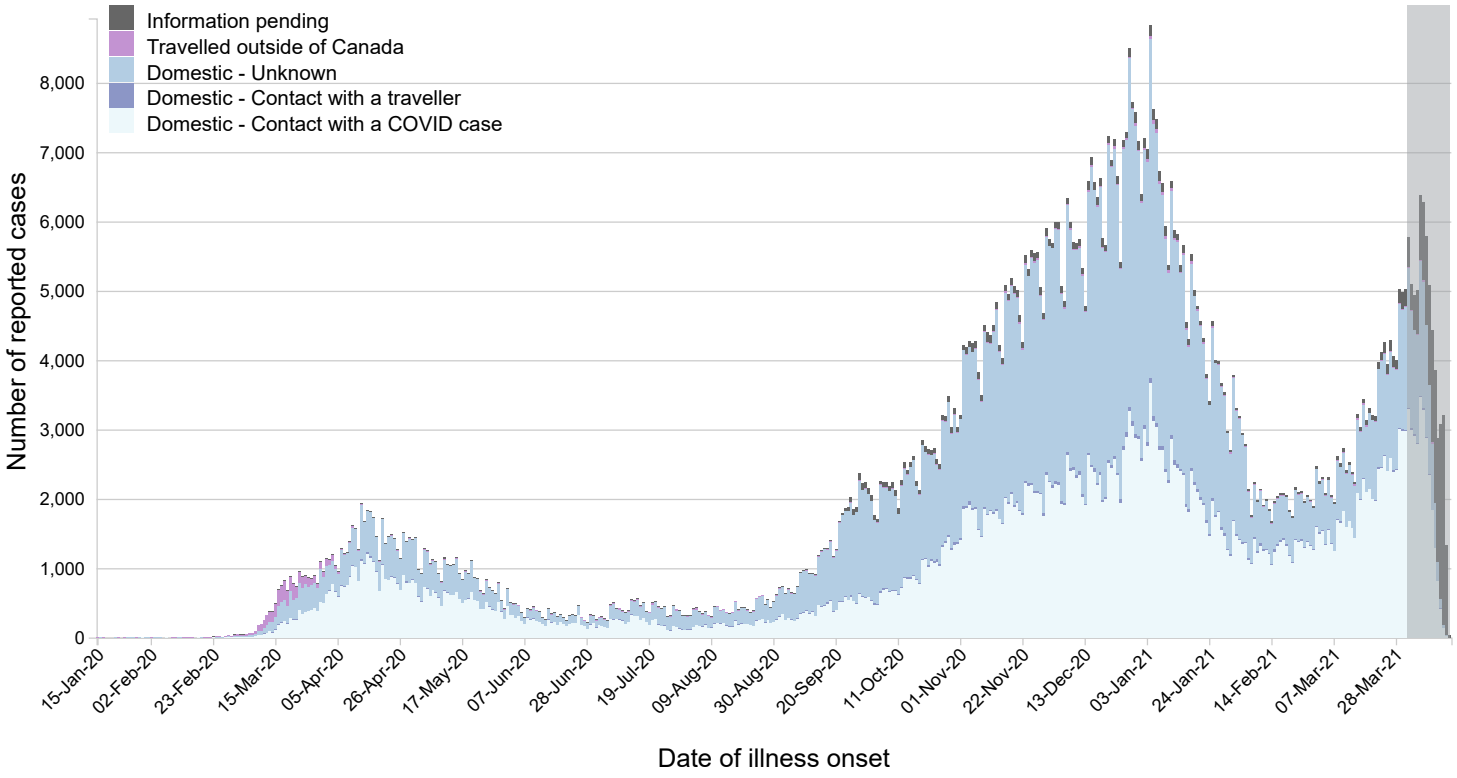

Figure 2. COVID-19 cases (n=1,077,735 [1]) in Canada by date of illness onset [2] as of April 16, 2021, 7 pm EST (by age - 10 year groups)

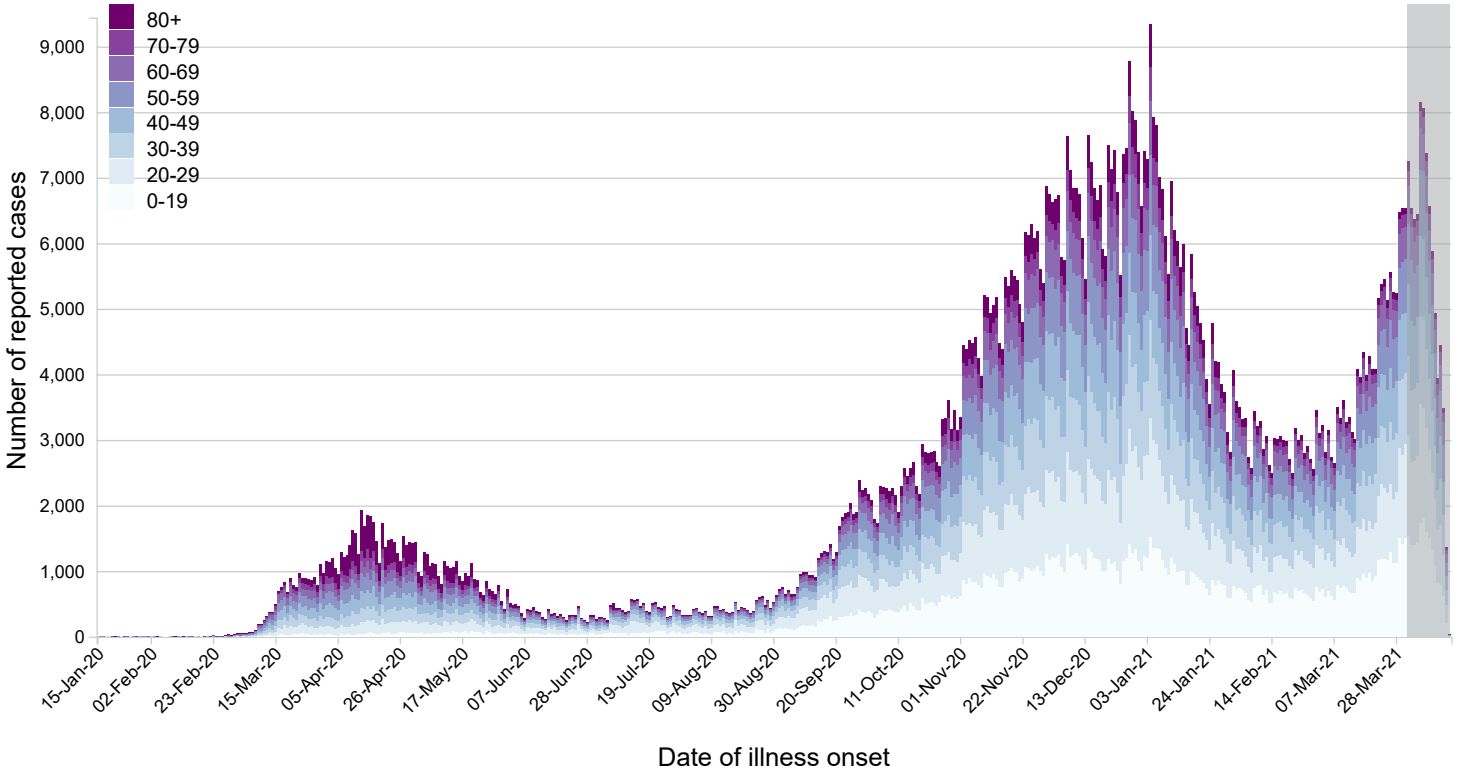

Figure 2. COVID-19 cases (n=1,077,735 [1]) in Canada by date of illness onset [2] as of April 16, 2021, 7 pm EST (by age - 20 year groups)

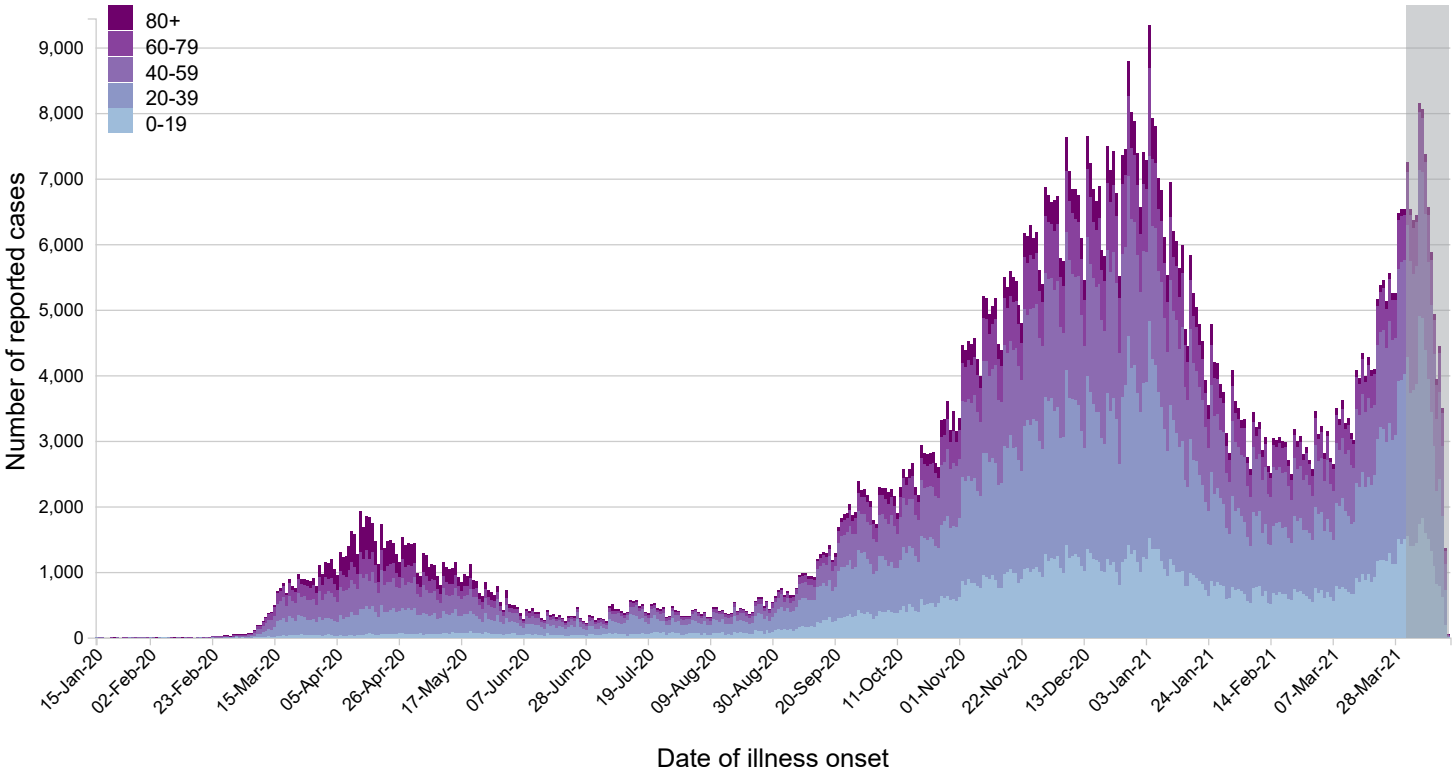


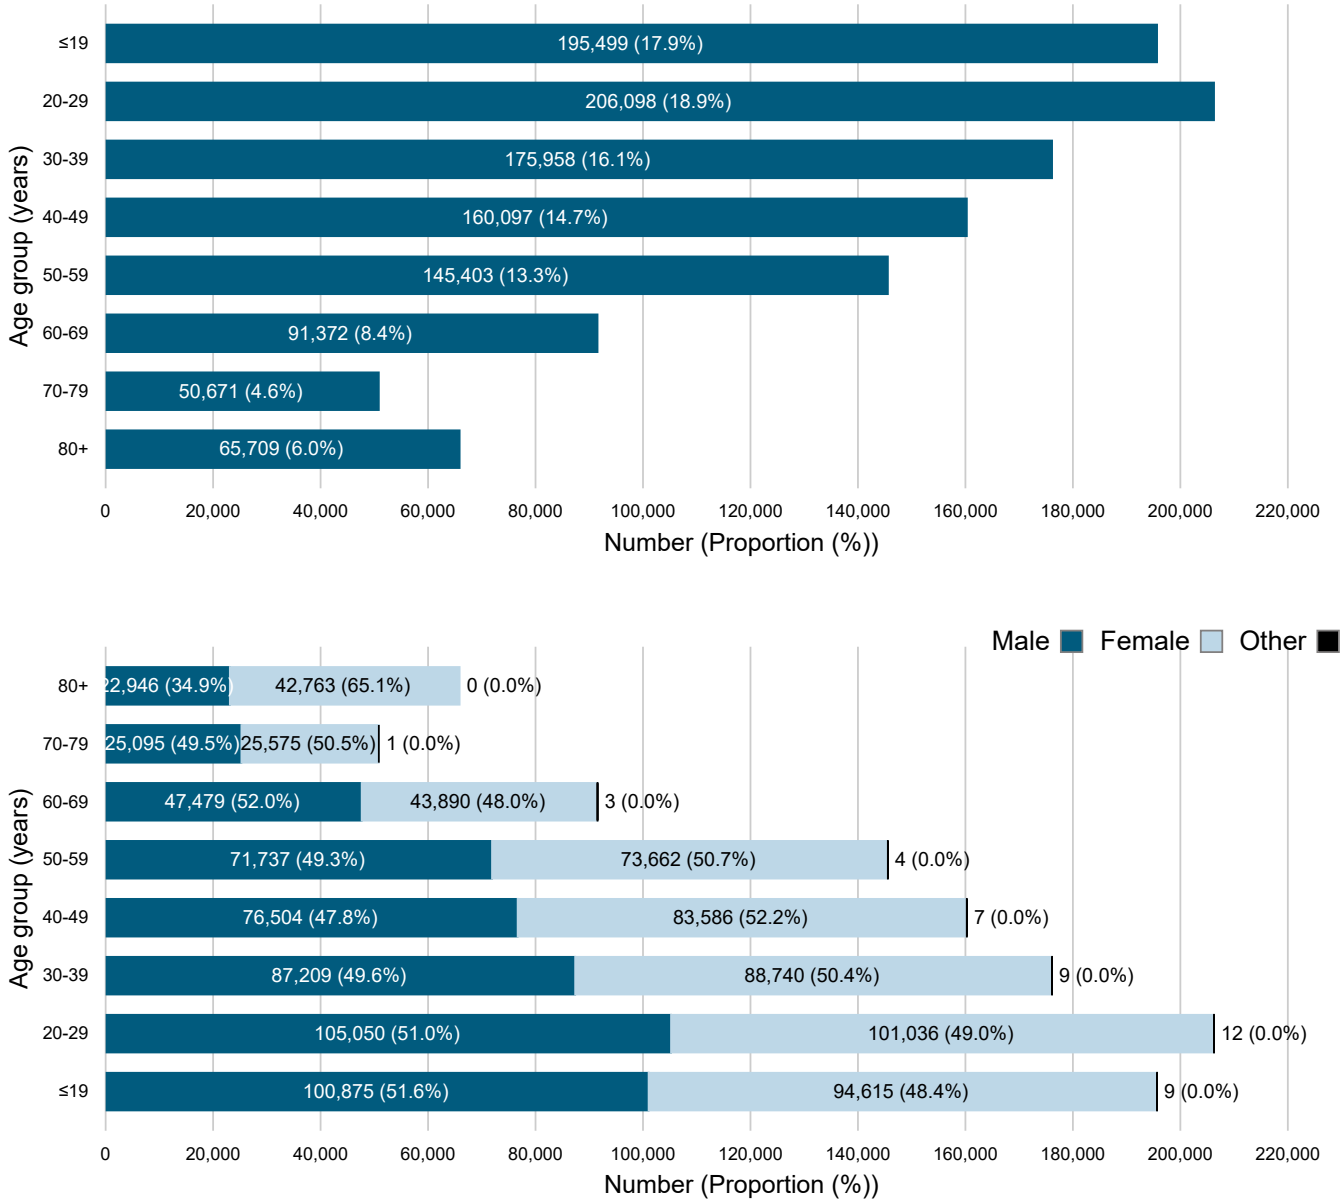
This figure may underestimate the total number of cases among returning travelers. Exposure history is not available for all cases and jurisdictions have not all consistently reported exposure history to PHAC throughout the pandemic.

Demographics

We have detailed case report data from 1,093,690 cases. We know the age of patients in 99.84% of cases, and both age and gender in 99.74% of cases.

Of the cases reported in Canada so far, about half (50.8%) were female. About one-fifth (19.0%) were 60 years old and over (Figure 3).

Figure 3. Age distribution of COVID-19 cases (n=1,091,940 [1]) in Canada as of April 16, 2021, 7 pm EST [4]



Age by gender [4] distribution of COVID-19 cases (n=1,091,940 [1]) in Canada, April 16, 2021, 7 pm EST

Age group (years)	Number of cases with case reports (percentage)	Number of male cases (percentage)	Number of female cases (percentage)	Number of other cases (percentage)
≤19	195,499 (17.9%)	100,875 (18.8%)	94,615 (17.1%)	9 (20.0%)
20-29	206,098 (18.9%)	105,050 (19.6%)	101,036 (18.2%)	12 (26.7%)
30-39	175,958 (16.1%)	87,209 (16.2%)	88,740 (16.0%)	9 (20.0%)
40-49	160,097 (14.7%)	76,504 (14.2%)	83,586 (15.1%)	7 (15.6%)
50-59	145,403 (13.3%)	71,737 (13.4%)	73,662 (13.3%)	4 (8.9%)
60-69	91,372 (8.4%)	47,479 (8.8%)	43,890 (7.9%)	3 (6.7%)
70-79	50,671 (4.6%)	25,095 (4.7%)	25,575 (4.6%)	1 (2.2%)
80+	65,709 (6.0%)	22,946 (4.3%)	42,763 (7.7%)	0 (0.0%)
Total	1,090,807 (100%)	536,895 (100%)	553,867 (100%)	45 (100%)

How people were exposed [3]

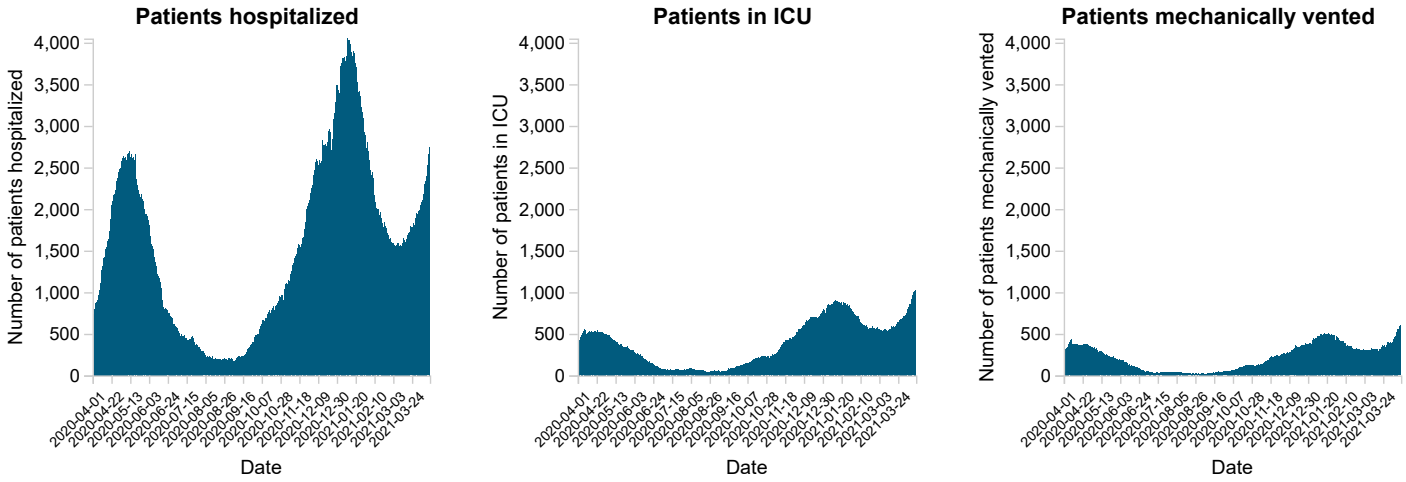
In Canada, detailed case report data were provided for 1,093,690 cases. We have exposure history for 979,763 (89.6%) cases. The probable exposure setting of these cases [1] are:

- any exposure that occurred in Canada: **937,657 (95.7%)**, including
  - from contact with a known COVID case: **446,990 (45.6%)**
  - from contact with a traveller: **7,034 (0.7%)**
  - from an unknown source: **483,633 (49.4%)**
- currently unknown (information pending): **33,491 (3.4%)**
- travelled outside of Canada: **8,615 (0.9%)**

Severe illness and outcomes

Hospital use

Figure 4. Daily number of hospital beds and ICU beds occupied by COVID-19 patients as of April 12, 2021



Between April 5, 2021 and April 12, 2021:

- the number of **hospital beds** occupied by COVID-19 patients **increased** from **2,182** to **2,741** beds.
- the number of **ICU beds** occupied by COVID-19 patients **increased** from **859** to **1,028** beds.
- the number of **COVID-19 patients who were mechanically vented increased** from **463** to **599**.

Hospitalizations and deaths to date

We have detailed case report data on 1,093,690 cases, and hospitalization status for 758,048 (69.3%) of them:

- **56,706** cases **(7.5%)** were hospitalized, of whom:
  - **10,166 (17.9%)** were admitted to the ICU
  - **1,729 (3.0%)** needed mechanical ventilation

The provinces and territories provided detailed case report forms for **23,476** deaths related to COVID-19.

Figure 5a. Age and gender [4] distribution of COVID-19 cases hospitalized in Canada as of April 16, 2021, 7 pm EST (n=56,594 [1])

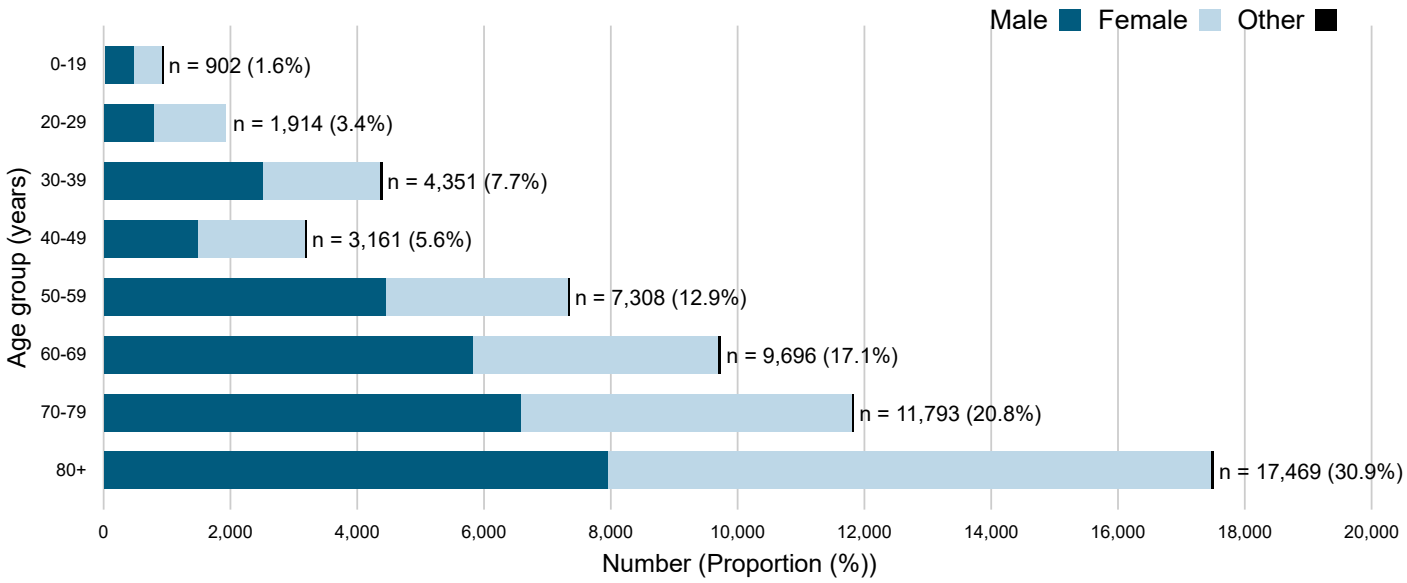


Figure 5b. Age and gender [4] distribution of COVID-19 cases admitted to ICU in Canada as of April 16, 2021, 7 pm EST (n=10,144 [1])

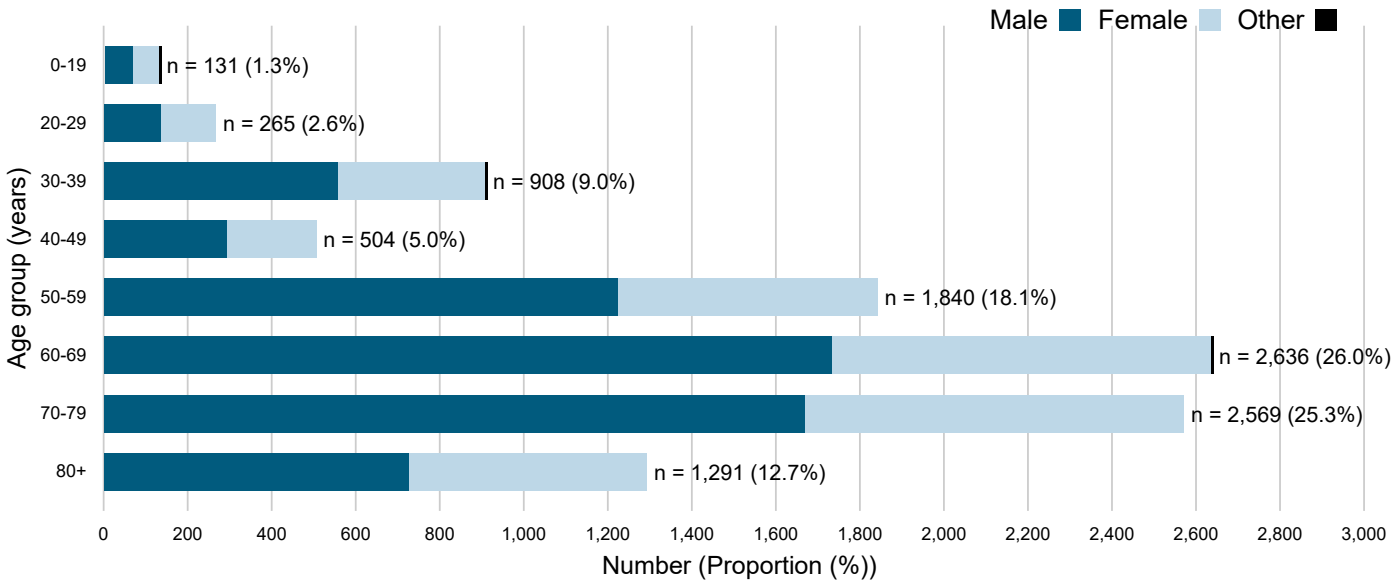

Figure 5c. Age and gender [4] distribution of COVID-19 cases deceased in Canada as of April 16, 2021, 7 pm EST (n=23,435 [1])

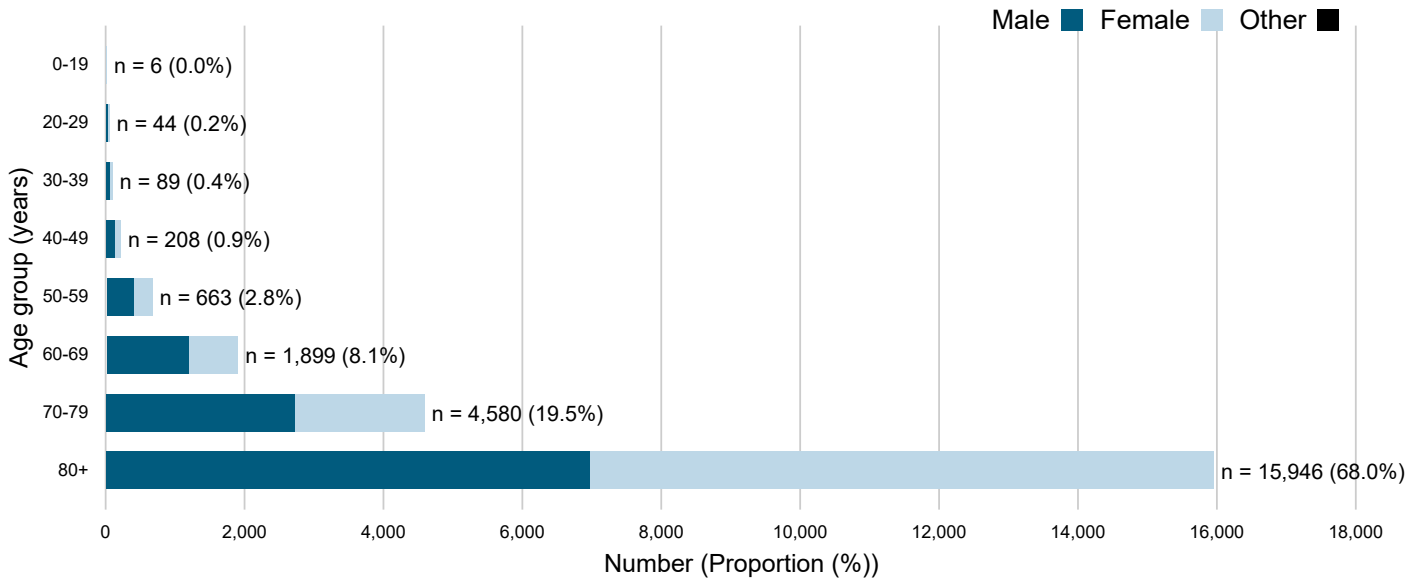

Data note: Figure 5 includes COVID-19 cases hospitalized, admitted to ICU, and deceased for which age and gender information were available. Therefore, some COVID-19 hospitalizations, ICU admissions, and deaths may not be included in Figure 5.

Age and gender [4] distribution of COVID-19 cases hospitalized in Canada as of April 16, 2021, 7 pm EST (n=56,594 [1])

---

1 This figure is based on cases for which a case report form was received by the Public Health Agency of Canada from provincial or territorial partners.

2 The shaded area represents a period of time (lag time) where it is expected that cases have occurred but have not yet been reported nationally. The earliest of the following dates were used as an estimate: Onset date, Specimen Collection Date, Laboratory Testing Date, Date Reported to Province or Territory, or Date Reported to PHAC.

3 Exposure information may not be available for all cases. Some jurisdictions haven't consistently reported to PHAC how people were exposed throughout the pandemic. As a result, this may underestimate the total number of cases by different exposures, especially among returning travelers.

4 Where available, gender data was used; when gender data was unavailable, sex data was used. Reliable data on gender diverse respondents are unavailable due to small counts.

Inverse correlation between average monthly high temperatures and COVID-19-related death rates in different geographical areas

Francesca Benedetti[1], Maria Pachetti[2,3], Bruna Marini[4], Rudy Ippodrino[4], Robert C. Gallo[5,6], Massimo Ciccozzi[7] and Davide Zella[1,6*]

Abstract

Background: With the aim of providing a dynamic evaluation of the effects of basic environmental parameters on COVID-19-related death rate, we assessed the correlation between average monthly high temperatures and population density, with death/rate (monthly number of deaths/1 M people) for the months of March (start of the analysis and beginning of local epidemic in most of the Western World, except in Italy where it started in February) and April 2020 (continuation of the epidemic). Different geographical areas of the Northern Hemisphere in the United States and in Europe were selected in order to provide a wide range among the different parameters. The death rates were gathered from an available dataset. As a further control, we also included latitude, as a proxy for temperature.

Methods: Utilizing a publicly available dataset, we retrieved data for the months of March and April 2020 for 25 areas in Europe and in the US. We computed the monthly number of deaths/1 M people of confirmed COVID-19 cases and calculated the average monthly high temperatures and population density for all these areas. We determined the correlation between number of deaths/1 M people and the average monthly high temperatures, the latitude and the population density.

Results: We divided our analysis in two parts: analysis of the correlation among the different variables in the month of March and subsequent analysis in the month of April. The differences were then evaluated. In the month of March there was no statistical correlation between average monthly high temperatures of the considered geographical areas and number of deaths/1 M people. However, a statistically significant inverse correlation became significant in the month of April between average monthly high temperatures ($p = 0.0043$) and latitude ($p = 0.0253$) with number of deaths/1 M people. We also observed a statistically significant correlation between population density and number of deaths/1 M people both in the month of March ($p = 0.0297$) and in the month of April ($p = 0.0116$), when three areas extremely populated (NYC, Los Angeles and Washington DC) were included in the calculation. Once these three areas were removed, the correlation was not statistically significant ($p = 0.1695$ in the month of March, and $p = 0.7076$ in the month of April).

Conclusions: The number of COVID-19-related deaths/1 M people was essentially the same during the month of March for all the geographical areas considered, indicating essentially that the infection was circulating quite uniformly except for Lombardy, Italy, where it started earlier. Lockdown measures were implemented between the end of March and beginning of April, except for Italy which started March 9th. We observed a strong, statistically significant inverse correlation between average monthly high temperatures with the number of deaths/1 M people. We confirmed the data by analyzing the correlation with the latitude, which can be considered a proxy for high temperature. Previous studies indicated a negative effect of high climate temperatures on Sars-COV-2 spreading. Our data indicate that social distancing measure are more successful in the presence of higher average monthly temperatures in reducing COVID-19-related death rate, and a high level of population density seems to negatively impact the effect of lockdown measures.

Keywords: SARS-CoV, SARS-CoV-2, COVID-19, Temperature, Latitude, Death rate

Background

Recently a novel, human pathogen Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) emerged in China and its worldwide spread created a global health emergency. The World Health Organization publicly declared the SARS-CoV-2 outbreak a pandemic on March 11th 2020, and so far the virus has caused more than 200,000 deaths worldwide, strongly impacting the global economy and human habits. Different environmental conditions can affect host–pathogen interactions. In particular most respiratory viruses are sensitive to local geographical conditions like local temperature and humidity [1]. This in turn generates seasonal waves of outbreaks, by impacting viral transmission and survival [2, 3].

Some studies indicate that warm climates influences SARS-CoV-2 geographical distribution by reducing its infectivity rates [4–9], and others include additional factors, like air pollution, as responsible for increased viral spread [10].

In this study we correlate the average monthly high temperatures and the population density of different geographical areas with number of deaths/1 M people. We focused our analysis on the number of deaths/1 M people instead of number of SARS-CoV-2 RNA-positive people to avoid potential bias due to the different number of total PCR tests in the different areas considered. The areas in the Northern hemisphere were selected to provide a wide range among the different parameters, and the death rate data were gathered from an available dataset. In order to provide a dynamic correlation, the average monthly high temperatures and deaths numbers data were compared for the months of March (start of the analysis and beginning of local epidemic in most of the Western World) with the month of April. Except in Italy, which started at the beginning of March, lockdown measures were implemented between the end of March and the beginning of April in the remaining areas. By reasoning that the latitude is a proxy for temperature, as a further control we then calculated the latitude of the same areas with the number of deaths/1 M. Our data may help to understand the impact of daily temperatures on COVID-19-related death rate and modeling the containment measures according to different geographical areas, and suggest that factors other than social practices contributed to the infection of SARS-CoV-2.

Methods

Twenty-five areas located in Europe and in the United States have been selected as representative of the region/country where major outbreaks have been detected up to April 30th, 2020. We downloaded the number of deaths of confirmed COVID-19 cases of these areas [11] and we calculated the monthly number of deaths/1 M people. We then included in the dataset the average monthly high temperatures (°F) and latitude of these areas as climatic variables that can affect the spread and the lethality of COVID-19. The relationships among these variables have been analyzed with the R *tydiverse* package.

The data were obtained from the European Centre for Disease Prevention and Control (ECDC). We note that the criteria for defining death caused by or associated with COVID-19 are not homogenous internationally and therefore should be taken with caution [12, 13]. In addition, increased mortality indirectly related to COVID-19 may be indicative of sudden exhaustion of the hospital and health systems with a negative impact on the main mortality drivers (cancer, cardiovascular diseases and others). To overcome as much as possible these potential drawbacks, we selected geographical regions implementing homogenous parameters accounting for deaths related to COVID-19. More in detail, as it is standard in death reporting, Countries are asked to follow the "cause of death" classifications from the WHO's *International Classification of Diseases* guidelines [14]. In addition, National guidelines are also implemented, with the aim to better define the cause of death as related to COVID-19. Although confirmed cases are reliant on a positive

laboratory confirmation of the COVID-19 PCR test, a laboratory diagnosis may not be required for it to be listed as the cause of death. As a result, in some circumstances, depending on national guidelines, medical practitioners can record COVID-19 deaths if they think the signs and symptoms point towards this as the underlying cause.

Results

We selected several geographical areas in the Northern hemisphere of the United States and Europe, based on providing a range among the different parameters considered. The States and regions considered are outlined in Table 1. Between parenthesis we indicated the locations selected to obtain the latitudes and temperatures used for our analysis. We compared the data related to the month of March 2020. Lockdown measures were implemented between the end of March and beginning of April, except in Italy which started earlier. The death rate data were gathered as described in the Methods section.

First, we analyzed the correlation between number of deaths/1 M people and the average monthly high temperatures registered in each city considered (Fig. 1). The number of COVID-19-related deaths/1 M people was essentially the same during the month of March for all the geographical areas considered, indicating essentially that the infection was circulating quite uniformly ($p=0.2514$). In April, we observed instead a significant increase in number of deaths/1 M people in those areas where the average monthly high temperatures registered were below 65 °F (Fig. 1a). We found a statistically significant correlation between the decreased number of deaths/1 M people with the increase of the average monthly high temperatures ($p=0.0043$) (Fig. 1b). The same inverse correlation between average monthly high temperatures and COVID-19-related deaths was observed in two regions in Italy (Lombardy in the North and Sicily in the South, respectively) (Table 2). The difference was already noticeable in March, due to the early start of the epidemic, and become progressively accentuated in April (Table 2).

We confirmed these data by analyzing the correlation between the number of deaths/1 M people and the latitude, considered as a proxy for the temperature, of each area (Fig. 2a, b). In March, we don't see any statistically significant difference ($p=0.1016$), while in April, the latitude of 40° is a clear separator: in areas located above 40° the number of deaths increase significantly compared to the number of deaths in areas located below 40° ($p=0.0253$). The same inverse correlation between high latitude and COVID-19-related deaths was observed by comparing Lombardy to Sicily (Table 2).

Finally, we observed a statistically significant correlation between population density and number of deaths/1 M people in March (Fig. 3a, b) ($p=0.0297$) and April ($p=0.0116$). However, this statistical significance is due to the presence of three areas with extremely high population density: New York City, Los Angeles (CA) and Washington DC (Fig. 3c). Once these three areas were removed, the correlation was not statistically significant ($p=0.1695$ in the month of March, and $p=0.7076$ in the month of April).

In conclusion, our data indicate that there is a strong correlation between the number of deaths/1 M people

Table 1 Selected geographical areas

Location	Latitude	Average temperature March (°F)	Average temperature April (°F)
United Kingdom (London)	51.5	52.65	63.60
Belgium (Brussels)	50.84	51.16	63.80
Washington (Seattle)	47.6	50.65	60.17
Lombardy (Italy)	45.46	57.26	69.70
Massachusetts (Boston)	42.35	47.84	49.80
Michigan (Ann Harbor)	42.28	47.58	53.70
Illinois (Chicago)	41.88	47.71	56.27
Connecticut (Waterbury)	41.55	49.42	52.10
New Jersey (Newark)	40.73	54.52	57.70
New York (New York City)	40.71	53.94	56.60
Pennsylvania (Philadelphia)	39.95	56.48	59.27
Maryland (Baltimore)	39.29	59.65	61.73
Washington, D.C.	38.9	60.74	63.57
Sicily (Italy)	38.11	60.77	64.77
Malta (La Valletta)	35.93	62.77	68.53
New Mexico (Albuquerque)	35.08	62.58	71.23
California (Los Angeles)	34.05	67.74	73.40
Georgia (Atlanta)	33.74	69.00	70.77
Arizona (Phoenix)	33.44	73.55	86.45
South Carolina (Charleston)	32.77	71.48	75.60
California (San Diego)	32.71	63.90	67.40
Mississippi (Jackson)	32.3	75.13	74.37
Texas (Austin)	30.26	76.29	79.93
Louisiana (New Orleans)	29.95	78.94	80.60
Florida (Miami)	27.53	84.39	84.67

Between parenthesis are indicated the location considered for the latitude and to calculate the average monthly high temperatures

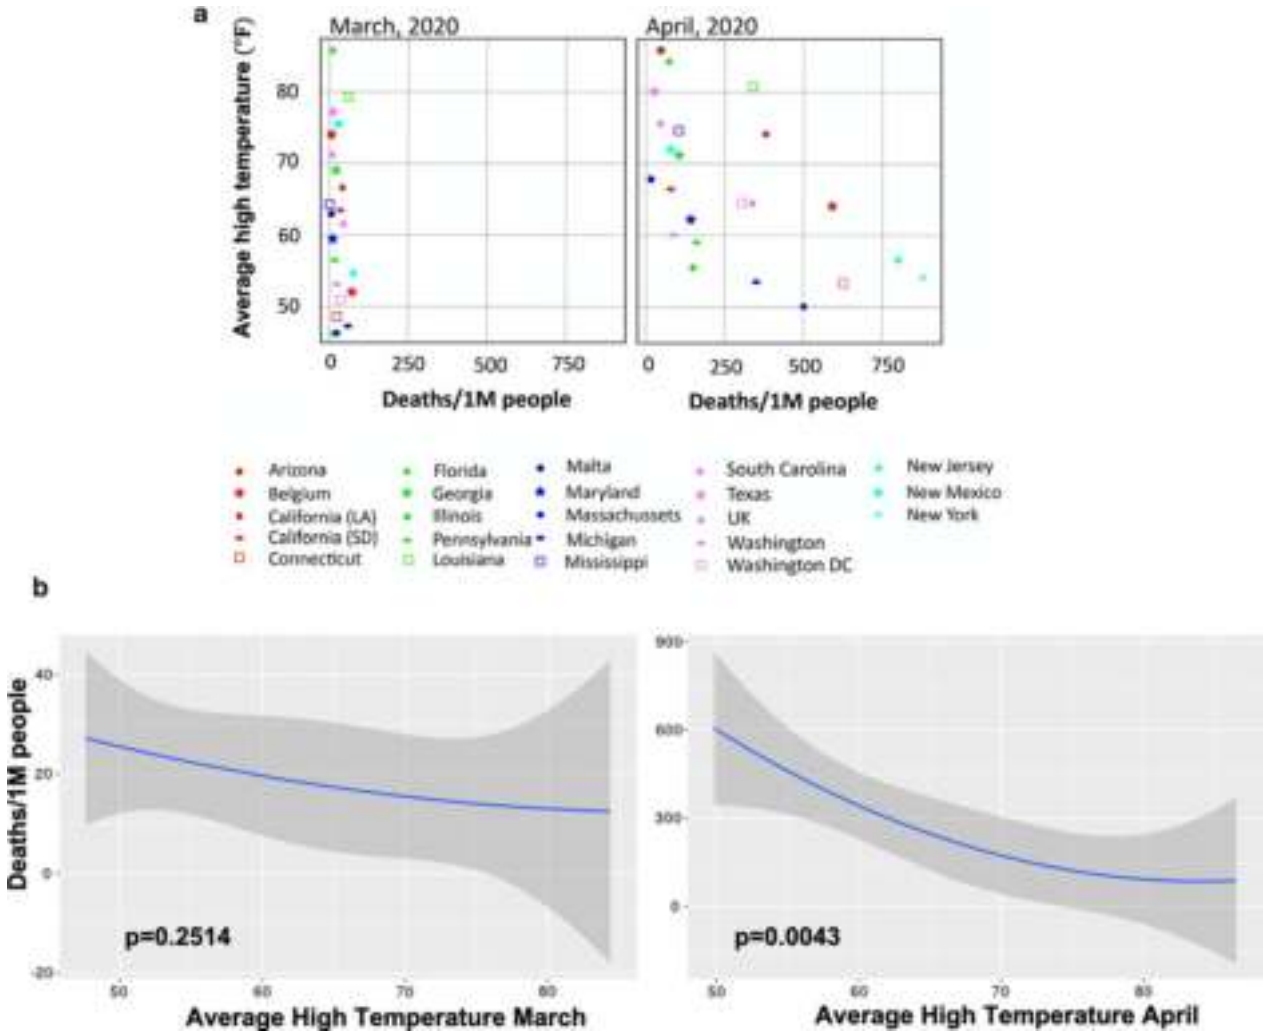

Fig. 1 Correlation between average monthly high temperatures and number of deaths/1 M people. **a** The relationship between the number of deaths/1 M people and the average monthly high temperatures (°F) for the months of March (left) and April (right) 2020 is represented for 25 areas located in Europe and in the US using scatter plots graphs. **b** The not linear correlation between these two variables is calculated using the squared transformation of the average monthly high temperatures. The p-values for each month are indicated

Table 2 Number of deaths per millions of people, average high temperatures for the months of March and April, and population density of two different Italian regions, Lombardy (North) and Sicily (South)

Location	Deaths/million of people in March	Deaths/million of people in April	Average high temperature in March (°F)	Average high temperature in April (°F)	Latitude (°)	Population density (sq ft)
Lombardy	500	700	57.26	69.70	45.46	420
Sicily	10	35	60.77	64.77	38.11	200

and climate. It is likely that social distancing measure are more successful in the presence of average monthly high temperatures in reducing COVID-19-related death rate, and high level of population density seems to reduce the effect of lockdown measures.

Discussion

We correlate the average monthly high temperatures and the population density of different geographical areas with number of deaths/1 M people. The data were analyzed for the month of March and April.

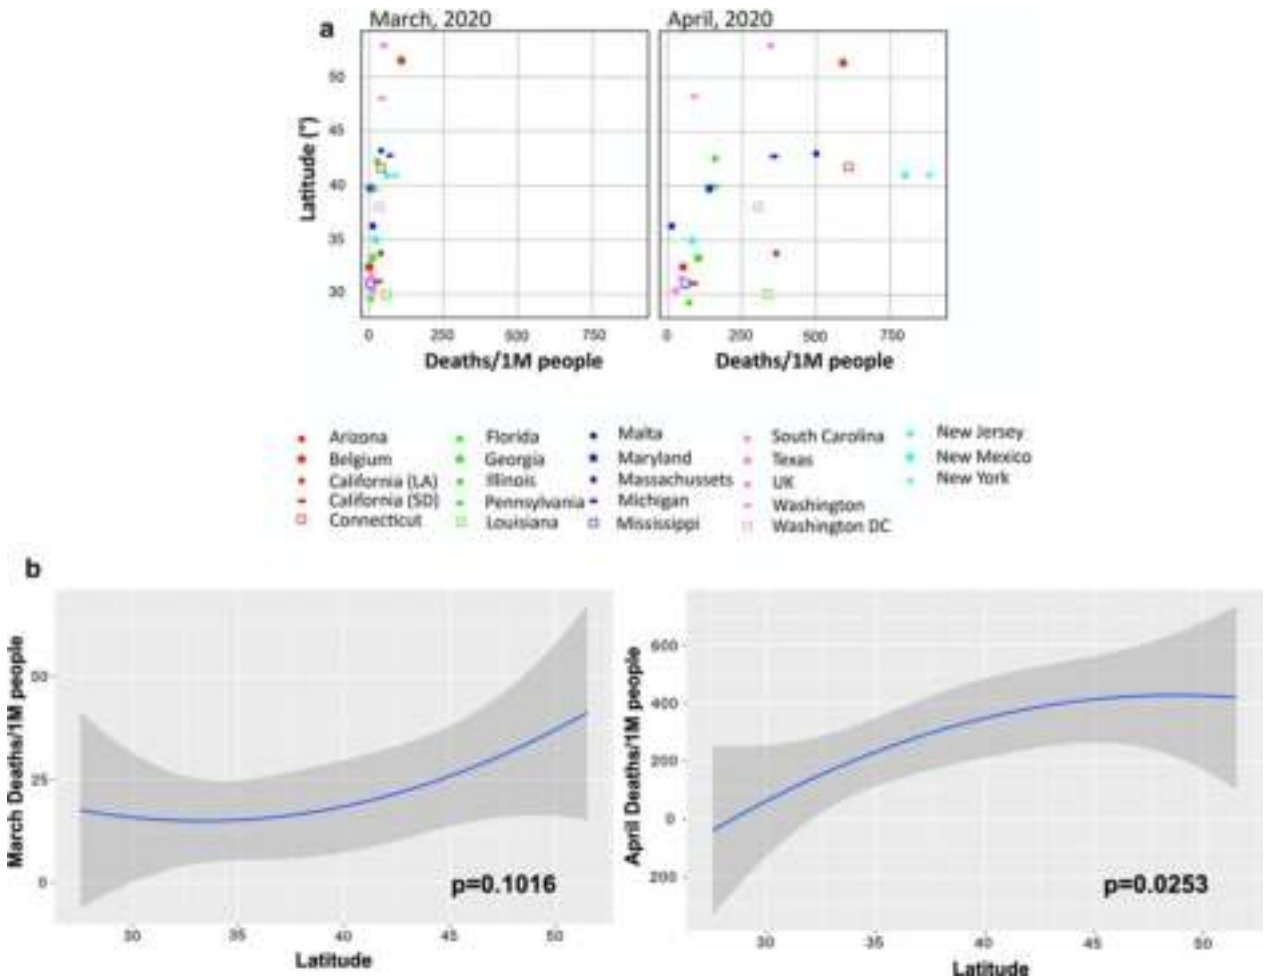

Fig. 2 Correlation between latitude and number of deaths/1 M people. **a** The relationship between the number of deaths/1 M people and the latitude (used as a proxy of the average monthly high temperatures registered) for the months of March (left) and April (right) 2020 is represented for 25 areas located in Europe and in the US using scatter plots graphs. **b** The not linear correlation between these two variables is calculated using the squared transformation of the latitudes. The p-values for each month are indicated

We did not find any correlation between temperatures and number of deaths in the month of March. On the contrary, there was a strong statistical correlation between the temperature values and number of deaths in the month of April. These data were further confirmed when we used latitude as a proxy of the temperature. It is noteworthy to remember that in all the areas considered, lockdown measures were implemented between the end of March and beginning of April (except in Lombardy and Sicily, Italy, which started earlier), and all had substantial forms of social distancing by April. Our results indicate that the areas considered started from a very similar number of deaths in the month of March, but the implementation of social distancing seems to be more successful in those areas with higher average monthly temperatures during the month of April.

We could not find a correlation between population density and number of deaths once the especially densely populated areas were removed. These data seem to indicate a possible threshold of population density as a factor contributing to virus spread.

Conclusion

Our data indicate that social distancing measures are more successful in the presence of higher daily temperature in reducing COVID-19-related death rates. On the contrary, high level of population density seems to reduce the effect of lockdown measures. Though more studies are necessary to confirm these data, we believe they help understand the impact of temperature on COVID-19-related death rate and modeling the containment measures according to different geographical areas.

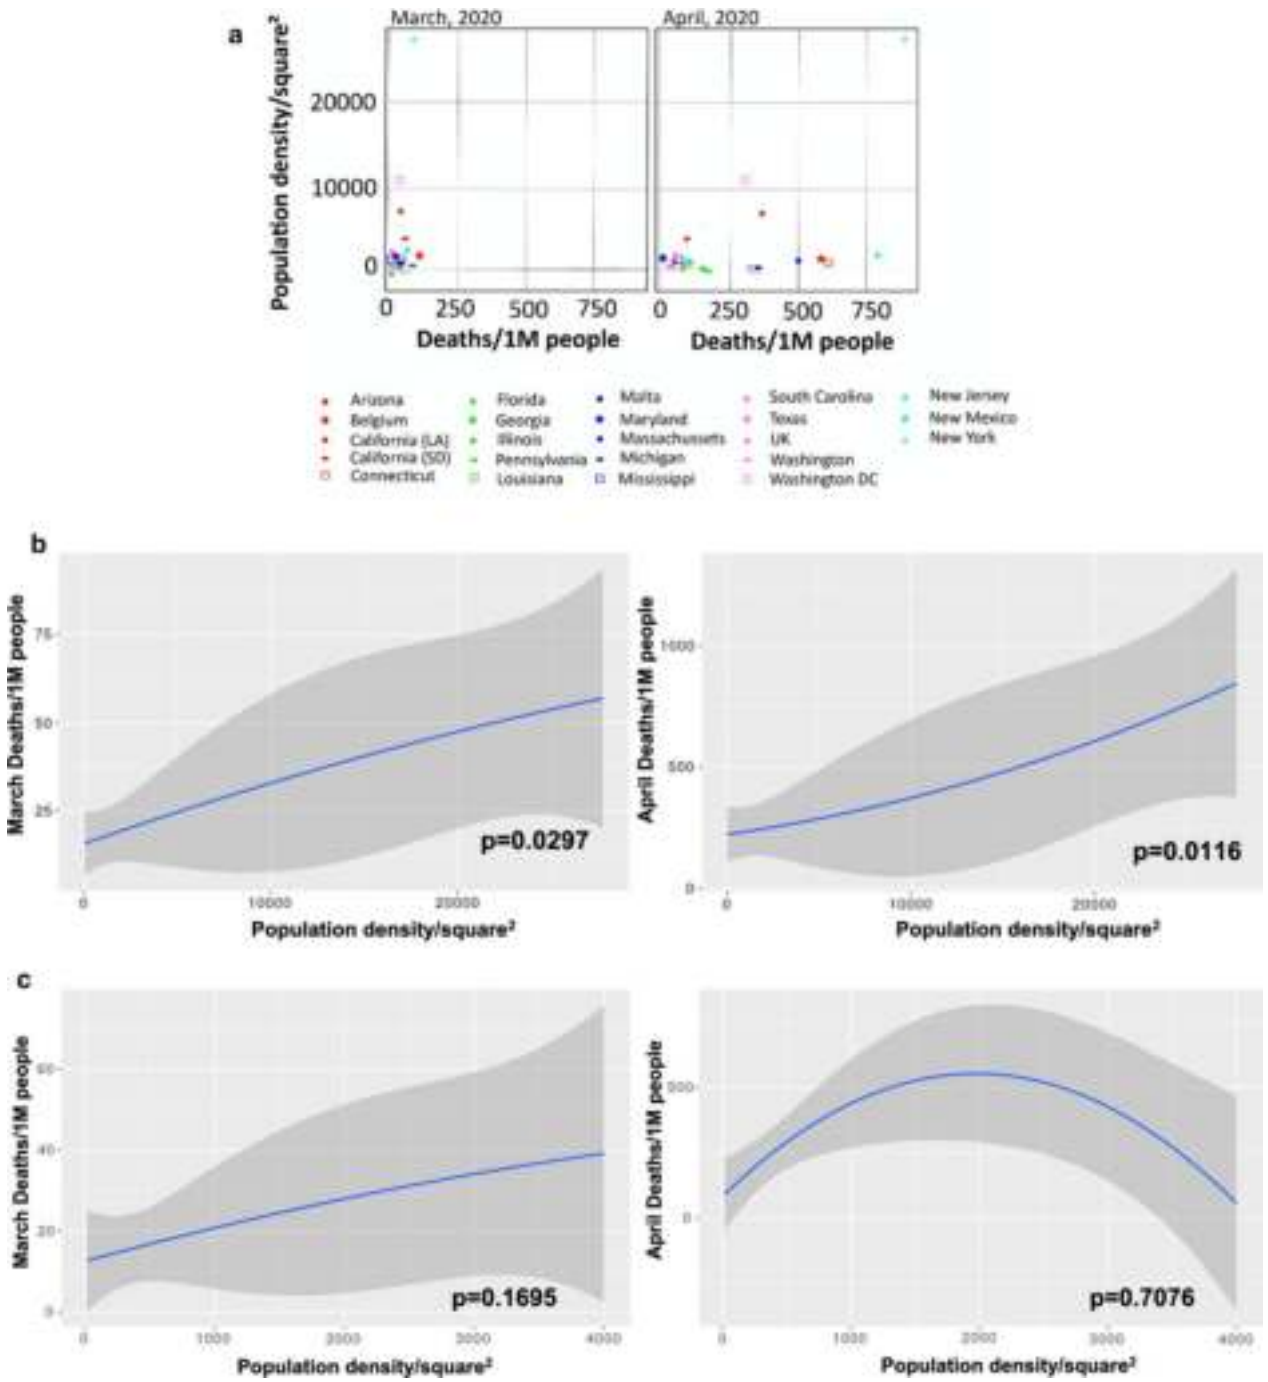

Fig. 3 Correlation between population density and number of deaths/1 M people. **a** The relationship between the number of deaths/1 M people and the population density for the months of March (left) and April (right) 2020 is represented for 25 areas located in Europe and in the US using scatter plots graphs. **b** The not linear correlation between these two variables is calculated using the squared transformation of the population density including the three highly densely populated areas (New York City, Los Angeles and Washington, DC), and **c** excluding these areas. The p-values for each month are indicated

Structural equation modeling to shed light on the controversial role of climate on the spread of SARS-CoV-2

Alessia Spada[1,5], Francesco Antonio Tucci[2,4,5], Aldo Ummarino[2,3]✉, Paolo Pio Ciavarella[2], Nicholas Calà[2], Vincenzo Troiano[2], Michele Caputo[2], Raffaele Ianzano[2], Silvia Corbo[2], Marco de Biase[2], Nicola Fascia[2], Chiara Forte[2], Giorgio Gambacorta[2], Gabriele Maccione[2], Giuseppina Prencipe[2], Michele Tomaiuolo[2] & Antonio Tucci[2]

Climate seems to influence the spread of SARS-CoV-2, but the findings of the studies performed so far are conflicting. To overcome these issues, we performed a global scale study considering 134,871 virologic-climatic-demographic data (209 countries, first 16 weeks of the pandemic). To analyze the relation among COVID-19, population density, and climate, a theoretical path diagram was hypothesized and tested using structural equation modeling (SEM), a powerful statistical technique for the evaluation of causal assumptions. The results of the analysis showed that both climate and population density significantly influence the spread of COVID-19 ($p < 0.001$ and $p < 0.01$, respectively). Overall, climate outweighs population density (path coefficients: climate vs. incidence = 0.18, climate vs. prevalence = 0.11, population density vs. incidence = 0.04, population density vs. prevalence = 0.05). Among the climatic factors, irradiation plays the most relevant role, with a factor-loading of − 0.77, followed by temperature (− 0.56), humidity (0.52), precipitation (0.44), and pressure (0.073); for all $p < 0.001$. In conclusion, this study demonstrates that climatic factors significantly influence the spread of SARS-CoV-2. However, demographic factors, together with other determinants, can affect the transmission, and their influence may overcome the protective effect of climate, where favourable.

On March 11, 2020, the respiratory disease (COVID-19) caused by the coronavirus SARS-CoV-2, after having reached a global scale, was classified by the World Health Organization as a pandemic. Still progressing, COVID-19 has completely reshaped our world from all points of view, with dramatic social, economic, and psychological consequences.

Data provided by government and health organizations show a different distribution of the epidemic across countries[1], advocating a possible relationship between COVID-19 and climate factors. To address this issue, several studies have been carried out, but their results are mixed and conflicting, leading to deeply different conclusions[2–10].

The reasons for such contrasting findings are several. Firstly, some studies have been designed with intrinsic limitations that do not allow for a comprehensive view of the role of climate in COVID-19 spread, whether because they considered only one or few countries, without a global perspective[3,7], or due to short observation period chosen (2–8 weeks)[4,9,11], or the low number of climatic variables considered (however divergent between the various investigations)[2,5]. Secondly, none of the studies published so far have considered the role played by the demographic factors. These variables are relevant to correctly interpret the apparently inconsistent results in some areas of the globe (such as India, Brazil or USA). Thirdly, procedural unintentional biases have been made in many reports[12–16], leading to other insidious pitfalls and to the aforementioned discrepancy. One of these biases is the onset of the outbreak[12]. As the beginning of the infection did not occur simultaneously across the countries, if evaluated at the same time point, the countries whose outbreak started earlier tend to record

0152

higher prevalence of infection than the others. This requires a relative time scale, synchronizing the countries based on the beginning of the epidemic, prior to any statistical analysis.

Another pitfall is the single point of estimation[13,15]. Climatic conditions across countries vary considerably from region to region. Data collection limited to a restricted area (e.g. the capital city) is not representative of the whole country, and this may cause misleading results. Therefore, more data collection points within the same country should be taken into account. A further pitfall is the lag interval[11,14,16]. Incubation period, delayed testing from the onset of symptoms, as well as, late communication of test results, all contribute to a time shift between the infection exposure and the confirmation of diagnosis. Consequently, a lag time must be considered between the collection of climatic data for the analysis and the collection of COVID-19 data.

Finally, the interdependence of variables[17,18]. Climatic variables are commonly considered as stand-alone factors. Instead, they interact with each other. Therefore, an integrative and specific analysis is necessary for a comprehensive understanding of their effects, as their partial consideration could be misleading.

A comprehensive and detailed review of the existing literature about COVID-19 and climate is reported in the Supplementary Table S1.

Altogether, these questions may account for the discrepancy among the numerous studies published, leaving the debate about the relationship between climatic factors and COVID-19 still open.

Surely, knowing the factors influencing the epidemic and understanding the dynamics of its spread is strategic and crucial. This would allow us not only to limit the contagion, but also to better calibrate the containment policies, thus reducing the psychological, social, and economic repercussions. Starting from these considerations, we carried out an extensive and comprehensive analysis, based on as many as 134,871 data, using structural equation modeling (SEM), a statistical technique for testing the linear relationships between observed variables and latent variables, based on statistical data and causal qualitative hypothesis and developed by "LISREL" models, i.e. linear structural relationships[19–21]. Applied for the first time in the 70s in the field of social sciences with variables that could not be directly observed or measured, SEM later spread among the scientific community, thanks to both its flexibility and rigorous approach. One of the main advantages of SEM is the possibility to take into consideration several dependent variables simultaneously.

Flexibility and potential of this analysis were the key for the evaluation of climatic factors and their role in the outbreak of SARS-CoV-2, trying to overcome the limitations and the pitfalls above-mentioned. In addition, since COVID-19 seems to spread more widely in highly populated areas, we also investigated the influence of some socio-demographic variables (such as population density) over the incidence and prevalence of the disease.

Results

Descriptive statistics. Statistics of meteorological variables, population density, weekly incidence and prevalence of SARS-CoV-2, are summarized in Table 1. The data have been stratified by climatic zones and are relative to the first 16 weeks of infection, in the 209 countries considered in this study. From the analysis, it has emerged that there is an increasing (although apparently imperfect) trend of both incidence and prevalence from warm to cold geoclimatic areas. Low values of incidence and prevalence (both for 100,000 people) were recorded in the equatorial ($\mu \pm \sigma = 4.28 \pm 12.89$ and $\mu \pm \sigma = 11.84 \pm 35.67$, respectively) and arid zones ($\mu \pm \sigma = 10.77 \pm 34.01$ and $\mu \pm \sigma = 27.78 \pm 95.75$), areas with the hottest temperature and greater solar irradiation; while the highest values of incidence ($\mu \pm \sigma = 24.68 \pm 46.33$) and prevalence ($\mu \pm \sigma = 564.38 \pm 2986.82$) were observed in the warm temperate zone, the zone also recording the highest value of population density ($\mu \pm \sigma = 564.38 \pm 2986.82$), an important factor in virus transmission through both respiratory droplets and contact routes.

To verify the previous findings, namely that the morbidity indices (incidence and prevalence) depend on the geoclimatic zones where the countries are geographically located, the non-parametric k-sample test for median equality has been applied. The results of the test showed statistically significant differences in incidence and prevalence among the geoclimatic zones (incidence, Chi square = 309.0387 $p < 0.001$; prevalence, Chi square = 317.6152 $p < 0.001$), confirming that the transmission of the virus is indeed influenced by the climate.

To highlight and further investigate the relationship between morbidity, climatic variables, and population density, thematic world maps have also been devised (Fig. 1). For each country, the maps illustrate the following features: (a) median incidence and prevalence values of COVID-19 in the first 16 weeks of infection, (b) median values of all climatic variables (detected with a time shift of two weeks prior to the collection of virological data) in the same period, and c) population density.

From the comparison of the maps, it resulted that, with few exceptions, no evident spatial correlation seems to exist among the investigated variables. Only solar irradiation, temperature, and humidity showed an albeit modest relationship with the morbidity indices: countries with higher solar irradiation reported lower values of incidence and prevalence, while highest incidence and prevalence values were mainly recorded in areas with lower median temperatures (e.g., United States, Europe and China) and higher humidity.

To better explore the relationship between climate and incidence/prevalence of SARS-CoV-2, the bivariate correlation between these indices and all the main meteorological variables (considered individually) was investigated by means of the Spearman's rank correlation coefficient. Then, since population density represents an important factor in the transmission of the virus, the correlation between incidence/prevalence and population density was also calculated.

The results of this analysis, in agreement with the findings of thematic world maps, demonstrated only a moderate concordance between solar irradiation and temperature ($r = 0.58$; $p < 0.05$) and a significant (albeit low) negative correlation of temperature with incidence and prevalence ($r = -0.37$ and $r = -0.34$, respectively) (Table 2).

However, the weak correlations detected may have been due to the heterogeneity of the climatic conditions in the numerous countries considered. In this case, a simple bivariate regression model (such as the Spearman's rank

Table 1. Summary statistics of meteorological variables, *weekly incidence* and *weekly prevalence* of SARS-CoV-2, population density, by climatic zone, in the first 16 weeks of the infection, in 209 countries.

test) may be insufficient to reveal complex relationships. Therefore, a more specific analysis, in which climatic variables can be considered simultaneously and in an integrated way, is needed.

SEM analysis. To understand the intricate interactions among geoclimatic and epidemiological variables, a more consistent and suitable mathematical model, such as the multivariate regression approach of structural equation modeling (SEM), was necessary. With this statistical model it was possible to consider the integrated effects of all the meteorological variables on COVID-19 and, at the same time, to investigate the effects of population density too.

To analyze the relations among the above-mentioned variables, the theoretical path diagram reported in Fig. 2 was supposed. In this theoretical path, meteorological factors were hypothesized to be correlated to each other and linked to a variable that cannot be directly measured (*Climate*). In addition, it was assumed that *Climate* and population density are regressors on incidence and prevalence, whose covariation is expressed by an arc. Therefore, the theoretical path was then tested by SEM.

The results of the analysis showed a clear causative role of climate. For paths *Climate* → *Incidence* and *Climate* → *Prevalence*, the integrated effects of meteorological factors, measured at two-week lag and expressed by a single latent variable (*Climate*), resulted to be significantly ($p < 0.001$) linked to incidence and prevalence by a standardized positive path coefficient ($b = 0.18$ and $b = 0.11$, respectively) (Fig. 3).

0155

	Precipitation	Humidity	Pressure	Temperature	Wind	Solar irradiation	Population density	Incidence	Prevalence
Precipitation (mm/day)	1.00								
Humidity (%)	0.55*	1.00							
Pressure (kPa)	−0.11	0.15*	1.00						
Temperature (°C)	−0.02	−0.16	0.22*	1.00					
Wind (m/s)	−0.19	−0.03	0.41*	0.09*	1.00				
Solar irradiation (MJ/m^2/day)	−0.38	−0.50	0.05*	0.58*	0.02	1.00			
Population density (n/km^2)	−0.04	0.01	0.22*	0.13*	0.05*	0.11*	1.00		
Weekly incidence (per 100,000)	0.05*	0.09*	0.07*	−0.37	−0.01	−0.15	−0.01	1.00	
Weekly prevalence (per 100,000)	0.04	0.06*	0.07*	−0.34	−0.02	−0.08	0.01	0.95*	1.00

Table 2. Spearman's rank correlation coefficient between meteorological variables, *weekly incidence* and *weekly prevalence* of SARS-CoV-2, and *population density*. *$p < 0.05$.

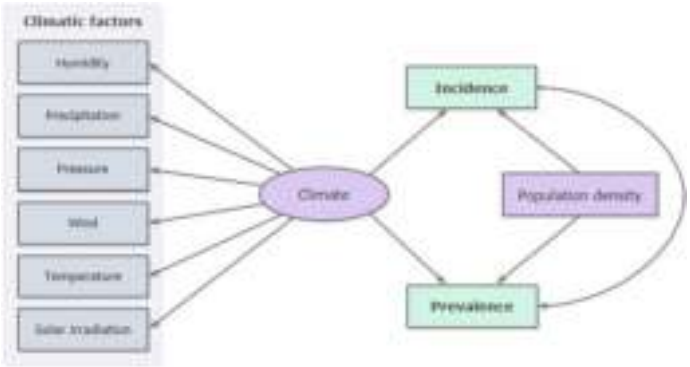

Figure 2. Theoretical path diagram used to analyze the effects of climate and population density on the spread of SARS-CoV-2. This diagram was generated using Office Power Point software, version 2010 (https://www.microsoft.com/it-it/microsoft-365/powerpoint).

In turn, the different climatic factors were found to be correlated with *Climate* in another way. Specifically, solar irradiation and temperature were negatively correlated, with a factor loading of −0.77 ($p < 0.001$) and −0.56 ($p < 0.001$), respectively. While, relative humidity, precipitation and pressure showed a positive correlation, with factor loading of 0.52, 0.44, and 0.073, (for all, $p < 0.001$). Wind was negatively correlated (−0.046) but without a significant p-value.

For paths *Population density* → *Incidence* and *Population density* → *Prevalence*, population density resulted to be linked to incidence and prevalence by standardized positive path coefficients ($b = 0.043$, $p < 0.01$ and $b = 0.051$, $p < 0.01$, respectively), although to a lesser extent than those exhibited by *Climate*. The variables, incidence and prevalence observed, being by their nature closely related, showed a high covariance between errors of 0.96 ($p < 0.001$).

An interesting outcome is given by the residual variance ($var(\varepsilon_1) = 0.97$ for incidence and $var(\varepsilon_2) = 0.98$ for prevalence). This parameter represents the effects of unmeasured factors influencing incidence and prevalence. It indicates that factors other than climate and population density affect SARS-CoV2 incidence and prevalence, but also random errors, errors in data entry, and systematic errors leading to biases in the measurement of values.

Finally, the goodness of fit of the model was tested, and the results of the evaluation showed an overall good fit (CD = 0.826, RMSEA = 0.088, SRMR = 0.078). This demonstrates that SEM adequately confirms the theoretical path diagram of Fig. 2, indicating the strength and direction of association between incidence and prevalence of SARS-CoV-2, climatic variables, and population density.

Overall, the results of the analysis demonstrated that (a) climate has a relevant impact on incidence and prevalence of SARS-CoV-2 (at least in the first 16 weeks), stronger than that exhibited by density of population;

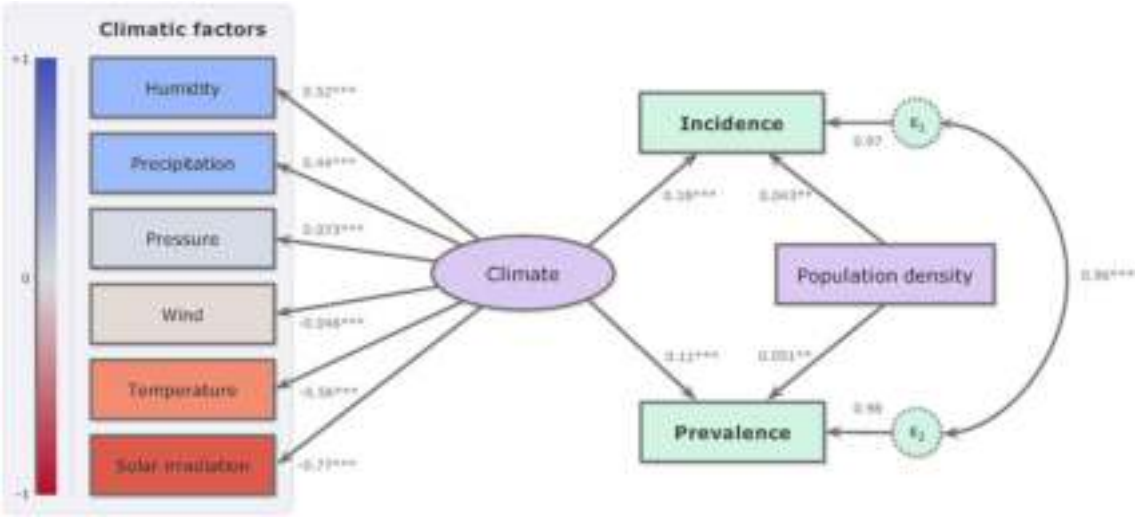

Figure 3. SEM path diagram for the effect of the climate and the population density on the spread of SARS-CoV-2. Observed variables are represented by boxes, latent variable by an ellipse, and residual terms by circles. The values on the straight arrows between latent and observed variables and those between latent and observed indicators represent the standardized path coefficients and the factors loading, respectively. The values on the straight arrows between residual terms and observed variables represent the residual variance. The diagram was generated using Office Power Point software for Microsoft 365 (https://www.microsoft.com/it-it/microsoft-365/powerpoint). ***$p < 0.001$; **$p < 0.01$.

(b) among the climatic variables, solar irradiation proved to be the most influential factor, followed (but in the opposite direction) by relative humidity, and by temperature (in the same direction of solar irradiation).

Discussion

COVID-19 pandemic represents a serious threat for people worldwide, with an alarming day-by-day increasing number of infections and death cases. Consequently, the scientific community worldwide is constantly seeking for new and useful knowledge aimed at contrasting the spread of SARS-CoV-2.

Climatic factors seem to play an important role in the epidemiology of the infection, although the results of the recent literature failed to give a unique and unequivocal knowledge on this subject.

In this paper, we have carried out an extensive and comprehensive analysis to determine the role of climate and some demographic factors in the spread of COVID-19. For this purpose, we used a particular and powerful statistical technique (the structural equation modeling), for the evaluation of causal assumptions, taking into consideration, as dependent variables, both weekly incidence and weekly prevalence.

The key objective of this study was to overcome the limitations of previous investigations. In line with this perspective, we have (a) conducted research on a global scale (on all countries in the world), (b) carried out observation over a long period of time (to our best knowledge, the longest among the studies published so far), (c) considered not some but all the main six climatic factors, (d) used a relative time scale, synchronizing the countries based on the beginning of the epidemic, (e) taken into account not a single point but multiple points of evaluation for climatic variables for each country, (f) considered a lag interval between the acquisition of climatic data and the collection of COVID-19 data for the analysis, (g) not considered the variables as stand-alone factors but taken into account their interdependence and used an integrative statistical investigation to evaluate their effects.

In light of this, the choice of SEM was very strategic. It allowed to test a complex model of relationships among climatic variables, population density and morbidity indices. Alternatively, several separate analyses, with less solid results in statistical terms, would have been required. The use of SEM has also the advantage of including, in the exploration model, variables (such as *Climate*) which cannot be directly observed. In addition, it solved the problem of the interdependence among the meteorological variables, allowing to address them in a comprehensive analysis.

Overall, this approach helped us to build a more solid analysis, yielding robust and reliable findings, highly consistent with the hypothesis that both climate and population density significantly influence the spread of COVID-19. Moreover, climate outweighs population density, and, in this context, solar irradiation, plays the most relevant role.

This is in line with the results of some epidemiological reports[10,11] and with a recent experimental investigation demonstrating that UV radiation, in very small doses, is able to inactivate SARS-CoV-2[22]. Although to a lesser extent, temperature, humidity, and precipitation also resulted to significantly influence SARS-CoV2 incidence and prevalence. Instead, the role of wind was demonstrated to be small, while that of pressure was not relevant. Overall, these findings may account for the different initial distribution of the epidemic across the countries, with the cold countries being affected more quickly and more intensely than the hot ones.

Similarly, the aforementioned results provide support to the common opinion that the climate is a determining factor in the spread of the pandemic. They also provide grounds for recent clusters of infections developed

0157

during the summer in different European working places, all characterized by a lack of solar irradiation and low temperature (i.e. a sausage factory in Mantova, Italy; a slaughterhouse in Gütersloh, Germany; a slaughterhouse in Tipperary, Ireland).

However, the high rates of COVID-19 observed in the last weeks in Brazil, India, and the USA seems to contradict the conclusions drawn in the present study, as this outbreak of pandemic occurred in countries with high temperature and adequate solar irradiation. However, SEM has shown that SARS-CoV-2 incidence and prevalence are influenced not only by climate but also by population density, and that factor is very high in the three countries mentioned. Therefore, if accurately interpreted, the findings of the present study may explain this apparent paradox, as well.

A puzzling result of the SEM that needs clarifications (to avoid possible misinterpretation) is the high value of residual variance (the value on the straight arrows between residual terms and dependent variable). As stated in the Methods section the residual term (the effect of which is represented by the residual variance) includes other possible variables having effects on the dependent variable. To the untrained eye, the high value of residual variances in our study (0.97 and 0.98) seems to significantly weaken the worth of the path coefficients (having lower magnitudes: 0.04–0.18). In fact, such an approach is conceptually wrong since path coefficient and residual variance are two different entities which cannot be compared to each other. Moreover, it should not be forgotten that the residual variance includes, within itself, the effects of a lot of components (various forms of errors and other causal variables), each of which may have very little relevance. So, due to its cumulative nature, residual variance may also reach high values, without, however, affecting or weakening the worth of path coefficients, whose value is confirmed by the very low p-values (<0.001 and <0.01) in our analysis. Finally, the weight that the residual terms may have in SEM can be calculated and expressed by the fit index SRMR. In the present study the value of SRMR was only 0.078, which testifies that the weight of residual terms on the tested model is irrelevant and that SEM adequately confirms the theoretical path.

In view of the causal implications of climatic factors on the spread of SARS-CoV-2, it may be tempting to identify a threshold of solar irradiation or temperature or any other climatic factor, above which the COVID-19 spread is negatively affected. This thought is deeply appealing and was also one of our main goals before collecting, analyzing and, most importantly, understanding our data. In addition, several studies had already identified a cut-off value, although with very different results[2,8,10,14,29,33–38].

However, in the case of COVID-19, considering only one climatic factor and trying to identify its threshold values, although potentially feasible, would be a constraint and, consequently, any resulting formula, would be conceptually wrong.

The correlation analyses of our study (reported in Table 2) and numerous meteorological studies incontrovertibly demonstrate that the main climatic factors (the 6 we considered) are interconnected. Therefore, focusing on single threshold values, above or below which a given event occurs, would have no mathematical or logical rationale, neither does (for example) trying to identify a threshold temperature value below which snowfall occurs. Snowfall does not depend only on temperature, but on the interaction of several atmospheric factors. Therefore, considering only the temperature will not lead to reliable forecasts since snow formation also depends on other factors (humidity, pressure, and wind). It is only through the calculation of all these variables together and the historical data collected over decades that the most likely scenarios can be identified.

Now, when it comes to SARS-CoV-2, the scenario becomes even more complex. In fact, not only is there a lack of reliable historical data on the epidemic in relation to climatic factors, but also there is the severely aggravating circumstance that, besides climatic factors, the spread of SARS-CoV-2 is influenced by countless other factors (population density, cultural habits, severity and observance of containment measures, intensity of trade and human contact, hygiene measures, etc.).

During our study, we soon realized that, due to the highly complex nature regulating the relationships between the variables, identifying a cut-off value was not feasible, precisely because too many causal variables are involved, each with a very wide range of variation. We thus decided to focus on the analysis of the relationships between climatic factors and virus spread, in order to identify the main players involved in the phenomenon and understand their effect. The magnitude and the algebraic sign of the factor loadings we calculated, led to understanding the type of correlation between each climatic variable and the latent variable Climate, identifying its strength and direction. In turn, the path coefficients linking Climate to the observed variable (incidence and prevalence) proved its correlation. Which is not negligible.

Basically, our study demonstrates that it is not possible to identify a mono-factorial threshold value to predict a reversal of COVID-19 spread. Only complex mathematical patterns (such as meteorological forecasting patterns), supported by an enormous amount of data sets (possibly also historical), may sufficiently define reliable predictability conditions.

In conclusion, the present study demonstrates that climatic factors significantly affect the spread of SARS-CoV-2 (probably and especially by influencing the air transmission through respiratory droplets). Among the variables investigated, solar irradiation proved to be the most influential factor, followed by temperature, humidity, precipitation, and, with a minimal or non-significant impact, pressure, and wind. However, demographic factors, together with other determinants, can affect the transmission (probably and especially through direct contact routes), and the influence of these can be such that they may overcome the protective effect of climate in some countries. Compared with the other studies reported in the literature, the present research has the merit of having addressed and overcome the limits of the previous investigations. To do so, however, it was necessary to use a robust mathematical model for the analysis (SEM), which required a considerable effort in terms of information needs, in order to function properly. The large amount of data used represents only a small part of the tremendous effort required, while greater effort was necessary for the selection of data and the evaluation of the criteria to be adopted for data processing. Only by respecting all these conditions, SEM could function properly and provide the results otherwise unattainable.

Methods

Data collection. Data regarding COVID-19 were collected from Johns Hopkins GitHub repository Systems Science and Engineering[23]. The information on governmental measures (school and university closures) were acquired from the UNESCO database[24]. The climatic parameters reported were taken from the dataset of the NASA Langley Research Center (LaRC) POWER Project[25] and the demographic estimates (population size, land area, population density) were obtained from the United Nations population estimates and from the World Factbook of Central Intelligence Agency (CIA)[26].

In order to evaluate the relation of COVID-19 with geo-climatic environment, the world has been divided into five geoclimatic zones, according to the updated Koppen-Geiger classification: polar, cold-temperate, warm-temperate, arid, and equatorial[27].

For SARS-Cov-2 analysis, all the UN 193 countries have been taken into account. Among these, 16 small countries, with a population below one million and a density of less than 100 people/km^2, as well as 18 countries with insufficient data on COVID-19 have been excluded. Conversely, all 50 states of the United States of America have been considered individually. Therefore, a total of 209 Countries have been included in the present study.

A total of 134,871 data were acquired from the sources mentioned above and inserted in a Microsoft Excel spreadsheet (Supplementary Table S2). Thirteen variables have been considered for the analysis and organized into the 3 groups herein reported.

1. Demographic: population size (number of people), land area (square kilometer—km^2), population density (people/km^2).
2. Climatic: climatic zone (one to five), temperature at two meters (degree Celsius—°C), solar irradiation (megajoule/square meter/day—MJ/m^2/day), relative humidity (percentage—%), wind speed at two meters (meter per second—m/s), surface pressure (kilopascal—KPa), precipitation (millimeters/day—mm/day).
3. COVID-19: date of the first confirmed case, number of new weekly cases, and number of active weekly cases.

Data processing. To ensure that the data collected met the purposes of the study, a set of specific criteria was established for the selection of the appropriate sample, and separate studies were performed to confirm the appropriateness of these choices. In particular:

1. Data on weekly new cases and active cases of SARS-CoV-2 infection were collected for a period of 16 weeks. Since the beginning of the infection did not occur simultaneously across all the countries, the data collected start from the first documented case in each country.
2. To evaluate the relationship between COVID-19 and climatic factors, matching epidemic and climatic data was found to be of importance. In each country, climatic conditions vary considerably across regions. Therefore, one to four cities, one for each of the regions most affected by COVID-19, were chosen for each country. Then, the weekly average was calculated for all the six climatic variables. Finally, the weekly means of all the cities were averaged to get the six total national weekly values. The process was repeated for all the weeks considered.
3. To evaluate the relationship between COVID-19 and climatic factors, a shift time between the collection of virologic data and the acquisition of climatic data had to be taken into consideration. In fact, the incubation period, the delay between symptom onset and testing, and the delay due to the communication of the result, contribute to a time shift between the infection exposure and the publication of the virologic data. Consequently, it is necessary to take into account a lag time between the collection of virologic data and the acquisition of climatic data for the analysis. According to the literature data[28–30], a lag time of two weeks was considered in the present study.

Data analysis. Data relative to SARS-CoV-2 were collected into a balanced panel dataset of 209 countries, starting from the first week of outbreak, until the sixteenth week. Due to data skewness (i.e. data with a non-Gaussian distribution), logarithmic transformation was applied to the analyzed variables.

The weekly incidence and prevalence of COVID-19 were calculated for each country, starting from the week of the first infection case and ending at week 16, according to the following formulas:

$$\text{Incidence} = \frac{\text{Number of new cases of Covid during week}}{\text{Population}} \times 100{,}000 \quad (1)$$

$$\text{Prevalence} = \frac{\text{Number of confirmed cases per week}}{\text{Population}} \times 100{,}000 \quad (2)$$

To verify whether the morbidity indices (incidence and prevalence) depend on the geoclimatic zones where countries are geographically located, the non-parametric k-sample test for median equality was applied and a geographic representation (thematic world map) was constructed for each of the explored variables.

To further investigate whether there is a correlation between incidence/prevalence and each climatic variable (considered individually), the Spearman rank correlation coefficient was calculated considering a two-week interval between the climatic data and the virological data. Furthermore, the correlation between incidence/prevalence and population density was also calculated.

Subsequently, on the basis of the results of the descriptive analysis, a path diagram was proposed (Fig. 2) to explore the potential relationships between meteorological variables, population density and morbidity indices.

In this theoretical path it was assumed that meteorological factors were correlated to each other and linked to an unobserved/unmeasurable variable (or latent variable), indicated by the *Climate* label. Furthermore, it was hypothesized that *Climate* (that integrates the effects of meteorological variables) and *Population Density*, were regressors of *Incidence* and *Prevalence*, assuming the following pathways: *Climate* → *Incidence*, *Climate* → *Prevalence*, *Population Density* → *Incidence*, *Population Density* → *Prevalence*. Finally, *Incidence* and *Prevalence*, being closely connected by their nature, were linked by an arc that expresses their covariance.

To test this theoretical path and convert it into a set of equations, the authors applied the SEM, a broad and flexible statistical technique for modeling causal chain of effects simultaneously. Using a confirmatory approach (hypothesis-testing), this technique, examines the relationships between observed variables and not observed (latent) variables, in turn linked to observed variables, their indicators.

The SEM graphical representation is given by a path diagram, a kind of flow-chart that uses boxes, ellipses, and circles linked via arrows. Observed variables are represented by a box, and latent variables by an ellipse. Straight single-headed arrows express causal relations and double-headed curved arrows express correlations or covariance (without a causal interpretation). The values on the straight arrows between latent and observed variables and those between latent and observed indicators, represent, respectively, the path coefficients and the factors loading (the last being the correlation coefficient for the latent and observed indicators).

The circles with short arrows pointing to dependent variables refer to residual terms ε_i. They include other possible variables that may influence dependent variables, but also random errors, errors in data entry, systematic errors leading to bias in the measurement of values. The value on the straight arrows between residual terms and dependent variables represents the residual variance (var ε_i). Two important issues of SEM that deserve to be comprehensively addressed are the path coefficient and the residual variance. The path coefficient is a basic element in the SEM model. It indicates strength and direction of the causal impact of a variable considered as a cause on another variable that is considered, instead, an effect; it is like the regression coefficient. There are two types of path coefficients: non-standardized and standardized. Both express the influence of the causal variable on the dependent variable, but the first (the non-standardized one) reflects the change in terms of unit, while the second (the standardized), changes in terms of standard deviation. For example, in path A → B, a non-standardized path coefficient of 0.20 indicates that, if variable A increases by 1-unit, variable B is be expected to increase by 0.20 unit. In the case of standardized path coefficient, if variable A increases by one standard deviation from its mean, variable B is expected to increase by 0.20 its own standard deviation from its own mean. Frequently, SEM models include more than one variable as causative factor, often with different measurement units and order of magnitude. In these cases, the use of a non-standardized path coefficient is inappropriate because the effects of these variables on the dependent variable cannot be directly compared. Instead, the standardized path coefficient, being based on a normalised parameter (the standard deviation of the mean), allows for a direct comparison of the effects of variables, regardless of their original measurements.

Since both climatic variables and population density have very different scales of measurement and order of magnitude, in the present study the standardized path coefficient was considered for the analysis.

As for the residual variance, it is worth pointing out that it includes the effects of a lot of components (errors and other variables), each of which may have very little relevance. For its cumulative nature, residual variance may also reach high values, but the actual weight that it had in SEM is expressed by the fit index SRMR (reported below).

In order to reduce the random error, observations with missing values were excluded from the SEM model processing because the interpolation approach (often used for missing data) would have introduced other sources of errors in addition to those already present and due to (a) the large number of variables considered, (b) the large number of data processed, (c) the large number of Countries from which the data were collected, and (d) the heterogeneity of the same (often very different in a number of aspects).

To evaluate the adequacy of the model, the following fit indices were considered[31]: (a) coefficient of determination (CD) (similar to the R-squared value, ranging 0–1, good fit for values close to 1); (b) root mean square error of approximation (RMSEA) (good fit for RMSEA < 0.08), and (c) standardized root mean square residual (SRMR) (adequate fit for SRMR < 0.08).

SEM was fitted by maximum likelihood estimation (MLE) method and p-value less than 0.05 was considered as statistically significant. All of the statistical analysis was performed using STATA 14.0 (STATA Corp, College Station, TX)[32], using the commands and the code reported below.

(a) Commands:

- *tsset command*, to structure in form of panel data the database containing the climate, socio-demographic and covid data of the 209 countries (for a total of 3764 records);
- *sem command*, to transform the relationships hypothesized between the variables (previously logarithmized) in a model of linear structural equations;
- *sem, standardize*, to obtain the standardized path coefficients;

(b) Code:

tsset id week_index
sem (*Climate -> L2.ln_Precipitation,*) (*Climate -> L2.ln_Humidity,*) (*Climate -> L2.ln_Pressure,*) (*Climate -> L2.ln_Temperature,*) (*Climate -> L2.ln_Wind,*) (*Climate -> L2.ln_Solar,*) (*Climate -> ln_Prevalence,*) (*Climate -> ln_Incidence,*) (*ln_Population_density -> ln_Incidence,*) (*ln_Population_density ->*

Abstract: After the first pandemic wave, a nationwide survey assessed the seroprevalence of SARS-CoV-2 antibodies in Spain and found notable differences among provinces whose causes remained unclear. This ecological study aimed to analyze the association between environmental and demographic factors and SARS-CoV-2 infection by province. The seroprevalence of SARS-CoV-2 antibodies by province was obtained from a nationwide representative survey performed in June 2020, after the first pandemic wave in Spain. Linear regression was used in the analysis. The seroprevalence of SARS-CoV-2 antibodies of the 50 provinces ranged from 0.2% to 13.6%. The altitude, which ranged from 5 to 1131 m, explained nearly half of differences in seroprevalence ($R^2 = 0.47$, $p < 0.001$). The seroprevalence in people residing in provinces above the median altitude (215 m) was three-fold higher (6.5% vs. 2.1%, $p < 0.001$). In the multivariate linear regression, the addition of population density significantly improved the predictive value of the altitude ($R^2 = 0.55$, $p < 0.001$). Every 100 m of altitude increase and 100 inhabitants/km^2 of increase in population density, the seroprevalence rose 0.84 and 0.63 percentage points, respectively. Environmental conditions related to higher altitude in winter–spring, such as lower temperatures and absolute humidity, may be relevant to SARS-CoV-2 transmission. Places with such adverse conditions may require additional efforts for pandemic control.

1. Introduction

The first wave of the SARS-CoV-2 pandemic spread in Europe in March and April 2020, showing important geographical differences whose causes remain unclear [1]. The role of environmental and demographic conditions on SARS-CoV-2 transmission is not well known. Geographical comparisons have associated higher atmospheric temperature and humidity with lower SARS-CoV-2 transmission [2–5]. However, these studies may be affected by differences in the completeness of COVID-19 reporting in the first wave, because a high and variable percentage of cases were not confirmed [5]. Furthermore, those studies that compare countries may also be affected by the differences in the introduction of preventive interventions [6,7].

Altitude above sea level could be a potential factor related to SARS-CoV-2 transmission and COVID-19 severity [8]. Studies in Bolivia and Ecuador have suggested that physiological adaptation to hypoxia in high-altitude regions could be protective for SARS-CoV-2 infection [9,10]. However, other authors have also shown that case-fatality rate may not be reduced at high altitude [11]. Indeed, higher mortality rates attributable to COVID-19 have

been reported in areas located over 2000 m of altitude against those located below 1500 m in the United States and Mexico [12].

Several studies support the hypothesis that low temperature and low absolute humidity favor SARS-CoV-2 transmission. In Italy, a lower risk of hospitalization by COVID-19 was observed in cases in people living near the coast [13].

Spain is a mountainous and climatically diverse territory. Compared to other European countries, the altitude in Spain is higher on average and the geographical diversity is wider, resulting in a major climatic contrast. However, because the altitude range of the Spanish municipalities does not exceed 1700 m, its relevance as a cause of hypoxic effects is low.

Spain was one of the European countries first and most severely affected by COVID-19 [1,14]. Transmission increased steeply during the first half of March, and the main intervention was a lockdown implemented simultaneously in all Spanish regions on 15 March 2020 [15]. No other relevant intervention was introduced; therefore, the important geographical differences observed in COVID-19 cumulative incidence in the first pandemic wave were probably related to case reporting, and to environmental and sociodemographical factors [2–13].

This study aimed to assess the possible influence of several environmental and demographic factors on the differences in the transmission of SARS-CoV-2 among provinces in Spain.

2. Materials and Methods

This ecological study analyzed environmental and demographic factors to explain the geographical differences among provinces in the seroprevalence of SARS-CoV-2 antibodies after the first pandemic wave in Spain.

Spain is divided into 50 provinces whose capital city is usually the most populated municipality. A nationwide Seroepidemiological Survey of SARS-CoV-2 Infection was performed in a representative sample of the population [16]. The first round of this survey included a representative sample of persons of each province who were recruited from 27 April to 11 May 2020. Immunoassays were performed for the detection of IgG against SARS-CoV-2 in 51,958 persons. The seroprevalence of IgG antibodies was estimated by province [16].

Province population data by January 2020 were obtained from the National Institute for Statistics. The Geographical Institute was consulted to obtain the province extension, as well as the latitude and altitude above sea level of their respective capital city (https://www.ign.es/web/ign/portal/ane-datos-geograficos/-/datos-geograficos/datosPoblacion?tipoBusqueda=capitales, accessed date 21 January 2021). Population density was calculated as inhabitants per km^2.

The increasing part and the peak of the pandemic wave took place in March 2020, and the lockdown started on March 15 and continued up to May; therefore, the meteorological conditions in March were considered relevant to evaluate their potential effect on SARS-CoV-2 transmission. From the National Meteorological Agency, we obtained the monthly mean of each capital city for relative humidity, as well as daily maximum, minimum and mean temperatures in degrees Celsius (°C) (https://opendata.aemet.es/centrodedescargas/productosAEMET?, accessed date 21 January 2021). Absolute humidity was calculated as a function of relative humidity, mean temperature, and atmospheric pressure.

Quantitative variables were presented as the mean, standard deviation, median, and range. Means were compared by the Student's *t*-test. Categorical variables were presented as percentages and compared by χ^2. Linear regression analysis was used to test the predictive value of each variable on the seroprevalence by province. The determination coefficient (R^2) was calculated as an indicator of the proportion of the seroprevalence variability that was explained by the model. A multivariate linear regression model was fitted, starting with the most predictive variable and adding the variables that significantly

increased the predictive capacity of the model. *p*-values lower than 0.05 were considered as statistically significant. The IBM-SPSS Statistics 25 package was used for statistical analysis.

3. Results

The seroprevalence of SARS-CoV-2 IgG antibodies of the 50 Spanish provinces ranged from 0.2% to 13.6%. Variability among capital cities was considerable in altitude (ranging from 5 to 1131 m) and population density (ranging from 9 to 840 inhabitants/km^2). Very important differences were also observed in the average maximum, minimum, and mean temperatures in March 2020, as well as in average atmospheric absolute humidity (Table 1).

Table 1. Descriptive analysis of the variables considered for the 50 provinces in, Spain.

Variables Analyzed	Mean	SD	Range	Median
Seroprevalence of SARS-CoV-2 IgG, % *	4.3	3.8	0.2–13.6	2.8
Altitude above sea level, m **	370	362	5–1131	215

Density of population (inhabitants/km^2)	132	174	9–840	63

* Seroprevalence of SARS-CoV-2 IgG antibodies obtained by immunoassay tests from 27 April to 11 May 2020. ** Data refer to the capital city of the province. Meteorological variables were average variables of March 2020. Temperature is in degrees Celsius.

In bivariate analyses, a higher altitude, a lower absolute humidity, and lower averages of daily maximum, minimum and mean temperatures were statistically significantly associated with a higher seroprevalence in the province. Living in a province with a coast was also significantly associated with an average decrease in seroprevalence of 4.1 percentage points ($p < 0.001$; $R^2 = 0.30$) (Figure 1). However, altitude was the strongest predictive variable for the seroprevalence ($R^2 = 0.47$) (Table 2 and Figure 2).

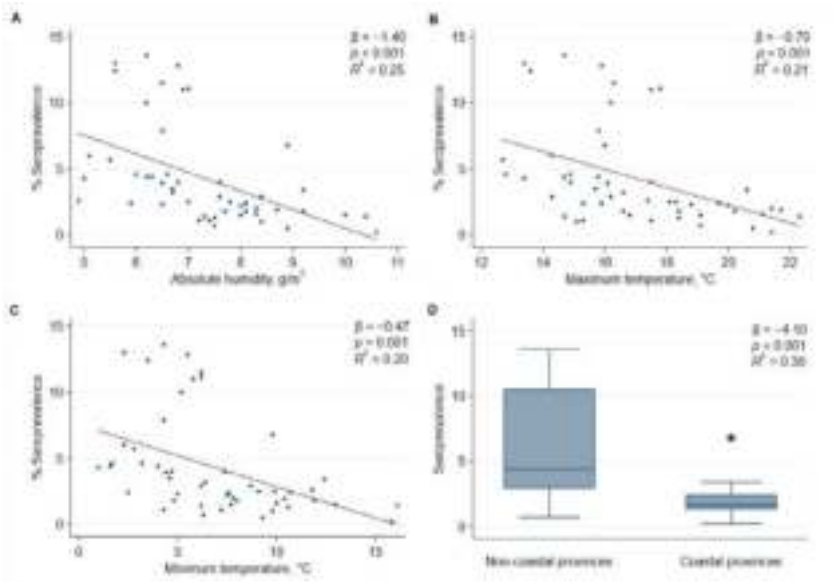

Figure 1. Bivariate association of the seroprevalence of IgG antibodies against SARS-CoV-2 as a function of four environmental parameters by province. The seroprevalence was obtained by immunoassay tests in samples collected from 27 April to 11 May 2020, in Spain. (**A**) Average of absolute humidity; (**B**) average of daily maximum temperatures; (**C**) average of daily minimum temperatures; and (**D**) box-plot of comparison between coastal and non-coastal provinces.

Table 2. Results of linear regression at the province level (n = 50) between environmental and demographic variables and the seroprevalence of IgG antibodies against SARS-CoV-2 obtained by immunoassay tests from 27 April to 11 May 2020, in Spain.

Analyses and Variables	Beta	SE	p-Value	R^2
Bivariate analyses				
Altitude above sea level (per 100 m) *	0.71	0.11	<0.001	0.47
Latitude in degrees *	0.19	0.17	0.261	0.03
Average absolute humidity (g/m^3) *	−1.40	0.35	<0.001	0.25
Average of daily maximum temperatures, °C *	−0.70	0.19	<0.001	0.21
Average of daily minimum temperatures, °C *	−0.47	0.13	0.001	0.20

Altitude above sea level (per 100 m) *	0.84	0.11	<0.001	
Density of population (inhabitants per km^2)	0.63	0.23	0.009	

* Data refer to the capital city of the province; R^2, determination coefficient. SE, standard error; We used bold case to distingish the analysis, because normal case is used to variables.

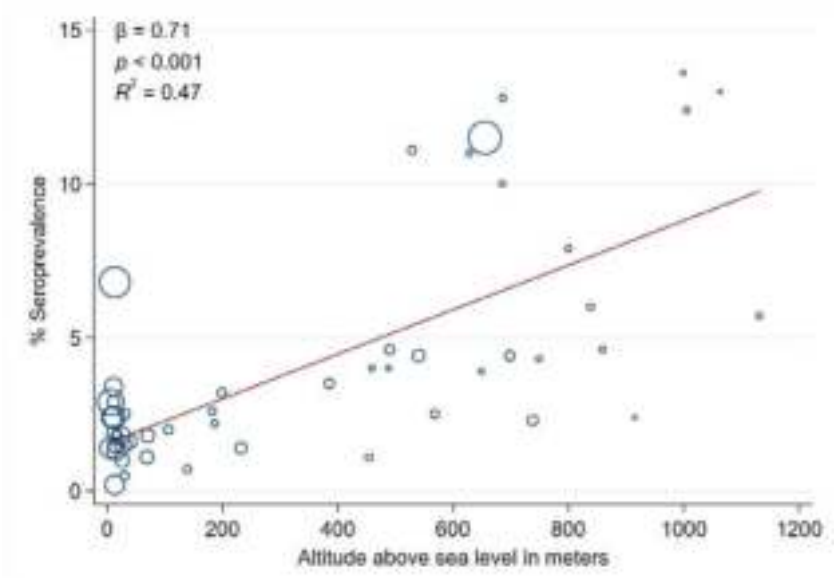

Figure 2. Linear regression analysis of the seroprevalence of IgG antibodies against SARS-CoV-2 as a function of the altitude above sea level in meters by province. The diameter of the circles is proportional to the population density. The seroprevalence was obtained by immunoassay tests in samples collected from 27 April to 11 May 2020, in Spain.

In the multivariate linear regression model, population density was the only variable that significantly improved the predictive value of the altitude (R^2 = 0.55). Each 100 m increase in altitude and 100 inhabitants/km^2 of increase in density, the seroprevalence increased by 0.84 and 0.63 percentage points, respectively (Table 2).

The 25 provinces with altitude above the median (215 m) showed a three-fold higher seroprevalence (6.5% vs. 2.1%, $p < 0.001$), lower absolute humidity (6.4 vs. 8.3 g/m^3, $p < 0.001$), and lower averages of the daily maximum, minimum and mean temperatures than the others (15.5 vs. 18.6, 4.3 vs. 9.6, 9.9 vs. 13.8 °C, respectively, $p < 0.001$) (Table 3).

Table 3. Comparison of average characteristics between provinces (n = 50) with altitude above and below the median (215 m). Spain, 2020.

Variables Analyzed	Provinces with Altitude >215 m (n = 25)		Provinces with Altitude <215 m (n = 25)		p-Value

Seroprevalence of SARS-CoV-2 IgG, % *	6.5	4.1	2.1	1.3	<0.001
Latitude in degrees **	40.8	1.7	39.0	4.0	0.043
Average absolute humidity (g/m^3) **	6.4	0.7	8.3	1.2	<0.001
Average of daily maximum temperatures, °C **	15.5	1.7	18.6	2.3	<0.001
Average of daily minimum temperatures, °C **	4.3	1.9	9.6	2.8	<0.001
Average of daily mean temperatures, °C **	9.9	1.7	13.8	2.7	<0.001
Density of population (inhabitants per km^2)	69	163	194	164	<0.001

* Seroprevalence of SARS-CoV-2 IgG antibodies obtained by immunoassay tests from 27 April to 11 May 2020. ** Data refer to the capital city of the province. Meteorological variables were average variables of March 2020.

4. Discussion

Nearly half (47%) of the important geographical differences in SARS-CoV-2 infection during the first pandemic wave in Spain may be explained by the altitude of the province of residence, and this proportion increased up to 55% when population density was also considered. The seroprevalence of SARS-CoV-2 antibodies was three-fold higher in people living in provinces with altitude above the median. The hypothesis derived from these results is that environmental factors may have a role in SARS-CoV-2 transmission greater than previously considered. More studies are needed to evaluate the role of these factors in geographical differences observed in the pandemic. These environmental conditions should be considered in the comparison of the effects of preventive interventions.

It has been suggested that geographical differences in the cumulative incidence of COVID-19 could be indicative of the success of preventive measures implemented [6,7]. However, in the first wave in Spain, a decisive part of SARS-CoV-2 transmission happened before the relevant preventive measures had been introduced, and the lockdown was implemented simultaneously in all regions. Spain has coastline almost all around the country and many mountain ranges. Some provinces in close proximity have notable altitude differences, while some distant provinces have similar altitude; this geographical pattern seems to have carried over to SARS-CoV-2 infection [16].

Bivariate analysis highlighted several environmental variables associated to the higher seroprevalence of SARS-CoV-2 antibodies, including a higher altitude, lower absolute humidity, and lower averages of daily maximum, minimum and mean temperatures, as well as living in a province with a coast. In the present study, the altitude above sea level was more predictive than any meteorological parameter. In Spain in March, those provinces with a higher altitude had, on average, lower absolute humidity, lower temperature in winter, and less sea influence, and these three factors have been related to increases in respiratory virus transmission [2–4]. Therefore, the strongest association between higher altitude and SARS-CoV-2 seroprevalence may be explained because this factor combines the effects of absolute humidity, temperature, and proximity to the coast. Environmental factors may modify the efficiency of SARS-CoV-2 transmission; however, they are not sufficient to stop the spread. Therefore, while preventive interventions are necessary for all regions [5,7,17], places with adverse conditions may have additional difficulties for the effective control of transmission and may need more strict preventive measures to achieve similar results.

Other ecological studies have evaluated the relationship between environmental factors and SARS-CoV-2 infection, and many have found an inverse relationship between air temperature and humidity and SARS-CoV-2 infection [2,12,13,18–22]. These studies have been based on COVID-19 reported cases that may be affected by differences in the completeness of reporting. In the first pandemic wave, a high percentage of cases were not confirmed, and this percentage may be different among regions and countries [5]. Furthermore, those studies that compare countries may be also affected by the differences

in the introduction of preventive interventions [6,7]. Our results are consistent with most of these studies, and additionally have the advantage of the optimal comparability among Spanish provinces because seroprevalence was assessed with the same protocol, interventions were simultaneously introduced, and social differences within the same country are probably smaller.

Studies in Latin America have not found altitude to be associated with higher transmission [16–18], but the wider altitude range and the tropical latitude make comparisons with our results difficult.

We found a lower seroprevalence of SARS-CoV-2 antibodies in provinces with a coast. This result might be consistent with the lower risk of hospitalization among COVID-19 cases in people living near the coast, which has been found in Italy [13].

The results of our bivariate analysis are consistent with worldwide and large countries' studies that did not find association between population density and SARS-CoV-2 spread [2,20]. However, a higher population density in the province was an independent predictor of SARS-CoV-2 seroprevalence when altitude was an adjusted factor. Although population density was not an important factor in COVID-19 spreading under strict lockdown policies [23], it has been also described as a relevant factor for SARS-CoV-2 transmission in less strict conditions [24–27]; therefore, some effect of population density on transmission in the period before the lockdown in Spain seems plausible.

The main strengths of this study are that Spain met special conditions in the first pandemic wave to evaluate this association, because it is an environmentally diverse territory, the lockdown was implemented simultaneously in all regions, and a nationwide survey was performed to obtain comparable estimates of the seroprevalence of SARS-CoV-2 by provinces.

This study has limitations, however. The ecological analysis may suggest a hypothesis but cannot conclude causality. Parameters of the capital city were assigned to the whole province; although, in most provinces, parameters of the capital city are a good proxy of the average conditions to which the population of the province is exposed. These results may not predict infections in further waves because a part of the population may have acquired immunity; many preventive interventions have been introduced; and the weather conditions in other months may be different. Social interaction and differences between rural and urban residence have been suggested as important factors for SARS-CoV-2 transmission; however, population density alone was not predictive for higher seroprevalence in the present study. Several potential risk factors have not been considered in the analysis, but the strong association that we found between altitude and seroprevalence is unlikely to be totally explained by confounding factors. Furthermore, because altitude is a primary factor, other environmental and social variables might act as intermediate factors explaining the association between altitude and SARS-CoV-2 infection.

5. Conclusions

In summary, important differences among Spanish provinces were observed in the seroprevalence of SARS-CoV-2 antibodies after the first pandemic wave. Nearly half of these differences may be explained by altitude. Environmental conditions related to higher altitude in winter–spring, such as the combination of low temperature and absolute humidity, may be relevant for SARS-CoV-2 transmission. A higher population density was also a predictive factor for transmission. Although spread of SARS-CoV-2 widely depends on social behaviors and preventive interventions, places with adverse environmental conditions may require additional efforts to achieve similar pandemic control.

July 2, 2020

The SARS-CoV-2 pandemic has caused significant mortality and morbidity worldwide, sparing almost no community. As the disease will likely remain a threat for years to come, an understanding of the precise influences of human demographics and settlement, as well as the dynamic factors of climate, susceptible depletion, and intervention, on the spread of localized epidemics will be vital for mounting an effective response. We consider the entire set of local epidemics in the United States; a broad selection of demographic, population density, and climate factors; and local mobility data, tracking social distancing interventions, to determine the key factors driving the spread and containment of the virus. Assuming first a linear model for the rate of exponential growth (or decay) in cases/mortality, we find that population-weighted density, humidity, and median age dominate the dynamics of growth and decline, once interventions are accounted for. A focus on distinct metropolitan areas suggests that some locales benefited from the timing of a nearly simultaneous nationwide shutdown, and/or the regional climate conditions in mid-March; while others suffered significant outbreaks prior to intervention. Using a first-principles model of the infection spread, we then develop predictions for the impact of the relaxation of social distancing and local climate conditions. A few regions, where a significant fraction of the population was infected, show evidence that the epidemic has partially resolved via depletion of the susceptible population (i.e., "herd immunity"), while most regions

in the United States remain overwhelmingly susceptible. These results will be important for optimal management of intervention strategies, which can be facilitated using our online dashboard.

Introduction

The new human coronavirus SARS-CoV-2 emerged in Wuhan Province, China in December 2019 (Chen et al., 2020; Li et al., 2020), reaching 10,000 confirmed cases and 200 deaths due to the disease (known as COVID-19) by the end of January this year. Although travel from China was halted by late-January, dozens of known introductions of the virus to North America occurred prior to that (Holshue et al., 2020; Kucharski et al., 2020), and dozens more known cases were imported to the US and Canada during February from Europe, the Middle East, and elsewhere. Community transmission of unknown origin was first detected in California on February 26, followed quickly by Washington State (Chu et al., 2020b), Illinois and Florida, but only on March 7 in New York City. Retrospective genomic analyses have demonstrated that case-tracing and self-quarantine efforts were effective in preventing most known imported cases from propagating (Ladner et al., 2020; Gonzalez-Reiche et al., 2020; Worobey et al., 2020), but that the eventual outbreaks on the West Coast (Worobey et al., 2020; Chu et al., 2020b; Deng et al., 2020) and New York (Gonzalez-Reiche et al., 2020) were likely seeded by unknown imports in mid-February. By early March, cross-country spread was primarily due to interstate travel rather than international imports (Fauver et al., 2020).

In mid-March 2020, nearly every region of the country saw a period of uniform exponential growth in daily confirmed cases — signifying robust community transmission — followed by a plateau in late March, likely due to social mobility reduction. The same qualitative dynamics were seen in COVID-19 mortality counts, delayed by approximately one week. Although the qualitative picture was similar across locales, the quantitative aspects of localized epidemics — including initial rate of growth, infections/deaths per capita, duration of plateau, and rapidity of resolution —were quite diverse across the country. Understanding the origins of this diversity will be key to predicting how the relaxation of social distancing, annual changes in weather, and static local demographic/population characteristics will affect the resolution of the first wave of cases, and will drive coming waves, prior to the availability of a vaccine.

The exponential growth rate of a spreading epidemic is dependent on the biological features of the virus-host ecosystem — including the incubation time, susceptibility of target cells to infection, and persistence of the virus particle outside of the host — but, through its dependence on the transmission rate between hosts, it is also a function of external factors such as population density, air humidity, and the fraction of hosts that are susceptible. Initial studies have shown that SARS-CoV-2 has a larger rate of exponential growth (or, alternatively, a lower doubling time of cases[1]) than many other circulating human viruses (Park et al., 2020). For comparison, the pandemic influenza of 2009, which also met a largely immunologically-naive population, had a doubling time of 5–10d (Yu et al., 2012; Storms et al., 2013), while that of SARS-CoV-2 has been estimated at 2–5d (Sanche et al., 2020; Oliveiros et al., 2020) (growth rates of $\sim 0.10\mathrm{d}^{-1}$ vs. $\sim 0.25\mathrm{d}^{-1}$). It is not yet understood which factors contribute to this high level of infectiousness.

While the dynamics of an epidemic (e.g., cases over time) must be described by numerical solutions to nonlinear models, the exponential growth rate, λ, usually has a simpler dependence on external factors. Unlike case or mortality incidence numbers, the growth rate does not scale with population size. It is a directly measurable quantity from the available incidence data, unlike, e.g., the reproduction number, which requires knowledge of the serial interval distribution (Wallinga and Lipsitch, 2007; Roberts and Heesterbeek, 2007; Dushoff and Park, 2020), something that is difficult to determine empirically (Champredon and Dushoff, 2015; Nishiura, 2010). Yet, the growth rate contains the same threshold as the reproduction number ($\lambda = 0$ vs. $R_0 = 1$), between a spreading epidemic (or an unstable uninfected equilibrium) and a contracting one (or an equilibrium that is resistant to flare-ups). Thus, the growth rate is an informative direct measure on that space of underlying parameters.

In this work, we leverage the enormous data set of epidemics across the United States to evaluate the impact of demographics, population density and structure, weather, and non-pharmaceutical interventions (i.e., mobility restrictions) on the exponential rate of growth of COVID-19. Following a brief analysis of the initial spread in metropolitan regions, we expand the meaning of the exponential rate to encompass all aspects of a local epidemic — including growth, plateau and decline — and use it as a tracer of the dynamics, where its time dependence and geographic variation are dictated solely by these external variables and per capita cumulative mortality. Finally, we use the results of that linear analysis to calibrate a new nonlinear model — a renewal equation that utilizes the excursion probability of a random walk to determine the incubation period — from which we develop local predictions about the impact of social mobility relaxation, the level of herd immunity, and the potential of rebound epidemics in the Summer and Fall.

[1] The doubling time is $\ln 2$ divided by the exponential growth rate.

Figure 1: *Mobility and COVID-19 incidence data examples, and the results of linear regression to extracted initial exponential growth rates, λ_{exp}, in the top 100 metropolitan regions. (A) Three example cities with different initial growth rates. Data for Google mobility (blue points), daily reported cases (black points), and weather (red and blue points, bottom) are shown with a logistic fit to cases (green line). Data at or below detection limit were excluded from fits (dates marked by red points). Thin grey bars at base of cases graphs indicate region considered "flat", with right end indicating the last point used for logistic fitting; averaging over "flat" values generates the thick grey bars to guide the eye. [See Supp. Mat. for additional information and for complete data sets for all metropolitan regions.] (B) Weighted linear regression results in fit to λ_{exp} for all metropolitan regions. (C) Effect of each variable on growth rate (i.e., $\Delta\lambda$ values) for those regions with well-estimated case and death rates; white/yellow indicates a negative effect on λ, red indicates positive.*

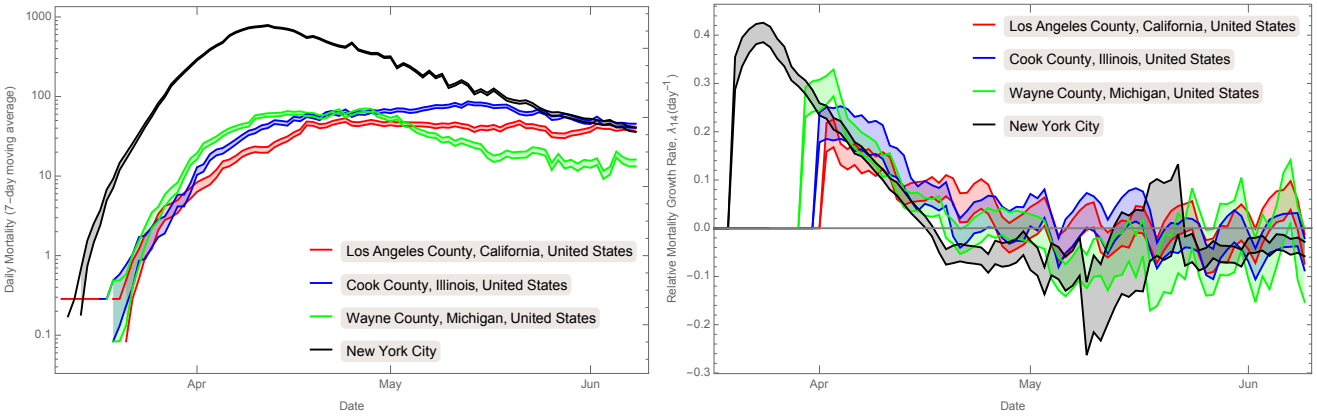

Figure 2: *COVID-19 mortality incidence (7-day rolling average, left) and exponential growth rate (λ_{14}, determined by regression of the logged mortality data over 14-day windows, right) for the four US counties with >2400 confirmed COVID-19 reported deaths (as of 8th June, 2020).*

Results

Initial growth of cases in metropolitan regions is exponential with rate depending on mobility, population, demographics, and humidity

As an initial look at COVID-19's arrival in the United States, we considered the $\sim$100 most populous metropolitan regions — using maps of population density to select compact sets of counties representing each region (see Supplementary Material) — and estimated the initial exponential growth rate of cases in each region. We performed a linear regression to a large set of demographic (sex, age, race) and population variables, along with weather and social mobility (Fitzpatrick and Karen, 2020) preceding the period of growth (Figure 1). In the best fit model ($R^2 = 0.75$, $\mathrm{BIC} = -183$), the baseline value of the initial growth rate was $\lambda = 0.21\mathrm{d}^{-1}$ (doubling time of 3.3d), with average mobility two weeks prior to growth being the most significant factor (Figure 1B). Of all variables considered, only four others were significant: population density (including both *population-weighted density* (PWD) — also called the "lived population density" because it estimates the density for the average individual (Craig, 1985)— and *population sparsity*, γ, a measure of the difference between PWD and standard population density, see Methods), $p < 0.001$ and $p = 0.006$; specific humidity two weeks prior to growth, $p = 0.001$; and median age, $p = 0.04$.

While mobility reduction certainly caused the "flattening" of case incidence in every region by late-March, our results show (Figure 1C) that it likely played a key role in reducing the *rate* of growth in Boston, Washington, DC, and Los Angeles, but was too late, with respect to the sudden appearance of the epidemic, to have such an effect in, e.g., Detroit and Cleveland. In the most extreme example, Grand Rapids, MI, seems to have benefited from a late arriving epidemic, such that its growth (with a long doubling time of 7d) occurred almost entirely post-lockdown.

Specific humidity, a measure of absolute humidity, has been previously shown to be inversely correlated with respiratory virus transmission (Lowen et al., 2007; Shaman and Kohn, 2009; Shaman, Goldstein, and Lipsitch, 2011; Kudo et al., 2019). Here, we found it to be a significant factor, but weaker than population density and mobility (Figure 1C). It could be argued that Dallas, Los Angeles, and Atlanta saw a small benefit from higher humidity at the time of the epidemic's arrival, while the dry late-winter conditions in the Midwest and Northeast were more favorable to rapid transmission of SARS-CoV-2.

Exponential growth rate of mortality as a dynamical, pan-epidemic, measure

In the remainder of this report, we consider the exponential rate of growth (or decay) in local confirmed deaths due to COVID-19. The statistics of mortality is poorer compared to reported cases, but it is much less dependent on unknown factors such as the criteria for testing, local policies, test kit availability, and asymptomatic individuals (Pearce et al., 2020). Although there is clear evidence that a large fraction of COVID-19 mortality is missed in the official counts (e.g., Leon et al., 2020; Modi et al., 2020), mortality is likely less susceptible to rapid changes in reporting, and, as long as the number of reported deaths is a monotonic function of the actual number of deaths (e.g., a constant fraction, say 50%), the sign of the exponential growth rate will be unchanged, which is the crucial measure of the success in pandemic management.

To minimize the impact of weekly changes, such as weekend reporting lulls, data dumps, and mobility changes from working days to weekends, we calculate the regression of $\ln[\mathrm{Mortality}]$ over a 14-day interval, and assign this value, $\lambda_{14}(t)$, and its standard error to the last day of the interval. Since only the data for distinct 2-week periods are independent, we multiply the regression errors by $\sqrt{14}$ to account for correlations between the daily estimates. Together with a "rolling average" of the mortality, this time-dependent measure of the exponential growth rate provides, at any day, the most up-to-date information on the progression of the epidemic (Figure 2).

In the following section, we consider a linear fit to λ_{14}, to determine the statistically-significant external (non-biological) factors influencing the dynamics of local exponential growth and decline of the epidemic. We then develop a first-principles model for λ_{14} that allows for extrapolation of these dependencies to predict the impact of future changes in social mobility and climate.

Epidemic mortality data explained by mobility, population, demographics, depletion of susceptible population and weather, throughout the first wave of COVID-19

We considered a spatio-temporal dataset containing 3933 estimates of the exponential growth measure, λ_{14}, covering the three month period of 8 March 2020 – 8 June 2020 in the 187 US counties for which information on COVID-19 mortality and all potential driving factors, below, were available (the main barrier was social mobility information, which limited us to a set of counties that included 69% of US mortality). A joint, simultaneous,

$C_{\mathcal{H}}$	-0.154 ± 0.055	Dependence on specific humidity
C_γ	-5.52 ± 2.35	Dependence on population sparsity
C_{A_D}	-1.05 ± 0.25	Dependence on total annual deaths

Table 2: *Best-fit parameters for the nonlinear model using parametrization defined in the text.*

linear fit of these data to 12 potential driving factors (Table 1) revealed only 7 factors with *independent* statistical significance. Re-fitting only to these variables returned the optimal fit for the considered factors ($\mathrm{BIC} = -5951$; $R^2 = 0.674$).

We found, not surprisingly, that higher population density, median age, and social mobility correlated with positive exponential growth, while population sparsity, specific humidity, and susceptible depletion correlated with exponentially declining mortality. Notably the coefficients for each of these quantities was in the 95% confidence intervals of those found in the analysis of metropolitan regions (and vice versa). Possibly the most surprising dependency was the negative correlation, at $\simeq -3.7\sigma$ between λ_{14} and the *total* number of annual deaths in the county. In fact, this correlation was marginally more significant than a correlation with $\log$(population), which was -3.3σ. One possible interpretation of this negative correlation is that the number of annual death is a proxy for the number of potential outbreak clusters. The larger the number of clusters, the longer it might take for the epidemic to spread across their network, which would (at least initially) slow down the onset of the epidemic.

Nonlinear model

To obtain more predictive results, we developed a mechanistic nonlinear model for infection (see Supplementary Material for details). We followed the standard analogy to chemical reaction kinetics (infection rate is proportional to the product of susceptible and infectious densities), but defined the generation interval (approximately the incubation period) through the excursion probability in a 1D random walk, modulated by an exponential rate of exit from the infected class. This approach resulted in a *renewal equation* (Heesterbeek and Dietz, 1996; Champredon and Dushoff, 2015; Champredon, Dushoff, and Earn, 2018), with a distribution of generation intervals that is more realistic than that of standard SIR/SEIR models, and which could be solved formally (in terms of the Lambert W function) for the growth rate in terms of the infection parameters:

$$\lambda = \frac{1}{2\tau}\left[\mathrm{W}\left(\sqrt{\frac{\beta\mathcal{S}\tau}{2}}\right)\right]^2 - d \qquad (1)$$

The model has four key dependencies, which we describe here, along with our assumptions about their own dependence on population, demographic, and climate variables. As mortality (on which our estimate of growth rate is based) lags infection (on which the renewal equation is based), we imposed a fixed time shift of Δt for time-dependent variables:

1. We assumed that the susceptible population, which feeds new infections and drives the growth, is actually a sub-population of the community, consisting of highly-mobile and frequently interacting individuals, and that most deaths occurred in separate sub-population of largely immobile non-interacting individuals. Under these assumptions, we found (see Supp. Mat.) that the susceptible density, $S(t)$, could be estimated from the cumulative per capita death fraction, f_D, as:

$$S(t-\Delta t) = S(0)\exp\left[-C_D\, f_D(t)\right] \quad (f_D = D_{\mathrm{tot}}/N)\ ,$$

   where D_{tot} is the cumulative mortality count, N is the initial population, and the initial density is $S(0) = k\,\mathrm{PWD}$.
2. We assumed that the logarithm of the "rate constant" for infection, β, depended linearly on social mobility, m, specific humidity, h, population sparsity, γ, and total annual death, A_D, as:

$$\begin{aligned}\ln\left[\beta\left(\mathcal{M},\mathcal{H},\gamma,A_D\right)\right] &= \ln\left[\beta_0\right] \\ &+ C_{\mathcal{M}}\left(\mathcal{M}-\bar{\mathcal{M}}\right) + C_{\mathcal{H}}\left(\mathcal{H}-\bar{\mathcal{H}}\right) \\ &+ C_{\gamma}\left(\gamma-\bar{\gamma}\right) + C_{A_D}\left(A_D-\bar{A}_D\right)\end{aligned} \qquad (2)$$

   where a barred variable represents the (population-weighted) average value over all US counties, and where the mobility and humidity factors were time-shifted with respect to the growth rate estimation window: $\mathcal{M} = m\left(t-\Delta t\right)$ and $\mathcal{H} = h\left(t-\Delta t\right)$.
3. The characteristic time scale to infectiousness, τ, is intrinsic to the biology and therefore we assumed it would depend only on the median age of the population, A. We assumed a power law dependence:

$$\tau = \tau_0\left(\frac{A}{A_0}\right)^{C_A} \qquad (3)$$

   where we fixed the pivot age, A_0, to minimize the error in τ_0.
4. The exponential rate of exit from the infected class, d, was assumed constant, since we found no significant dependence for it on other factors in our analysis of US mortality. From the properties of the Lambert W function, when the infection rate or susceptibility density approach zero — through mobility restrictions or susceptible depletion — the growth rate will tend to $\lambda \approx -d$, its minimum value.

With these parameterizations, we performed a nonlinear regression to $\lambda_{14}(t)$ using the entire set of US county mortality incidence time series (Table 2). Compared to the linear model of the previous section (Table 1b), the fit improved by 7.6σ ($\mathrm{BIC} = -6008$; $R^2 = 0.724$), despite both having 9 free parameters. Through the estimated parameter values, the model makes predictions for an

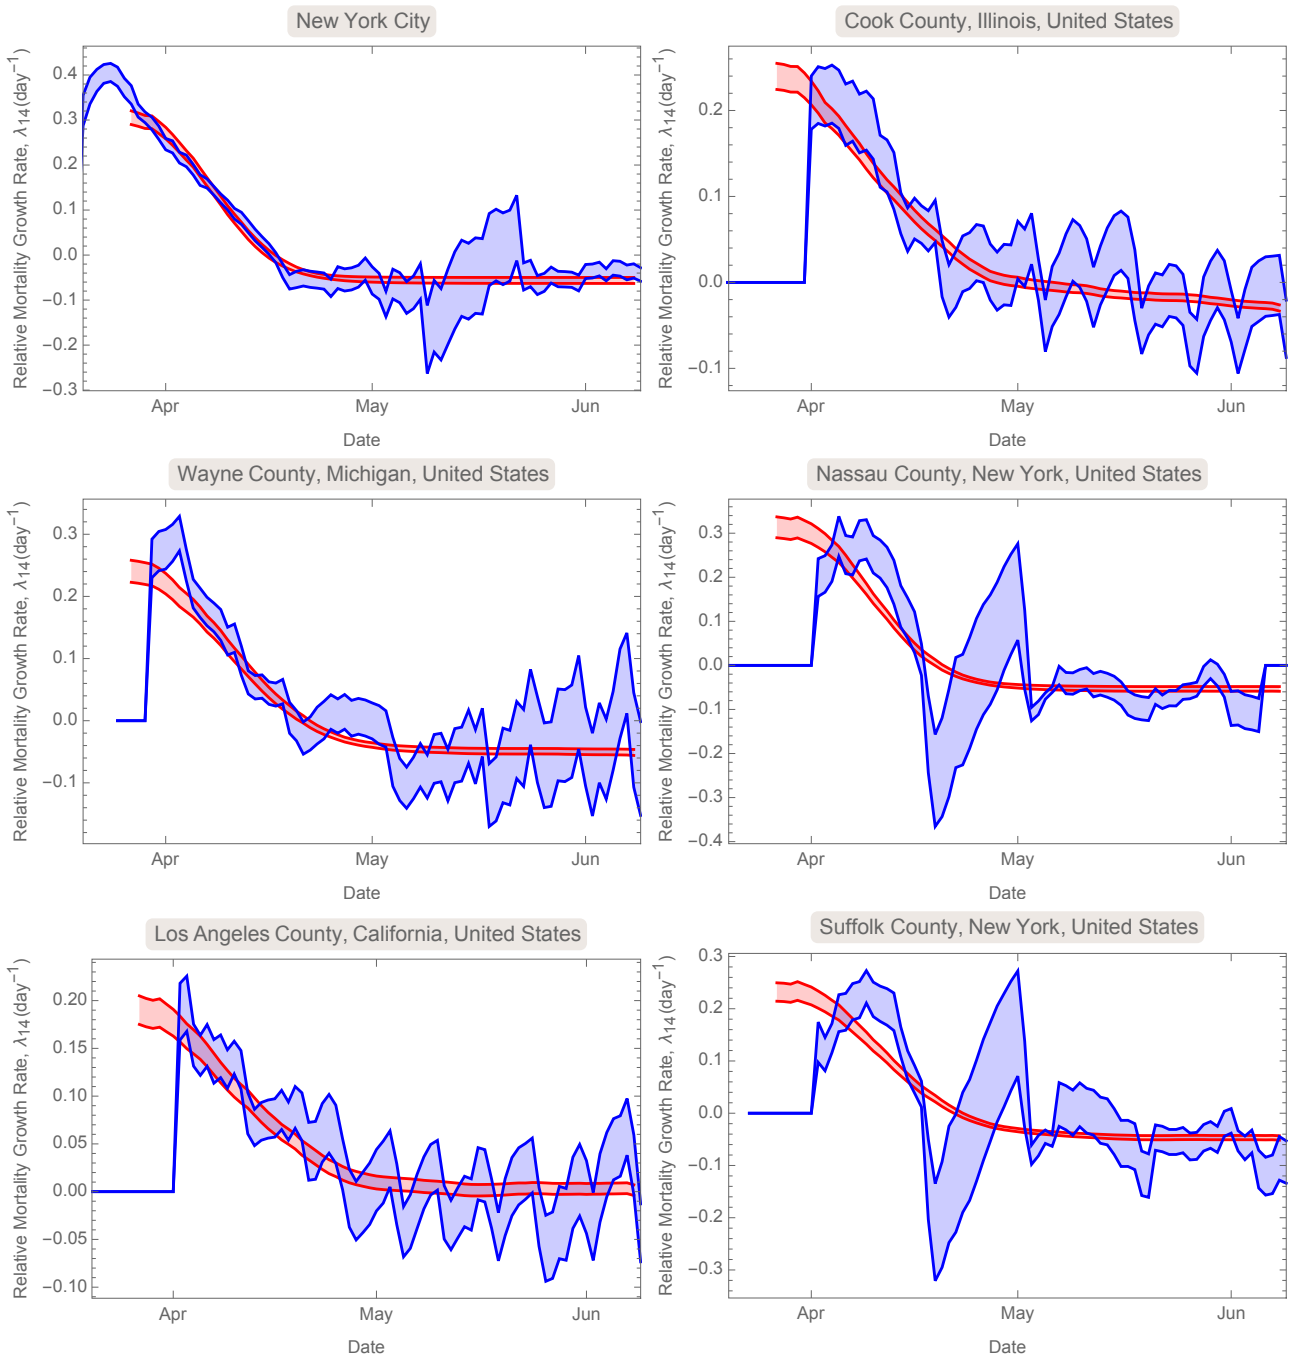

Figure 3: *Nonlinear model prediction (Eqn. 1, red) for the actual (blue) mortality growth rate, in the six counties with highest reported death. Bands show 1-σ confidence region for both the model mean and the λ_{14} value.*

individual's probability of becoming infectious, and the distributions of incubation period and generation interval, all as a function of the median age of the population (see Supplementary Material).

The model was very well fit to the mortality growth rate measurements for counties with a high mortality (Figure 3). More quantitatively, the scatter of measured growth rates around the best-fit model predictions was (on average) only 13% larger than the measurement errors, independent of the population of the county [2].

Importantly, when the model was calibrated on only a subset of the data — e.g., all but the final month for which mobility data is available — its 68% confidence prediction for the remaining data was accurate (Figure 4) given the known mobility and weather data for that final month. This suggests that the model, once calibrated on the first wave of COVID-19 infections, can make reliable predictions about the ongoing epidemic, and future waves, in the United States.

Predictions for relaxed mobility restrictions, the onset of summer, and the potential second wave

Possibly the most pressing question for the management of COVID-19 in a particular community is the combination of circumstances at which the virus fails to propagate, i.e., at which the growth rate, estimated here by λ_{14}, becomes negative (or, equivalently, the reproduction number R_t falls below one). In the absence of mobility restrictions this is informally called the threshold for "herd immunity," which is usually achieved by mass vaccination (e.g., John and Samuel, 2000; Fine, Eames, and Heymann, 2011). Without a vaccine, however, ongoing infections and death will deplete the susceptible population and thus decrease transmission. Varying the parameters of the nonlinear model individually about their Spring 2020 population-weighted mean values (Figure 5) suggests that this threshold will be very much dependent on the specific demographics, geography, and weather in the community, but it also shows that reductions in social mobility can significantly reduce transmission prior the onset of herd immunity.

To determine the threshold for herd immunity in the absence or presence of social mobility restrictions, we considered the "average US county" (i.e., a region with population-weighted average characteristics), and examined the dependence of the growth rate on the cumulative mortality. We found that in the absence of social distancing, a COVID-19 mortality rate of 0.13% (or 1300 per million population) would bring the growth rate to zero. However, changing the population density of this average county shows that the threshold can vary widely (Figure 5).

Examination of specific counties showed that the mortality level corresponding to herd immunity varies from 10 to 2500 per million people (Figure 9). At the current levels of reported COVID-19 mortality, we found that, as of June 22nd, 2020, only 128 ± 55 out of 3142 counties (inhabiting $9.4 \pm 2.1\%$ of US population) have surpassed this threshold at 68% confidence level (Figure 8). Notably, New York City, with the highest reported per capita mortality (2700 per million) has achieved mobility-independent herd immunity at the 10σ confidence level, according to the model (Figure 6). A few other large-population counties in New England, New Jersey, Michigan, Louisiana, Georgia and Mississippi that have been hard hit by the pandemic also appear to be at or close to the herd immunity threshold. This is not the case for most of the United States, however (Figure 8). Nationwide, we predict that COVID-19 herd immunity would only occur after a death toll of $340,000 \pm 61,000$, or 1058 ± 190 per million of population.

We found that the approach to the herd immunity threshold is not direct, and that social mobility restrictions and other non-pharmaceutical interventions must be applied carefully to avoid excess mortality beyond the threshold. In the absence of social distancing interventions, a typical epidemic will "overshoot" the herd immunity limit (e.g., Handel, Longini Jr, and Antia, 2007; Fung, Antia, and Handel, 2012) by up to 300%, due to ongoing infections (Figure 6). At the other extreme, a very strict "shelter in place" order would simply delay the onset of the epidemic; but if lifted (see Figures 6 and 7), the epidemic would again overshoot the herd immunity threshold. A modest level of social distancing, however — e.g., a 33% mobility reduction for the average US county — could lead to fatalities "only" at the level of herd immunity. Naturally, communities with higher population density or other risk factors (see Figure 5), would require more extreme measures to achieve the same.

Avoiding the level of mortality required for herd immunity will require long-lasting and effective non-pharmaceutical options, until a vaccine is available. The universal use of face masks has been suggested for reducing the transmission of SARS-CoV-2, with a recent meta-analysis (Chu et al., 2020a) suggesting that masks can suppress the rate of infection by a factor of 0.07–0.34 (95% CI), or equivalently $\Delta \ln(\text{transmission}) = -1.9 \pm 0.4$ (at 1σ). Using our model's dependence of the infection rate constant on mobility, this would correspond to an equivalent social mobility reduction of $\Delta\bar{\mathcal{M}}_{\rm mask} \simeq -24\% \pm 9\%$. Warmer, more humid weather has also considered a factor that could slow the epidemic (e.g., Wang et al., 2020a; Notari, 2020; Xu et

[2] See Supplementary Material for more detailed discussion of Error Diagnostics.

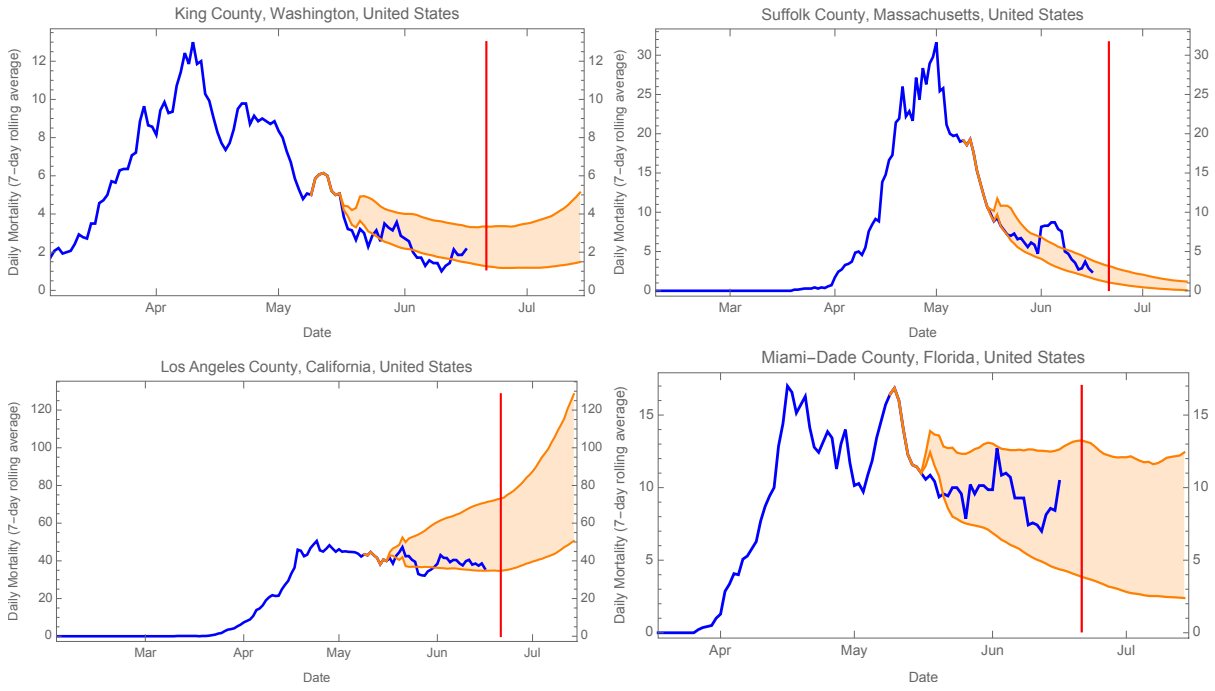

Figure 4: *Forecasts of COVID-19 mortality (orange) — based on the best-fit nonlinear model to data prior to May 16th, 2020 — versus actual reported mortality (blue) for 4 large US counties. The 68% confidence range (orange regions) were determined from 100 random 60-day long simulations (see Supplementary Methods). The vertical red lines indicate June 21st. Forecasts for most US counties can be found at our online dashboard: https://wolfr.am/COVID19Dash*

al., 2020a). Annual changes in specific humidity are $\Delta\bar{\mathcal{H}} \simeq 6\,\mathrm{g}/kg$ (Figure 10b in Supplementary Material), which can be translated in our model to an effective mobility decrease of $\Delta\bar{\mathcal{M}}_{\mathrm{summer}} \simeq -12\% \pm 5\%$. Combining these two effects could, in this simple analysis, yield a modestly effective defense for the summer months: $\Delta\bar{\mathcal{M}}_{\mathrm{mask+summer}} \simeq -37\% \pm 10\%$. Therefore, this could be a reasonable strategy for most communities to manage the COVID-19 epidemic at the aforementioned -33% level of mobility needed to arrive at herd immunity with the least excess death. More stringent measures would be required to keep mortality below that level. Of course, this general prescription would need to be fine-tuned for the specific conditions of each community.

Discussion and Conclusions

By simultaneously considering the time series of mortality incidence in every US county, and controlling for the time-varying effects of local social distancing interventions, we demonstrated for the first time a dependence of the epidemic growth of COVID-19 on population density, as well as other climate, demographic, and population factors. We further constructed a realistic, but simple, first-principles model of infection transmission that allowed us to extend our heuristic linear model of the dataset into a predictive nonlinear model, which provided a better fit to the data (with the same number of parameters), and which also accurately predicted late-time data after training on only an earlier portion of the data set. This suggests that the model is well-calibrated to predict future incidence of COVID-19, given realistic predictions/assumptions of future intervention and climate factors. We summarized some of these predictions in the final section of Results, notably that only a small fraction of US counties (with less than ten percent of the population) seem to have reached the level of herd immunity, and that relaxation of mobility restrictions without counter-measures (e.g., universal mask usage) will likely lead to increased daily mortality rates, beyond that seen in the Spring of 2020.

In any epidemiological model, the infection rate of a disease is assumed proportional to population density (Jong, Diekmann, and Heesterbeek, 1995), but, to our knowledge, its explicit effect in a real-world respiratory virus epidemic has not been demonstrated. The universal reach of the COVID-19 pandemic, and the diversity of communities affected have provided an opportunity to verify this dependence. Indeed, as we show here, it must be accounted for to see the effects of weaker drivers, such as weather and demographics. A recent study of COVID-19 in the United States, working with a similar dataset, saw no significant effect due to pop-

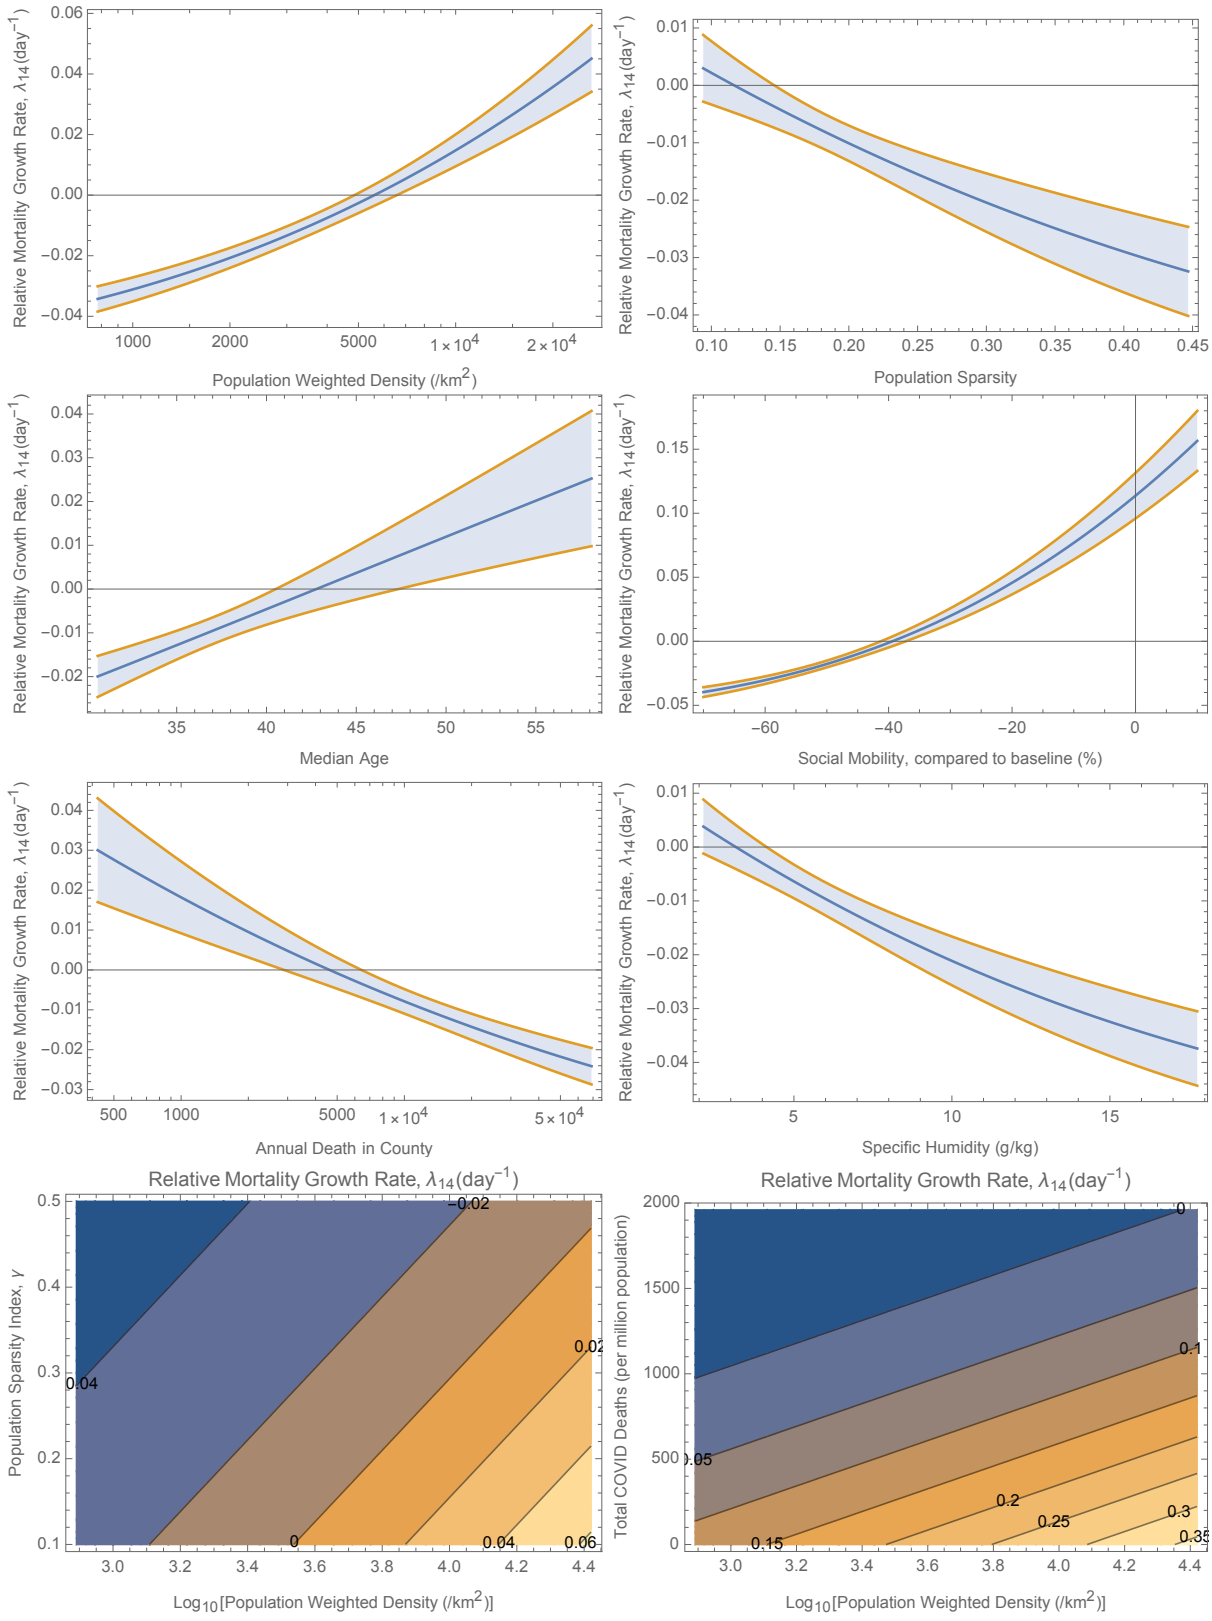

Figure 5: *Dependence and 68% confidence bands of the mortality growth rate — as specified by the nonlinear model (Eqn. 1) — on various parameters for an "average county." All parameters not being varied are fixed at their population-weighted mean values (as of 8th June, 2020): $\log_{10}$[PWD / km^{-2})] = 3.58, population sparsity = 0.188, COVID death fraction = 5.1×10^{-4} (510 deaths/million population), Median Age = 37.5 yr, log(Annual Death) = 4.04, social mobility $\bar{\mathcal{M}}$ = -44% , and specific humidity $\bar{\mathcal{H}}$=5.7 g/kg.*

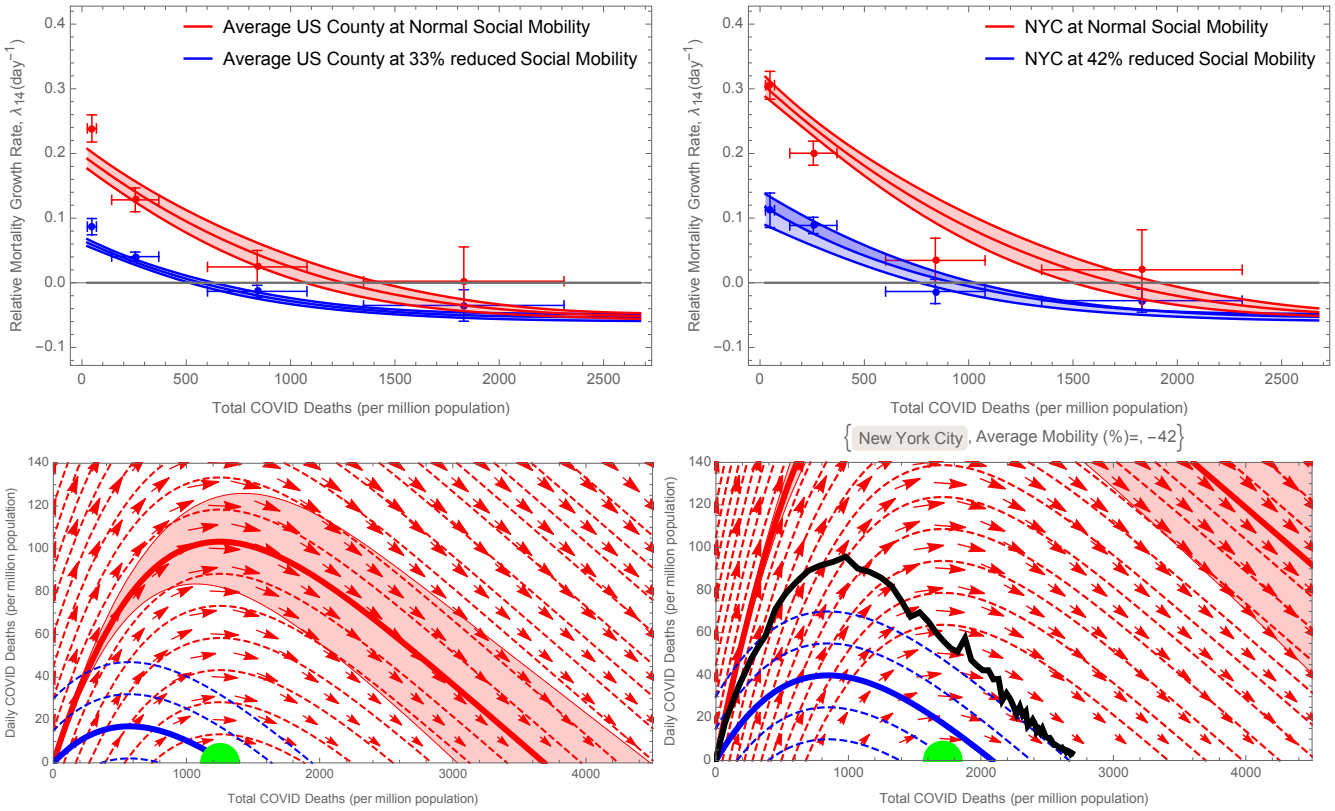

Figure 6: *Nonlinear model prediction of the exponential growth rate, λ_{14}, vs. cumulative COVID-19 mortality (top panels), assuming baseline social mobility, $\bar{\mathcal{M}} = 0$, in the "average US county" (see caption of Figure 5) on the left, and New York City, on the right. The curves show 68% predictions for the nonlinear model (Table 2), while the points with errorbars are linear fits to all the data within bins of death fraction. The threshold for "herd immunity" ($\lambda_{14} = 0$) is reached at a mortality of approximately 1300 (1700) per million for an average county (NYC), but this would be higher in counties with more unfavorable values of the drivers. The eventual mortality burden of the average county will be determined by its path through a "phase space" of Daily vs. Total Mortality (bottom panel). An epidemic without intervention (red curves, with the particular trajectory starting at zero death shown in bold) will pass the threshold for herd immunity (1300 deaths per million; note that at zero daily deaths this is a fixed point) and continue to three times that value due to ongoing infections. A modest 33% reduction in social mobility (blue curves), however, leads to mortality at "only" the herd immunity level (the green disk). The black curve on the bottom right panel shows the 7-day rolling average of reported mortality for NYC, which appears to have "overshot" the "herd immunity threshold".*

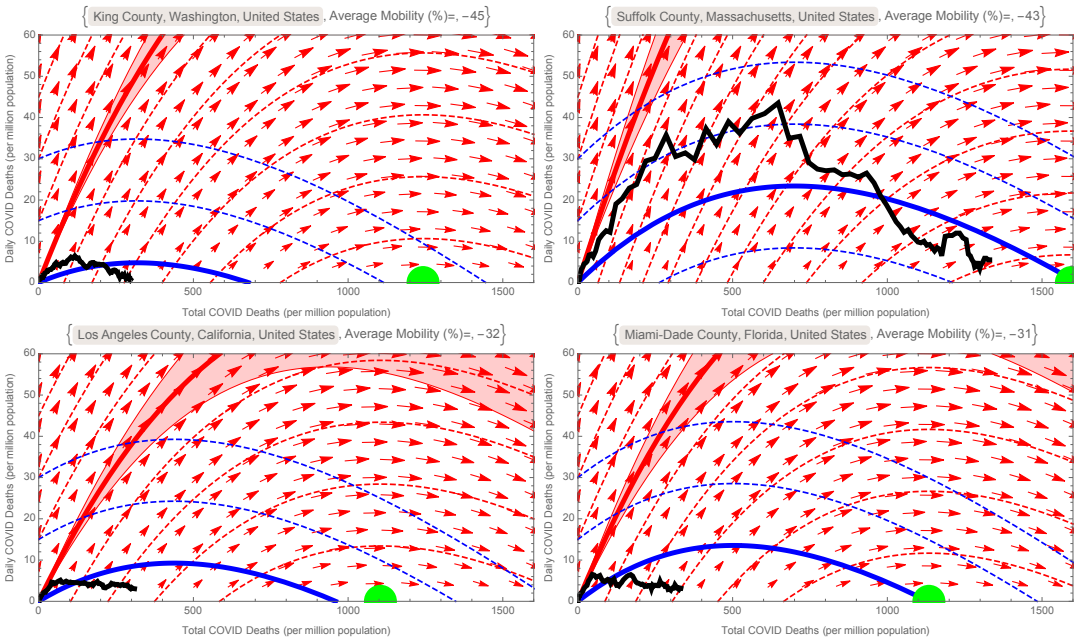

Figure 7: *Epidemic Phase Portraits for the same four counties as in Figure (4), similar to the Phase portrait in Figure (6). The blue curves are for the county's average Social Mobility during Feb. 15 through June 12, 2020, while red curves/arrows are at normal (pre-covid) social mobility. The thick black curve is the 7-day rolling average of the official reported mortality, while the green disk shows the threshold for "herd immunity".*

ulation density (Hamidi, Sabouri, and Ewing, 2020), but our analysis differs in a number of important ways. First, we have taken a dynamic approach, evaluating the time-dependence of the growth rate of mortality incidence, rather than a single static measure for each county, which allowed us to account for the changing effects of weather, mobility, and the density of susceptible individuals. Second, we have included an explicit and real-time measurement of social mobility, i.e., cell phone mobility data provided by Google (Fitzpatrick and Karen, 2020), allowing us to control for the dominant effect of intervention. Finally, and perhaps most importantly, we calculate for each county an estimate of the "lived" population density, called the population-weighted population density (PWD) (Craig, 1985), which is more meaningful than the standard population per political area. As with any population-scale measure, this serves as a proxy — here, for estimating the average rate of encounters between infectious and susceptible people — but we believe that PWD is a better proxy than standard population density, and it is becoming more prevalent, e.g., in census work (Dorling and Atkins, 1995; Wilson, 2012).

We also found a significant dependence of the mortality growth rate on specific humidity (although since temperature and humidity were highly correlated, a replacement with temperature was approximately equivalent), indicating that the disease spread more rapidly in drier (cooler) regions. There is a large body of research on the effects of temperature and humidity on the transmission of other respiratory viruses (Moriyama, Hugentobler, and Iwasaki, 2020; Kudo et al., 2019), specifically influenza (Barreca and Shimshack, 2012). Influenza was found to transmit more efficiently between guinea pigs in low relative-humidity and temperature conditions (Lowen et al., 2007), although re-analysis of this work pointed to absolute humidity (e.g., specific humidity) as the ultimate controller of transmission (Shaman and Kohn, 2009) . Although the mechanistic origin of humidity's role has not been completely clarified, theory and experiments have suggested a snowballing effect on small respiratory droplets that cause them to drop more quickly in high-humidity conditions (Tellier, 2009; Noti et al., 2013; Marr et al., 2019), along with a role for evaporation and the environmental stability of virus particles (Morawska, 2005; Marr et al., 2019). It has also been shown that the onset of the influenza season (Shaman et al., 2010; Shaman, Goldstein, and Lipsitch, 2011) — which generally occurs between late-Fall and early-Spring, but is usually quite sharply peaked for a given strain (H1N1, H3N2, or Influenza B) — and its mortality (Barreca and Shimshack, 2012) are linked to drops in absolute humidity. It is thought that humidity or temperature could be the annual periodic driver in the resonance effect causing these acute seasonal outbreaks of influenza (Dushoff et al., 2004; Tamerius et al., 2011), although other influences, such as school

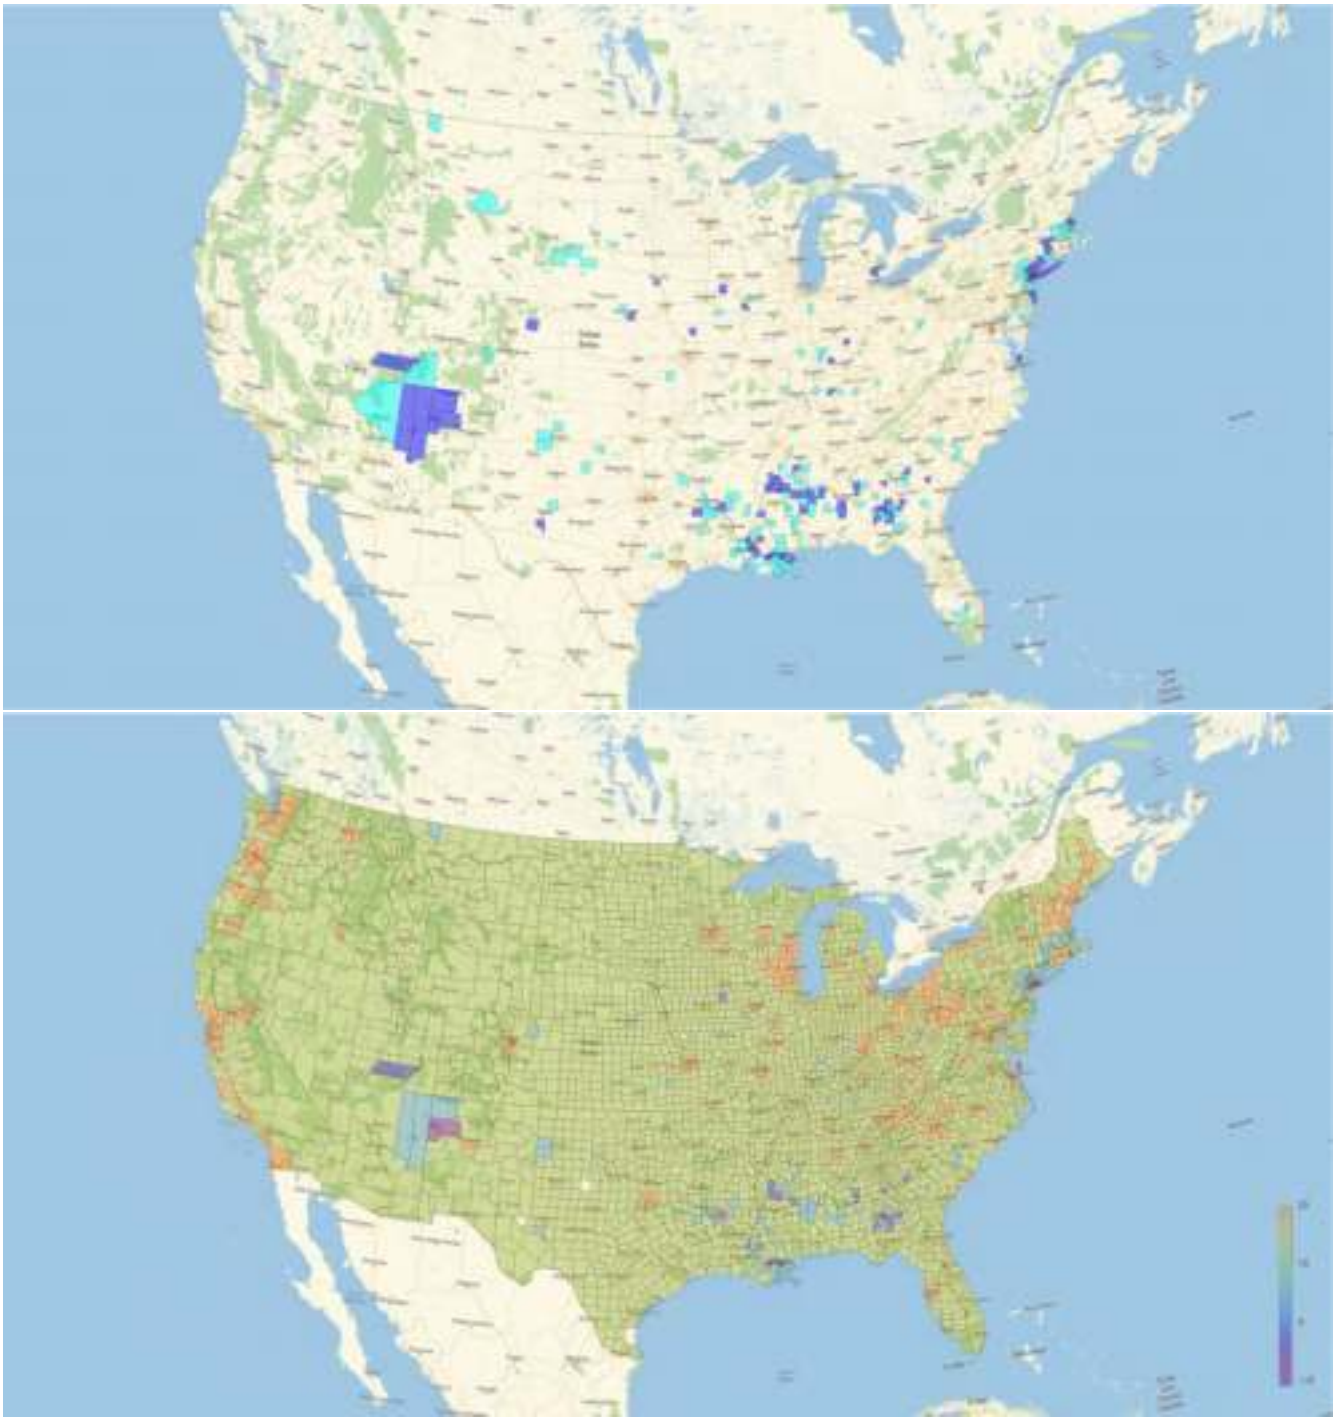

Figure 8: *Top: United States counties that have passed (blue), or are within (cyan), the threshold for "herd immunity" at the 1-σ level, as predicted by the nonlinear model. Bottom: Predicted confidence in the growth of COVID-19 outbreak (defined as predicted daily growth rate divided by its uncertainty), for all counties should they return today to their baseline (pre-COVID) social mobility. Counties that have approached the threshold of herd immunity have lower growth rates due to the depletion of susceptible individuals.*

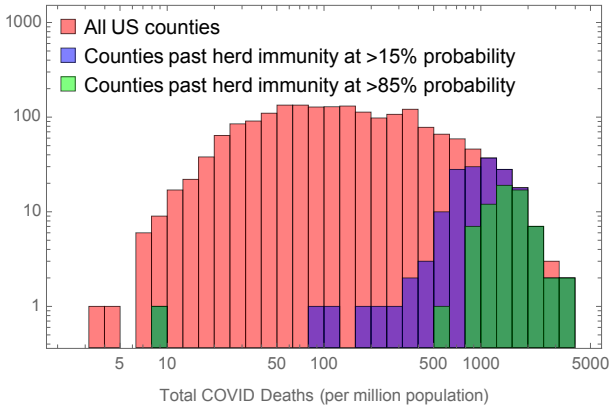

Figure 9: *Histogram of reported COVID-19 deaths per million for all US counties, showing the proportion that have passed "herd immunity" threshold, according to fit of the nonlinear model.*

openings/closings have also been implicated (Earn et al., 2012). While little is yet known about the transmission of SARS-CoV-2 specifically, other coronaviruses are known to be seasonal (Moriyama, Hugentobler, and Iwasaki, 2020; Neher et al., 2020), and there have been some preliminary reports of a dependence on weather factors (Xu et al., 2020b; Schell et al., 2020). We believe that our results represent the most definitive evidence yet for the role of weather, but emphasize that it is a weak, secondary driver, especially in the early stages of this pandemic where the susceptible fraction of the population remains large (Baker et al., 2020). Indeed, the current early-summer rebound of COVID-19 in the relatively dry and hot regions of the Southwest suggests that the disease spread will not soon be controlled by seasonality.

We developed a new model of infection in the framework of a renewal equation (see, e.g., Champredon, Dushoff, and Earn, 2018 and references therein), which we could formally solve for the exponential growth rate. The incubation period in the model was determined by a random walk through the stages of infection, yielding a non-exponential distribution of the generation interval, thus imposing more realistic delays to infectiousness than, e.g., the standard SEIR model. In this formulation, we did not make the standard compartmental model assumption that the infection of an individual induces an autonomous, sequential passage from exposure, to infectiousness, to recovery or death; indeed, the model does not explicitly account for recovered or dead individuals. This freedom allows for, e.g., a back passage from infectious to noninfectious (via the underlying random walk) and a variable rate of recovery or death. We assumed only that the exponential growth in mortality incidence matched (with delay) that of the infected incidence — the primary dynamical quantity in the renewal approach — and we let the cumulative dead count predict susceptible density — the second dynamical variable in the renewal approach — under the assumption that deaths arise from a distinct subset of the population, with lower mobility behavior than those that drive infection (see Supplementary Material). Therefore, we fitted the model to the (rolling two-week estimates of the) COVID-19 mortality incidence growth rate values, λ_{14}, for all counties and all times, and used the per capita mortality averaged over that period, f_D, to determine susceptible density. Regression to this nonlinear model was much improved over linear regression, and, once calibrated on an early portion of the county mortality incidence time series, the model accurately predicted the remaining incidence.

Because we accounted for the precise effects of social mobility in fitting our model to the actual epidemic growth and decline, we were then able to, on a county-by-county basis, "turn off" mobility restrictions and estimate the level of cumulative mortality at which SARS-CoV-2 would fail to spread even without social distancing measures, i.e., we estimated the threshold for "herd immunity." Meeting this threshold prior to the distribution of a vaccine should not be a goal of any community, because it implies substantial mortality, but the threshold is a useful benchmark to evaluate the potential for local outbreaks following the first wave of COVID-19 in Spring 2020. We found that a few counties in the United States have indeed reached herd immunity in this estimation — i.e., their predicted mortality growth rate, assuming baseline mobility, was negative — including counties in the immediate vicinity of New York City, Detroit, New Orleans, and Albany, Georgia. A number of other counties were found to be at or close to the threshold, including much of the greater New York City and Boston areas, and the Four Corners, Navajo Nation, region in the Southwest. All other regions were found to be far from the threshold for herd immunity, and therefore are susceptible to ongoing or restarted outbreaks. These determinations should be taken with caution, however. In this analysis, we estimated that the remaining fraction of susceptible individuals in the counties at or near the herd immunity threshold was in the range of 0.001% to 5% (see Supplementary Materials). This is in strong tension with initial seroprevalence studies (Rosenberg et al., 2020; Havers et al., 2020a) which placed the fraction of immune individuals in New York City at 7% in late March and 20% in late April, implying that perhaps 75% of that population remains susceptible today. We hypothesize that the pool of susceptible individuals driving the epidemic in our model is a subset of the total population — likely those with the highest mobility and geographic reach — while a different subset, with very low baseline mobility, contributes most of the mortality (see Supplementary Ma-

terial). Thus, the near total depletion of the susceptible pool we see associated with herd immunity corresponds to the highly-mobile subset, while the low-mobility subset could remain largely susceptible. One could explicitly consider such factors of population heterogeneity in a model — e.g., implementing a saturation of infectivity as a proxy for a clustering effect (Capasso and Serio, 1978; Mollison, 1985; De Boer, 2007; Farrell et al., 2019) — but we found (in results not shown) that the introduction of additional of parameters left portions of the model unidentifiable. Despite these cautions, it is interesting to note that the epidemic curves (mortality incidence over time) for those counties that we have predicted an approach to herd immunity are qualitatively different than those we have not. Specifically, the exponential rise in these counties is followed by a peak and a sharp decline — rather than the flattening seen in most regions — which is a typical feature of epidemic resolution by susceptible depletion.

At the time of this writing, in early Summer 2020, confirmed cases are again rising sharply in many locations across the United States — particularly in areas of the South and West that were spared significant mortality in the Spring wave. The horizon for an effective and fully-deployed vaccine still appears to be at least a year away. Initial studies of neutralizing antibodies in recovered COVID-19 patients, however, suggest a waning immune response after only 2–3 months, with 40% of those that were asymptomatic becoming seronegative in that time period (Long et al., 2020). Although the antiviral remdesivir (Beigel et al., 2020; Grein et al., 2020; Wang et al., 2020b) and the steroid Dexamethasone (Horby et al., 2020) have shown some promise in treating COVID-19 patients, the action of remdesivir is quite weak, and high-dose steroids can only be utilized for the most critical cases. Therefore, the management of this pandemic will likely require non-pharmaceutical intervention — including universal social distancing and mask-wearing, along with targeted closures of businesses and community gathering places — for years in the future. The analysis and prescriptive guidance we have presented here should help to target these approaches to local communities, based on their particular demographic, geographic, and climate characteristics, and can be facilitated through our online simulator dashboard. Finally, although we have focused our analysis on the United States, due to the convenience of a diverse and voluminous data set, the method and results should be applicable to any community worldwide, and we intend to extend our analysis in forthcoming work.

Data & Methods

Datasets, Resources, Definitions

All data for cases and mortality, demographics, mobility, and weather were incorporated into the publicly-available Wolfram COVID-19 Dataset and the Wolfram|Alpha Knowledgebase (*COVID-19 Data & Resources* 2020). COVID-19 confirmed case and mortality data were obtained from both the NYTimes and Johns Hopkins University Github repositories (Johns Hopkins University, CSSE, 2020; The New York Times, 2020); the former was used for the analysis initial case data in metropolitan regions, while the average of the two data sets was used for all other analyses. In each case, daily confirmed counts were utilized. Demographic data by county, including people per household, estimated 2019 population, annual births, and annual deaths were obtained from the US Census 2019 *County Population Estimates* data set (United States Census, 2019a). Median ages were determined from the US Census 2018 *County Characteristics Resident Population Estimates* data set (United States Census, 2018). For the Median Age, Wolfram|Alpha has curated the raw data from *United States Census Bureau, American Community Survey 5-Year Estimates: B01002, the Median Age By Sex, American FactFinder*; for the People per Household and Annual Death, the source of curated data is *United States Census Bureau, State & County QuickFacts*. County outline polygons were obtained from the US Census 2019 *TIGER/Line shapefiles* database (United States Census, 2019c). Local weather data (Figure 10 was obtained from the NOAO *Global Surface Summary of the Day* (GSOD) database (National Oceanic and Atmospheric Observatory, 2020). The nearest WBAN station with daily dew point and pressure values (for calculation of specific humidity), and daily average temperature was chosen for each county or metropolitan region. Weather data was averaged over a two-week period for λ_{14}, and over a window equal to the growth period for metropolitan regions. Google's *COVID-19 Community Mobility Reports* dataset (Fitzpatrick and Karen, 2020), specifically "Workplace mobility," was used to estimate the human social mobility in each county (Figure 10).

Population-weighted population density (or, population weighted density, PWD) (Craig, 1985; Wilson, 2012; Dorling and Atkins, 1995), was calculated using the Global Human Settlement Population raster dataset (European Commission Joint Research Centre, 2019), which contains $250\,\mathrm{m}$-resolution population values worldwide, taken from census data. The value of PWD for a county — or for a set of counties, in the metropolitan region analysis — was calculated as the population-weighted average

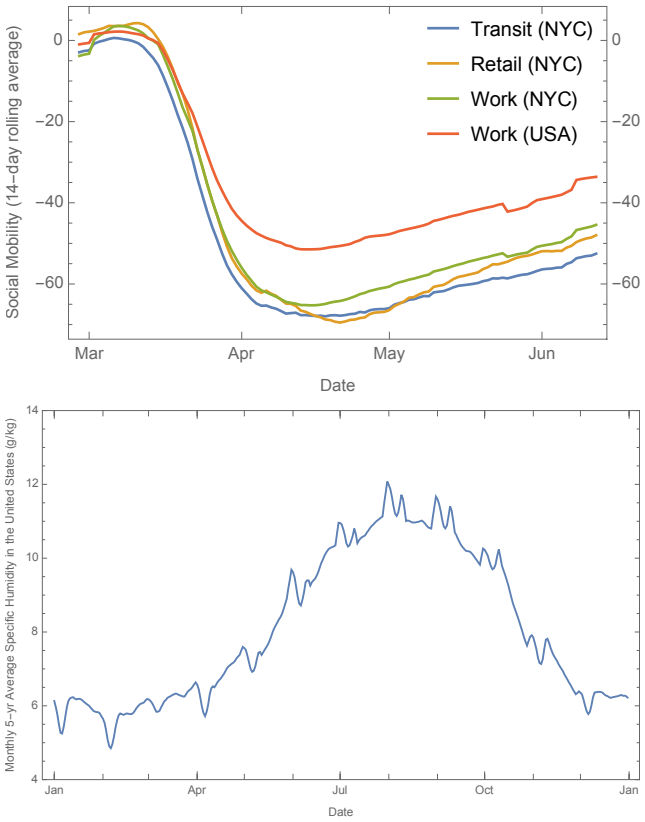

Figure 10: *(Top)(a)The 14-day rolling average of (population-weighted) social mobility (Fitzpatrick and Karen, 2020) for NYC, as well as all US counties considered here. For our analysis, we only use "work places" as an indicator, as others do not appear to show any independent correlation with $\lambda_{14}(t)$. (Bottom)(b) 28-day moving average of historical annual specific humidity in the United States (weighted-averaged by population).*

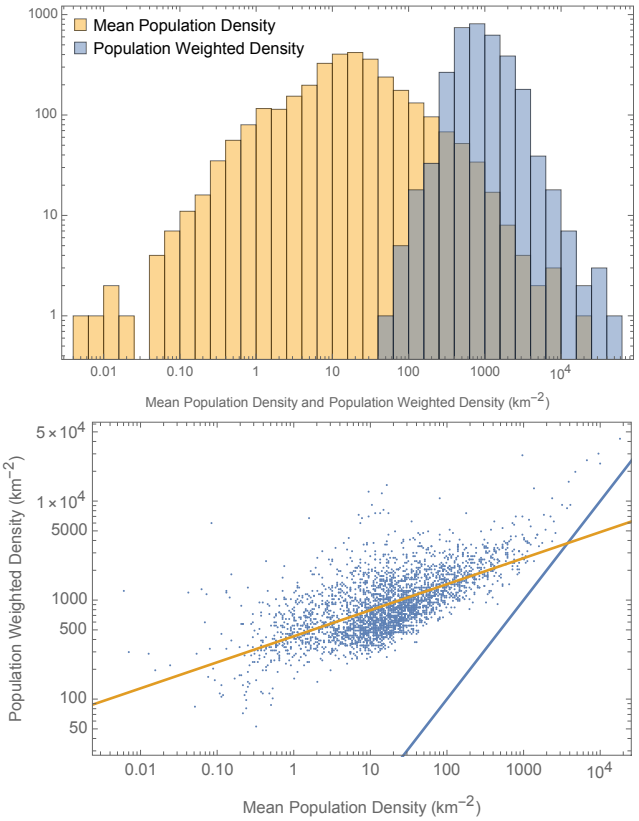

Figure 11: *Comparison of the distribution of Population Weighted Density with the Crude population density of US counties: (a)(Top): Histograms, (b)(Bottom): Relative distributions: The blue line shows the one-to-one correspondence, while the orange line is the best-fit power-law* $\mathrm{PWD}_{250}(\mathrm{km}^{-2}) \simeq 430 \times \left[D(\mathrm{km}^{-2})\right]^{1/4}$.

of density over all $(250\,\mathrm{m})^2$-area pixels contained within the region, i.e.,

$$\mathrm{PWD} = \sum_j \frac{(p_j/a_j)\,p_j}{\sum_i p_i}\,, \tag{4}$$

where p_j is the value (i.e., the population) of the jth pixel, $a_j = 0.0625\ \mathrm{km}^2$ is the area of each pixel (the GHS-POP image uses the equal-area Molleweide projection), and $\sum_i p_i$ is the total population of the region. This measure has also been called the *lived population density* because it is the population density experienced by the average person.

In high density counties, the population weighted density PWD is close to the mean density of the county $D = \mathrm{Pop}/\mathrm{Area}$, suggesting a uniform distribution of population (see Figure 11). However, in lower density counties, the mean density is much lower than the population weighted density, due to heterogeneous dense pockets of population amidst vast empty spaces outlined

by political boundaries. To represent the degree to which the population density changes across the region (county or metropolitan region) we define the *population sparsity index*, γ. Assuming that the population-weighted population density declines approximately as a power law with "pixel" area, $\mathrm{PWD}_{\sqrt{\mathrm{Area}}} \sim \mathrm{Area}^{-\gamma}$, we define:

$$\gamma = \frac{\log\left(\mathrm{PWD}_{250\,\mathrm{m}}\right) - \log(D)}{\log\left[\mathrm{Area}\right] - \log\left[(250\,\mathrm{m})^2\right]}\,. \tag{5}$$

In other words we estimate the assumed power-law decline using two data points. The distribution of γ and its correlation with county population and population density are shown in Figure (12). We can see that γ ranges from 0.09 (i.e., very uniform) for the most populous/dense counties to 0.88 (i.e. very sparse) for least populated/dense counties. For reference, the value of γ for New York City is 0.14.

Initial growth of confirmed cases for metropolitan regions

For each of the top 100 metropolitan regions (United States Census, 2019b), a logarithmic-scale population heat map, windowed from the full GHS-POP raster image, was used to select a minimal connected set of US counties enclosing the region of population enhancement. In this process, overlap and merger reduced the total number of metropolitan regions under consideration to 89.

As is discussed in the main text, nearly every metropolitan region saw, in mid-March 2020, an exponential increase of daily confirmed cases, followed by a flat/plateau period of nearly constant daily confirmed cases. In a few cases, the second phase — primarily caused by the country-wide lockdown — lasted only days or weeks (possibly signaling a depletion of the susceptible population, see discussion in main text), but for most metropolitan regions the plateau persisted for months (indeed, persists or is again increasing at the time of this writing). Thus, the initial value of the exponential growth rate, λ, of daily confirmed cases could be reliably and automatically estimated by fitting the case numbers to a logistic function

$$f_{\mathrm{logistic}}(t) = \frac{f_{\max}}{1 + \exp\left[-\lambda\,(t - t_0)\right]} \tag{6}$$

where t_0 represents the transition time from exponential growth to a constant, $f_{\max}$ is the plateau value in case numbers, and $f_{\mathrm{logistic}}(t) \propto \exp[\lambda t]$ for $t \ll t_0$. Fits were performed on the logarithm of the case numbers, yielding the maximum likelihood estimation of parameters under the assumption lognormally-distributed errors (an analysis of the fit residuals, not shown, confirmed this assumption: case number fluctuations exhibit a variance

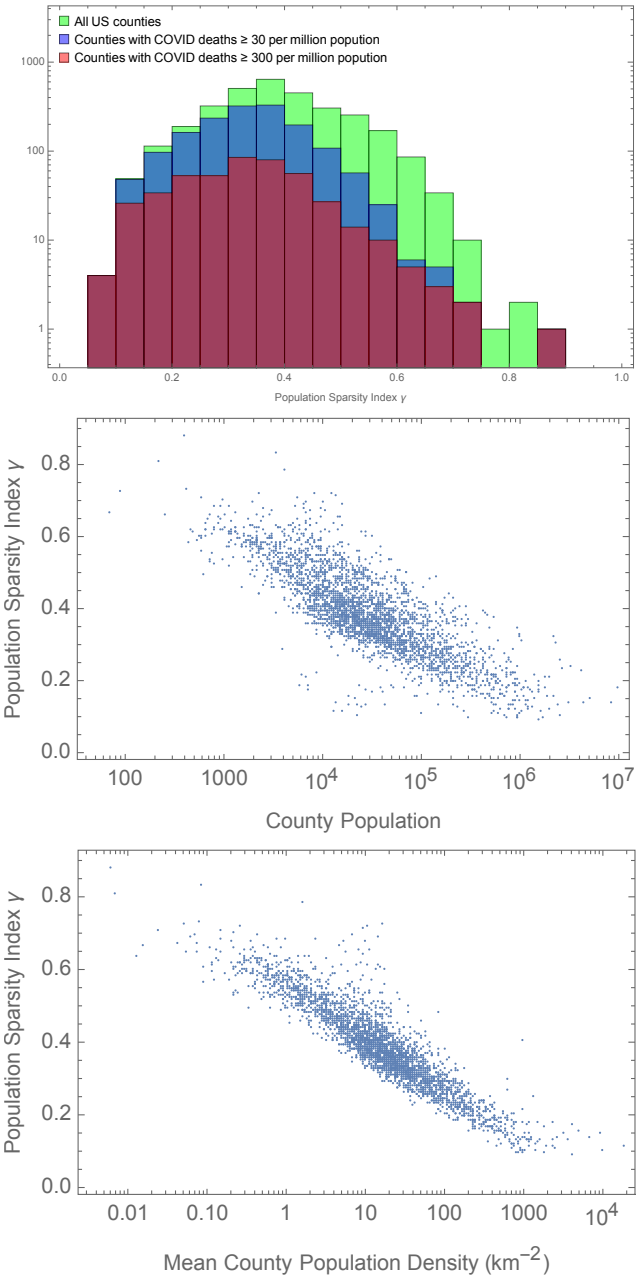

Figure 12: *(a)(Top)Distribution of Population Sparsity Index γ (b)(Middle) its correlation with total population of the county (c)(Bottom) and its average population density*

far in excess of Poisson noise, but are well modeled by a log-normal probability density function with constant width), and associated estimates of the variance in each parameter. To avoid polluting the exponential growth phase with singular early cases, a "detection limit" of 3 was imposed, and all daily case values less than or equal to that limit were ignored in fitting. The only manual intervention required for this fit was the specification of the upper limit of its range, i.e., the *end* of the plateau region, for each data set.

To analyze the effect of demographic, population, mobility, and weather variables on this initial growth rate, we perform a weighted linear regression to the lambda values (and their standard errors) of the 89 metropolitan regions.

To choose representative cities for the visual examples in Figures 1A and 1C, we performed an additional logistic fit to the mortality incidence data of each region and retained for Figure 1C only those that had (1) less than 15% error in both growth rates, and (2) $|\lambda_{\rm case} - \lambda_{\rm death}| < 0.15 d^{-1}$. This was done in an effort to specifically comment on or highlight only those cities for which the growth rate was accurately determined, and was well correlated with the more reliable measure, mortality growth, that we used for the remainder of the analysis.

Linear Dynamical Model of Mortality Data

A standard weighted least squares analysis was performed on the measured exponential growth rate, λ_{14}, as a function of demographic, mobility, population and weather variables, with weights equal to inverse root of the estimated variance.

Nonlinear Model

We construct a model where, in the standard analogy to chemical reaction kinetics, the incidence of infections per unit area at time, $i(t)$, is proportional to the product of the density of susceptible individuals, $S(t)$, and the density of infected individuals, $I(t)$. But, we allow for the rate constant for infection[3] in the encounter, β, to depend on the infected individual's "stage" of infection, C, with $C = 0$ immediately following infection. The incidence then has the form:

$$i(t) = -\dot{S}(t) = S(t) \int_0^\infty \beta(C)\, \mathcal{I}(C,t)\, \mathrm{d}C\,, \qquad (7)$$

where $\mathcal{I}(C,t)$ is the density of infected per stage at time t, and the first equality expresses that we neglect changes to the susceptible population by all means other than infection. The density of infected individuals is found by integration over the stages of infection,

$$I(t) = \int_0^\infty \mathcal{I}(C,t)\, \mathrm{d}C\,. \qquad (8)$$

If the rate constant were taken to be independent of stage, i.e., $\beta(C) = \bar{\beta}$, we would obtain the familiar expression $\dot{S}(t) = -\bar{\beta} S(t) I(t)$. We will assume spatial homogeneity and that the total density of individuals is constant and equal to $S(0)$ for a particular region, but, that the density could vary when comparing different regions.

We assume that an infected individual's evolution through the stages of infection, C, follows a Gaussian random walk in time, but modulated by an exponential rate, d, of death or recovery. Therefore we have

$$\mathcal{I}(C,t) = \int_0^\infty i(t-a)\, f_{\rm rw}\,(C;a)\, \mathrm{e}^{-d\,a}\, \mathrm{d}a \qquad (9)$$

where a is the "age" of an infection (time since infection), and the probability density function for the stage at a given age is given by

$$f_{\rm rw}\,(C;a) = \sqrt{\frac{2\tau}{\pi a}}\, \exp\left[-\frac{\tau C^2}{2a}\right]\,, \qquad (10)$$

where τ is the characteristic time scale of the random walk[4]. Integrating the expression for $\mathcal{I}(C,t)$ over all stages and taking the derivative with respect to time yields the familiar expression $\dot{I}(t) = i(t) - dI(t)$, showing that the model reduces to the SIR model if a stage-independent rate constant, $\bar{\beta}$, is assumed.

As we show here, using the random walk to specify the dependence of infection stage on time allows for both a non-exponential distribution of delays to infectiousness (which is more realistic than that of the simplest model with incubation, the SEIR model) and a formal solution for the exponential growth rate. Inserting the expression for $\mathcal{I}(t,C)$ into the incidence equation yields

$$i(t) = S(t) \int_0^\infty i(t-a) \left[\mathrm{e}^{-d\,a} \int_0^\infty \beta(C)\, f_{\rm rw}\,(C;a)\, \mathrm{d}C\right] \mathrm{d}a \qquad (11)$$

which is in the form of a *renewal equation* (Heesterbeek and Dietz, 1996; Champredon and Dushoff, 2015; Champredon, Dushoff, and Earn, 2018), with the bracketed expression being the expected infectivity of an individual with infection age a. To obtain the simplest nontrivial incubation period, we assume that $\beta(C) = \bar{\beta}\,\Theta(C-1)$ — where $\Theta(x)$ is the Heaviside step function — meaning

[3] In a physical picture of collisions, the rate constant of infection is $\beta(C) = \langle \sigma v \rangle_{\rm eff}(C)$, i.e., the scattering cross section of an encounter between a susceptible individual and an infectious individual in stage C, σ, multiplied by their relative velocity, v.

[4] More precisely: C is the absolute value of the position of a 1D random walker, taking one step every Δt, with step size drawn from a normal distribution with mean zero and variance $\Delta t/\tau$. The variance of the walker position at time t is then t/τ

that an infected individual is only infectious once they reach stage $C = 1$, and the infection rate constant is otherwise unchanging. This implies that the incidence is

$$i(t) = S(t) \int_0^\infty i(t-a)\, \bar{\beta}\, \mathcal{F}(a)\, \mathrm{d}a\,. \tag{12}$$

where

$$\begin{aligned} \mathcal{F}(a) &= \mathrm{e}^{-d\,a} \int_1^\infty f_{\mathrm{rw}}\,(C;a)\,\mathrm{d}C \\ &= \mathrm{e}^{-d\,a} \left[1 - \mathrm{erf}\left(\sqrt{\frac{\tau}{2a}}\right)\right] \end{aligned} \tag{13}$$

is the probability that an individual infected a time units ago is infectious.

If we now assume that the density of susceptibles is constant $S(t) = \bar{S}$ over some interval of time, and that the incidence grows (or decays) exponentially in that interval, $i(t) = A\mathrm{e}^{\lambda t}$, we find

$$1 = \bar{\beta}\bar{S} \int_0^\infty \exp[-a\lambda]\, \mathcal{F}(a)\, \mathrm{d}a \tag{14}$$

which, assuming $\lambda + d > 0$ (i.e., the exponential growth rate cannot go below $-d$), can be integrated to obtain

$$(\lambda + d)\, \exp\left[\sqrt{2\,(\lambda+d)\,\tau}\right] = \bar{\beta}\bar{S}\,. \tag{15}$$

This expression for $(\lambda + d)$ has a formal solution in terms of the *Lambert W-function*, with simple asymptotic forms:

$$\begin{aligned} \lambda + d &= \frac{2}{\tau}\left[\mathrm{W}\left(\sqrt{\frac{\bar{\beta}\bar{S}\tau}{2}}\right)\right]^2 \\ &\approx \begin{cases} \frac{1}{2\tau}\left\{\ln\left[\frac{2\bar{\beta}\bar{S}\tau}{\ln^2\left(\bar{\beta}\bar{S}\tau/2\right)}\right]\right\}^2 & \left(\bar{S}\bar{\beta}\tau \gg 1\right) \\ \bar{\beta}\bar{S} & \left(\bar{S}\bar{\beta}\tau \ll 1\right) \end{cases} \end{aligned} \tag{16}$$

For the early stages of the epidemic, when we can assume that the population of susceptibles is approximately constant and large, we see that the growth rate depends approximately linearly on the square of the logarithm of the density. In later stages, when either the base contact rate declines due to social distancing interventions, or the population of susceptibles decreases, we see that the exponential rate takes the value $\lambda \approx -d$.

In practice, we utilize the exact Lambert W-function expression as our "nonlinear model" for fitting λ_{14}, where we parameterize β and τ by the demographic, population, and weather variables (see main text). To estimate the susceptible density, $\bar{S}$, in this procedure we must use the reported mortality statistics. Thus far we have not specified the dynamics of death. We now make the assumption that the probability of death increases proportionally to the number of exposures an individual experiences. As we prove in a separate section, below, this implies that the susceptible density is related to the fraction of dead in the community, $f_D = D_{\mathrm{tot}}/N$ (where D_{tot} is the cumulative mortality and N is the total population), by $S(t) = S(0)\exp\left[-C_D\, f_D\right]$.

The *basic reproduction number*, R_0, and the distribution of *generation intervals*, $g(t_g)$, are defined (Champredon and Dushoff, 2015; Nishiura, 2010) through the function $\mathcal{F}(a)$:

$$g(t_g) = \frac{\bar{\beta}S(0)\,\mathcal{F}(t_g)}{R_0} \quad \text{with} \quad R_0 \stackrel{\mathrm{def}}{=} \int_0^\infty \bar{\beta}S(0)\,\mathcal{F}(t_g)\,\mathrm{d}t_g\,. \tag{17}$$

The generation interval (or, generation time), t_g, is the time between infections of an infector-infectee pair, and is often estimated from clinical data by the *serial interval*, which is the time between the start of symptoms (Britton and Scalia Tomba, 2019), and the basic reproduction number is the average number of infectees produced by a single infected individual, assuming a completely susceptible population. These quantities can be calculated exactly for our model, as

$$R_0 = \frac{\bar{\beta}S(0)}{d}\,\mathrm{e}^{-\sqrt{2d\tau}} \tag{18}$$

and

$$g(t_g) = d\,\mathrm{e}^{\sqrt{2d\tau}-dt_g} \int_1^\infty \sqrt{\frac{2\tau}{\pi t_g}}\,\exp\left[-\frac{\tau C^2}{2t_g}\right]\mathrm{d}C\,, \tag{19}$$

where the expected value and variance of the generation interval are then:

$$E\left[t_g\right] = \frac{1}{d} + \sqrt{\frac{\tau}{2d}} \quad \text{and} \quad \mathrm{Var}\left[t_g\right] = \frac{1}{d^2} + \sqrt{\frac{\tau}{8d^3}}\,. \tag{20}$$

Extended Results and Analysis

Relation between the remaining susceptible density, $S(t)$ and the death fraction, $f_D(t)$

In epidemic models the infection of susceptible individuals is typically determined by

$$\dot{S} = -\beta\, S\, I_* \tag{21}$$

where I_* is the density of infectious (contagious) individuals, and for our model, $\beta S I_*$ is the right-hand side of Eqn. 7. This can be solved, formally, as:

$$S(t) = S(0)\exp\left[-\beta \int^t I_*(s)\,\mathrm{d}s\right] \tag{22}$$

Alternatively, the susceptible density can be expressed in terms of the cumulative number of infected individuals, I_{tot}, i.e.,

$$S(t) = S(0)\left[1 - f_I(t)\right] \tag{23}$$

where $f_I(t) = I_{\rm tot}/N$, with N the total population. When fitting the exponential growth rate of mortality, $\lambda_{14}(t)$ to our nonlinear model, Eqn. (16) (see main text), we must estimate the value of the susceptible density driving growth at that time. Without any reliable information about the true infected or infectious populations, we must do so using the mortality statistics. We show here how the previous two equations can be used, along with reasonable assumptions about distinct sub-populations driving infection and death, to determine a relationship between the reported cumulative mortality (per capita) and the remaining susceptible density.

Our basic assumption is that there are two different categories of susceptible individuals underlying the dynamics of the epidemic: (A) highly mobile individuals with a large geographic reach that frequently interact with other individuals (in particular, infectious individuals) and thus drive the dynamics of infection (these could be termed "super-spreaders" (Liu, Eggo, and Kucharski, 2020)); and (B) essentially non-mobile individuals that have quite rare contacts with infectious individuals, but have a much higher probability of death once infected, and therefore make up the majority of the mortality burden. The dynamics of each susceptible population is governed by an equation of the form in Eqn. (21), with a common density of infectious individuals, I_*, but with different rate constants, $\beta_A \gg \beta_B$. From Eqn. (22), we see that the susceptible densities of the two populations are then related, at any time, by:

$$\frac{S_A(t)}{S_A(0)} = \left[\frac{S_B(t)}{S_B(0)}\right]^{\beta_A/\beta_B} . \tag{24}$$

Expressing the non-mobile population in terms of the cumulative fraction infected, we have

$$\frac{S_A(t)}{S_A(0)} = \left[1 - f_I^{(B)}(t)\right]^{\beta_A/\beta_B} , \tag{25}$$

and, assuming that the infection fatality rate (IFR) is a constant factor, $f_D(t) = \mathrm{IFR} \times f_I(t - \Delta t)$, where Δt is the delay from infection to death, we can write:

$$\frac{S_A(t)}{S_A(0)} = \left[1 - \frac{f_D^{(B)}(t + \Delta t)}{\mathrm{IFR}}\right]^{\beta_A/\beta_B} . \tag{26}$$

Finally, having assumed that the ratio of infection rates is large, we can approximate this as:

$$\frac{S_A(t - \Delta t)}{S_A(0)} \approx \exp\left[-\frac{\beta_A}{\beta_B\,\mathrm{IFR}}\, f_D^{(B)}(t)\right] \tag{27}$$

The "A" category of individuals, as defined above, are exactly those individuals driving the infection in our model (and, presumably, in the real world), and, therefore, the susceptible density S_A is exactly that which must be estimated for Eqn. (16). On the other side, with people aged 65 and over accounting for ∼80% of COVID-19 deaths, and with approximately ∼45% of deaths linked to nursing homes, the mortality statistics are clearly tracing individuals similar to category "B." Therefore, we use this relationship,

$$S(t - \Delta t) = S(0)\, \exp\left[-C_D\, f_D(t)\right] ,$$

to estimate the susceptible density in terms of the reported per capita mortality, where we assume $S(0)$ is proportional to the population weighted density (PWD).

We also considered the standard approach, in which the population is a single homogeneous group. In that case, the susceptible density could be estimated as

$$S(t) = S(0)\,[1 - f_I(t)] = S(0)\left[1 - \frac{f_D(t + \Delta t)}{\mathrm{IFR}}\right] . \tag{28}$$

In testing both models, we found that the two-component population scenario was preferred by the data at the $\sim 10\sigma$ confidence level, with the homogeneous population model failing to capture the observed dependence of the growth rate on the per capita mortality (Figure 13).

The broader implications of our assumption of two populations is that the required proportion of individuals with immunity for "herd immunity" to take effect, is lower than population with homogeneous mobility characteristics, i.e., the epidemic will slow as a significant proportion of the "super-spreader" category have been infected (category A, above), regardless of the level of infection and immunity in the rest of the population. Indeed, the effect of population heterogeneity on lowering the "herd immunity" threshold for COVID-19 was recently noted (Britton, Ball, and Trapman, 2020), and will be important in interpreting the results of randomized serology tests across the entire population (Havers et al., 2020b).

Incubation Time

The nonlinear epidemic model described above posits that the incubation of SARS-COV2 virus within an infected individual can be modelled by a stochastic random walk starting at zero, with excursions beyond ± 1 corresponding to episode(s) of infectiousness. This makes our model distinct from the standard SE^{m}I^{n}R compartmental models (see, e.g., (Champredon, Dushoff, and Earn, 2018)), where the progress of the disease is only in one direction — $E^1 \to E^2 \to \ldots \to I^1 \to I^2 \to \ldots$ — while in our model (Figure 14), the individual can jump back and forth between different stages (with the obvious exception of Death), with a constant exit rate of d for quarantine, recovery, or death. This can be described

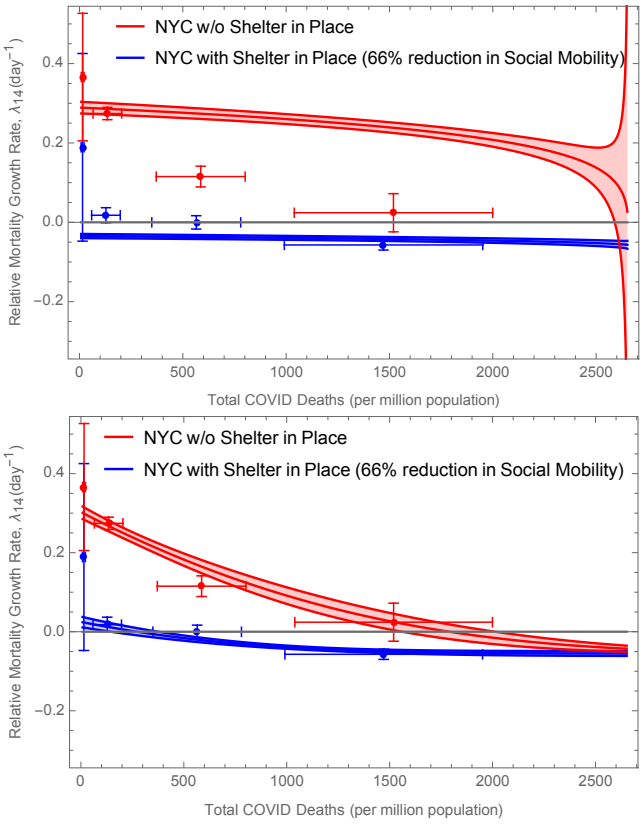

Figure 13: *Comparison of hypotheses regarding the relationship between the susceptible fraction, $S(t)/S(0)$, and the dead fraction, $f_D(t)$. A model in which deaths are suffered by a largely immobile population, while the infection is driven by a mobile category of individual (bottom) was preferred to one with a single homogenous population (top) at the 9σ confidence level. Similar to Figure 6, the points show the best-fit linear model prediction for NYC, fitted independently in different bins of mortality to population ration, while the lines show best-fit $\pm$ 1σ nonlinear models. Note that while we show the nonlinear model predictions for a county similar to NYC, we use all US data to find the best fits.*

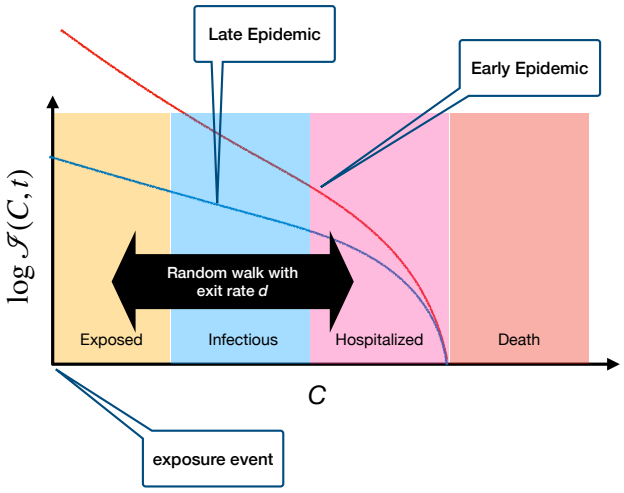

Figure 14: *The stages of COVID-19 infection, as a continuous variable C. We model the disease as a random walk, starting at $C = 0$, and a uniform exit rate (due to either quarantine or recovery). The curves show the resulting distribution in C, during the growing (early) and decaying (late) epidemic. Note that the Hospitalization and Death are not directly modelled in the Nonlinear model, as they should have a small effect on the spread of the epidemic.*

using a (leaky) diffusion equation:

$$\frac{\partial \mathcal{I}}{\partial t} = \frac{1}{2\tau}\frac{\partial^2 \mathcal{I}}{\partial C^2} - d\mathcal{I}. \tag{29}$$

Based on this picture, and the best-fit parameters to the US county mortality data (Table 2), we can infer the probabilities associated with the different stages of the disease. For example, by looking at the steady-state solutions of Equation (29), we can compute the probability that an exposed individual (who starts at $C = 0$) will ever become infectious (i.e., make it beyond $C = C_{\rm inf} = 1$):

$$P_{\rm inf} = \exp[-\sqrt{2d\tau}C_{\rm inf}], \quad \text{where} \quad C_{\rm inf} = 1, \tag{30}$$

This is plotted as a function of the median age of the community in Figure (15a). For example, for the median age of all US counties, $A = 37.4$-yr, we get:

$$P_{\rm inf}(37.4 \text{ years}) = 0.08^{+0.04}_{-0.03}\ (68\%\ \text{C.L.}), \tag{31}$$

i.e., less than 12% of exposed individuals will ever be able to infect others, although this fraction increases in older communities.

Next, we can compute the distribution of times for the onset of infectiousness, i.e., the incubation period. This can be done by using a first crossing probability of a random walk, which we did by solving Equation

(29) using a discrete Fourier series in the $(0, +1)$ interval. The resulting probability density is shown in Figure (15b), again showing a shorter incubation period in older communities.

Finally, we can compute the probability density function for the generation interval, $g(t_g)$, defined in Equation (19) (Figure 15c). This shows a similar qualitative dependence on age as the incubation period, but the median incubation period is, as expected, shorter than the generation interval for each age group. Using Eqn. (20) and our parameterization of τ, we find a mean generation interval of

$$E[t_g](37.4 \text{ years}) = 43 \pm 23 \text{ d}\,. \tag{32}$$

This estimate is much longer than those found by tracking the serial interval (time from between the start of symptoms for an infector-infectee pair) in COVID-19 patients (Ganyani et al., 2020; Nishiura, Linton, and Akhmetzhanov, 2020), which are on the order of 5–10 d. It is possible that the long tail of these distributions, generated by the slow asymptotic exponential decay at rate $d \approx 0.06 d^{-1}$, raises the mean generation interval, while a clinical study, is necessarily biased toward shorter serial intervals.

Error Diagnostics and Forecasting COVID-19 Mortality

One of the most pressing questions in any exercise in physical modelling is whether we have a good understanding of the uncertainty in the predictions of the model. While we have an estimate of the measurement uncertainties for the mortality growth rates, λ_{14}, which we discussed in the main text, we also should characterize whether the deviation of the best-fit model from the measurements are consistent with statistical errors. To evaluate this, we can look at the average of the ratio of the variance of the model residuals to that of the measurement errors, otherwise known as reduced χ^2, or χ^2_{red}. This is shown in Figure (16), demonstrating that we see no systematic error in model that is significantly bigger than statistical errors, across counties with different populations.

As another consistency check, Table (3) examines whether the parameters of the model change significantly from urban counties with large, uniform populations, to rural counties with a small and more sparse population (Figures 11-12). From counties with enough COVID mortality data, roughly those with population $\gtrsim 10^6$ inhabit half of the total population, which we chose as our threshold, separating large from small counties. We notice no statistically significant difference, and Table (3) even suggests that Fisher errors quoted here might be overestimating the true errors. This comparison brings

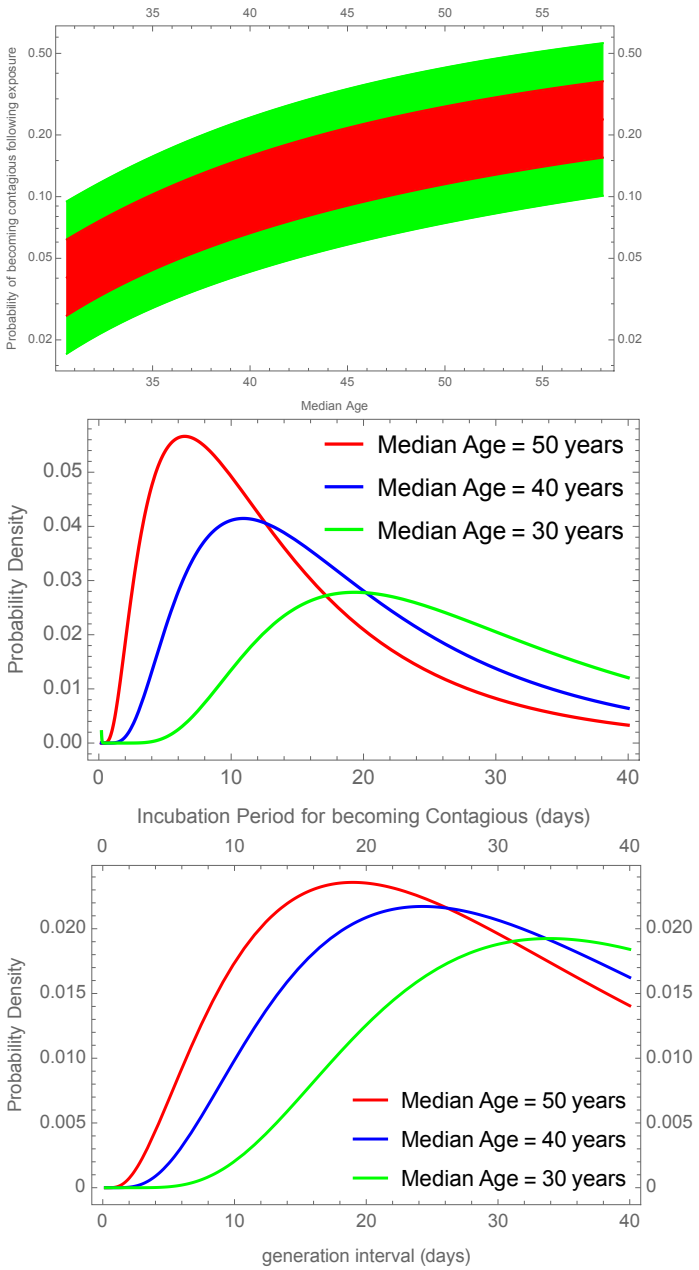

Figure 15: *(Top)(a) The probability that an individual exposed to the virus will ever become infectious. (Middle)(b) The probability distribution for incubation period for onset of virus shedding. (Bottom)(c) Distribution of the generation Interval, $g(a)$, i.e., the time from an individual's infection to them infecting another.*

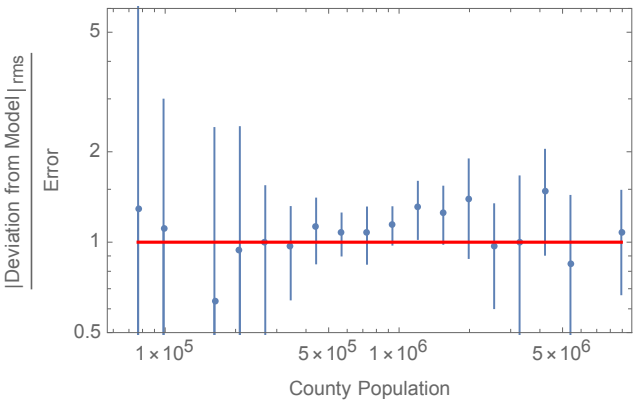

Figure 16: *Root Mean Square of the Ratio of the Simplified Nonlinear model residual to measurement errors (i.e. the $\sqrt{\chi^2_{\rm red}}$), as a function of the population of the county. We see that the residuals are consistent with measurement errors.*

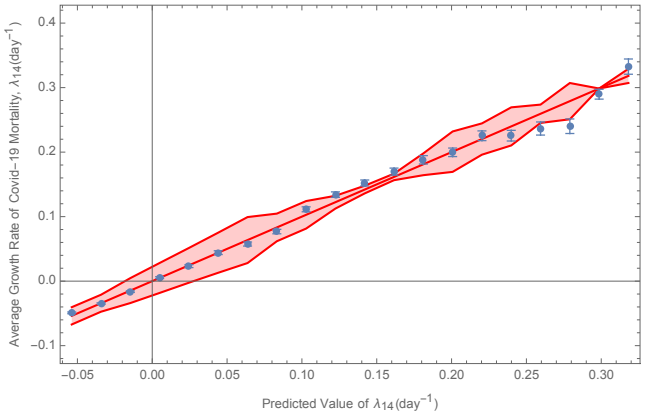

Figure 17: *Observed versus Best-Fit model prediction for bins of λ_{14}. The points show the mean of measured I_7 within each predicted bin, as well as the error on the mean. The red region shows the mean excess model error, on top of measurement uncertainties.*

further confidence in the universality of the nonlinear model across geography and demography.

On average, we find that (either county-weighted or population-weighted) $\chi^2_{\rm red} \simeq 1.28$, suggesting that the model errors are only 13% bigger than statistical errors.

We further compare the model-prediction vs measured mortality growth rate in Figure (17) for all our available data. We find that the 1-σ error in the model prediction (in excess measurement errors) is on average $\pm\sigma_{14} = \pm 0.0180$, i.e. 1.8% error in the daily mortality growth rate. This is shown in Figure (17) as the red region, which compares the model prediction with the observed mortality growth rates. We can also see that there appears to be no significant systematic deviation from the predictions, at least for $\lambda_{14} < 0.23$/day.

Given an understanding of the physical model and its uncertainties, we can provide realistic simulations to forecast the future of mortality in any community, similar to those provided in the main text (Figure 4), which can be made on-demand using our online dashboard: https://wolfr.am/COVID19Dash.

In order to perform these simulations, we follow these simple steps. To predict the daily mortality on day $t+1$, $D(t+1)$, we use the prior 13 days of $D(t)$, as well as the total mortality up to that point:

1. Use Equation (1), plugging in prior total mortality, county information, weather, mobility and parameters in Table 2 to find λ_{14}. Every simulation uses a random realization of model parameters (from their posterior fits), which remain fixed through that simulation.
2. Add the random model uncertainty to λ_{14} using:

$$\lambda_{14}(t+1) \to \lambda_{14}(t+1) + \frac{\sigma_{14}}{\sqrt{14}} \sum_{t'=t-12}^{t+1} g_{t'}, \quad (33)$$

   where $g_{t'}$s are random independent numbers drawn from a unit-variance normal distribution. This captures the model uncertainty mentioned above, while ensuring that it remains correlated across the 14 days that are used to define λ_{14}.
3. Having fixed the logarithmic slope for daily mortality λ_{14}, find the best-fit intercept and its standard error for $\ln[D(t')+1/2]$ for the preceding 13 days, i.e. $t-12 \le t' \le t$, which can then be used to find a random realization for $\ln[D(t+1)+1/2]$
4. Advance to next day and return to step 1.

Parameter	Small Counties	Large Counties	Difference/Error
$\tau_0(\mathrm{day})$	126. $\pm$ 58.9	219. $\pm$ 124.	-0.37
$d^{-1}(\mathrm{day})$	18.4 $\pm$ 3.92	18.1 $\pm$ 2.32	0.0104
$\ln\left[\beta_0\tau_0^{-2}(\mathrm{m}^2/\mathrm{day}^3)\right]$	-2.23 $\pm$ 1.57	-0.519 $\pm$ 2.1	-0.747
C_D	2743. $\pm$ 845.	4425. $\pm$ 958.	-0.323
C_A	-4.73 $\pm$ 2.31	-2.87 $\pm$ 1.75	-0.338
$100C_{\mathcal{M}}$	0.0527 $\pm$ 0.0162	0.0732 $\pm$ 0.0233	-0.227
C_γ	-1.97 $\pm$ 2.13	-8.37 $\pm$ 4.48	0.744
C_T	-0.0415 $\pm$ 0.0251	-0.0768 $\pm$ 0.0342	0.405
C_{A_D}	-1.36 $\pm$ 0.632	-0.588 $\pm$ 0.641	-0.521

Table 3: *Comparison of nonlinear model parameters between small (population < 1 million) with large (population > 1 million) counties. We see no significant statistical difference, as demonstrated by the values in the last column that remain below 1. Note that, in contrast to Table (2), we use temperature rather than specific humidity (C_T rather than $C_{\mathcal{H}}$), as the latter was not available for some small counties. Nevertheless, the parameters remain also statistically consistent with Table (2).*

COVID-19 Deaths: Which Explanatory Variables Matter the Most?

PETE RILEY*, ALLISON RILEY, JAMES TURTLE,

MICHAL BEN-NUN

Predictive Science Inc., San Diego, California, USA

pete@predsci.com

Summary

As Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) spreads around the World, many questions about the disease are being answered; however, many more remain poorly understood. Although the situation is rapidly evolving, with datasets being continually corrected or updated, it is crucial to understand what factors may be driving transmission through different populations. While studies are beginning to highlight specific parameters that may be playing a role, few have attempted to thoroughly estimate the relative importance of these disparate variables that likely include: climate, population demographics, and imposed state interventions. In this report, we compiled a database of more than 28 potentially explanatory variables for each of the 50 U.S. states through early May 2020. Using a combination of traditional statistical and modern machine learning approaches, we identified those variables that were the most statistically significant, and, those that were the most important. These variables were chosen to be fiduciaries of a range of possible drivers for COVID-19 deaths in the USA. We found that

population-weighted density (PWD), some "stay at home" metrics, monthly temperature and precipitation, race/ethnicity, and chronic low-respiratory death rate, were all statistically significant. Of these, PWD and mobility metrics dominated. This suggests that the biggest impact on COVID-19 deaths was, at least initially, a function of where you lived, and not what you did. However, clearly, increasing social distancing has the net effect of (at least temporarily) reducing the effective PWD. Our results strongly support the idea that the loosening of "lock-down" orders should be tailored to the local PWD. In contrast to these variables, while still statistically significant, race/ethnicity, health, and climate effects could only account for a few percent of the variability in deaths. Where associations were anticipated but were not found, we discuss how limitations in the parameters chosen may mask a contribution that might otherwise be present.

Key words: COVID-19; Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2); Mechanistic Modeling; SEIRX.

1. Introduction

Following the first signs of its presence in December 2019 (Huang *and others*, 2020), COVID-19 has rapidly spread across the world, impacting almost every country in its wake (Dong *and others*, 2020). However, its impact has been markedly different (at least as of late May) in different locations, a consequence of factors that remain actively debated. We can categorize these factors as follows. First, imposed societal interventions, in the form of social distancing measures (e.g., "shelter in place" orders, self-isolation, school closures, etc.). Second, demographic differences in the population including age distribution, health, gender, and race of the populations. Third, climatic variability (e.g., temperature, precipitation, or humidity variations), and spatial heterogeneity in terms of the density of people that a person is typically exposed to. Fourth, environmental variability such as pollution. Fifth, virus connectivity factors, such as the likelihood

that the disease will be imported into an area from outside. These are not mutually exclusive categories, and, indeed, we would anticipate a number of confounding variables amongst them.

Our objective in this study is to assess which of these explanatory (independent) variables are clearly important for predicting COVID-19 deaths, primarily to aid in the development of mechanistic model refinements (Riley *and others*, 2013, 2015, 2017; Ben-Nun *and others*, 2019; Turtle *and others*, 2019). Mechanistic models, as opposed to statistical or machine-learning models are typically developed by incorporating the minimum number of underlying processes necessary to describe the observations sufficiently well to answer specific questions. The types of questions being asked about COVID-19 include, but are not limited to: What impact will interventions have on the trajectory of the disease? Will weather conditions cause the disease to (at least temporarily) abate as we approach the northern summer? Which locations are likely to suffer the most severe outcomes? Which populations will likely fair better, and which will fair worse? A crucial step in answering these questions using models, then, is to understand what factors appear to matter.

In this report we assemble an illustrative dataset of parameters that capture, at least in principle, these factors. We perform several multiple-linear-regression (MLR) and machine learning (ML) analyses on the data to identify the key explanatory variables that are likely driving the variations in the number of deaths per 100,000 for the 50 contiguous U.S. states (i.e., their statistical significance). Additionally, we assess the degree to which these variables can explain the observed deaths (i.e., their importance).

2. Methodology

2.1 *Data*

Data were collected from a variety of sources, each chosen as a fiduciary of one of the factors described above. They are summarized in Table 1. Briefly, the first six parameters (retail, grocery,

medRxiv preprint doi: https://doi.org/10.1101/2020.06.11.20129007; this version posted June 14, 2020. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY-NC-ND 4.0 International license .

parks, transit, workplaces, and residential) were scraped from Google's Mobility Reports on April 20 (Google), and represent the fractional change (expressed as a percentage) in people's travel to these locations. Thus, a mean value of 11.38% in 'residential' represents the increase in people remaining at home since the start of "shelter in place" orders. Similarly, a decrease of 46.58% in 'retail' reflects the drop in people going to retail locations. Many of the parameters are self-explanatory, including: age, % 65 years and over (USCensus), obesity rates (LiveScience), chronic lower respiratory death rates (CDC), pollution indices (USNews), the date that a state of emergency was declared (Wikipedia), average relative annual and spring-time humidity, dew point, temperature, precipitation (Brettschneider; CurrentResults), and UV index (USEPA). However, several require further explanation.

Table 1: **List of parameters used in multiple-regression analysis, together with their basic statistical properties.** See text for detailed explanation of each parameter.

Population-weighted density (PWD) is, the average of each resident's census tract density, effectively, the density at which the average person lives. It is important to distinguish this from the average population density for a location if there is any significant heterogeneity in population density. For example, the population density of the entire U.S. is approximately 90 people per square mile. In contrast, the population-weighted density is more than 5,000 people per square mile. These data were derived from the WorldPop dataset (Worldpop).

The reported date of the first death in each state is used as a proxy for initial seeding of the virus in each state, and, by extension, a proxy for the connectivity of the state to likely sources of the disease (e.g., China, Europe, or other states).

Race parameters 1 through 4 are an attempt to identify any possible links with the underlying races/ethnicities within each state (USCensus). Specifically, they are: (1) Percent Estimate-Race alone or in combination with one or more other races-Black or African American; (2) Percent

medRxiv preprint doi: https://doi.org/10.1101/2020.06.11.20129007; this version posted June 14, 2020. The copyright holder for this preprint

It is made available under a CC-BY-NC-ND 4.0 International license .

Estimate-Race alone or in combination with one or more other races-Asian; (3) Percent Estimate-Hispanic or Latino (of any race); and (4) Percent Estimate-One race-White (Smith, 2014).

Finally, our response (dependent) variable is the number of deaths per 100,000 (JHU). All values reported here are correct through May 10 2020. This is, of course, an ever-changing value; however, both the cumulative number of confirmed cases as well as the number of deaths per 100,000 for each state tended to maintain similar relative slopes (Figure 1), such that the results do not depend sensitively on the precise date chosen to represent the number of deaths in each state. In fact, the analysis was repeated for five different dates from April 25 through May 10 with no qualitative difference in the results, or their interpretation. It is, nevertheless, worth noting several outliers. Washington, in particular, was the first state to report an appreciable number of deaths in mid-March; however, its initial slope remained shallower than other states, and, by early April, became even flatter. The net effect of this is that in terms of relative number of deaths, from early April to early May, it exchanged position with a dozen other states. The relative positions of other states has also changed during the course of the last two months. In general, however, the changes were likely driven by a particular event that changed the evolving slope of the profile at some point. These typically occurred in the early portion of the outbreak, and the relative positions of the states in the last month has remained largely unaltered.

Fig. 1. **The variation of (Left) Cumulative number of confirmed cases per 100,000 for each state (colored arbitrarily to better separate each curve). (Right) Cumulative number of deaths per 100,000 for each state**. Data runs from 2020-03-06 through 2020-05-10.

2.2 *Models*

Multiple regression models were analyzed using several packages in *R*, primarily relying on 'lm' (R Core Team, 2019). To identify the explanatory variables that provided the best performing model (i.e., one that lowered the prediction error), we used the 'stepAIC' function from the MASS package (Venables and Ripley, 2002). Both forward selection and backward selection (i.e., backward elimination) were performed (James *and others*, 2013). In the former, initially, no predictors are included in the model, and the algorithm iteratively adds the most contributory variables, stopping when the improvement is no longer statistically significant.

These regression techniques, however, only identify the statistical significance of the variables. To estimate the relative importance of each explanatory variable in describing the variability in deaths, we applied a number of traditional statistical and more modern machine learning (ML) approaches. Using multiple approaches is important for assessing the uncertainty that should be ascribed to a particular ordering of the variables, since different techniques rely on different metrics for importance. The techniques applied included: random forest (Liaw *and others*, 2002), Xgboost (Chen and Guestrin, 2016), relative importance (Grömping *and others*, 2006), earth (wrapper, 2019), step-wise regression (Bendel and Afifi, 1976), and DALEX (Biecek, 2018). It is important to underscore that these techniques use different definitions of what signifies"important", and, thus, we do not expect agreement between the results. Nevertheless, where the results do agree is where we can be most confident that the explanatory variable importance is significant, and where they do not, we must remain more cautious.

3. Results

When a multiple linear regression analysis was performed on the 28-parameter dataset, four explanatory variables were found to be significant: retail, average annual precipitation, average spring precipitation, and PWD (Table S1). Together, R^2 for these variables was 0.973, and thus,

medRxiv preprint doi: https://doi.org/10.1101/2020.06.11.20129007; this version posted June 14, 2020. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

these variables are capable of explaining 97% of the variations in deaths/100,000 (n_{deaths}). We then applied a heuristic, recursive process of elimination to each of the parameters to identify those that, under a more focused analysis might raise to the point of significance. From this process, we identified five explanatory variables: retail, grocery, PWD, average spring temperature and precipitation. Thus, annual precipitation was no longer deemed to be significant, but grocery and average spring temperature now were (Table S2).

Comparison of the five most significant variables with one another showed several illuminating features (Figure S1). First, the number of deaths per 100,000 were clustered below 100 per 100,000, with New York being a significant outlier. Second, unsurprisingly, retail and grocery mobility metrics appear to be the most highly correlated of the explanatory variables. Third, the best fit curve to the number of deaths per 100,000 and PWD appears to (1) be linear, and (2) display the strongest correlation with n_{deaths}.

An analysis of the residuals suggests that Hawaii, New Mexico, and Rhode Island (observations 11, 31, and 39) deviate most (Figure S2 (left)). The fitted line through the residuals suggest the possibility that a non-linear relationship might be more appropriate, however, given the relatively high $R^2 \sim 0.9$, we suggest that this is not necessarily so. Comparing the standardized residuals against theoretical quantiles suggests that the errors are approximately normally distributed, at least for most of the states. Notably, New York (32) and Hawaii (11) (and, to a lesser extent, Rhode Island (39)) are outliers (Figure S2 (right)). To check for homoscedasticity, that is, the assumption of equal variance, we can assess whether the residuals are spread equally along the ranges of the predictors. The notable outliers are, once again, Hawaii (11), Rhode Island (39), and New York (32). Although there is variability, with the exception of New York, the standardized residuals are roughly equal to one and constant along the fitted values (Figure S3 (left)).

Finally, considering the variation of the residuals against leverages, we can estimate to what extent the outliers are influential in the regression analysis. The leverage of a particular observa-

medRxiv preprint doi: https://doi.org/10.1101/2020.06.11.20129007; this version posted June 14, 2020. The copyright holder for this preprint

tion (state) is related to how much its value on the predictor variable differs from the mean of the predictor variable. We use Cook's distance as a measure of the influence of an observation, with values lying in the upper-right or lower-right being indicative of unduly influential observations. Unsurprisingly, New York (32) is clearly influential (Figure S3 (right)). Following this, Hawaii (11), and to an even lesser extent, New Jersey are leveraging the results.

In summary, based on this exploratory analysis, the strongest explanatory variable for deaths per 100,000 is PWD (Figure 2). There is a clear trend for states with increasing PWD to have higher number of deaths. There is, however, substantial scatter away from the smooth line through the data, at least in part due to the contribution(s) from some of the other explanatory variables (as well as potentially other equally, or more important variables not included). For example, it is worth noting that, geographically, the states substantially below the line are located at higher latitudes and away from either coast (N. and S. Dakota, Wyoming, Utah, Nebraska, Nevada). On the other hand, many of the states substantially above the line are from southern regions (Mississippi, Alabama, S. Carolina, Kentucky, Missouri, Louisiana). It could also be argued that this demarcation is reflective of other factors, including political affiliation, which may have modulated the timing and/or efficacy of the "shelter in place" orders. Finally, we remark that Hawaii, and to a lesser extent (because of the log-log scale) Alaska, are unique outliers in terms of unusually low deaths given their relative PWD.

Fig. 2. **The relationship between the number of deaths per 100,000 and PWD.** Each state is identified with a dot and the variability and smooth profile are shown with the dark grey region and blue line, respectively.

While the preceding analysis heuristically investigated the possible contribution of the explanatory variables in describing the variations in n_{deaths}, we next apply more robust techniques using a variety of algorithms to assess both statistical significance and importance. In these ap-

medRxiv preprint doi: https://doi.org/10.1101/2020.06.11.20129007; this version posted June 14, 2020. The copyright holder for this preprint

proaches, explanatory variables are iteratively added or removed to identify the subset of variables that produce the best performing model, that is, the model with the lowest prediction error.

First, using *R*'s MASS package, we applied both forward selection, where variables were added iteratively, until the improvement is no longer statistically significant, and backward elimination, where variables are iteratively removed until the point is reached where all the variables are statistically significant (Table S3). Based on this analysis, 14 variables can account for 97% of the variability in n_{deaths}. This is approximately the same as including all 28 variables, and substantially higher than the 87.5% that we computed using our *ad hoc* approach of searching through the variables. PWD, race parameter 1, average annual temperature and precipitation, average spring precipitation are the strongest contributors.

Using the Random Forest method to assess the importance of the variables, we found (in order of importance): PWD, retail, chronic low-respiratory death rate, residential, race parameter 3, obesity rates, average spring temperature, average dew point, race parameter 1, and date of first death were the most important (Table S4). Comparing this list with the significant variables identified earlier, suggests that any subset of significant *and* important explanatory variables would include at least PWD, retail, chronic low-respiratory death rate, race parameter 1, and date of first death.

Applying the Xgboost method for ranking explanatory variables in order of their importance identified the 'retail' mobility metric as the most important variable, followed by PWD, and then two more mobility metrics (workplaces and grocery). Race parameter 1, relative humidity (afternoon), date of first death, and average spring temperature and dew point followed. Finally, Chronic low-respiratory death rate was the remaining variable but only 1% as important as the most important variable (Table S5).

The Multivariate Adaptive Regression Splines (MARS) model can also be used to rank explanatory variables. Unlike the random forest, it has been shown to be more susceptible to

medRxiv preprint doi: https://doi.org/10.1101/2020.06.11.20129007; this version posted June 14, 2020. The copyright holder for this preprint

unstable explanatory variables. Nevertheless, it is a flexible technique and is included here to provide evidence for the sensitivity of our results to the technique implemented. PWD, race parameter 2, and retail captured more than 90% of the importance (Table S6), with grocery and averge annual precipitation rounding out the top-five variables.

The step-wise regression method can also be combined with the Akaike Information criteria (AIC) to identify the best model, that is, the best combination of parameters to explain the output variable. Using this approach, in order of importance, PWD, grocery, retail, average spring temperature and precipitation were all found to be important (Table S7).

Finally, we consider the DALEX package, which is, in fact, a meta-package in the sense that it can compare responses from different models to allow for direct comparison. Here, though, we apply the DALEX machinery with the random forest technique and use the 'explain' and 'variable_importance' functions to quantify their relative importance (Table S8). PWD, retail/workplaces, chronic low respiratory death rate, average relative humidity, grocery, and race parameter 1 describe most of the observed variability in n_{deaths}. The degree to which these variables contribute to the overall variations can also be visualized graphically (Figure 3). Thus, we infer that the first four variables account for most of the observations. Of these, however, average relative humidity was not found to be statistically significant in any of our analyses. Thus, while humidity was "important", it wasn't "significant".

Fig. 3. **Relative importance of explanatory variables using the DALEX method.** See text for more details.

4. Discussion

In this study, we have presented an illustrative, but not exhaustive multiple-regression analysis of 28 explanatory variables, in an attempt to identify those parameters that can best predict

medRxiv preprint doi: https://doi.org/10.1101/2020.06.11.20129007; this version posted June 14, 2020. The copyright holder for this preprint

deaths per capita in U.S. states. Our results are not surprising in the sense that we would have anticipated that PWD and lockdowns, in particular, would likely explain at least some of the variations in deaths. It is also reassuring that our results support other studies highlighting the association of race/ethnicity (Yancy, 2020), climatic conditions (Sajadi *and others*, 2020), and population demographics (Flaxman *and others*, 2020*a*) with deaths. In fact, given the relative homogeneity of the U.S. population, it is somewhat remarkable that small variations from state to state would result in measurable and statistically-significant results.

Our initial dataset contained a number of other variables that were dropped from the formal analysis, primarily because, although there might be an obvious association with deaths, there was no conceivable driving mechanism (i.e., causal relationship). For example, we found that the political affiliation of each state (as measured by the results of the 2016 election) was a strong and statistically significant explanatory variable. In addition to this simply being a confounding variable for several others, such as PWD (republican states tend to be more rural) and the efficacy of lockdowns (democratic states typically implemented orders earlier and/or more stringently), its variation serves no useful role in explaining the number of deaths. Nevertheless, we emphasize the point here to highlight the dangers in over-interpreting what, based on the analysis presented here, can only be considered associations.

Making the leap from associations to causal relationships can be accomplished by mathematical models. Thus, we suggest that the results presented here can be further tested within various types of mechanistic models. Indeed, the two major associations of PWD and mobility metrics are, to varying degrees, already incorporated into models. Individual-based spatial models, for example, can explicitly account for the population-weighted density of the population as well as (at least parametrically) the mobility of people (Flaxman *and others*, 2020*b*). The significance of climate (particularly temperature, precipitation, and/or humidity) can readily be incorporated as well (Riley *and others*, 2017; Ben-Nun *and others*, 2019; Turtle *and others*, 2019).

It is not surprising that PWD was the most important explanatory variable. It also must be recognized that this variable is related to each state's social distancing orders, with the primary difference that PWD is generally immutable, whereas social distancing can and will change over time. It may be tempting, particularly for vulnerable individuals to move to a region of lower PWD, as this will likely have a strong impact on their likelihood of dying from COVID-19. It could be argued that this should be balanced with the likelihood of the quality of healthcare being proportionately worse in more rural areas. However, based on the simple, but clear relationship between the number of deaths per 100,000 and PWD, this appears not to be the case: Regions of lower PWD are experiencing lower deaths per capita. Moreover, based on the roughly constant gradients (Figure 1(b)), this has been true for the past two months, and will likely hold for the foreseeable future.

Although it is intuitively obvious that PWD and n_{deaths} should be positively correlated in terms of causality, increases in PWD would primarily drive higher incidence, which would, in turn, result in more deaths. However, an interesting question not addressed here is whether the relationship between PWD and deaths is linear? If a disproportionate number of more vulnerable people live in higher-PWD regions, this would result in a plot of n_{deaths} versus PWD curing upwards. There is some suggestion of this in our results (Figure 2); however, such an inference is at best tentative and requires more detailed analysis, including additional datasets that are likely not yet available.

It was somewhat surprising that no significance was found for any measures of age, chronic disease, pollution, or some of the race parameters. In some cases, this is likely due to the fact that the variability was just too small to drive a signal in the results. For example, while the average obesity rate across the 50 states is 27.7%, the standard deviation is only 3.3%. In these cases, we suggest that rather than there not being contribution, we were unable to identify it because of the quality of the parameter. Indeed, several recent studies, which have focused

specifically on a particular parameter, such as race or ethnicity, were able to identify it within smaller populations with higher heterogeneity (Raifman and Raifman, 2020). Additionally, where explanatory variables are co-linear, the explanatory capability might be absorbed by another parameter.

Equally remarkable is that small differences in race/ethnicity amongst states were statistically significant, albeit only accounting for a small fraction in the variability of the deaths. This suggests that these factors may be more important than those that were not found to be statistically significant here. Of course, this remains speculation until more definitive studies are completed.

5. Conclusions

In this study, we have applied MLR and ML analyses to a large number of potentially promising explanatory variables. We found that population-weighted density (PWD), as well as metrics for the efficacy of lock-down orders were the most significant explanatory variables in explaining the variability in the rate of deaths across U.S. states. Race/ethnicity, health, and climate effects, while statistically significant, were not as significantly important. This may reflect an intrinsic truth, or, more, more likely, is a consequence of the limitations in the data collected. Further studies with more extensive and accurate datasets (as they become available) will likely resolve these issues.

ABSTRACT

COVID-19 pandemic is a global threat to human health and economy that requires urgent prevention and monitoring strategies. Several models are under study to control the disease spread and infection rate and to detect possible factors that might favour them, with a focus on understanding the correlation between the disease and specific geophysical parameters. However, the pandemic does not present evident environmental hindrances in the infected countries. Nevertheless, a lower rate of infections has been observed in some countries, which might be related to particular population and climatic conditions.

In this paper, *infection rate* of COVID-19 is modelled globally at a 0.5° resolution, using a Maximum Entropy-based Ecological Niche Model that identifies geographical areas potentially subject to a high infection rate. The model identifies locations that could favour infection rate due to their particular geophysical (surface air temperature, precipitation, and elevation) and human-related characteristics (CO^2 and population density). It was trained by facilitating data from Italian provinces that have reported a high infection rate and subsequently tested using datasets from World countries' reports. Based on this model, a *risk index* was calculated to identify the potential World countries and regions that have a high risk of disease increment.

The distribution outputs foresee a high infection rate in many locations where real-world disease outbreaks have occurred, e.g. the Hubei province in China, and reports a high risk of disease increment in most World countries which have reported significant outbreaks (e.g. Western U.S.A.). Overall, the results suggest that a complex combination of the selected parameters might be of integral importance to understand the propagation of COVID-19 among human populations, particularly in Europe. The model and the data were distributed through Open-science Web services to maximise opportunities for re-usability regarding new data and new diseases, and also to enhance the transparency of the approach and results.

1. Introduction

The spread of the COVID-19 pandemic, caused by the SARS-CoV-2 virus, is significantly afflicting both society and the global economy, and urgently calls for the development of systems capable of monitoring and predicting the risk of infection. The modelling of SARS-CoV-2 spread is being approached with heterogeneous methodologies, ranging from pure time series analysis to ecological models using climatic parameters, especially temperature and humidity (Giuliani et al., 2020; Nickbakhsh et al., 2020; Sajadi et al., 2020; Wang et al., 2020). However, the pandemic seems to be spreading in all World cities without evident environmental hindrances. Nevertheless, some countries are experiencing a lower rate of disease cases that might be related to their particular population and climatic conditions, but the exact effect of these conditions on infection rate is still unclear (Roser et al., 2020).

Several approaches have been used to estimate the potential spatial outreach of the virus and the geophysical and climatic data that may foster disease transmission. Ecological Niche Models (ENMs) have been extensively and effectively used in this context (Costa and Peterson, 2012; Davison, 2007; Misra and Kalita, 2010; Wahlgren, 2011; Zhang et al., 2019). ENMs' aim is to predict the presence of a particular species in a geographical area by correlating species-specific occurrence records in its native habitat (presence records) with specific environmental parameters (Elith and Leathwick, 2009). The species' niche can be defined as the space within a hypervolume of numerical vectors - corresponding to environmental parameter ranges - which is correlated with the species' presence, and that fosters population persistence (*Hutchinsonian* ecological niche). Accuracy in the identification of this hypervolume can also be enhanced if the species' absence information is included in the model, as either expert-estimated or mathematically

simulated information (Chuine and Beaubien, 2008; Coro et al., 2016; 2015b; Pearson, 2012; Peterson et al., 2011). ENMs have heterogeneous approaches and implementations, for example they can explicitly model a species' environmental preferences and physiological limits (*mechanistic models*), or they can automatically estimate the correlation between the parameter vectors and the species' presence (*correlative models*). Once the model has estimated the species' ecological niche, it can then project the niche characteristics across the native geographical area to reproduce the actual species' distribution, and subsequently extrapolate across another area (even at the global scale) to discover new potential suitable places for the species' persistence. Most ENMs that predict virus' spread use *correlative* approaches implemented as machine-learning or statistical models. These models can reach a high prediction accuracy on disease outreach because viruses and pandemics are known to be supported by particular geophysical characteristics and, potentially, by ecological and socioeconomic changes (Carlson et al., 2016; Earn et al., 2000; Morse et al., 2012; Scheffer, 2009; Scheffer and Van Nes, 2018). ENMs have been extensively used to discover these characteristics directly, or indirectly by tracing viruses' principal vectors (Fuller et al., 2013; Linden, 2006; Medley, 2010; Peterson et al., 2006; Samy et al., 2016; Signorini et al., 2014; Tachiiri et al., 2006; Valiakos et al., 2014; Walton et al., 2010; Zhu and Peterson, 2014). In particular, the Maximum Entropy model (MaxEnt) has been often used as an ENM due to its flexibility to work with both presence and presence/absence data scenarios (Coro et al., 2015b; 2013; Elith et al., 2011; Phillips et al., 2004). Also, MaxEnt can estimate the influence of each parameter on the identification of the niche, i.e. the most important parameters to understand a virus' preferred conditions. For these reasons, MaxEnt has often been used to trace the ecological niche of a virus based on pure geophysical parameters or human-related parameters (e.g. population density and urbanised area), and also to understand how climate change might foster the virus' spread (Koch et al., 2016; Miller et al., 2012; Peristeraki et al., 2006; Samy and Peterson, 2016).

In this paper, MaxEnt is used to estimate a *global-scale distribution of SARS-CoV-2 high infection rate*, and consequently of potential COVID-19 high spread rate. Differing from the other cited works, this model concentrates on infection *rate* rather than on absolute *spread* numbers. Further, the proposed model uses a complex combination of parameters to identify locations that could favour infection due to their particular geophysical- and human-related characteristics. As a result, it predicts a high probability of infection increase in many actual known infection areas, e.g. the Hubei province in China. The presented ENM is trained based on locations in Italy that have reported a high rate of new infections. Also, it facilitates geophysical (surface air temperature, precipitation, and elevation) and human-related (carbon dioxide and population density) data-vectors associated with these locations. The implemented model produces a probability map where higher values indicate a correlation with high infection rate; lower non-zero values indicate a lower correlation, and zero indicates unsuitable conditions for infection increase. A *risk index* is also calculated out of the produced probability distribution and identifies most World countries, with known high COVID-19 spread rate, as high-risk zones. Overall, the present work suggests that the involved parameters may play a key role in monitoring COVID-19 spread rate. The research question answered by the present work is: *Given the climatic, geophysical, and human-related parameters that other studies have individually correlated with a high COVID-19 infection rate, and that are publicly accessible, can we infer their overall weights and predict infection rate with high accuracy?*

This paper is organised in the following way: Section 2 describes the used data and the modelling approach and subsequently Section 3 reports performance evaluation metrics, model's parametrisation, and performance at predicting global high-infection-rate zones. Section 4 discusses results and conclusions, reporting the possible applications and future extensions of the presented model.

Precipitation	NASA Earth Exchange Platform
Elevation	United Stated National Geophysical Data Center
Carbon Dioxide	Copernicus Atmosphere Monitoring Service
World Population Density	Center for International Earth Science Information Network

2. Material and methods

2.1. Data

2.1.1. Data selection methodology and data availability

The methodology presented in this paper aims to be repeatable, reproducible, and re-usable for experiments on COVID-19 and other diseases. For this reason, only data which met the principles of findability, accessibility, interoperability, and re-usability were used (FAIR data). Geospatial data accessible through representational standards, published on public geospatial services, were preferred in order to maximise their usage in the implemented model and further experiments. All used data (Table 1) were post-processed and transformed into gridded raster files, and were made available through the Zenodo open-access repository (Coro, 2020a) and the Unidata Thredds service of the D4Science e-Infrastructure (Coro, 2020b) while respecting their primary sources' citation requirements. The model used an annual data set so as not to be limited to the last winter/spring season.

2.1.2. Training and test data

The Italian Civil Protection Department - the national body that deals with emergency events - publishes daily updates on the number of people infected, recovered, and mortalities from COVID-19 per region and province (Italian Civil Protection Department, 2020). Data up to the end of March 2020 (Fig. 1-a), i.e. the period of maximum infection rate in Italy, were used as a reference to identify locations with high infection rates on the basis of the derivative of the values. Among all available COVID-19 global reports, Italian data are particularly applicable to train an ENM because (i) Italy has been the first European country to be both heavily impacted by the virus and to study the virus, and (ii) infections in Italy have been reported on the basis of tens of thousands blanket tests. In Italy, a correlation between temperature and humidity increase and COVID-19 spread has been assessed (Italian Ministry of Health, 2020; Scafetta, 2020; Tuscany Regional Health Agency, 2020), in agreement with studies on other areas (Section 2.1.3). Indeed, despite the easing of the lockdown to lower levels and the consequential increase of human interactions, the disease spread has been decreasing from May 2020 (GEDI, 2020). At the end of April 2020, the Italian Prime Minister presented a plan of progressive lockdown level reduction, which also included possible regional restrictions in the case of a localised disease rate increase (Italian Government, 2020). However, significant increments were not observed and thus special regional restrictions were not applied. To better understand this phenomenon, Italy has started national projects to investigate the cause and effect relationships between the lockdown, environmental factors, and tourism, and to publish data and results under FAIR principles (CNR, 2020). Due to this range of considerations, Italy presents an optimum scenario to apply the proposed analysis. However, other countries are experiencing a high infection rate but have climatic conditions that are very different from the European ones. The identification of all these conditions would require more significant research and data collection initiatives.

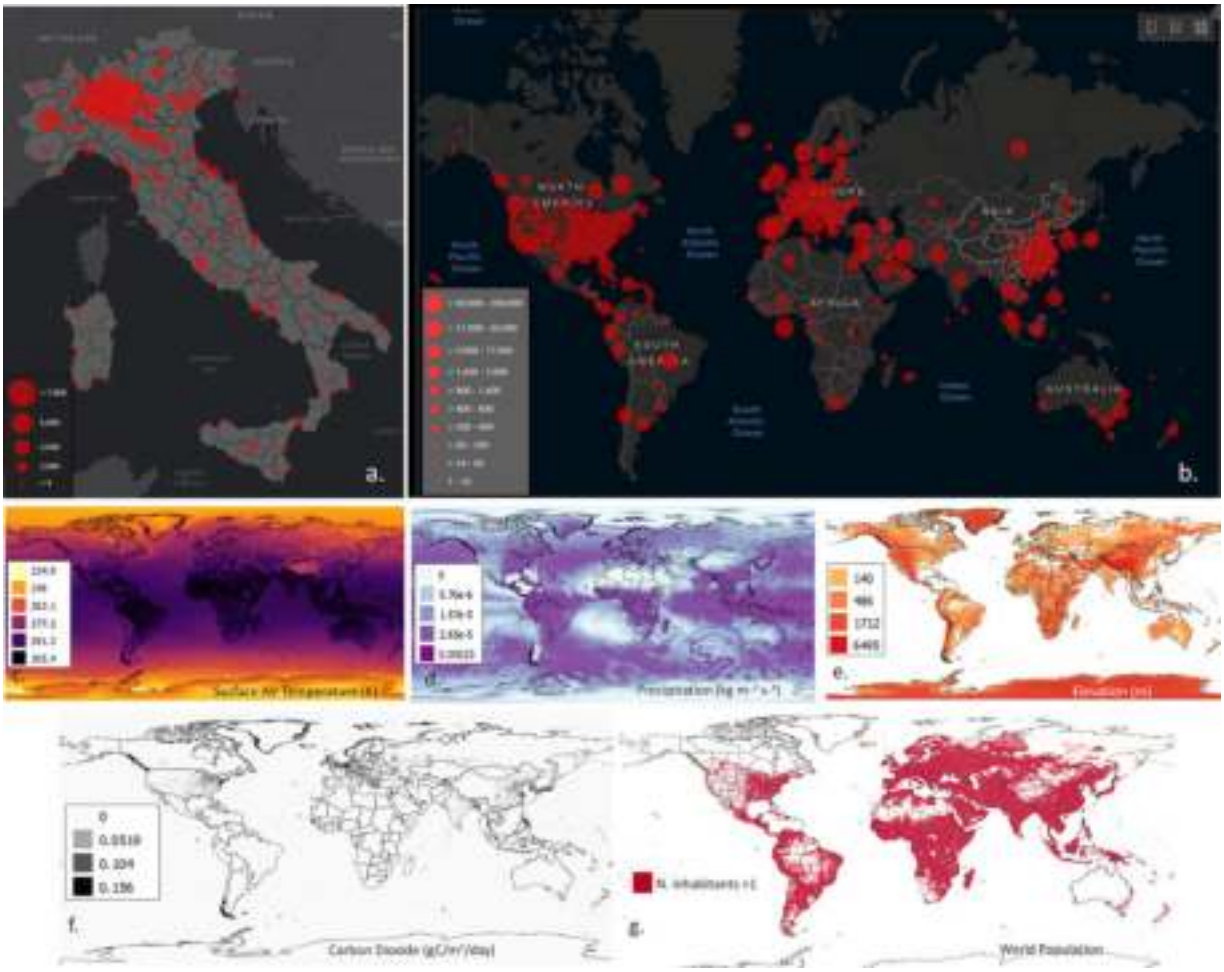

Fig. 1. Visual comparison of the global-scale data used in the presented model: (a) number of infections in Italian provinces (31 March 2020), (b) global infections (31 March 2020), (c) surface air temperature, (d) precipitation, (e) elevation, (f) carbon dioxide, (g) World population.

For the scopes of the presented experiment, Italian locations with a high virus infection rate were selected, by first calculating average rates of infected people per province and then by studying the distribution of these quantities. A total of 54 provinces was selected by applying this approach (the detailed table is available in Coro (2020a)). A Chi-squared test confirmed that the distribution of infection rates could be approximated by a log-normal distribution. Consequently, provinces with a high infection rate were identified and selected as those with infection rates over the geometric mean of the rates. These data were used as reference observations of the modelled phenomenon to train an ecological niche model. It is worth noting that using average infection *rate* instead of absolute infection *counts* helps reducing a data bias due to the number of undetected cases of infection in Italy.

John Hopkins University publishes daily updates regarding COVID-19 infections and mortality statistics by collecting reports from the World countries (Dong et al., 2020). Data are given at a national scale for most countries, and at a regional scale for other countries (e.g. China, U.S.A., and Canada) (Fig. 1-b). Unfortunately, reports from different countries are poorly comparable between them, given the different countries approaches to disease identification and monitoring (Reuters, 2020). Thus, mixing these data with Italian province data was not optimal for modelling. Nevertheless, global data were used as a reference to test the prediction performance of an aggregated *risk index* built upon the model's output (Section 2.3). To this aim, the countries/regions with the highest infection rates were selected using the same statistical analysis applied to Italian data, which resulted in 72 locations (the detailed table is available in Coro (2020a)).

2.1.3. Input parameters

Surface air Temperature and Precipitation

The NASA Earth Exchange platform hosts long-term daily forecasts between 1950 and 2100 at a 0.25° resolution for minimum and maximum surface air temperature and precipitation at the surface (NASA-NEX, 2020). Forecasts come from 20 weather models developed by the Coupled Model Intercomparison Project Phase 5 (CMIP5, 2019). The D4Science e-Infrastructure hosts these data sets averaged in time and space, for 2018 and at a 0.5° resolution as gridded NetCDF-CF files (Coro and Trumpy, 2020a). In particular, data of average surface air temperature and precipitation (Figs. 1-c and -d) were used due to their correlation with COVID-19 and similar viruses (Casanova et al., 2010; Chan et al., 2011; Chaudhuri et al., 2020; Ficetola and Rubolini, 2020; Ma et al., 2020; Oliveiros et al., 2020; Qi et al., 2020; Wang et al., 2020; Wu et al., 2020), and their general coupled involvement in virus ecological niche models (Carlson et al., 2016; Fuller et al., 2013; Patz, 1998; Valiakos et al., 2014). Additionally, precipitation was also used as a surrogate of humidity (Baskerville and Cobey, 2017; Chen et al., 2012; Masunaga, 2012). Italian provinces present a high variability of surface air temperature and precipitation. At the same elevation, there are temperature differences as high as 7° and precipitation differing of more than one order of magnitude. This variability increases the representativeness of Italian provinces as a training set.

Elevation

The United States National Geophysical Data Center (NGDC) hosts a global dataset of elevation and depth at a 0.33° resolution (ETOPO2, NOAA (2001)), which includes localised correction and integration of

satellite, ocean sounding, and land data. Elevation has been used in several ecological niche models for viruses (Miller et al., 2012; Peterson et al., 2006; Valiakos et al., 2014) and thus was included in this experiment. The D4Science e-Infrastructure hosts a FAIR ETOPO2 dataset as a gridded NetCDF-CF file (Coro and Trumpy, 2020a; 2020b) downsampled at a 0.5° resolution (Fig. 1-e).

2.1.4. Human-related parameters

The Copernicus Atmosphere Monitoring Service hosts a global-scale uniform distribution of carbon dioxide (CO^2) flux with monthly estimates (CAMS, 2019) deriving from both human and natural activity. A FAIR dataset of averaged data from January 1979 to December 2013 with a 0.5° spatial resolution is hosted by D4Science (Coro and Trumpy, 2020a) as a gridded NetCDF-CF file (Fig. 1-f). This dataset aims at combining CO^2 values preceding the higher industrialisation rate of the last decades with the natural presence of CO^2 in the soil. It summarises both natural emission and the evolution of human emission (Coro and Trumpy, 2020b). For the scope of this paper, this dataset was used as a surrogate of air pollution and human-related activity, which are generally correlated with virus spread and may foster COVID-19 spread (BBC, 2020; Clay et al., 2018; Godzinski and Suarez Castillo, 2019; Han et al., 2020; ISPRA, 2020; Lam et al., 2016; Liu et al., 2019; Tasci et al., 2018; Ye et al., 2016). Alternative parameters of CO^2, correlated with air pollution, were also tested but produced more adverse results (Section 3.2).

Population Density

Studies on complex systems' dynamics have highlighted that epidemics happen only beyond a critical threshold of population density that depends on infectivity, recovery, and mortality rates (Earn et al., 2000; Scheffer, 2009). The Center for International Earth Science Information Network openly publishes up-to-date population density data as gridded datasets with resolutions ranging from30″ to 1° (Warszawski et al., 2017). For the scopes of this paper, the Gridded Population of the World dataset - Version 4, was used at a 0.5° resolution (Fig. 1-g) to include population density factors that could be correlated with infection rate.

2.2. Modelling

The experiment presented required training of MaxEnt models with several alternative parametrisations in order to identify the model with the highest performance and the best combination of parameters (Section 2.3). To this aim, the *gCube DataMiner* cloud computing platform was used. This is an open-source system that is able to process big data and offers over 400 free-to-use processes as-a-service from multiple domains (Assante et al., 2019; Coro et al., 2015a). This platform maximises the re-usability of processes through a standard Web Processing Service (WPS) interface (Coro et al., 2017). Further, DataMiner parallelises the training of models on a network of 100 machines while choosing the best computational configuration among a range of powerful multi-core virtual machines (Ubuntu 14.04.5 LTS x86 64 with 16 virtual CPUs, 16 GB of random access memory and 100 GB of storage capacity). Additionally, the system stores all trained models and their respective parametrisations under the standard and exportable Prov-O ontological format (Lebo et al., 2013). This representation allows to recover the complete set of input/output data and metadata which enable any other authorised user to reproduce and repeat an experiment (*provenance* of the computation). The Open Science concepts of re-usability of processes, and of reproducibility and repeatability of the experiments, allow the implementation of a methodology that can, in principle, be extended to analyse other diseases (Section 4). To this aim, DataMiner hosts a MaxEnt model as-a-service (CNR, 2019; Phillips et al., 2019), which can work on textual input files (CSVs) - that include pairs of coordinates related to a certain phenomenon - and FAIR input geospatial data. The WPS interface allows (i) inclusion of this service in complex workflows through a wide range of workflow management systems which support this standard (Berthold et al., 2009; QGis, 2011; Wolstencroft et al., 2013), and (ii) re-use of the service across multiple domains (Coro et al., 2015b; 2013; Coro and Trumpy, 2020b; Coro et al., 2018).

2.2.1. Model description

MaxEnt is a machine learning model commonly used in ecological niche modelling (Baldwin, 2009; Coro et al., 2015b; 2018; Phillips et al., 2006; Phillips and Dudik, 2008; Phillips et al., 2004). It simulates a probability density function $\pi(\bar{x})$ defined on real-valued vectors of parameters $\bar{x}$ taken at locations where a species occurs in its native habitat (Coro et al., 2018; Pearson, 2012). The advantage of MaxEnt with respect to other models is that it can learn from positive examples only. Thus, it does not necessarily need absence data, which are instead automatically estimated. Considering the high-infection-rate of Italian provinces as species occurrences, the parameters associated with these areas were treated as a positive example of input vectors to train the model. One drawback of MaxEnt, is that its prediction performance is very sensitive to data quality (Elith and Leathwick, 2009), an additional consideration for using only Italian data and not combining data from other countries (Reuters, 2020).

The MaxEnt training algorithm adjusts the model's internal variables so that (i) the simulated density function $\pi(\bar{x})$ is compliant with pre-calculated mean values at training-set locations and (ii) the entropy of the density function $H = -\sum \pi(\bar{x}) \ln(\pi(\bar{x}))$ is maximum for these locations (Elith et al., 2011). MaxEnt maximises the entropy function for training locations divided by the entropy values of the parameters of random points taken in the training-set area (*background points*, Phillips et al. (2006)). The model involves a linear combination of the input parameters, whose coefficients reproduce the influence of each variable on the prediction of the training set locations (*percent contribution*). Further, the model estimates the dependency of the performance on the permutation of each parameter in the training vectors (*permutation importance*).

In this experiment, MaxEnt uses the data vectors $\bar{x}$ of Italian high-infection-rate provinces (and of *background points* in Italy) to estimate the probability density $\pi(\bar{x}) = P(high - infection - rate|\bar{x})$ that a location would foster a high infection rate. To this aim, the model estimates the ratio between the probability density $f(\bar{x})$ of the vectors across Italy and the probability density in the high-infection-rate locations $f_1(\bar{x})$. The Bayes' rule defines the relation between $P(high - infection - rate|\bar{x})$, $f(\bar{x})$, and $f_1(\bar{x})$:

$$P(high - infection - rate|\bar{x}) = \frac{f_1(\bar{x})P(high - infection - rate)}{f(\bar{x})}$$

with $P(high - infection - rate)$ being the prior distribution of high-infection-rate zones in Italy (*prevalence*), fixed to 0.5 by default (i.e. no prior assumption is given). MaxEnt hypothesises that the optimal $f_1(\bar{x})$ distribution is the closest distribution to $f(\bar{x})$, because without any training-set location there would be no expectation about certain conditions over the others (i.e. $f(\bar{x})$ is a null model for $f_1(\bar{x})$). Also, the model constraints $f_1(\bar{x})$ to reflect the observations on the training set, i.e. $f_1(\bar{x})$ should estimate high probability on parameters' values close to the parameters' means over the training set. The model uses Kullback-Leibler divergence (relative entropy) to measure the distance between the two functions:

$$d(f_1(\bar{x}), f(\bar{x})) = \sum_{\bar{x}} f_1(\bar{x}) log_2\left(\frac{f_1(\bar{x})}{f(\bar{x})}\right)$$

The aim of the training algorithm is to minimise this distance under the above constraints, which in turn maximises the entropy of the target probability density. It can be demonstrated that this characterization uniquely determines $f_1(\bar{x})$ as belonging to the following family of Gibbs distributions (Phillips et al., 2006):

$$f_1(\bar{x}) = f(\bar{x})e^{\eta(\bar{x})}$$

with $\eta(\bar{x}) = \alpha + \beta\, h(\bar{x})$; α being a normalization constant that makes $f_1(\bar{x})$ sum to 1; h being an optional transformation of the vectors $\bar{x}$ that possibly models complex relationships between parameters; β being the vector of coefficients that reports the *percent contribution* of each parameter. Thus, the ratio $f_1(\bar{x})/f(\bar{x})$ is equal to $e^{\eta(\bar{x})}$, i.e. MaxEnt needs to solve a log-linear model based on the background and training vectors to estimate the α and β parameters, which can be implemented through a penalised maximum likelihood algorithm (Phillips and Dud, 2008).

After the training phase, the parameters' *percent contribution* can be used to select the most influential parameters for the model. This potentially allows to use MaxEnt as a filter to select those parameters carrying the highest quantity of information (Coro et al., 2015b; 2013; 2018). A MaxEnt model trained on 0.5˚ resolution parameters can be reasonably used to produce probability distributions at the same resolution. Given the semantics of the selected training locations, the model produced a distribution function that could be interpreted as a global-scale probability distribution for SARS-CoV-2 high infection rate.

2.3. Evaluation metrics

The model training phase estimates the average Area Under the Curve (AUC), i.e. the integral of the Receiver Operating Characteristic (ROC) curve that plots *sensitivity* ($\frac{True\ Positives}{True\ Positives + False\ Negatives}$) against 1-*specificity* ($1 - \frac{True\ Negatives}{True\ Negative + False\ Positives}$). AUC values closer to 1 indicate high classification performance of training sites. Reference cut-off thresholds on π were also calculated during the training phase (Phillips et al., 2019) and represent (i) the value balancing *omission rate* ($\frac{False\ Negatives}{True\ Positives + False\ Negatives}$) and *sensitivity* (*balanced threshold*), (ii) the value at which *sensitivity* and *specificity* are equal, and (iii) the minimum threshold at which all training locations are correctly classified as high-infection-rate areas.

In order to numerically estimate the prediction performance of the trained model, a *risk index* was also calculated, defined as the normalised density of non-zero MaxEnt probability locations (Coro et al., 2018; McGeoch et al., 2006) for all countries/regions reported in the global dataset of infection rates (Section 2.1). High-risk zones were identified as those with a *risk index* higher than the geometric mean of the *risk* values. Accuracy on the correct identification of *high-infection-rate countries/regions* as *high-risk zones* was calculated as $\frac{n.\ of\ high-infection-rate\ areas\ identified}{overall\ n.\ of\ high-infection-rate\ areas}$. Moreover, agreement between high-risk zones' classification and high-infection-rate country/region reports was calculated using Cohen's Kappa (Cohen et al., 1960). This statistical coefficient estimates the agreement between the two classifications with respect to purely random classifications (agreement by chance). An overall interpretation of this value was assigned using Fleiss' tables (Fleiss, 1971).

3. Results

3.1. Global-scale distribution and performance

The MaxEnt model was trained using different combinations of parameters associated with Italian locations reporting a high rate of infections up to the end of March 2020 (Section 2.1). Training the model on all parameters produced the highest AUC and optimal estimates for the three model's thresholds (Table 2-a). When the model was trained with any other parameter subset, AUC resulted lower. This property indicates that all parameters bring useful information to estimate training set locations correctly. Nevertheless, the *percent contribution* and *permutation importance* of carbon dioxide, surface air temperature, and precipitation are much higher than the ones of elevation and population density (Table 3). The model using all parameters also indicates a correlation with high infection rate for particular parameter ranges (i.e. the boundaries of the niche hypervolume): CO^2 has the highest correlation around 0.03 (0.01;0.08) $g\ C\ m^{-2}\ day^{-1}$ (*moderate-high*), air temperature around 11.8 (8.0;16.0) ˚C (*moderate-low*), and precipitation around 0.3 (0.2;0.45) 10^{-4} $kg\ m^{-2}\ s^{-1}$ (*moderate*).

Table 2
Report of (a) the performance and optimal thresholds of the trained MaxEnt model, and (b) the performance of the *risk index* on the identification of global high-infection-rate countries/regions.

Model Performance - a	
AUC	0.994
Balanced omission-sensitivity threshold	0.4
Equal training sensitivity and specificity threshold	0.1
Minimum training presence threshold	0.008
Risk Index Performance - b	
Accuracy	77.25%
Kappa	0.46
Kappa Interpretation	Good

Table 3
Percent contribution and permutation importance of the parameters involved in the presented experiment, as estimated by the optimal Maximum Entropy model.

Parameter name	Percent contribution	Permutation importance (%)
Carbon Dioxide	87.2	52.8
Surface Air Temperature	7.6	40
Precipitation	5.3	6.9
Elevation	0.01	0.01
Population Density	0.01	0.2

The model was projected at the global scale to produce a global infection-rate probability distribution at a 0.5˚ resolution (Fig. 2). For each cell, this map reports the probability that the cell has suitable conditions for infection increase. Locations with a value higher than the balanced threshold ($\pi(\bar{x}) \geq 0.4$) can be classified as high-infection-rate locations, whereas the other two thresholds indicate medium infection-rate ($0.1 \leq \pi(\bar{x}) < 0.4$) and low infection-rate ($0.008 \leq \pi(\bar{x}) < 0.1$) locations. Zero probability locations indicate unsuitable areas for an infection rate increase.

As a qualitative evaluation, it can be observed that the model correctly and precisely identifies the locations of real World high infection rates, e.g. the Hubei Chinese region, Western United States, and most of Europe. Instead, wrongly classified places are, for example, Peru and Brazil, that have parameter ranges out of the niche hypervolume. The identification of the climatic/geophysical parameters fostering infection rate increase in these countries would require further research, based on a more extensive and globally shared data collection (Section 3.3).

In order to quantify the prediction accuracy of the map, the *risk index* was used to select high-risk zones and compare them with global reports of high infection rates (Fig. 3 and Table 2-b). Accuracy at predicting high-infection-rate countries/region reached 77.25%, and the overall agreement (0.46) was *good* according to Fleiss' classification. This result indicates that most countries/regions are correctly and non-randomly classified, and thus the model has extracted a correct characterisation of the actual risk of infection increase based on the considered parameters.

3.2. The weight of the CO^2 parameter

The high correlation of CO^2 with high infection rate requires a further investigation, starting from the correlation between air pollution and COVID-19 spread (Section 2.1.4). The Copernicus Atmosphere Monitoring Service provides FAIR data correlated with greenhouse gas concentration and fluxes, i.e. methane (CH_4), nitrous oxide (N_2O), and

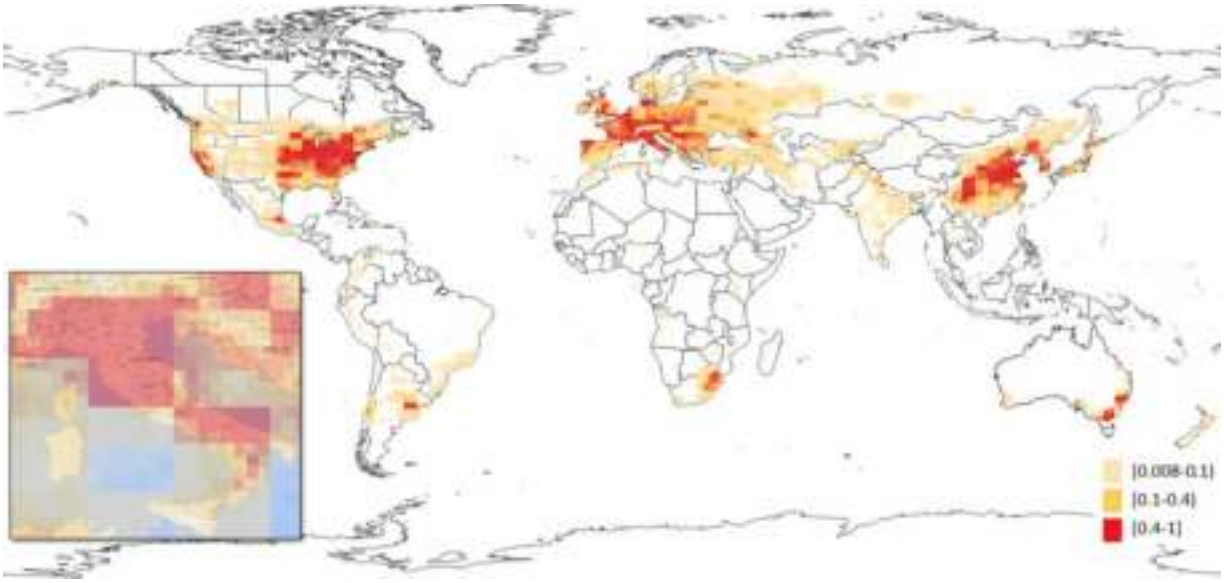

Fig. 2. Global-scale probability distribution of SARS-CoV-2 infection rate produced by the presented model, with Italy magnified at the lower-left hand side.

CO^2 (CAMS, 2020). The CH_4 and N_2O influence on prediction performance was evaluated by substituting these parameters to CO^2 in the all-parameter model (*individual* models), and then by using them together with CO^2 (*mixed* model). The aggregated data used for this analysis were published as FAIR data on Zenodo (Coro, 2020a). Executing the MaxEnt individual models revealed that CH_4 and N_2O have a much lower *percent contribution* ($\sim$ 52% for both models) to infection rate prediction than CO^2 (87.2%). Furthermore, their individual models reported a lower AUC (0.90 v.s. 0.994 of the CO^2 model). However, in these models, CH_4 and N_2O were always the parameters having the highest *percent contribution* to infection rate prediction. This property indicates that the parameters correlated with greenhouse gases concentration are of high importance for prediction accuracy, which confirms the correlation between air pollution and infection rate highlighted by other studies (Section 2.1.4). The mixed model further confirmed this result because it gained the same performance as the CO^2 individual model to predict high risk zones (77.25%). However, the mixed model reported a much higher *percent contribution* of CO^2 (85.9%) than of CH_4 (0.4%) and N_2O (0.4%). This result indicates that CH_4 and N_2O are not adding a substantially more predictive information than CO^2. Overall, this analysis indicates that CO^2 is the correct choice to represent air pollution in the experiment.

3.3. Training and input data completeness

In order to evaluate if Italian provinces were a sufficient representative training set for the reported experiment, the all-parameter MaxEnt model was executed by incrementally adding more World areas to the training set. First, the geographical areas of large cities correctly predicted by the original model were added, i.e. Madrid, London, Istanbul, Buenos Aires. This operation did not change the model's risk prediction performance (77.25%), which indicates that Italian provinces are strong representation of the correctly detected World cities. As an additional step, World city areas that were wrongly predicted by the original model were incrementally introduced, i.e. São Paulo, Lima, Santiago de Chile, Guayaquil. This process produced a continuously

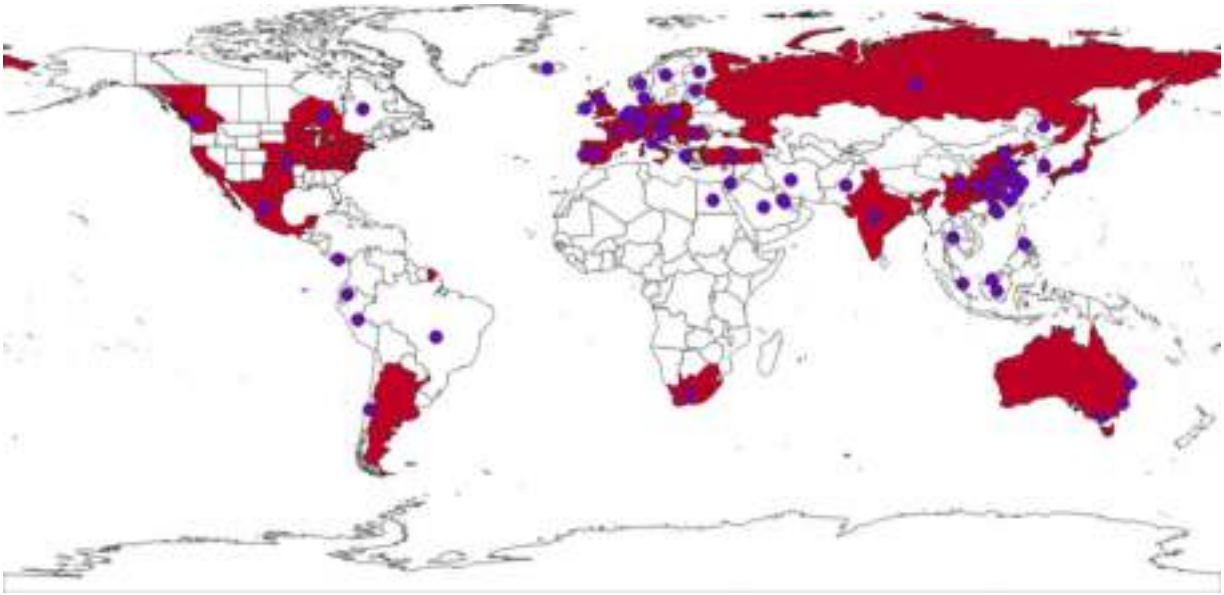

Fig. 3. Overlap between estimated high-infection-rate risk zones (coloured countries/regions) and actual reported high-infection-rate countries/regions (circles).

0225

decreasing AUC, also if CH_4 and N_2O were used instead of CO^2. When involving these World cities, one major effect on the parameter ranges was a change in the upper confidence limit, which increased for temperature (from 16.0 to 18.8 °C) and precipitation (from 0.45 to 0.6 10^{-4} $kg\ m^{-2}\ s^{-1}$) and the decreased for CO^2 (from 0.08 to 0.05 $g\ C\ m^{-2}\ day^{-1}$). The decreasing AUC, indicates that these ranges are not able to make the model cover all the areas of the training set. This result indicates that the used input parameters are insufficient to understand the infection rate increase in these areas, independent of the use of Italian provinces as the training set.

4. Discussion and conclusions

This paper has presented a methodology to estimate a geographical probability distribution of *high infection rate* for SARS-CoV-2, based on geophysical and human-related parameters. A *risk index* has been proposed based on this probability distribution, to identify global countries and regions that would mostly favour a high infection rate. A *good* concurrence with country-reported data and a moderate-high accuracy at predicting high-infection-rate countries/regions indicates that the model was able to identify real conditions of increased infection rate in many World areas. Generally, the model indicates a high infection rate in areas characterised by an annual moderate-high level of CO^2, moderate-low temperatures, and moderate precipitation. The most notable result is that, although the model was trained only with Italian cities, it assigns a high-infection-rate probability and a high-risk classification to most real World scenarios where a high infection rate has been actually reported. Also, the results indicate that climatic parameters such as air temperature and precipitation (or air humidity) play a critical role at defining locations that may be subject to a high infection rate. The model also indicates a temperature range which other studies have also correlated with the spread of COVID-19 (Sajadi et al., 2020). Additionally, estimated high-rates in moderate-precipitation regions might be related to reduced transmission in high-humidity zones (Wang et al., 2020). Carbon dioxide is the most influential parameter, which is correlated directly with pollution (which concurs with COVID-19 spread, Han et al. (2020)) and indirectly with population density. Correlation with population density could be one reason for the lower influence of this parameter on prediction performance. However, the fact that all parameters are necessary to achieve the optimal model performance indicates that they all contain complementary information. Thus, population density is not entirely covered by CO^2. Indeed, it affirms the complex system dynamics theory that if a population is vulnerable to a virus and its density exceeds a threshold, an epidemic will occur (Scheffer, 2009). In the case of SARS-CoV-2, the presented results indicate a likely scenario where, after this threshold, population density does not influence infection rate anymore. This observation is valid in Italy, where provinces with population densities distant of almost two orders of magnitude have reported similar infection rates for a long period (e.g. Lucca and Naples). As for elevation, the model indicates that this is not a discriminant feature, as also demonstrated by the variability in the altitudes of high-infection-rate Italian provinces. However, elevation brings some information to the model - probably related to drier weather conditions - because without this parameter the model's AUC decreases.

Currently, the complete set of parameters correlated with COVID-19 infection rate increase remains unknown. The reported results indicate that the used parameters are sufficient to predict the situation in Europe and in many World countries, however there are additional unknown factors to be investigated in the misidentified countries (e.g. Brazil, Ecuador, and Peru). The identification of all these factors is a broader question that goes beyond this paper and would require on-the-field data collection and a global-scale effort, also to make data available under FAIR principles.

The proposed Open Science-oriented methodology is quickly reusable on new infections and epidemics, for example, to predict the risk that a particular country will be subject to a high rate of cases of a new infection. Also, the results may be the basis of other models that may refine the resolution of the presented model and revise the parameters used. One fundamental step is to collect and prepare FAIR data correlated to infection rate as open-access standardised geospatial datasets. The D4Science e-Infrastructure can be used freely and openly to this aim. Moreover, the Maximum Entropy process was published as a free-to-use service (CNR, 2019) intended for global health-care systems and epidemic prevention organizations, and for possibly contributing to COVID-19 spread control.

Overall, the presented results clearly indicate and identify that the influence of geophysical, climatic, and human-related parameters on COVID-19 infection rate should be further investigated. As a future extension, the model will be enhanced by increasing the projection resolution to 0.1° on specific areas to produce regional-scale distributions. The corresponding cloud computing service will be used to (i) explore a more extensive set of parameters taken from open-access repositories, (ii) understand the importance of climatic factors with respect to human-related factors in COVID-19 infection rate, and (iii) detect seasonal trends.

Abstract: The transmission of the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and the severity of the related disease (COVID-19) are influenced by a large number of factors. This study aimed to investigate the correlation of COVID-19 case and death rates with possible causal climatological and sociodemographic factors for the March to May 2020 (first wave) period in a worldwide scale by statistically processing data for over one hundred countries. The weather parameters considered herein were air temperature, relative humidity, cumulative precipitation, and cloud cover, while sociodemographic factors included population density, median age, and government measures in response to the pandemic. The results of this study indicate that there is a statistically significant correlation between average atmospheric temperature and the COVID-19 case and death rates, with chi-square test *p*-values in the 0.001–0.02 range. Regarding sociodemographic factors, there is an even stronger dependence of the case and death rates on the population median age (p = 0.0006–0.0012). Multivariate linear regression analysis using Lasso and the forward stepwise approach revealed that the median age ranks first in importance among the examined variables, followed by the temperature and the delays in taking first governmental measures or issuing stay-at-home orders.

Keywords: COVID-19; weather; sociodemographic factors; response measures

1. Introduction

At the end of 2019, a new virus causing severe acute respiratory syndrome (SARS-CoV-2) was reported in Wuhan, China, and, due to its high human-to-human transmissibility [1], it quickly spread worldwide, resulting in the ongoing COVID-19 pandemic [2]. By the end of May 2020, which roughly signified the end of the first epidemic wave for most of the countries of the northern hemisphere, the total number of worldwide confirmed cases of COVID-19 was around six million, while the total worldwide deaths had reached 0.37 million [3], causing serious problems to the health systems of many countries.

By a simple examination of the pandemic data so far, one can easily notice the striking disparities (of orders of magnitude) in the reported confirmed case and death counts between countries (Figure 1). If certain socioeconomic indexes are considered alone, counterintuitive and irrational trends may be observed. For example, taking the Human Development Index (an index that includes the gross national income (GNI) per capita, the life expectancy, and the education level of each country) into account and comparing it with the total deaths per million of inhabitants (TDM) for the period of 3/2020–5/2020, it seems as if the countries of high development (and thus generally better health systems) are more susceptible to COVID-19 (Figure 2A). However, if we consider parameters directly associated with how aged is the population of a given country, e.g., the health index as defined by the United Nations Development Program (UNDP) or the median age (Figure 2B,C), it becomes obvious that the trend of Figure 2A can be explained, at least partly, by the fact that the populations of the more

developed countries have a comparatively larger proportion of aged persons that are, in turn, more susceptible to develop heavy illness due to the SARS-CoV-2.

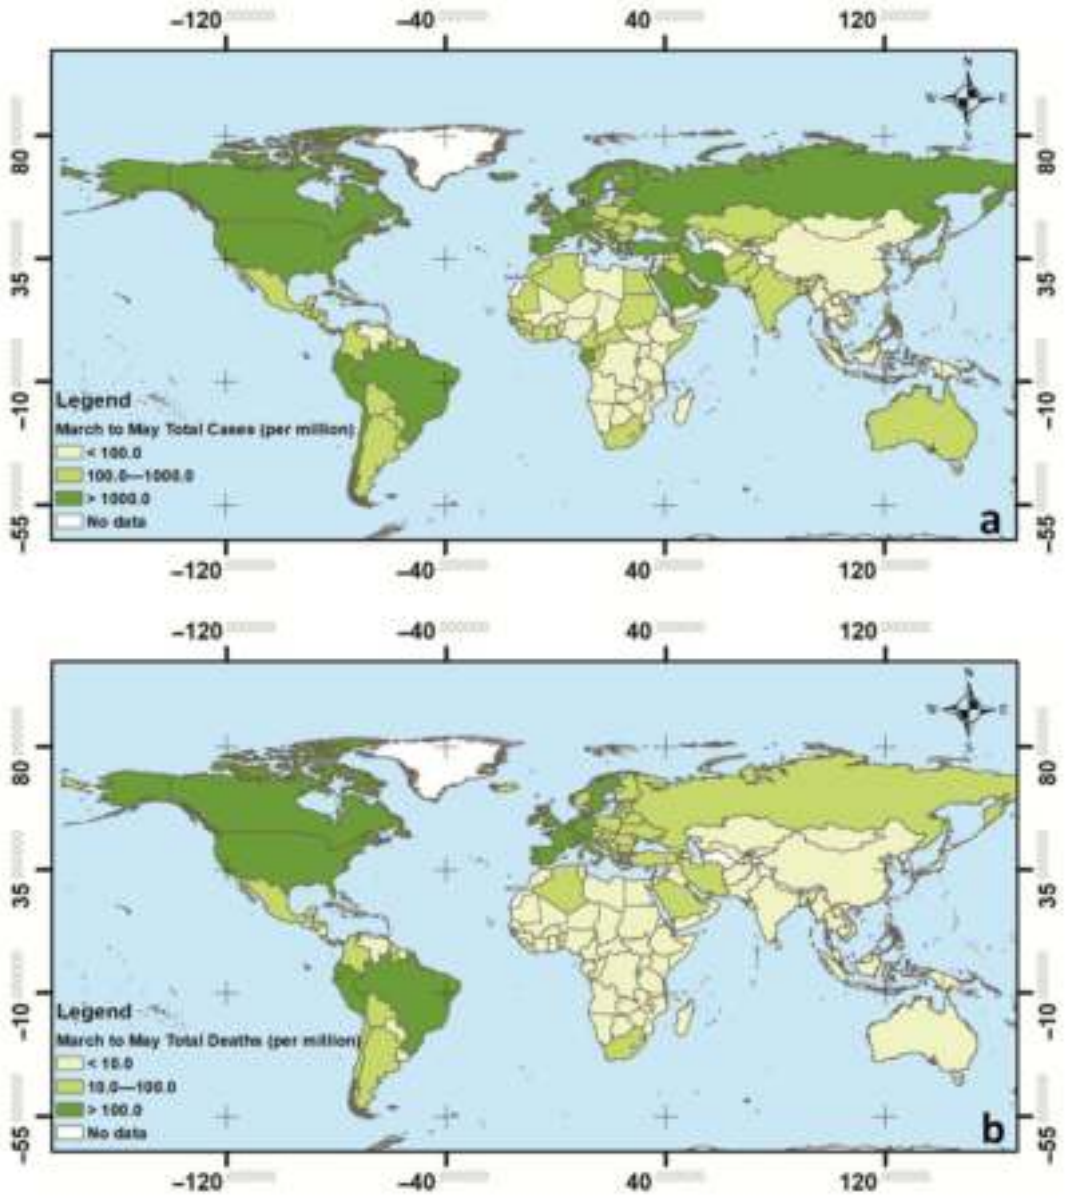

Figure 1. Worldwide distribution of (**a**) COVID-19 cases and (**b**) COVID-19-related deaths for the period of 1/3/2020–31/5/2020.

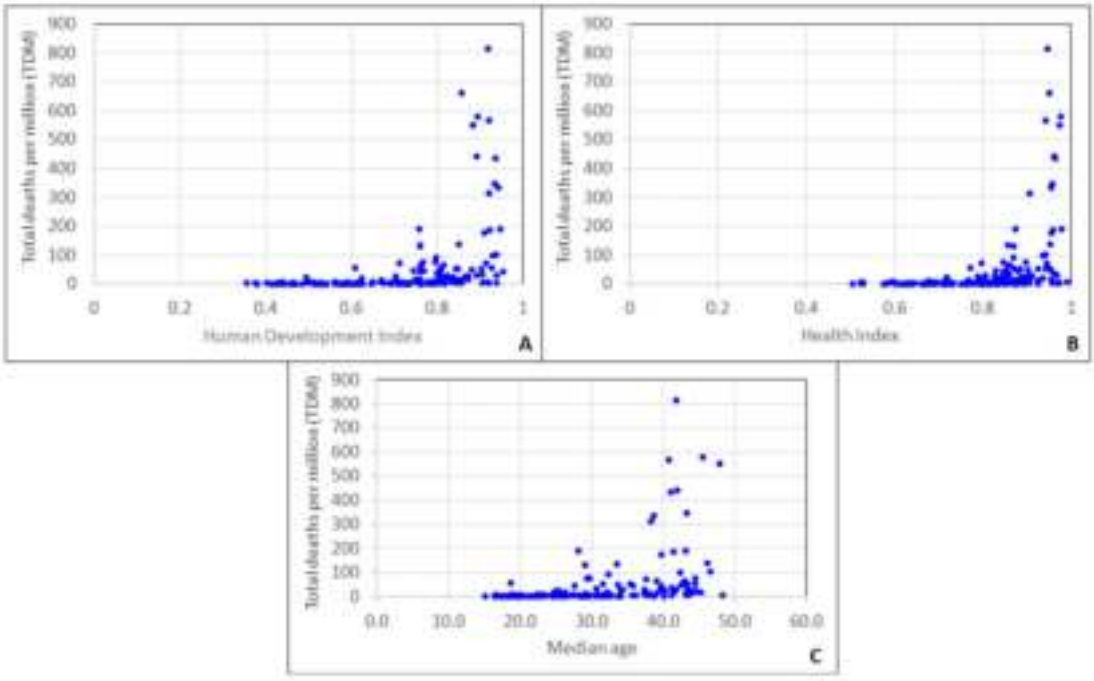

Figure 2. Variation of the total deaths per million for the period of 1/3/2020–31/5/2020 with (**A**) Human Development Index, (**B**) health index, and (**C**) median age (data for 167 countries).

The vast ranges of case and death rates observed in Figure 1 could also be partially attributed to differences in the testing rates arising from the inherent difficulties faced when dealing with a new highly transmissible pathogen (e.g., access to adequate numbers of test kits and the availability of qualified laboratories). Nonetheless, large disparities in case and death rates are observed even among countries with similar economic prosperity, age structure and social characteristics. For example, in eurozone countries (the governments of which responded alike to the pandemic), the number of deaths per million of inhabitants in the 3/2020–5/2020 period ranged from 5 to over 800, i.e., two orders of magnitude difference. Thus, it becomes evident that the pathogen's spread and impact are strongly affected by additional factors. These can be weather conditions, the promptness and mix of governmental response measures, air pollution, the volume of external travel, the frequency of use of public transportation, or other habitual and cultural/behavioral factors.

The effect of climatic factors on influenza epidemics has long being recognized [4–9]. More recently, after the onset of the new pandemic, a number of studies have been carried out to investigate the possible effect of weather on the spread of COVID-19. Some of these studies have focused on specific regions and countries, such as 122 cities in China [10], Wuhan, China [11], Mainland China [12], Jakarta, Indonesia [13], India [14,15], Iran [16], Brazil [17], Europe and United States [18], and Russia [19], while others have examined the effect of weather conditions on the pandemic at a global scale [20–41]. Smit et al. [42], who presented a comprehensive critical review of the relevant literature published in the first half of 2020, concluded that it is important for studies to include the effects of socio-economic factors and non-pharmaceutical interventions (such as government response measures) in their analysis.

This paper attempts to shed light on the degree of influence of climatic factors, namely temperature, relative humidity, precipitation, and cloud cover, on the intensity of the COVID-19 epidemic by examining the data of reported cases and deaths on a worldwide scale for the period of 3/2020–5/2020 (first wave) while simultaneously considering other important factors (social, economic, government response) that are expected to have a strong effect. First, one-to-one correlations are examined between the total numbers of deaths or cases (epidemic effects) and probable causal variables. Then, interference between causal variables is taken into account in order to reveal the actual degree of influence of the climatic factors in relation to sociodemographic ones and those related to government response.

The results of this study, which help understand the relationship between the spatial distribution of the climatic conditions and the severity of COVID-19 on a worldwide scale, could be useful to decision-making authorities for the assessment of the pandemic risk and the management of the response measures.

2. Data Collection

The epidemiological data of total cases and total deaths due to COVID-19 in each country were taken from European Commission (EC) [43], Beltekian et al. [44], and Hale et al. [45] for the period between 1/3/2020 and 31/5/2020. These were used to calculate case and death rates as the total cases per million of inhabitants (TCM) and the total deaths per million of inhabitants (TDM) due to COVID-19 using the following formulas:

$$\text{TCM} = \frac{\text{Total number of cases on } 31/5/2020 \ - \text{Total number of cases on } 1/3/2020}{\text{Country population} \times 10^{-6}} \quad (1)$$

$$\text{TDM} = \frac{\text{Total number of deaths on } 31/5/2020 \ - \text{Total number of deaths on } 1/3/2020}{\text{Country population} \times 10^{-6}} \quad (2)$$

Furthermore, data about the median age and the government response measures taken in each country to reduce the spread of the pandemic—namely the overall stringency index of the government measures and the dates of officially recorded first cases, the imposition of first measures, and the imposition of 'stay-at-home' order—were gathered from Beltekian et al. [44] and Hale et al. [45], while data on the Human Development Index (HDI), population, etc., were collected from the Global Data Lab (GDL) database originating from the United Nation Development Program and referring to the year 2018 [46].

Weather data, such as the monthly average atmospheric temperature (°C), monthly average relative humidity (%), and cumulative precipitation (mm), were collected from the Copernicus Program database [47] as raster files. These variables were estimated from climate reanalysis ERA-Interim and ERA5, depending on the source. The fraction of cloud cover, which is the proportion of a grid box covered by cloud (liquid or ice) and varies between 0 and 1, was taken from the Copernicus Program for a pressure level of 1000 hpa [48]. Then, the spatial analysis tool of the ArcGIS software (by ESRI) was employed to derive the spatial average of these variables across the entire territory of each country. After spatial averaging, the temporal average values were computed for the temperature, relative humidity, and cloud cover for the March 2020 to May 2020 period. Figure 3 presents maps showing the distribution of country average values of temperature, humidity, and cumulative precipitation.

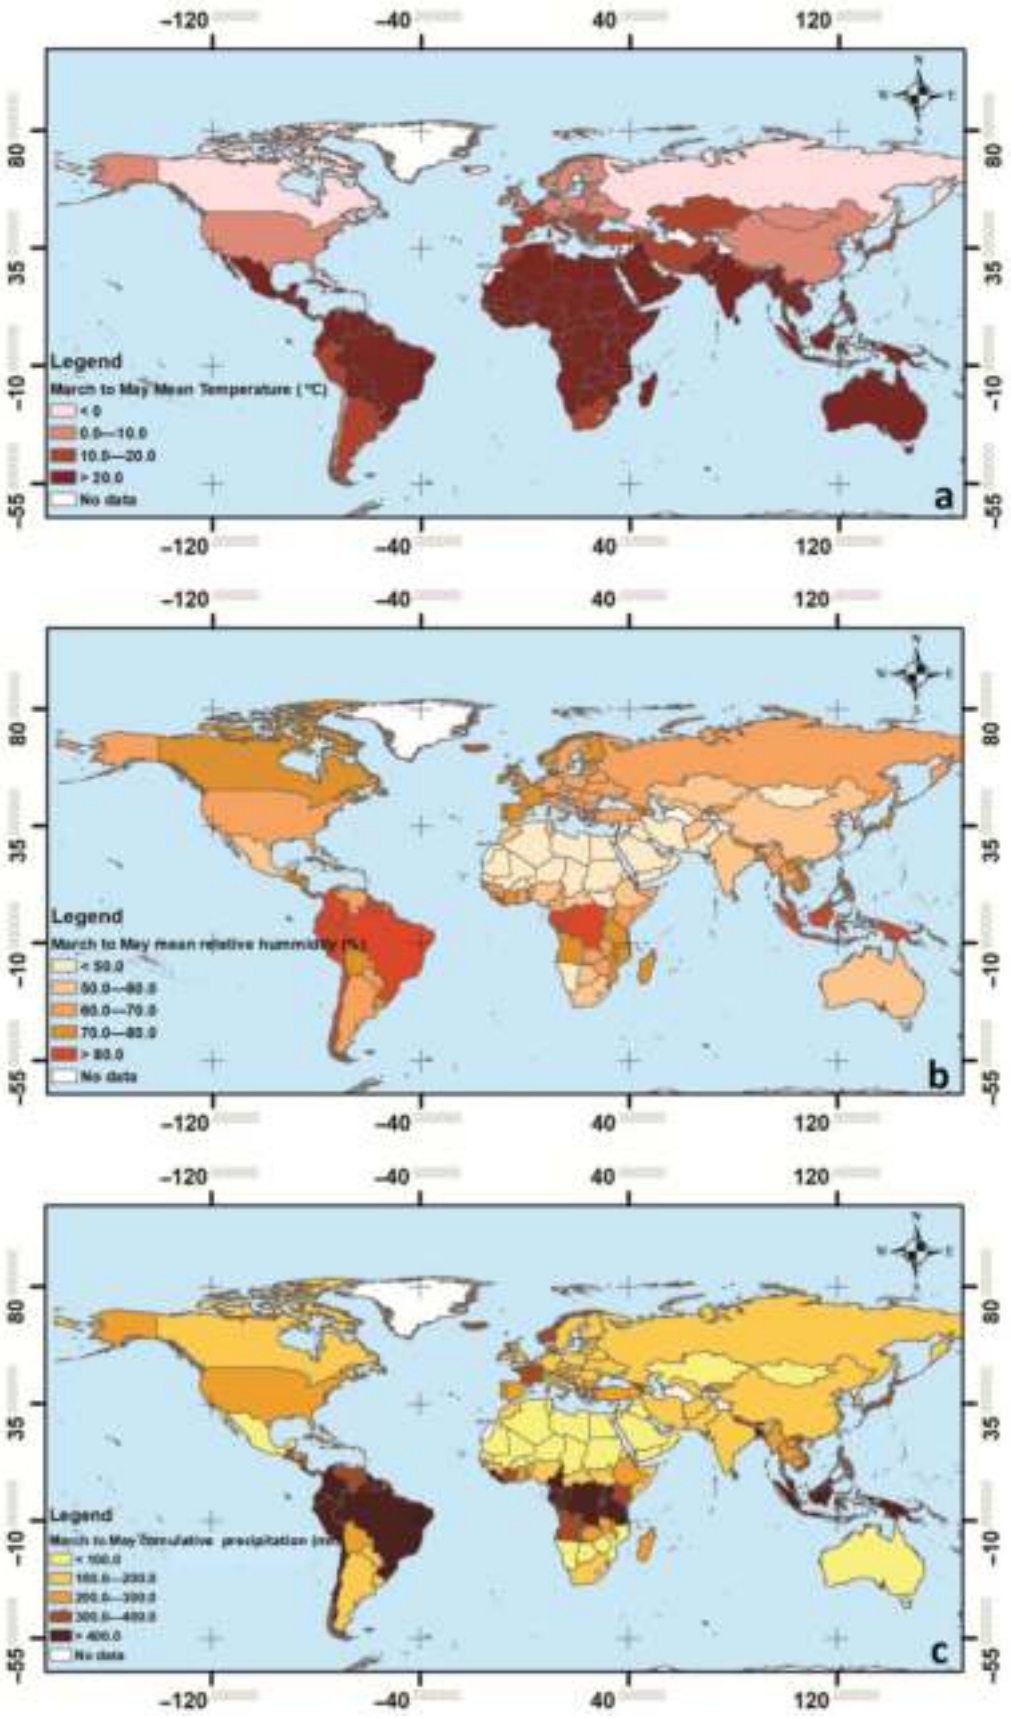

Figure 3. Worldwide distribution of (**a**) mean temperature, (**b**) mean relative humidity, and (**c**) cumulative precipitation for the period of 1/3/2020–31/5/2020.

3. Data Analysis

The collected data were divided in three groups of variables (Table 1). These were (i) the causal variables, i.e., the factors for which it was reasonable to assume that they may have an effect on the development of the pandemic; (ii) the effect variables, namely the total deaths and total cases per million of inhabitants; and (iii) the filtering variables, which were used to split and isolate datasets in order to minimize potential bias.

Table 1. Variables considered in the statistical analysis.

Effect Variables	Causal Variables	Filtering Variables
	Climatic	
	Temperature (°C)	
	Relative humidity (%)	
	Cumulative precipitation (mm)	
	Cloud cover	
Total Deaths per Million (TDM)	*Sociodemographic*	Human Development Index (HDI)
	Population density (persons/km^2)	
	Median age (years)	
Total Cases per Million (TCM)	Percentage of Population over 65 (%)	Median Age (years)
	Government response	
	Stringency IndexDelay between first case and first measures (days)	
	Delay between first case and "stay at home" order (days)	

Regarding the filtering variables, due to many differentiations among countries arising from the difficulties faced during the early stage (first wave) of the pandemic that could affect the reported epidemiological data and, thus, the TCM and the TDM (e.g., the availability of test kits and equipment, the extent and intensity of testing campaigns, and consistency in reporting of cases and deaths), it was decided to not include in the analysis the least developed countries. For this purpose, the countries were sorted with respect to their Human Development Index (HDI), and those with an HDI < 0.7 were excluded from further statistical processing. The cut-off value of 0.7 coincides with the divider considered by the United Nations Development Program (UNDP) between the "high human development" and "medium human development" classes. This choice left the dataset with an adequately large number of countries (101 from the 169 for which data were available) and still contained the full spectrum of TDM values, including all countries with TDM > 100 (Figure 1a). Given the strong dependence of the TDM on the population age (Figure 1b,c), a second group was created by isolating the countries with a median age of 35 years and larger. The second group, which numbered 55 countries, turned out to be a subgroup of the first one, i.e., all countries in it also had an HDI > 0.7. It should be stressed that both groups covered the full range of climate types, from tropical to polar.

The causal variables included climatic and sociodemographic factors, as well as factors related to the government response to the pandemic. The climatic factors examined herein, namely the temperature, relative humidity, precipitation, and cloud cover, are generally thought to have a role in influenza epidemics, a connection investigated in previous studies mentioned in the introduction. It has been observed that cold weather aggravates the spread of respiratory infections [5,49–51], while clouds block solar UV light, which decreases the survivability of viruses in the outdoor environment [52,53]. It has long been debated whether absolute humidity or relative humidity should be considered as a proper driver of the influenza seasonality [6,54,55]. Marr et al. [55] pointed out that, nowadays, it is possible to explain the mechanism of how relative humidity may influence the transmission of the influenza virus (i.e., via its role in aerosol droplet size, evaporation, and salt concentration), but a plausible mechanism explaining how absolute humidity can directly affect droplet size has not yet been established.

Regarding social structural characteristics, given the fact that COVID-19 is associated with very high mortality among the elderly, we considered the median age and the percentage of the population that is above 65 years old to quantify how aged a society is. Moreover, high population density is also thought to be a risk factor [56]. It is reasonable to assume that delays in government response are affecting the outcome of the epidemic [57,58]. We considered two types of delays: the time difference between the officially recorded first case and (i) the imposition of a "stay-at-home" order and (ii) taking the "first measures." According to Hale et al. [45], a stay-at-home order is defined as any of the following: (a) the recommendation of not leaving the house; (b) the requirement of not leaving the house except for work, daily exercise, grocery shopping, and 'essential' trips; (c) the requirement of not leaving the house but with the exceptions being much stricter (e.g., allowed to leave the house only once a week or only one person can leave at a time). The first measures varied in kind from country to country, although in most cases involved either public information/awareness campaigns, international travel restrictions, or the cancelling of public events. Finally, the Stringency Index is a composite measure that is based on nine response indicators, such as school closures, workplace closures, travel restrictions, and stay-at-home orders [44]. This index was averaged for a longer period (1/1/2020–31/5/2020) than the climatic factors because it was considered that measures taken even before the detection of first cases, such as banning travel from countries that exhibited active cases, reduced the progress of the pandemic during the 1/3/2020–31/5/2020 period.

3.1. Climatic Factors

Figure 4 plots the frequency of TDM classes (low: <10; moderate: 10–100; high: >100) and TCM classes (low: <100; moderate: 100–1000; high: >1000) for three groups of average atmospheric temperature T. The ranges of values were selected in such a way that the number of countries in each group was similar. A strong dependence of both the TDM and the TCM on temperature is apparent, as the percentage of countries with high death rates (red group) decreases as T increases, while the percentage of countries with low death rates (green group) increases with T (Figure 4a,c). Similar trends are observed for TCM (Figure 4b,d). The vast majority of countries with $T > 20$ °C experienced the pandemic to a substantially lesser degree. The p-values from χ^2 tests are also reported in the figures, with the null hypothesis being that the intensity of the epidemic (quantified by the TDM and the TCM) is independent from temperature. In all cases, the p-value is clearly less than 0.05 (the null hypothesis is rejected), suggesting a statistically significant correlation of the intensity of the epidemic with the temperature, especially in the case of the death rate. A small rise in p-values is noted when isolating the group of countries with a population median age of >35 years.

Based on Figure 5, it could be argued that there is a correlation of the TDM (and to a much lesser extent TCM) with the average relative humidity (RH). Nonetheless, the χ^2 test p-values are higher in Figure 5 than in the case of temperature, suggesting a weaker correlation between relative humidity and intensity of the epidemic. From Figure 5a,c, it appears that the percentage of countries with a TDM > 100 (red group) is elevated when RH is larger than 60%. However, the group of countries with a TDM below 10 (green group) does not show a clear decreasing course with increasing RH, as their frequency is enhanced for $RH > 70\%$. Similar observations can also be made in Figure 5b,d with respect to TCM. This can be partially attributed to the fact that many countries with an $RH > 70\%$ are located close to the equator or in the southern hemisphere, such as countries in Southeast Asia (e.g., Brunei, Indonesia, Malaysia, and Philippines) or around the Caribbean (e.g., Belize, Costa Rica, Cuba, and Jamaica), as well as New Zealand and Uruguay, and consequently had high temperatures in the examined time period. This observation suggests that RH does not influence the pandemic above a certain threshold of temperature. Most importantly, however, the epidemic severity appears to be strongly intensified if RH is in the 60–80% range provided that T is less than 15 °C, as can be better seen in Figure 6.

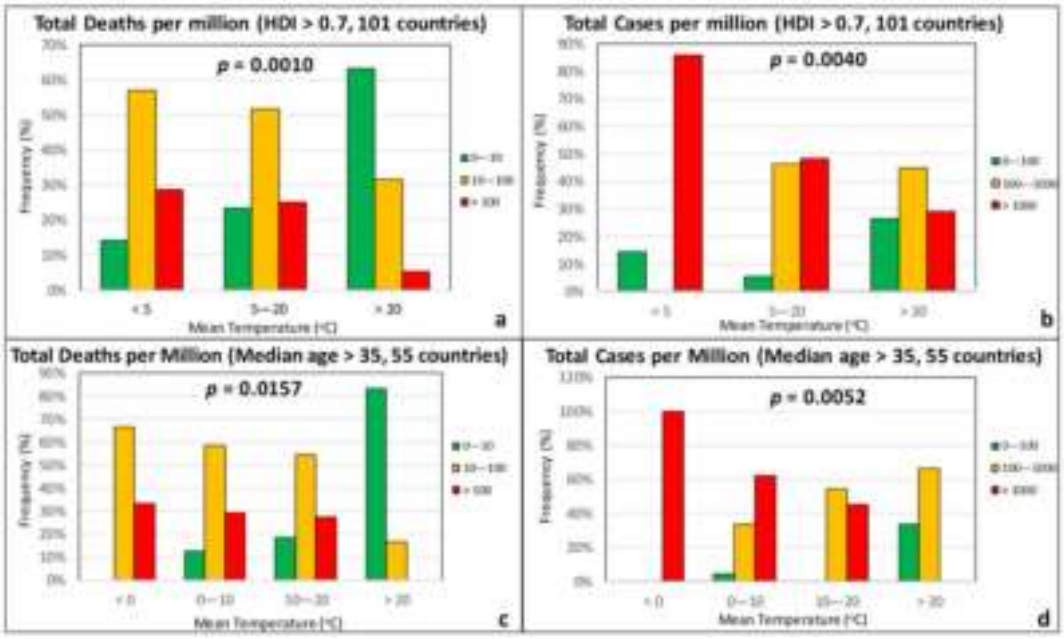

Figure 4. Frequency of total deaths per million (green: low, 0–10; orange: moderate, 10–100; red: high, >100) and total cases per million (green: low, 0–100; orange: moderate, 100–1000; red: high, >1000) as a function of the average temperature for countries with an HDI over 0.7 (**a**,**b**) and a median age over 35 years (**c**,**d**).

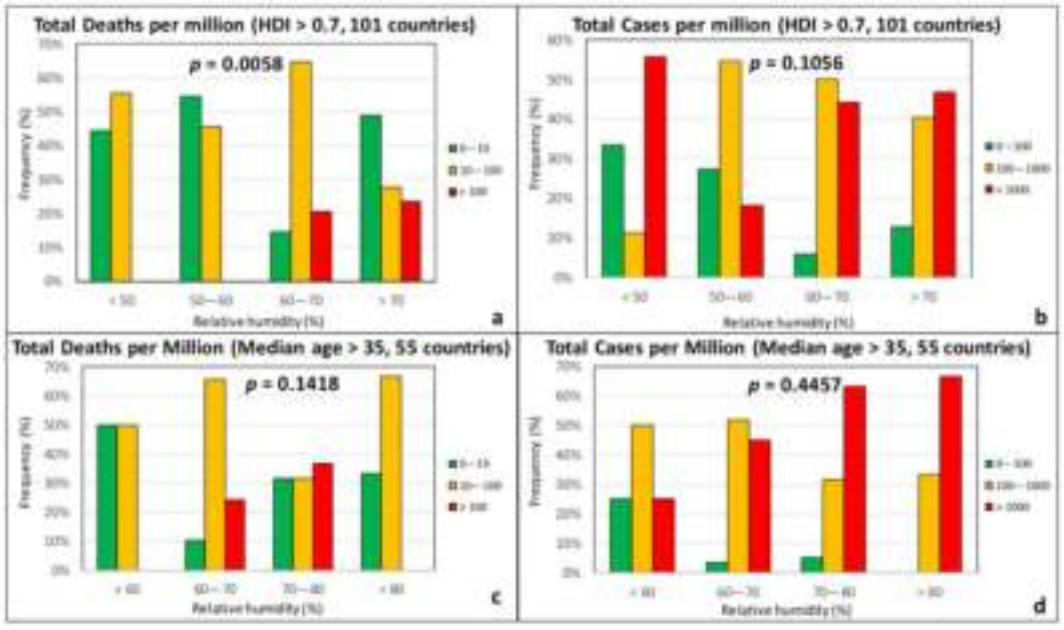

Figure 5. Frequency of total deaths per million (green: low, 0–10; orange: moderate, 10–100; red: high, >100) and total cases per million (green: low, 0–100; orange: moderate, 100–1000; red: high, >1000) as a function of the relative humidity for countries with an HDI over 0.7 (**a**,**b**) and a median age over 35 years (**c**,**d**).

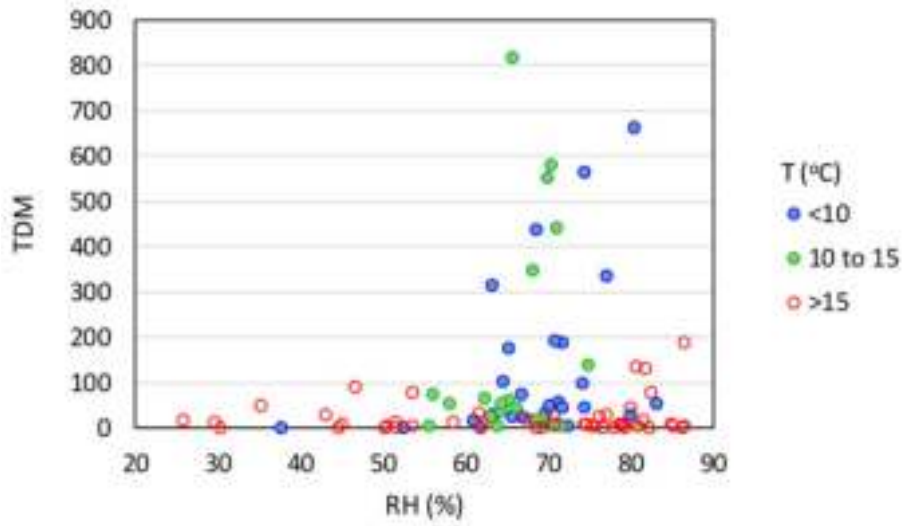

Figure 6. Total deaths per million as a function of the relative humidity and temperature (HDI > 0.7).

It is worth mentioning that studies on influenza [54,59,60] have shown that its transmissivity does not monotonically depend on *RH* if *T* lies between 10 and 25 °C, but it exhibits a local decrease ("valley") inside the range of 40–60% (in which case the virus particles become unstable) and a local peak for *RH* between 60% and 75%. For higher values of *RH*, the transmissivity decreases sharply, regardless of the temperature, as aerosol droplets take on water and increase in size, thus settling more quickly due to gravity [59].

Relative humidity, precipitation, and cloud coverage are climatic factors that are naturally related to each other. However, unlike *RH*, cumulative precipitation and cloud cover were found to correlate rather poorly with both the TDM and the TCM (Figures 7 and 8). The *p*-values in all cases are high, indicating that there is no statistically significant correlation.

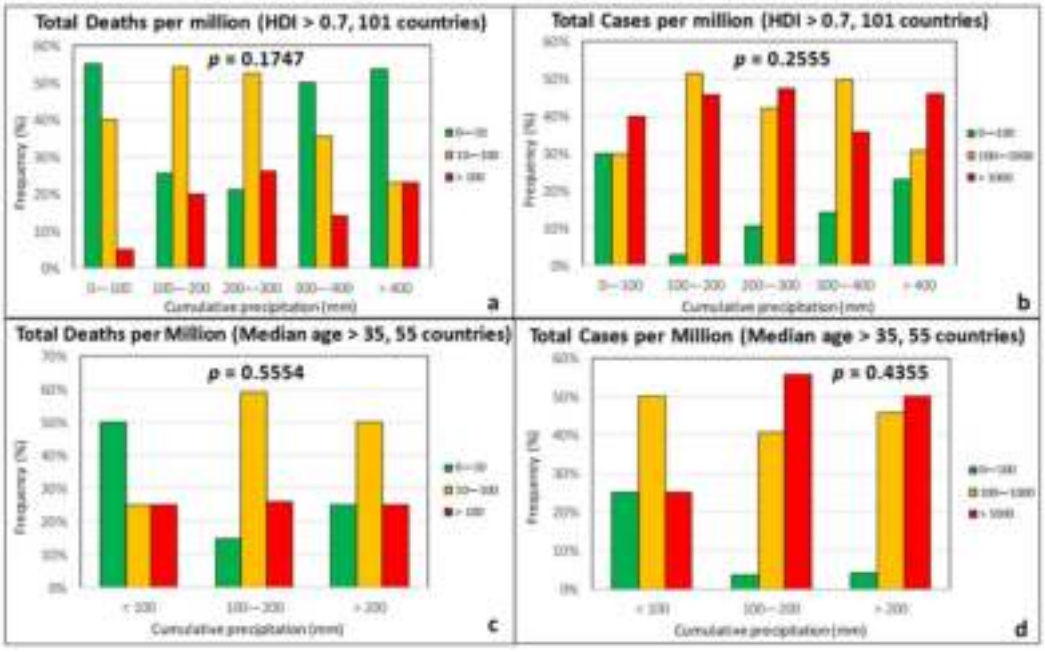

Figure 7. Frequency of total deaths per million (green: low, 0–10; orange: moderate, 10–100; red: high, >100) and total cases per million (green: low, 0–100; orange: moderate, 100–1000; red: high, >1000) as a function of the cumulative precipitation for countries with an HDI over 0.7 (**a**,**b**) and a median age over 35 years (**c**,**d**).

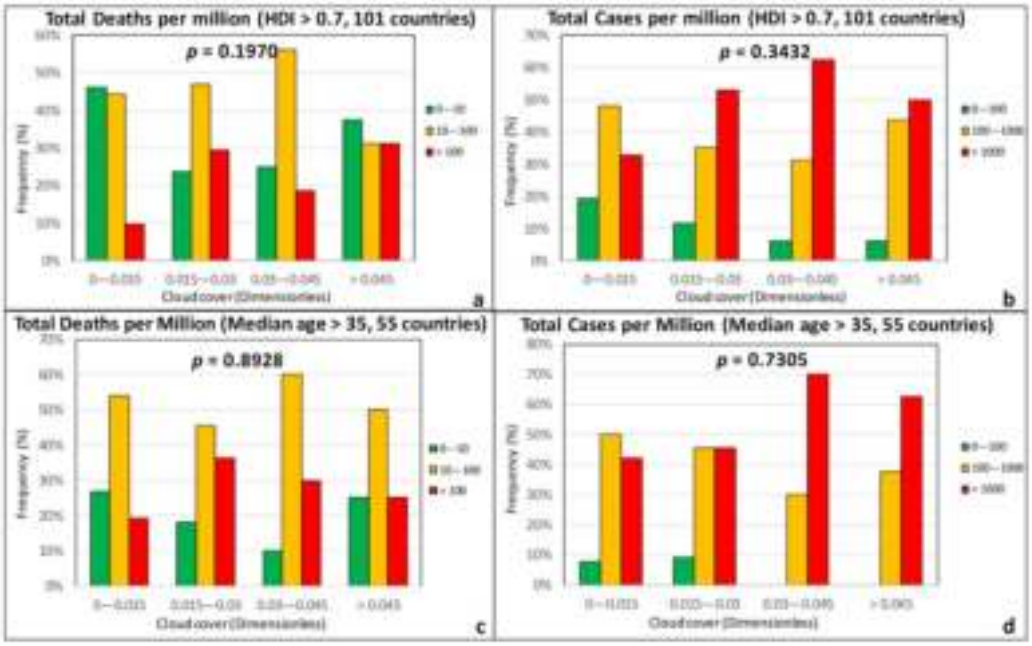

Figure 8. Frequency of total deaths per million (green: low, 0–10; orange: moderate, 10–100; red: high, >100) and total cases per million (green: low, 0–100; orange: moderate, 100–1000; red: high, >1000) as a function of the cloud cover for countries with an HDI over 0.7 (**a**,**b**) and a median age over 35 years (**c**,**d**).

3.2. Sociodemographic Factors

The contact numbers and transmission chains are larger in densely populated areas, and, thus, it would be reasonable to expect that countries with large population density would be more severely hit by the pandemic. Based on Figure 9, no specific trend can be discerned with respect to population density. This is also attested by the large *p*-values, which are in the 0.15–0.4 range. This admittedly counterintuitive observation is most likely caused by the treatment of data at a countrywide level, i.e., the population density treated herein was the total population of a country divided by its entire territorial area. For example, there are certain countries with a high TDM > 100 but with a population density below 50 inhabitants/km^2 (e.g., Brazil, Canada, and Peru). Though these countries occupy vast areas, large parts of the population are concentrated in densely populated urban centers. A more detailed spatial analysis at first or second level administrative divisions may more clearly demonstrate and accentuate the role of population density. Nonetheless, the recent epidemiologic study for COVID-19 by Hamidi et al. [61], which was done at the level of US counties, also showed weak to no dependence of the epidemic severity on population density.

Figure 10 indicates that there is a strong correlation between both the TDM and the TCM with the median age of the population, with the *p*-values being well-below 0.05. This finding is well-expected, since the rate of COVID-19 cases is known to be comparatively low among young persons [62]. Given that the death rate, in particular, increases sharply with patient age, Figure 11 shows plots of the TDM and TCM frequencies as a function of the percentage of the population aged 65 years and older. In this case, the correlation with the TDM is even stronger than in Figure 10a, while the correlation with the TCM is weaker but still statistically significant.

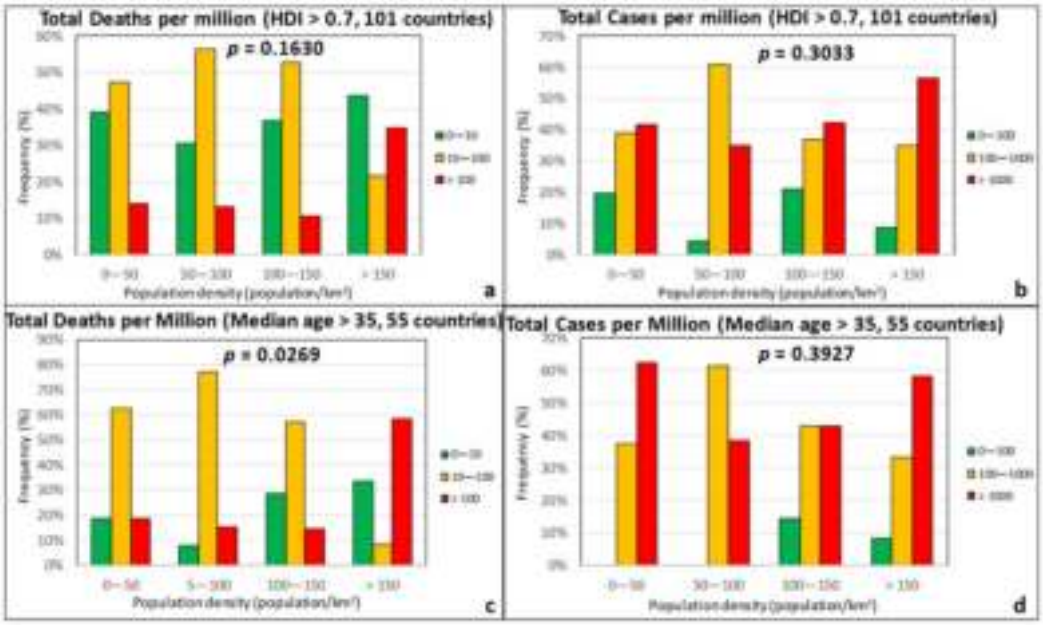

Figure 9. Frequency of total deaths per million (green: low, 0–10; orange: moderate, 10–100; red: high, >100) and total cases per million (green: low, 0–100; orange: moderate, 100–1000; red: high, >1000) as a function of the population density for countries with an HDI over 0.7 (**a**,**b**) and a median age over 35 years (**c**,**d**).

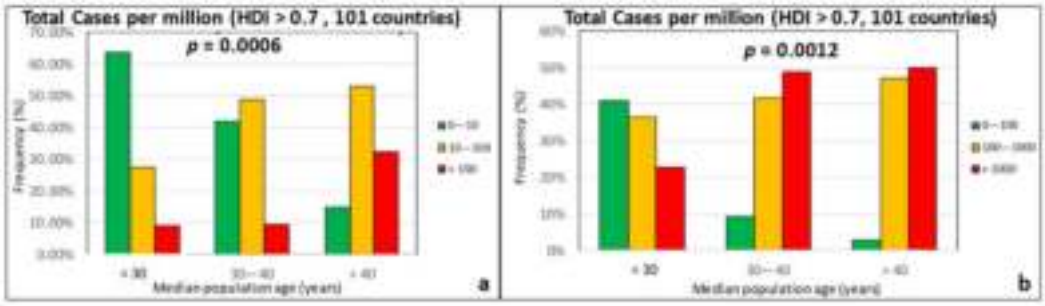

Figure 10. Frequency of (**a**) total deaths per million (green: low, 0–10; orange: moderate, 10–100; red: high, >100) and (**b**) total cases per million (green: low, 0–100; orange: moderate, 100–1000; red: high, >1000) as a function of the median age for countries with an HDI over 0.7.

Thus far, the TDM and the TCM have shown strong correlations with the average temperature and median age, with similar χ^2 test p-values. However, this does not necessarily mean that they are of similar significance. This is because of the correlation between these two causal variables. The first wave of COVID-19 unfolded during a period that was late winter and spring for the countries in the temperate zone of the northern hemisphere. Most of these countries happen also to be the most aged, while countries closer to the equator and most of the countries in the southern hemisphere have a relatively small median age. This fact is evident in Figure 12a, which plots the TDM as a function of the median age for three groups of countries separated based on the average temperature T. It can be seen that the majority of countries with $T < 15$ °C, which happen to be those most affected by COVID-19 (TDM > 100), have a median age larger than 35 years, while the opposite is true for the countries with T > 15 °C, most of which are located in South America, Africa, Middle East, and Southeast Asia. Similarly, most of the countries with average relative humidity in the 60–80% range have a median age larger than 35 years (Figure 12b). The interplay between the causal factors is addressed in Section 4, where their relative importance is examined using regression.

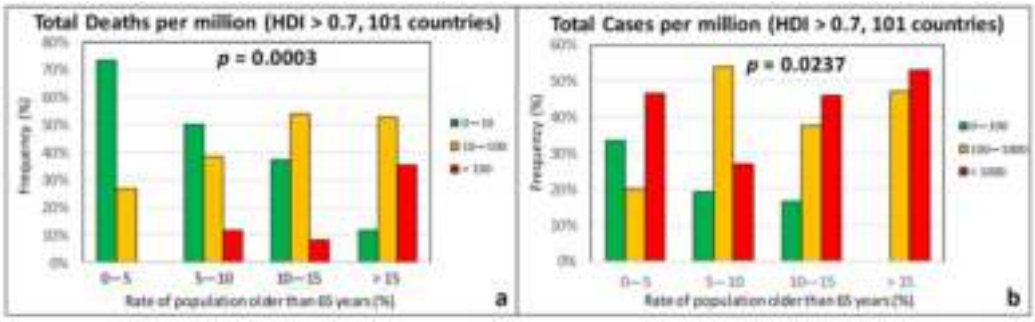

Figure 11. Frequency of (**a**) total deaths per million (green: low, 0–10; orange: moderate, 10–100; red: high, >100) and (**b**) total cases per million (green: low, 0–100; orange: moderate, 100–1000; red: high, >1000) as a function of the percentage of population with an age over 65 years for countries with an HDI over 0.7.

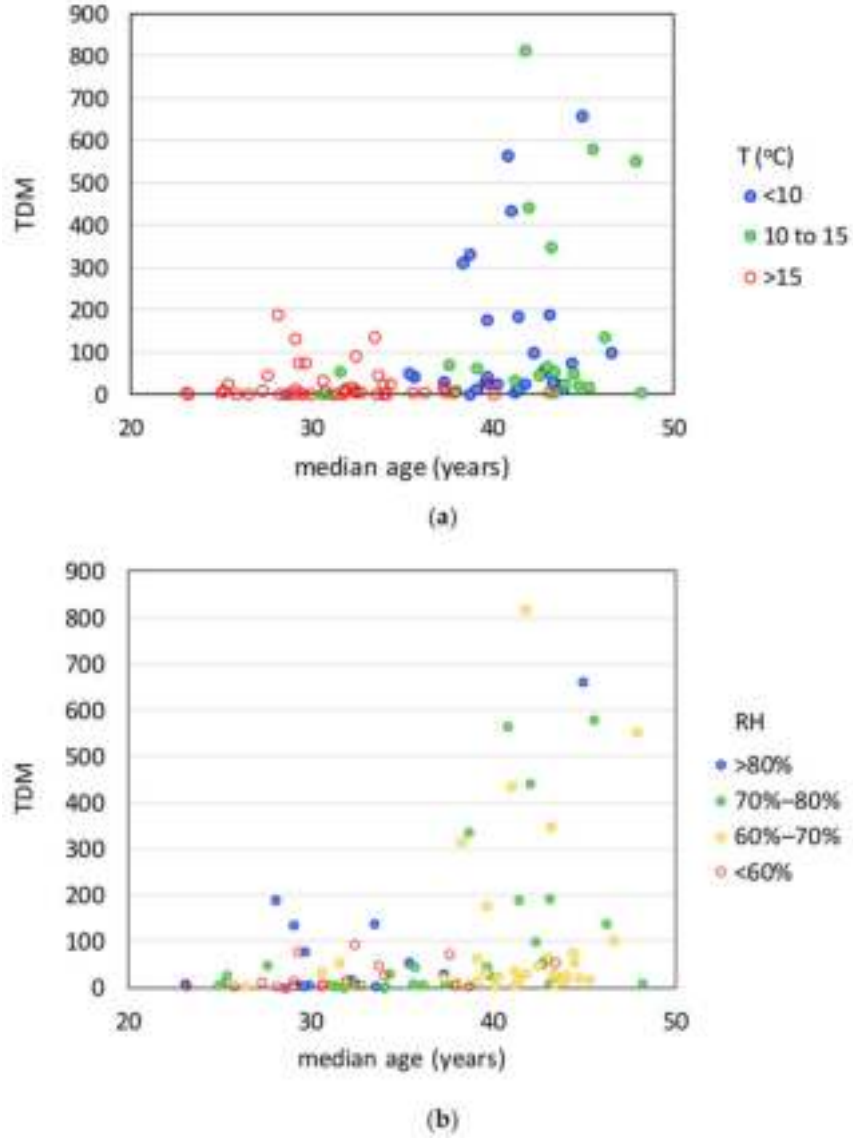

Figure 12. Total deaths per million as function of the population median age for different ranges of (**a**) temperature and (**b**) relative humidity (HDI > 0.7).

3.3. Government Response Measures

When considering the Stringency Index (SI) of the government response measures, as defined by Beltekian et al. [44], the *p*-values were found to be very high, indicating a weak correlation (Figure 13). On the contrary, the promptness of the governmental response seems to be instrumental in the containment of the epidemic. Based on Figure 14, countries that were proactive and responded by taking preventive measures one or two months before the officially recorded first case in the country ("negative" delay) experienced the first wave of COVID-19 less severely than countries that started taking the first measures after the detection of the first case.

When we isolated the countries with a median age >35 years (Figure 14b,c), the data suggested that the main role of the first governmental measures is to prevent a country from shifting from the group of moderate TDM and TCM values (orange) to the group with high values (red), while the frequency of countries that experienced the pandemic mildly is practically unaffected by the time difference between first measures and first case. Finally, according to Figure 15, the benefits of taking preventive measures early are rather independent from temperature, as a rising trend in the TDM with increasing time difference between the first measures and first case is observed in all temperature groups, especially those with $T < 15$ °C.

As seen in Figure 16, the frequency of countries that experienced the pandemic severely (TDM > 100 and TCM > 1000) increases steadily with increasing time difference between the official record of first case and the imposition of stay-at-home. With χ^2 test *p*-values generally close or well-below 0.05, the delay in issuing stay-at-home order is judged as statistically significant in limiting the intensity of the epidemic. Moreover, with only very few exceptions, countries that did not impose stay-at-home fall in the groups of moderate (orange) and high (red) death and case rates. On the other hand, the frequency of countries with low death and case rates (green group) is practically unaffected by a delay in imposing stay-at-home, even of the order of two months. This may suggest that stay-at-home is mostly effective in preventing the escalation of the impact from moderate (orange) to high (red) in countries that are more susceptible to the epidemic due to other factors.

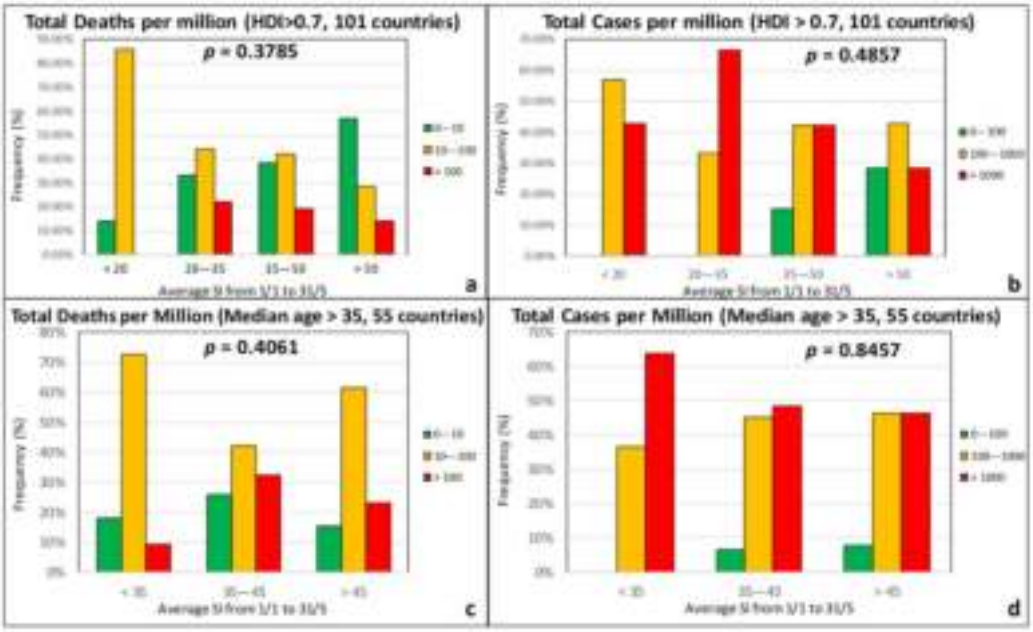

Figure 13. Frequency of total deaths per million (green: low, 0–10; orange: moderate, 10–100; red: high, >100) and total cases per million (green: low, 0–100; orange: moderate, 100–1000; red: high, >1000) as a function of the average Stringency Index for countries with an HDI over 0.7 (**a**,**b**) and a median age over 35 years (**c**,**d**).

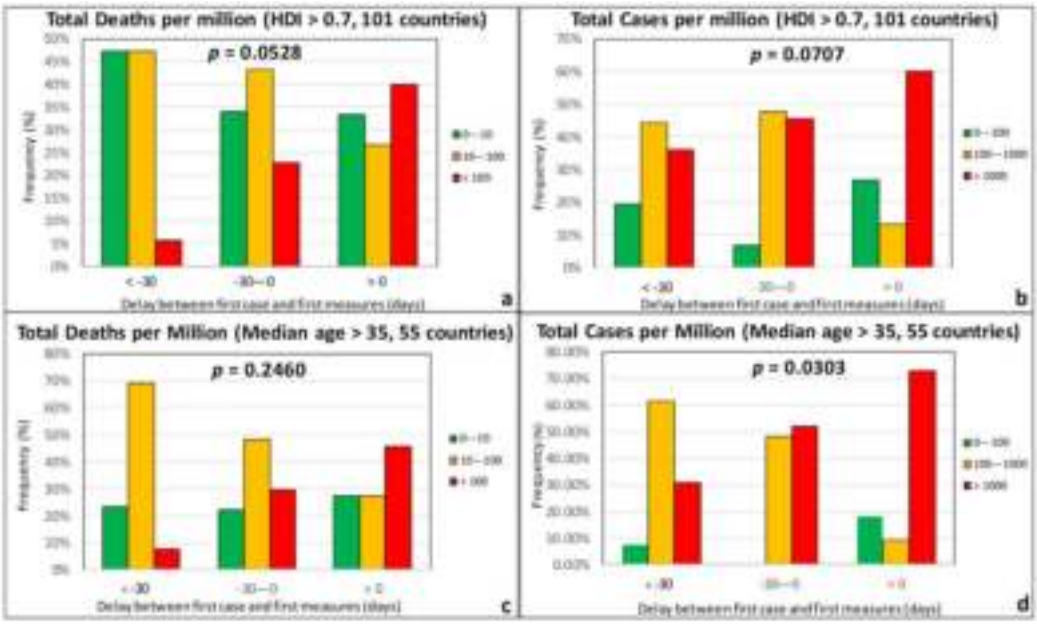

Figure 14. Frequency of total deaths per million (green: low, 0–10; orange: moderate, 10–100; red: high, >100) and total cases per million (green: low, 0–100; orange: moderate, 100–1000; red: high, >1000) as a function of the time difference between first case and first measures for countries with an HDI over 0.7 (**a**,**b**) and a median age over 35 years (**c**,**d**).

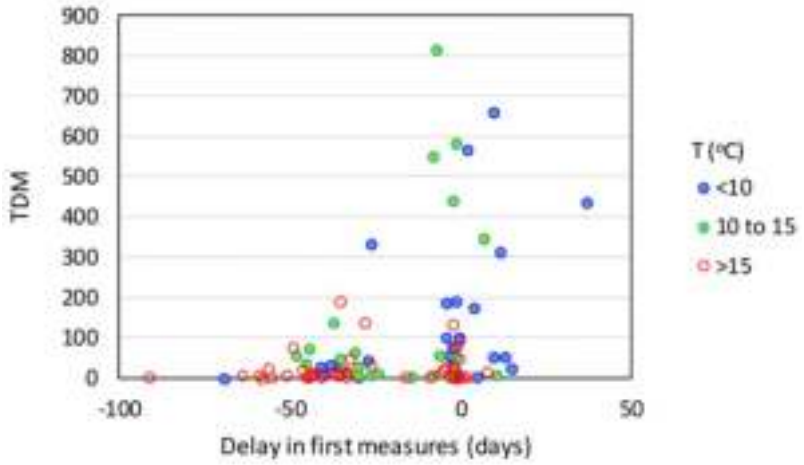

Figure 15. Total deaths per million as function of the time difference between the officially recorded first case and the first government measures for different temperature groups (HDI > 0.7).

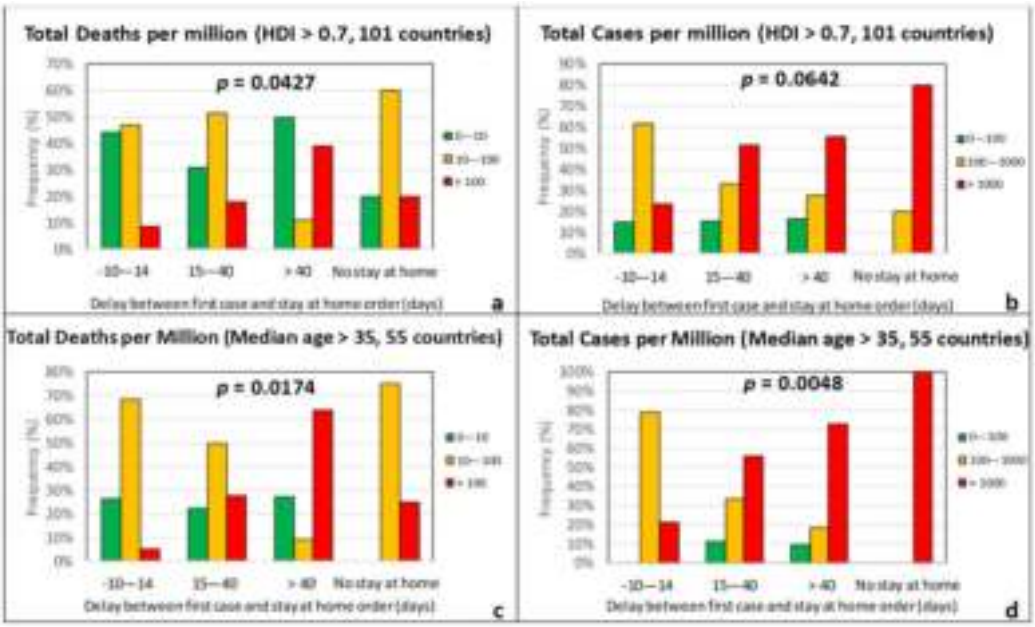

Figure 16. Frequency of total deaths per million (green: low, 0–10; orange: moderate, 10–100; red: high, >100) and total cases per million (green: low, 0–100; orange: moderate, 100–1000; red: high, >1000) as a function of the time difference between first case and the imposition of "stay-at-home" measure for countries with an HDI over 0.7 (**a**,**b**) and a median age over 35 years (**c**,**d**).

4. Multilinear Regression

4.1. Methodology

In the previous section, the epidemic effects were examined by considering each time a single causal variable, while the issue of possible interplay between certain causal variables was raised. In this section, we fit a linear equation combining all or groups of the causal variables, namely temperature, relative humidity, precipitation, cloud cover, population density, median age, government measures stringency index, delay in imposing first measures, and delay in imposing stay-at-home order. The percentage of population above 65 years old was not included in the set of variables since it exhibited a very strong correlation ($R^2 = 0.83$) with the median age. The dependent variable was set to be the TDM given that it generally exhibited the strongest correlations with the causal variables, as shown in the previous section, and is less prone to bias caused by the testing numbers. Each causal variable X_k enters the linear equation in the normalized form of $(X_k - X_{k,\min})/(X_{k,\max} - X_{k,\min})$, where $X_{k,\min}$ and $X_{k,\max}$ are the minimum and maximum values of the variable in the dataset. With this normalization, all independent variables of the equation vary from 0 to 1. Hence, the linear equation to be fitted takes the following form:

$$\begin{aligned} \mathrm{TDM} = C_0 + C_1 \frac{T - T_{\min}}{T_{\max} - T_{\min}} + C_2 \frac{RH - RH_{\min}}{RH_{\max} - RH_{\min}} + C_3 \frac{PR - PR_{\min}}{PR_{\max} - PR_{\min}} + C_4 \frac{CL - CL_{\min}}{CL_{\max} - CL_{\min}} + \\ + C_5 \frac{PD - PD_{\min}}{PD_{\max} - PD_{\min}} + C_6 \frac{MA - MA_{\min}}{MA_{\max} - MA_{\min}} + C_7 \frac{SI - SI_{\min}}{SI_{\max} - SI_{\min}} + C_8 \frac{FM - FM_{\min}}{FM_{\max} - FM_{\min}} + C_9 \frac{SH - SH_{\min}}{SH_{\max} - SH_{\min}} \end{aligned} \quad (3)$$

where T is the average temperature (°C), RH is the average relative humidity (%), PR is the cumulative precipitation (mm), CL is the average cloud cover, PD is the population density (persons/km^2), MA is the population median age, SI is the average stringency index, FM is the delay between first case and imposition of first measures (days), and SH is the delay between first case and stay-at-home order (days). To include the countries that did not impose stay-at-home in the regression analysis, their SH was calculated as the time difference between the officially recorded first case and the end of the investigated time period, i.e., 31/5/2020.

It must be stressed here that the purpose of the equation fitting was not to establish a predictive model but to discern the relative influence of the causal variables and rank them with respect to their importance. This is achieved herein using two conceptually different approaches: (i) the forward stepwise regression procedure and (ii) Lasso regression (along with its variation, the elastic net regression). The forward stepwise regression consists of performing consecutive multivariate linear regression calculations, starting with a single causal variable and adding in each step one more variable until the full set of n selected causal variables is exhausted [63,64]. With each step, the sum of squared errors (SSE) decreases. A measure of the importance of a variable k is the reduction increment in SSE induced by its inclusion in the equation (ΔSSE_k). Because ΔSSE_k depends on the order with which the variables are added to the linear model during the stepwise procedure, calculations are performed for all possible permutations of the causal variables (numbering $n!$ in total) and the average ΔSSE_k is calculated and subsequently used to rank the importance of each variable k. Moreover, it can be proven that, by normalizing ΔSSE_k with the total sum of squares SST, one can obtain the increase in the coefficient of determination R^2 caused by the inclusion of variable k in the equation ($\Delta {R^2}_k$). To perform the calculations, the above procedure was scripted in MATLAB.

Lasso regression [65] introduces in the objective function a penalty term which is the sum of the absolute values of the linear equation coefficients C_k (k = 1,2, … , n) times a user specified multiplier λ (i.e., $\lambda\Sigma|C_k|$). The elastic net regression [66] is a generalized version of Lasso in which the penalty term is a weighted average of the sum of the absolute values of the coefficients and the sum of their squares (i.e., $\lambda\alpha\Sigma|C_k| + \lambda(1-\alpha)\Sigma {C_k}^2$). If the weight factor α is set equal to 1.0, the regression is the same as the original Lasso, while as α decreases towards zero, the elastic net method tends to the ridge regression [67]. Herein, computations were performed for α = 1.0 and α = 0.9. By penalizing the presence of C_k's, these methods result in fittings that contain less non-zero coefficients (i.e., fewer causal variables than originally prescribed are effectively used) as λ is increased. Hence, a ranking of the importance of the causal variables could be obtained by repeating the regression calculations for a succession of increasing λ values. For very small λ values (negligible penalty), the fitted Equation (3) contains all nine causal variables. As λ increases, variables are successively dropped from the equation (their respective coefficients C_k became zero). The larger the λ for which C_k becomes zero (threshold value λ_T), the greater is the importance of the respective variable. The Lasso and elastic net calculations were performed using the pertinent built-in function in MATLAB.

4.2. Forward Stepwise Regression

The results of the stepwise linear regression approach are shown in Tables 2 and 3 for a selection of combinations of causal variables. The average values of the increase in R^2 due to the inclusion of each variable in the linear equation (ΔR^2) from all permutations are given in Table 2, while Table 3 shows the corresponding regression coefficients. Combination A contained all nine variables, and the number of all possible permutations in this case was 362,880. Combinations B, C, and D excluded the cloud cover, the SI, and both of them at the same time, respectively, from the equation, because, as shown the previous section, they manifested the weakest correlation with TDM. Moreover, cloud cover is naturally correlated to a certain degree with humidity and precipitation. The cloud cover and SI were left outside the equation along with other variables for the remaining combinations presented in Tables 2 and 3. Combinations E, G, I, and J contained only one of the three variables that are pertinent to atmospheric water (humidity, precipitation, and cloud cover). Finally, combinations H, I and J were set to contain only one variable pertaining to government response measures.

Table 2. Increase in coefficient of determination (ΔR^2) due to inclusion of variables in Equation (3).

Variable	Combination									
	A	B	C	D	E	F	G	H	I	J
Temperature	0.041	0.042	0.039	0.041	0.042	0.037	0.042	0.045	0.046	0.047

Table 3. Calculated values of regression coefficients.

Variable	Coefficient	Combination									
		A	B	C	D	E	F	G	H	I	J
Temperature	C1	−108.9	−88.9	−86.7	−89.7	−93.8	−60.6	−86.8	−103.9	−99.1	−90.9
Relative humidity	C2	82.2	79.1	34.8	34.9		62.7	46.1	34.7	54.2	40.6
Precipitation	C3	13.4	−17.9	11.3	16.3	45.0	−14.8		28.1		
Cloud cover	C4	−43.5		6.6							
Population density	C5	48.8	47.5	72.9	73.3	80.3		70.3	70.3	64.9	78.9
Median age	C6	113.8	120.2	109.2	108.1	112.6	125.7	106.4	110.1	107.1	127.7
Stringency index	C7	261.0	246.9								
Delay in first measures	C8	174.2	167.7	128.5	129.2	130.9	133.9	127.5	156.0	153.6	
Delay in stay-at-home	C9	158.8	157.3	94.7	94.4	94.3	91.4	95.5			122.1
Intercept	C0	−267.7	−270.4	−52.7	−50.4	−35.3	−78.2	−54.1	−31.5	−37.5	−3.9

In all combinations, the variable with the largest ΔR^2 is clearly the median age (Table 2). The delay in imposition of first measures and the average temperature come second and third interchangeably depending on the combination, producing practically the same ΔR^2 values, while the delay in stay-at-home ranks fourth (Figure 17). The variables related to atmospheric water appear to be of small to negligible importance, with the relative humidity being the most significant among the three. The very week correlation of TDM with cumulative precipitation and cloud cover is also manifested in the sign of the corresponding regression coefficients (C_3 and C_4), which, in certain combinations, turn out to be negative. It should be noted though that the actual significance of the relative humidity could be larger, given that it most likely has a non-monotonic effect on viral transmissibility, as discussed in Section 3.1, and that a linear regression inherently cannot capture non-monotonic dependencies. The same could be argued for the precipitation and cloud cover, given that these variables are interrelated with relative humidity.

As expected, the resulting coefficient for the temperature (C_1) is negative in all combinations (Table 3), i.e., the TDM decreases with increasing average atmospheric temperature. The same would be anticipated for the coefficient for the SI (C_7). However, C_7 turns out to be consistently positive, implying that the TDM increases with the overall strictness of the government response. This counterintuitive result is probably because the SI is not purely a causal variable and can be actually considered an effect of the observed case and death rates. For example, if the epidemic in a given country escalates beyond control and overwhelms the health system, it is understandable that the government will ramp up the response and impose increasingly stricter measures in order to regain control.

The delay in issuing a stay-at-home order can also be argued to be a mixed cause/effect variable, i.e., that the delay is, to a certain extent, the outcome of how the epidemic is unfolding in a given country. For example, a state may choose not to impose stay-at-home measures at all if the case or death rates remain low due to other factors, or they may choose to impose stay-at-home measures late when certain thresholds are eventually exceeded. In case the delay in issuing a stay-at-home order was

more an effect of the death rates rather than the cause, then it would correlate negatively with the TDM and the corresponding regression coefficient (C_9) would be negative. As seen in Table 3, the resulting C_9 values are always positive and the corresponding ΔR^2 values are not negligible, suggesting that the stay-at-home measure is a factor instrumental in preventing escalation of the epidemic.

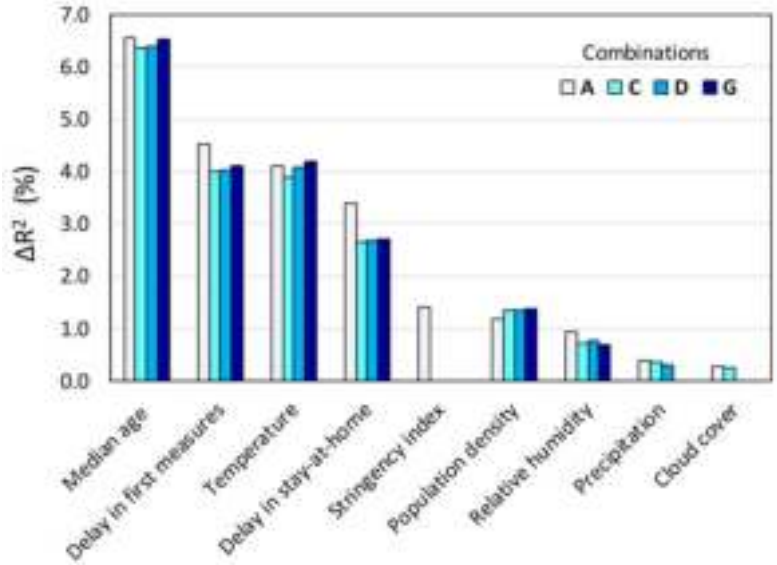

Figure 17. Rank of importance of causal variables based on stepwise regression.

This study relied on considering spatial averages across the entire territory of a country. It can be argued that such treatment may have been a source of bias in the analysis, especially in the case of large countries, as well as countries that span a wide latitude range in the temperate and arctic zones, in which case the differences in temperature (and possibly in other weather variables) are naturally large. Figure 18 shows the stepwise regression results for combination C when the six largest countries (Australia, Brazil, Canada, China, Russia, and USA) and two countries spanning a wide range of latitudes (Argentina and Chile) are removed from the dataset. It can be seen that exclusion of these countries has only a small effect on ΔR^2, and the ranking remains the same as in the case of the complete dataset.

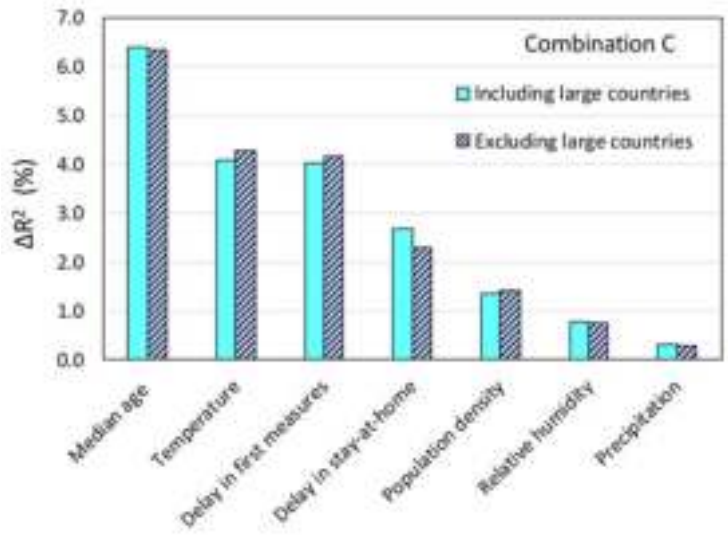

Figure 18. Effect of excluding large countries on the importance rank of causal variables resulting from stepwise regression.

4.3. Lasso and Elastic Net Regression

Figure 19 shows the variation of the coefficients C_k with increasing λ ("trace plots") from the application of Lasso regression ($\alpha = 1.0$) and elastic net regression with $\alpha = 0.9$, considering all nine causal variables of Equation (3). The λ values at which the curves reach the horizontal axis ($C_k = 0$) are the threshold λ_T values, which are plotted in Figure 20 (normalized with respect to the λ_T for the median age). It can be observed that for $\alpha = 1.0$ (Figure 19a), the curves dip more abruptly towards the horizontal axis and reach generally different λ_T values than in the case of $\alpha = 0.9$ (Figure 19b). Nonetheless, the inferred ranking of the importance of the variables is the same for both α values, with the exception of the stringency index and the cloud cover that switch places (Figure 20).

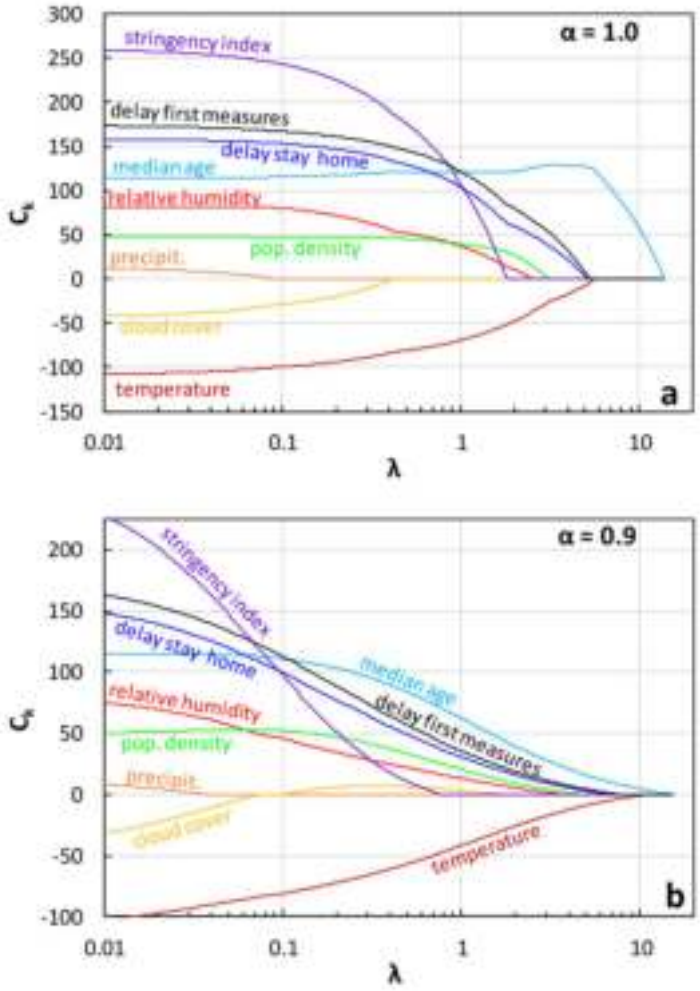

Figure 19. Trace plots of coefficients from: (**a**) Lasso regression and (**b**) elastic net regression.

The rankings from the Lasso regression and elastic net regression generally agree with that from the forward stepwise regression. As in the case of the stepwise regression results (Table 2 and Figure 17), the median age turns out to be by far the most important variable, while the variables related to atmospheric water (RH, precipitation, and cloud cover) are clearly less significant compared to the government response measures (Figure 20). Furthermore, based on the Lasso results, the temperature, the delay in taking the first measures, and the delay in imposing stay-at-home order were found to be of almost equal importance, with the temperature being only slightly ahead. The differences among them are accentuated if $\alpha = 0.9$. Figure 19 shows that the coefficient for the SI always remains positive (i.e., the severity of the epidemic increases with an increasing SI), an ambiguous outcome that, as discussed in the previous paragraph, probably stems from the fact that the stringency index is partially

an effect variable. It should be stressed here that excluding the SI from Equation (3) did not change the ranking sequence seen in Figure 20.

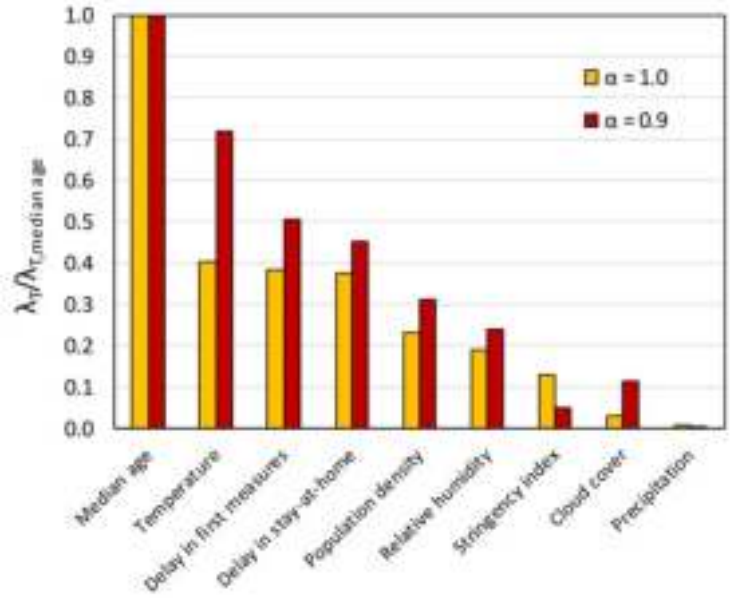

Figure 20. Rank of importance of causal variables based on Lasso and elastic net regression.

Finally, Lasso regression calculations were repeated excluding Argentina, Australia, Brazil, Canada, China, Chile, Russia, and USA in order to obtain results for a dataset in which the effect of spatial averaging across vast territories and wide range of latitudes was smaller. As seen in Figure 21, the exclusion of these countries caused insignificant changes in the λ_T, with the exception of that corresponding to the temperature, the role of which appears elevated. Despite this, the ranking of the variables remains the same as in the case of the complete dataset.

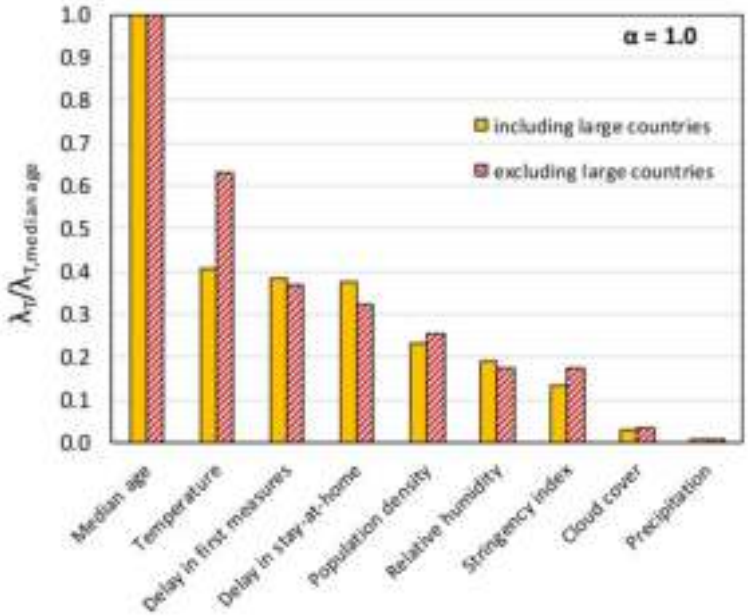

Figure 21. Effect of excluding large countries on the importance ranking of causal variables based on Lasso regression.

5. Conclusions

Due to its high human-to-human transmissibility, COVID-19 quickly spread worldwide. However, discrepancies of orders of magnitudes have been observed among the countries in terms of case and death rates. To discern the role which climatic factors play in the local epidemic intensity in conjunction with sociodemographic factors and government response measures, atmospheric data were processed in Geographic Information System (GIS) and statistically analyzed for the period of the first wave of the pandemic.

Based on the results of the present study, among the climatic variables, the average temperature showed a strong correlation with both death and case rates. Its influence appears to be of at least equal importance to the promptness of the governmental response. Relative humidity was found to have a noticeable influence that was not easily discerned, probably due to its non-monotonic character. Nonetheless, the age structure of the population clearly emerged as the most important risk factor. On the contrary, our analysis found that population density correlated rather weakly with the epidemic intensity.

With respect governments' response to COVID-19, the time difference between the first case detection in a given country and the imposition of first measures (which mainly consist of public information/awareness campaigns, international travel restrictions, and the cancelling of public events) appears to be instrumental in keeping case and death rates at moderate levels (less than 100 deaths and 1000 cases per million inhabitants). The present analysis suggests that the time difference between the occurrence of the first case and the issue of stay-at-home order also has a significant effect in preventing the escalation from moderate to high case and death rates but to a lesser degree compared to the promptness of first measures.

As final remark, it must be kept in mind that in this study, the data were treated by taking countrywide spatial averages, which had a data-smoothing effect. Future investigations relying on a more detailed, regional discretization may more clearly elucidate the role of weather on COVID-19. The temporal averaging during the span of three months may also have obscured the actual degree of the dependence of the epidemic intensity on the climatic factors. For example, the initial cold period of March 2020 (colder than the average for the entire March–May period) in countries located in the temperate zone of the northern hemisphere may have seeded large numbers of early infections that then persisted as temperatures rose in April and May to cause lower reproduction numbers R. In this case, high COVID-19 case and death rates would be paired with artificially (due to averaging) larger temperature values. Such skewing is expected to be almost absent in the case of countries in which the weather variation during this three-month period was small, such as those that are located closer to the equator.

Abstract

The emergence of a novel human coronavirus, SARS-CoV-2, has become a global health concern causing severe respiratory tract infections in humans. Human-to-human transmissions have been described with incubation times between 2-10 days, facilitating its airborne spread via droplets. The impact of environmental factors on the coronavirus disease 2019 (COVID-19) outbreak is under consideration. We therefore reviewed the literature on all available information about the impact of environmental factors on human coronaviruses. Temperature, humidity and other environmental factors have been recorded as environmental drivers of the COVID-19 outbreak in China and in other countries. Higher temperatures might be positive to decrease the COVID-19 incidence. In our review, the analysis of 23 studies show evidence that high temperature and high humidity reduce the COVID-19 transmission. However, further studies concerning other environmental (namely meteorological) factors' role should be conducted in order to further prove this correlation.

As no specific therapies are available for SARS-CoV-2, early containment and prevention of further spread will be crucial to stop the ongoing outbreak and to control this novel infectious thread.

Keywords: coronaviruses, covid-19, temperature, humidity, risk factor, epidemiology, survival

Introduction

A novel coronavirus (SARS-CoV-2) has recently emerged from China with a total of 45171 confirmed cases of pneumonia (as of February 12, 2020). Coronaviruses (CoVs) most commonly cause mild illness; but have occasionally, in recent years, led to major outbreaks of human disease. Approximately ten years after SARS, another novel, highly pathogenic CoV, in December 2019, SARS-CoV-2, a novel CoV, was identified in the City of Wuhan, Hubei Province, a major transport hub of central China. The earliest COVID-19 cases were linked to a large seafood market in Wuhan, initially suggesting a direct food source transmission pathway (Thompson 2020). Along with Severe Acute Respiratory Syndrome (SARS) coronavirus and Middle East Respiratory Syndrome (MERS) coronavirus (de Wit et al. 2016) (Peeri et al. 2020) , this is the third highly pathogenic human coronavirus that has emerged in the last two decades. In the months since the identification of the initial cases, COVID-19 has spread to 180 countries and territories and there are approximately 664,564 confirmed cases and 30,890 deaths (as of 29 March 2020).

Person-to-person transmission was confirmed as one of the main mechanisms of COVID-19 spread (Chan et al. 2020). The modes of transmission have been identified as host-to-human and human-to-human. Increased spread of SARS-CoV-2 causing COVID-19 infections worldwide has brought increased attention and fears surrounding the prevention and control of SAR-CoV-2 from both the scientific community and the general public. While many of the precautions typical for halting the spread of respiratory viruses are being implemented, other less understood transmission pathways should also be considered and addressed to reduce further spread.

The role of environment and its mediated pathways for infection by other pathogens have been a concern for decades. Substantial research into the presence, abundance, diversity, function, survival and transmission of microorganisms in the environment has taken place in recent years. There is preliminary evidence that environmentally mediated transmission may be possible; additionally, that COVID-2 could be affected by environmental factors such as seasonality,

medRxiv preprint doi: https://doi.org/10.1101/2020.05.10.20069732; this version posted May 15, 2020. temperature, humidity (Tan et al. 2005) (Shaman and Kohn 2009) (Geller, Varbanov, and Duval 2012).

The aim of the review was, therefore, to summarize all available data on the impact of environmental factors on the survival of all coronaviruses including emerging SARS-CoV and MERS CoV.

Methodology

Methodology of this systematic review and inclusion criteria were indicated in advance and recorded in *a priori* protocol in order to determine the rationale, the objectives, the eligibility and selection criteria, the search strategy and the study selection process of this systematic review. However, due to emergency of the subject and due to the pandemic awareness for COVID-19, this systematic review was not registered with PROSPERO (International Prospective Register of Systematic Reviews).

Eligibility criteria

All study design types were considered in this systematic review. Reviews were not included but screened for any information within the scope of this review. No language, publication status or publication year restrictions were imposed. As because of the COVID-19 emergency state, even not proofread publications were included in our study. All non-English studies, including Chinese, Japanese and French were translated via Google translator and were included in this systematic review. Although COVID-19 concerns years 2019 and 2020, no year of publication limit was applied, in order to exploit valuable information concerning the coronavirus relationship with environmental factors, as indicated by the past SARS and MERS lessons. All studies included, concern human coronavirus strains of various types. This systematic review was limited to studies focusing to environmental factors' impact on COVID-19. Searched experts' and researchers' opinions were not handed in this study.

The selection criteria developed a priori are described below:

- Year of publication
- Country of epidemics
- Continent of epidemics
- Environmental factor
- Assessing method

medRxiv preprint doi: https://doi.org/10.1101/2020.05.10.20069732; this version posted May 15, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

Information sources

The search strategy and analysis process were conducted according to the Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) statement for systematic reviews (Liberati et al. 2009; Page et al. 2018). Titles and abstracts of the retrieved articles were screened, while full length articles were evaluated for eligibility and were further acquired via SwetsWise Online Content. Search for articles was applied in three electronic databases: Google Scholar, PubMed & Springerlink. Google Scholar was our starting point. No unpublished information obtained. The literature search was performed from 25 to 28 of March 2020.

Search

The following terms were used to search all databases, always in combination with "coronavirus" and "COVID-19": "environmental factors", "clima", "temperature", "humidity", "absolute humidity", "relative humidity", "wind speed", "wind power", "precipitation", "rainfall". The search strategy was conducted by IPC and was peer-reviewed by AV as part of the systematic review process.

Study selection

Eligibility assessment procedure was performed in standardized and independent manner, primary by two authors (IPC and AV), to analyze and validate all relevant data to the top under discussion. Disagreements were resolved through discussion among all authors and resulted in a final consensus. After excluding records upon the eligibility criteria set, we screened all titles and abstracts of the retrieved studies, although full text review proves also to be necessary for further consideration.

Data Collection process

A data extraction sheet was developed in order to summarize the evidence of this systematic review, based on the Cochrane Consumers and Communication Review Group' data extraction

medRxiv preprint doi: https://doi.org/10.1101/2020.05.10.20069732; this version posted May 15, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

template for included studies (Cochrane Consumers and Communication 2016). This was pilot tested on the first ten randomly selected studies and no refinement was needed. One author (IPC) extracted all proper data from the included studies and another author (AV) checked all the extracted data. No disagreements arose. In order to ascertain duplicate publications, we used the tool "check for duplicates" of Mendeley Desktop software (Version 1.19.4).

Assessment of study quality

To ascertain the validity of the included studies, two reviewers (IPC and AV) in a blind manner and independently scored the included papers' quality upon the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) checklist (Von Elm et al. 2014). Both reviewers independently scored each included paper's quality and all studies received a score that ranged from 0 to 22 points by each reviewer. Base up on a criterion included in the initial protocol of the study, the scores between the reviewers should not differ from one to another reviewer by more than 2 points. In order to generate a final score, both scores of the reviewers were averaged.

Planned methods of analysis

In order to handle data and combine the results of all the included studies, we used SPSS (Statistical Package for the Social Sciences) (IBM SPSS Statistics for Macintosh, Version 25.0 n.d.) or R software (R Development Core Team 2013).

medRxiv preprint doi: https://doi.org/10.1101/2020.05.10.20069732; this version posted May 15, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

Results

Study selection and characteristics

The search of Google Scholar, Springerlink and PubMed provided a total of 14640, 51 and 28 articles, respectively. From the initially obtained 14719 articles, 8499 were excluded as duplicated ones upon "Check for duplicates" tool of Mendeley Desktop. The remaining 6220 articles were assessed for eligibility and a total of 6007 articles were discarded because based on a detailed evaluation of abstracts, they did not meet the eligibility criteria set and concerned: a) 2457 discussed clinical and epidemiological considerations of COVID-19, b) 813 discussed environmental factors associated with other diseases, c) 760 discussed ethical considerations od COVID-19, d) 743 discussed transmission dynamics of COVID-19, e) 655 discussed diagnostic and management outbreak investigations of COVID-19, f) 500 discussed prospects and advances in designing and developing vaccine and immuno-therapeutics of COVID-19 and g) 79 discussed socio-economic impact of COVID-19 . Of the remaining 213 articles, 124 were excluded because they did not meet the inclusion criteria. The full text of the rest 89 articles was evaluated in further detail. Finally, 23 were included for further analysis in this systematic review (Figure 1).

All 23 studies selected for this systematic review were published in 2020 and in English. 65.2% of the included studies reported China, 26.1% did not mention a certain country of epidemics, 4.3% concerned the epicentre of the disease, namely Iran, Italy, South Korea, etc. and 4.3% concerned Singapore. Upon continent of epidemics, Asia hold the leads with 69,6%, followed by Africa with 4.3%, whereas almost 21.7% did not mention specific continent and 4.3% refers to mixed continents (Asia, Europe, etc.). All included studies assessed the role of various environmental factors on transmission rates of the COVID-19.

In 24.1% of the studies, temperature was assessed for its impact on COVID-19, followed by humidity (11.1%), absolute humidity (5.6%), rainfall/precipitation (5.6%), relative humidity (5.6%), travel (5.6%), air travel (3.7%), wind speed/power (3.7%), latitude (3.7%), built

medRxiv preprint doi: https://doi.org/10.1101/2020.05.10.20069732; this version posted May 15, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

environment (1.9%), general lockdown (1.9%), visibility (1.9%), specific humidity (1.9%), airborne dust (1.9%), air pollution (1.9%), chemical pollution (1.9%), air index (1.9%), atmospheric radiation (1.9%), cloud cover (1.9%), precipitation of the driest month (1.9%), mean temperature of the wettest quarter (1.9%), isothermality (day-to-night temperatures difference relative to the summer-to-winter annual difference) (1.9%), annual mean temperature (1.9%), mean diurnal range (1.9%), minimum temperature of the coldest month (1.9%) and precipitation of the coldest quarter (1.9%).

In order to examine the association between those environmental factors and COVID-19, most of the studies employed the review method (20.4%), followed by maximum entropy model (13%), the model (11.1%), dynamical model and ERA-5 reanalysis (9.3%), the statistical modeling Loess regression (Generalized-linear or non-linear model) (7.4%), the R proxy method (5.6%), the R reproductive number (3.7%), the One-way ANOVA followed by a post-hoc Tukey's HSD test (3.7%), the distributed lag log-linear model (3.7%), the linear regression model (3.7%), the global meta-population disease transmission model (3.7%), the Mann-Whitney U test (3.7%), the mathematical model (3.7%), the restricted cubic spline function and the generalized linear mixture model (3.7%) and the multivariate analysis (3.7%). Figure 2 displays the environmental factor assessed, combined with the assessing method and the country of epidemics it concerns. Detailed characteristics of the studies included, like author, title and year of publication, country and continent of the study, method of assessing the impact of the environmental factors and the outcome variable are described in Table 1.

Figure 2 displays the exact temperature range proposed by certain studies included in this systematic review, in which virus survival is facilitated.

Results of individual studies

Gilbert et al. used the volume of air travel concerning the flights from the infected China provinces (Guangdong, Fujan and the city Beijing) to Africa and concluded that there are 2

medRxiv preprint doi: https://doi.org/10.1101/2020.05.10.20069732; this version posted May 15, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

identified clusters of African countries: a) those that have the higher importation risk of exposure to COVID-19, which have moderate to high capacity to face an outbreak, like Egypt, Algeria and South Africa and b) those that are at moderate risk and have high vulnerability and variable capacity (Gilbert et al. 2020). Mao et al. concluded that temperature has a non-linear dose response relationship with COVID-19 transmission, whereas there is a specific temperature range, in which virus transmission is facilitated and this might also explain the emergence of the epidemic in Wuhan city. Wang et al. suggest that regions with lower temperature records should take even stricter measures in order to prevent future outbreaks (Wang et al. 2020). Luo et al. and Poirier et al. suggest that changes in weather conditions alone, namely increase of humidity and temperature (which are usually met in spring and summer seasons) may not suffice to decrease the number of cases, if no proper public health interventions are adopted (Luo et al. 2020) (Poirier et al. 2020). Bonilla-Aldana et al. propose that temperature, rainfall and humidity may play a significant role in the virus transmission, as occurs for many zoonotic diseases (Bonilla-Aldana, Dhama, and Rodriguez-Morales 2020). Dietz et al. combined current literature and built environment and assessed its role in COVID-19 transmission, suggesting that built environment plays a significant role in the disease control and mediation and this may be taken into consideration in the building design market(Conraths et al. 2015). Oliveiros et al. regressed the doubling time of COVID-19 cases with the aid of temperature and humidity, whereas wind speed proved not be significantly associated (Oliveiros et al. 2020). Based on Shi et al. conclusions, lower and higher temperature rates may decrease the COVID-19 incidence rates and the role of absolute humidity has not yet been established (Shi et al. 2020). Lau et al. recorded an increase in the doubling time of COVID-cases and this was attributed to the lockdown measurements implemented (Lau et al. 2020). Chen et al. found out that the optimal temperature for COVID-19 is 8.07 °C, within a humidity range of 60-90% (Chen et al. 2020). Sun et al. concluded that cold and dry winter are considered as a common environmental condition conductive for COVID-19 (Sun et al. 2020). Peeri et al. attributed the increased and rapid

medRxiv preprint doi: https://doi.org/10.1101/2020.05.10.20069732; this version posted May 15, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

COVID-19 perforation to air travel frequency and circumstances (i.e. connection flights) (Peeri et al. 2020). Gostic et al. estimated that screening during travel may miss more than half of the infected cases, as the have not developed symptoms in the time of screening (Gostic et al. 2020). Sajadi et al. reached the conclusion that temperature range of 5-11°C, combined with low specific range of 3-6g/kg and absolute humidity range of 4-7 g/kg are the optimal environmental factors for COVID-19 transmission (Sajadi, Habibzadeh, Vintzileos, Shokouhi, et al. 2020). Qu et al. linked the COVID-19 transmission with airborne dust (Qu et al. 2020). Gupta showed that for every 1°C increase above 5 °C, the temperature as factor may decrease the COVID-19 transmission rate by 10% (Gupta 2020). Cai et al. found no correlation between the daily mean temperature and the epidemic growth rate in case of Hunan or Wuhan, but insist that there is a weak correlation between the daily mean temperature and the mortality rates in both provinces (Cai et al. 2020). Chinazzi et al. assessed travel limitations practices applied in China and international scale and verified travel quarantine delayed the epidemic progression 3 to 5 days in China or more in worldwide basis (Chinazzi et al. 2020). Lee et al. reviewed Singapore's approach to COVID-19 epidemic concerning travel restrictions applied at all ports of entry (Lee, Chiew, and Khong 2020). Wang et al. propose that high temperature and high relative humidity significantly affects the COVID-19 transmission rates (J. Wang et al. 2020). Poole suggests that a climatological range of 4-12°C within an area of 25-55° latitude may enhance the COVID-19 spread (Poole 2020). Bu et al. conclude that temperature rate of 13-19°C and humidity rate of 50-80% are conducive to the virus survival (Bu et al. 2020).

Study quality

The studies included in this systematic review were scored from 17 to 19.8, upon the criteria predefined. The criteria on which studies were assessed with the minimum score were related to their not clearly addressing the following items: report of the study design and assessing method

medRxiv preprint doi: https://doi.org/10.1101/2020.05.10.20069732; this version posted May 15, 2020. Discussion

To the best of our knowledge, the present systematic review is the first to summarize the available evidence on the association of COVID-19 with environmental factors. Taking into consideration that the new coronavirus is a new human pathogen, which due to its outbreak in China and its rapid spread worldwide, it is important to understand reliable epidemiological information for its survival in the environment (Chen et al. 2020). Therefore, it is necessary to find prognostic predictors to distinguish high-risk areas or countries and improve the new challenging situation.

Any infectious disease origins and spread occur only when affected by certain natural and social factors through acting on the source of infection, the mode of transmission and the susceptibility of the population. The environmental factors such as meteorological factors, namely temperature and humidity proved to play a part in coronavirus outbreak besides the social factors (Jia et al. 2020). In our systematic review, overall evidence is sufficiently robust to determine the impact of temperature in virus' survival via different methods, like the effect of each 1°C increase which lowers the virus' R by 0.225 (J. Wang et al. 2020) and the doubling time of the confirmed cases which is positively correlated with temperature (Oliveiros et al. 2020). Four, studies included in this systematic review determine the exact temperature range, within which temperature is conducive to virus spread and survival. The pooled results of these 4 studies indicated that temperature range different from 4-24°C is not conducive to the survival of the coronavirus (M. Wang et al. 2020) (Sajadi, Habibzadeh, Vintzileos, Miralles-wilhelm, et al. 2020) (Poole 2020) (Bu et al. 2020). Concerning humidity, although the results in this review did not reveal robust associations between humidity and coronavirus survival and are always validated in combination with temperature, they need to be interpreted carefully given the monotonic functional relationship between humidity and temperature. In other words, if temperature was associated to COVID-19 transmission, very likely absolute humidity would play a role. Pooled results of the studies included in this systematic review show that combined

medRxiv preprint doi: https://doi.org/10.1101/2020.05.10.20069732; this version posted May 15, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

with high temperature, absolute humidity range of 4-7 g/m^3 (Sajadi, Habibzadeh, Vintzileos, Miralles-wilhelm, et al. 2020) or specific humidity range of 3-6 g/kg (Sajadi, Habibzadeh, Vintzileos, Miralles-wilhelm, et al. 2020) or humidity of 50-80% (Sajadi, Habibzadeh, Vintzileos, Miralles-wilhelm, et al. 2020) may reduce the transmission of COVID-19. Other factors concerned, such as air index, rainfall/precipitation, wind speed, do not show to have significant impact to virus stability and survival and need to be further assessed. Although not all environmental factors and not in depth are clearly described by authors of the included studies, important associations are observed and need further investigation. Variability in the results among the studies included in our review may be attributed to i) the utilization of different types of assessing methods of each environmental factor, ii) the different qualitative characteristics of the populations used, iii) sample size, iv) duration of the study and others.

Environmental factors, characterized by lag effects and threshold effects, can target at two objects, host and virus, during infectious disease outbreak. On one hand, human activity patterns and immunity can be influenced by environmental factors. But the effect caused by environmental condition was limited during the COVID-19 outbreak, due to the absence of extreme weather and specific immunity for a newly emerging virus. On the other hand, environmental impacts on the SARS-CoV-2 are more significant than the host population because the transmission and virulence of the virus varies in different conditions. Finally, environmental impacts on transmission of virus should be characterized in the dynamic model, because infectiousness estimated in the traditional dynamic model is actually a confounding effect with environmental effect. It is necessary to take account of environmental issues based on dynamic transmission model so that the impacts could be isolated and qualified.

Apart from the he basic strengths of this review regards the study quality assessment, which was based on STROBE, its PRISMA compliance approach and the peer-review process followed.

Limitations

Due to limited data available, other meteorological factors such as air pressure, atmospheric particles, ultraviolet, and social factors such as population movement were not included for analysis. Inclusion of such factors will provide more accurate and reliable results.

In addition, the relatively short time length of the current outbreak, combined with imperfect daily reporting practices, make our results vulnerable to changes as more data becomes available. We have assumed that travel limitations and other containment interventions have been implemented consistently across provinces and have had similar impacts (thus population mixing and contact rates are assumed to be comparable), and have ignored the fact that different places may have different reporting practices. Further improvements could incorporate data augmentation techniques that may be able to produce historical time series with likely estimates of case counts based on onset of disease rather than reporting dates. This, along with more detailed estimates of the serial interval distribution, could yield more realistic estimates of R. Finally, further experimental work needs to be conducted to better understand the mechanisms of transmission of COVID-19. Mechanistic understanding of transmission could lead to a coherent justification of our findings.

Conclusions

In summary, this review provided evidence that high temperature and high humidity reduce the COVID-19 transmission. However, further studies concerning other environmental (namely meteorological) factors' role should be conducted in order to further prove this correlation.

ABSTRACT

There is evidence that COVID-19, the disease caused by the betacoronavirus SARS-CoV-2, is sensitive to environmental conditions. However, such conditions often correlate with demographic and socioeconomic factors at larger spatial extents, which could confound this inference. We evaluated the effect of meteorological conditions (temperature, solar radiation, air humidity and precipitation) on 292 daily records of cumulative number of confirmed COVID-19 cases across the 27 Brazilian capital cities during the 1st month of the outbreak, while controlling for an indicator of the number of tests, the number of arriving flights, population density, proportion of elderly people and average income. Apart from increasing with time, the number of confirmed cases was mainly related to the number of arriving flights and population density, increasing with both factors. However, after accounting for these effects, the disease was shown to be temperature sensitive: there were more cases in colder cities and days, and cases accumulated faster at lower temperatures. Our best estimate indicates that a 1 °C increase in temperature has been associated with a decrease in confirmed cases of 8%. The quality of the data and unknowns limit the analysis, but the study reveals an urgent need to understand more about the environmental sensitivity of the disease to predict demands on health services in different regions and seasons.

INTRODUCTION

The disease COVID-19, caused by the betacoronavirus SARS-CoV-2, has caused panic throughout the world by overwhelming medical services in many countries, leading to deaths that might have been avoided if patients had access to intensive-care units (ICUs). This has led to an unprecedented collaboration within and among countries to slow the spread of the disease, principally using social distancing (*Ebrahim et al., 2020*; *Wilder-Smith & Freedman, 2020*). While it is not clear how much present policies will reduce overall infection rates by SARS-CoV-2, there is consensus that slowing the spread of the

disease will save lives by tailoring patient demands to the capacity of health systems (*Ferguson et al., 2020*; *Walker et al., 2020*).

The strategies of social isolation applied in countries on all continents have allowed time for authorities to undertake interventions to strengthen their health systems, and one of the main actions is to estimate the number of cases of COVID-19 in each region (*Anderson et al., 2020*; *Walker et al., 2020*). This information is essential to scale the number of ICUs to the number of critically ill patients who normally require supportive lung ventilation (*Xu et al., 2020*). Brazil has a large per capita number of ICUs in comparison with Europe, but those units are not evenly spread among regions, with more ICUs per capita in southern states than in northern regions, leaving many Brazilians at large distances from the nearest ICU (*Rhodes & Moreno, 2012*). Moreover, the large demographic and socioeconomic discrepancies in the country create significant variation in susceptibility to infectious diseases (*Barreto et al., 2011*).

One of the problems in predicting the demand for hospital services is that the disease is new so that its behavior is still poorly understood, and the virus may be evolving rapidly (*Zhao et al., 2004*; *Yang et al., 2020*; *Morais et al., 2020*). Therefore, models developed in one country may give poor predictions in another. Habitat-specificity modeling suggests that SARS-CoV-2 spread may be related to environmental conditions, especially temperature and humidity (*Sajadi et al., 2020*; *Wang et al., 2020*). Further, at the host level, there is circumstantial evidence that COVID-19 is related to shortage of vitamin D, which could result from limited exposition to solar radiation (*Grant et al., 2020*). Indeed, it has been suggested that solar radiation might deactivate the virus (*Poole, 2020*). Although preliminary, these results provide a plethora of mechanistic processes linking weather and virus spread that need to be better understood.

Brazil is one of the largest countries in the world, spanning both hemispheres, with latitudes varying from 5°N to 33°S. This means that climatic conditions vary greatly and simple models that do not take into account the possible environmental sensitivity of COVID-19 might not be adequate to predict when and where there will be the greatest demand for health services in Brazil (Fig. 1). One difficulty in quantifying this sensitivity is that climate is likely to correlate with demographic and socioeconomic factors across larger spatial extents. Thus, environmental effects could be confounded unless risk factors for viral spread are taken into account, such as population density, transport connectivity and economic status (*Poole, 2020*; *Wang et al., 2020*; *Ribeiro et al., 2020*).

In an attempt to determine whether environmental variables have significant effects on the propagation of COVID-19, we modeled the daily cumulative number of confirmed cases among Brazilian capital cities in relation to meteorological variables during the 1st month of the disease in the country, while controlling for several demographic and socioeconomic factors. We used only capital cities because they are presently the only reliable sources of COVID-19 cases and represent much of the climatic variation within Brazil. Data on connectivity and frequency of cases is not presently adequate to model the spread of the disease at the municipal level, but this should be available in the future and can be used to test our hypotheses.

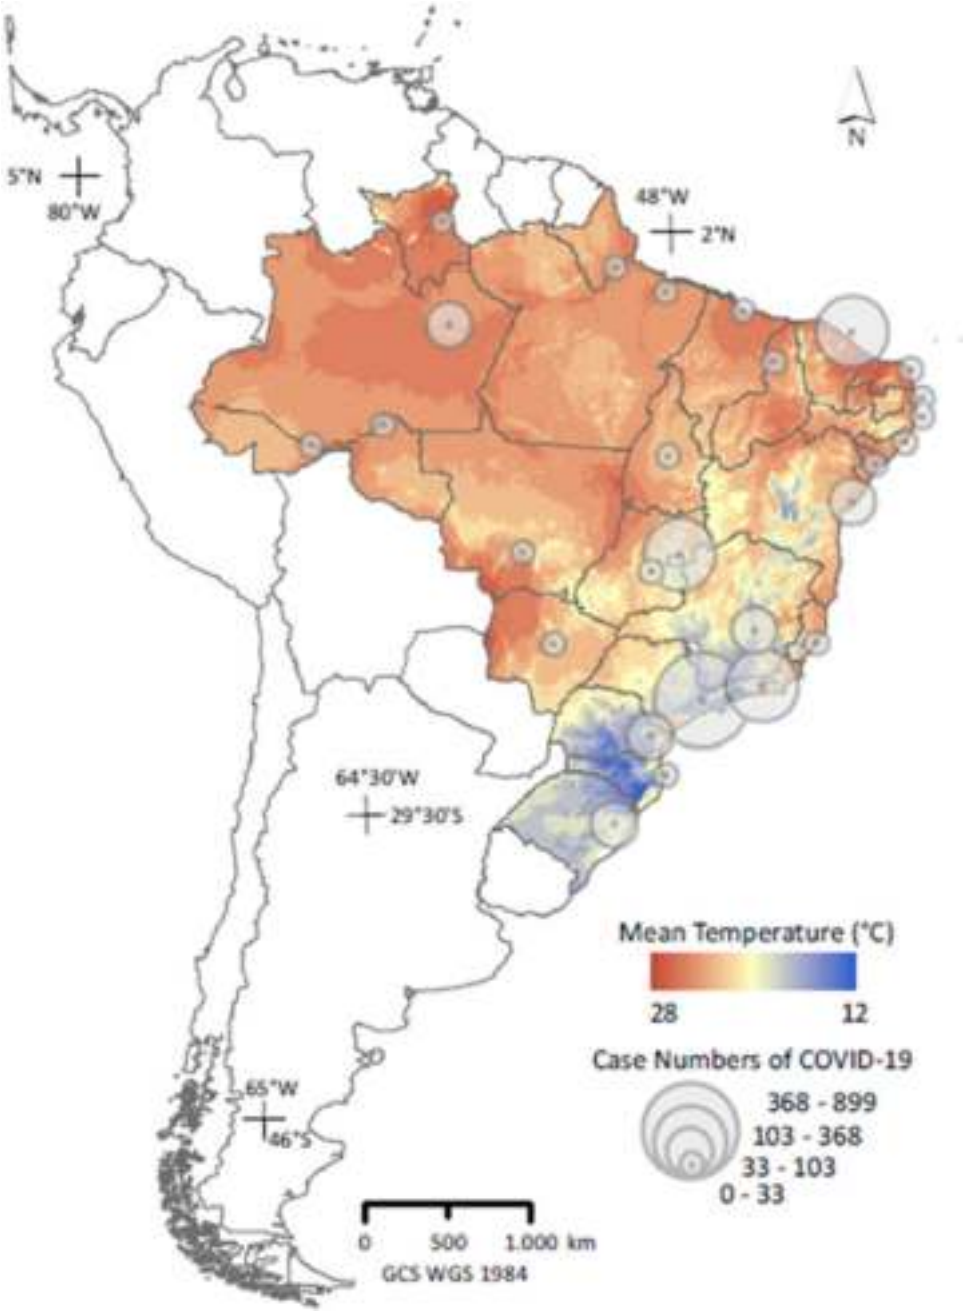

Figure 1 Distribution of counts of confirmed COVID-19 cases across capital cities in Brazil on 26 March, 2020 (n = 27); (*Secretarias de Saúde das Unidades Federativas, 2020*), superimposed on the country's thermal variability. Temperature data represent means for March over 1989–2019 (*Fick & Hijmans, 2017*), and were used only in the map; actual analyses used current, daily meteorological data. Full-size DOI: 10.7717/peerj.9322/fig-1

MATERIALS AND METHODS

We obtained daily cumulative counts of confirmed cases of COVID-19 for each of the 27 Brazilian state capital cities, as reported by State Health Secretaries and compiled by volunteers (Table S1; *Secretarias de Saúde das Unidades Federativas, 2020*).

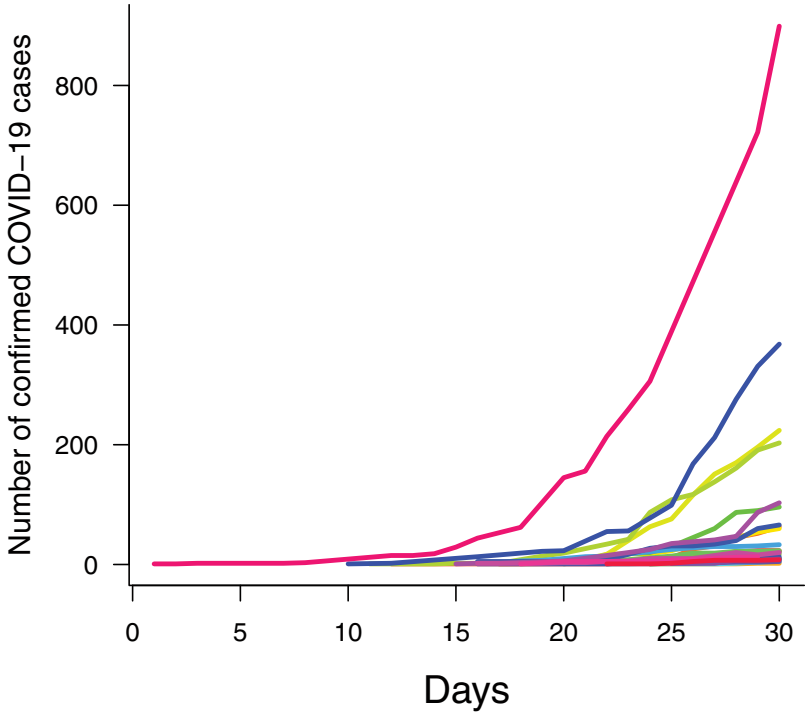

Figure 2 Daily counts of confirmed cases of COVID-2019 across Brazilian state capital cities during the first month. Exponential increase in daily counts of confirmed cases of COVID-2019 across Brazilian state capital cities (n = 292) during the first monitored month. Each line/colour represents one capital city (n = 27). Full-size DOI: 10.7717/peerj.9322/fig-2

We focused on the month since the first confirmed case, from February 26 to March 26, 2020, for which there were 292 reports on daily counts across cities.

We considered several potential predictors of the number of confirmed cases. First, it was important to account for the number of tests for COVID-19, as performing more tests tends to reveal more positive cases (*Roser et al., 2020*). The Brazilian Government has not been systematically reporting the number of performed tests, but has recommended testing of all suspected patients with severe symptoms, and the Ministry of Health reported the number of suspected cases per state until March 18, 2020. Therefore, we used the number of suspected cases per state on that date as a proxy for the number of tests, under the reasonable assumption that states with more suspected cases performed more tests.

Further, we considered the following predictors: (1) time in days, to account for the exponential growth in case numbers during this period (Fig. 2); (2) number of arriving flights in the city's metropolitan area in 2020, as airline connections can facilitate the spread of the virus (*Ribeiro et al., 2020*); (3) city population density, to account for facilitation of transmission under higher densities (*Poole, 2020*); (4) proportion of elderly people (≥60 years old) in the population, assuming that the elderly may be more likely to show severe symptoms of SARS-CoV-2 and, thus, to be diagnosed with COVID-19; (5) citizen mean income, which may affect the likelihood of people being infected by the virus, for example, due to limited access to basic sanitation or limited social isolation capabilities; (6) and the following meteorological variables: mean daily temperature (°C),

mean daily solar radiation (kJ/m^2), mean daily relative humidity (%) and mean daily precipitation (mm). The number of suspected cases and socioeconomic variables only varied across cities, whereas meteorological variables varied both between and within cities.

Data on population density, the elderly and income were obtained for the last quarter of 2019 from the Brazilian Institute for Geography and Statistics (IBGE), which samples Brazilian households quarterly for socioeconomic indicators (*Sidra, 2020*) (Table S2). Flight data were obtained from the current statistical annuary of the Brazilian Agency for Civilian Aviation (ANAC) (Table S3; *ANAC, 2020*). Hourly meteorological data were obtained from the automatic stations maintained by the Brazilian Institute for Meteorology (INMET) in the capital cities (Table S4; *INMET, 2020*).

We investigated the response of case counts to putative predictors using a Generalized Linear Mixed Model (GLMM) assuming Poisson-distributed errors and log link, and using capital-city identity as a random factor to account for autocorrelated errors within cities. This formulation induces a compound symmetry correlation structure on residuals within cities, which is mathematically equivalent to that of classical, "repeated measures" linear models (*Zuur et al., 2009*). The numbers of suspected cases and arriving flights were log-transformed to account for their highly skewed distributions, and all predictors were scaled to zero mean and unit standard deviation to facilitate parameter estimation. Consequently, estimated coefficients were scaled, thus providing a measure of predictor relative importance. Specifically, assuming a log link, a change of one unit in the scaled predictor implies a mean percent change of $(\exp(\text{coefficient}/\text{SD}) - 1) \times 100$ in the number of confirmed cases, where "coefficient" and "SD" are the predictor's model coefficient and standard deviation, respectively.

We considered time lags in the effect of meteorological conditions. Incubation time of COVID-19 averages 5 days (*Lauer et al., 2020*), and case confirmation in Brazil has taken from several days to 2 weeks due to overload of test laboratories. Therefore, the time between infection and case confirmation is likely to be longer than a week. Accordingly, we considered a set of models including all predictors but varying in the number of days meteorological predictors were lagged relative to case counts, ranging from 7 to 30 days with daily steps. Then, models were compared with Akaike's Information Criterion (AIC), a standard measure of model relative support, and the model with the lowest AIC was judged as the most supported.

Precipitation time series had missing intervals for some capital cities. Therefore, we performed two versions of the above analysis: one including all predictors but excluding days for which precipitation was lacking ($n = 269$) and another one excluding precipitation as predictor and using all counts of confirmed COVID-19 cases ($n = 292$). Because both analyses produced largely similar results, with precipitation having a negligible model coefficient (Figs. S1 and S2; Table S5), we present the analysis using the larger sample.

Lastly, we considered possible interactions between time and other predictors, assuming some factors could accelerate the temporal increase in number of confirmed cases. By definition, GLMMs assuming a log link implicitly account for interactive effects to some

degree, as log-linear models imply multiplicative effects. Still, we ran a separate GLMM which explicitly included interaction terms between time and the remaining predictors. To avoid model overparameterization, we only used the significant predictors identified in the previous analysis.

For all models, we computed the conditional predictive power (R^2_c), which indicates the variance explained jointly by predictors and the random factor, and the marginal predictive power (R^2_m), which only considers predictor effects. In these calculations, only significant predictors were retained in the model to avoid inflation of explained variance due to spurious parameters.

We acknowledge that it would be better to directly model the spread of SARS-CoV-2, but we cannot do that without making assumptions about the relationship between infection by the virus and the appearance of symptoms of the disease, which may be related to the factors that we are investigating. All analyses were performed in R 3.6.3 (*R Core Team, 2020*), with aid of packages "coronabr" (*Mortara, Sánchez-Tapia & Martins, 2020*) and "covid19br" (*Paterno, 2020*) for assessing counts of suspected cases by state, "lme4" for GLMM (*Bates et al., 2015*), "MuMIn" for AIC and R^2 calculations (*Bartoń, 2019*), and "visreg" for visualization of predictor effects (*Breheny & Burchett, 2017*).

RESULTS

There was strong support for the model whose meteorological predictors were lagged by 15 days, as indicated by its much lower AIC (Fig. 3). According to this model, the only significant predictors of the number of confirmed COVID-19 cases were time, the number of arriving flights, population density and temperature (Table 1). The number of confirmed cases increased with time (Fig. 4A), the number of arriving flights (Fig. 4B) and population density (Fig. 4C), whereas it decreased with temperature (Fig. 4D). Considering that model coefficients were scaled, comparing their values gives an indication of the relative importance of each predictor. Accordingly, time, the number of arriving flights and population density had the strongest effects (i.e., largest coefficients), followed by temperature (Table 1). Nevertheless, a change in 1 °C predicted a decrease in the number of confirmed cases by $(\exp(-0.26/3.11) - 1) \times 100 = 8\%$, independently of other factors (Table 1). Significant predictors explained 77% of the variance of daily counts of confirmed COVID-19 across capital cities in Brazil.

Explicitly accounting for interactions between time and the remaining predictors identified in the previous analysis suggested significant interactions between time and the number of arriving flights, and time and temperature, although the magnitude of the interaction coefficients was low (Table 2). On average, the temporal increase in confirmed COVID-19 cases began earlier in cities with more flights, causing a leftward shift in the relationship between confirmed cases and time (Fig. 5A). In parallel, the number of confirmed cases increased faster at lower temperatures, causing a steeper slope in the relationship between confirmed cases and time (Fig. 5B). However, these effects were relatively weak, and there was no improvement in predictive power (Table 2). Thus, the previous, simpler model captured the main patterns in the data very well.

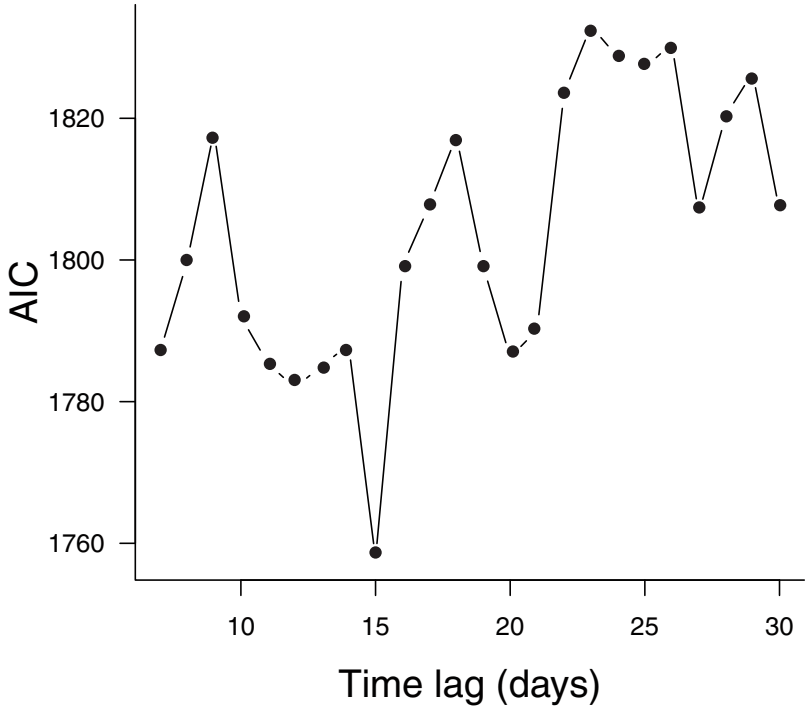

Figure 3 Models considering different time lags in meteorological predictors. Comparison of models considering different time lags in meteorological predictors using Akaike's Information Criterion (AIC). Each point represents one alternative model. Full-size DOI: 10.7717/peerj.9322/fig-3

Table 1 Results of the most supported Generalized Linear Mixed Model (GLMM) testing for independent effects on daily cumulative counts of confirmed COVID-19 across the 27 capital cities in Brazil (n = 292; R^2_c = 0.98; R^2_m = 0.77). The model assumed Poisson-distributed errors and log link, and used capital city identity as a random factor to account for autocorrelated errors of time series within cities. All predictors were scaled to zero mean and unit standard deviation. SD indicates predictor standard deviation; numbers in bold represent statistically significant effects (P < 0.05). Variables were as follows: time—time elapsed in days; Log suspected—log-transformed number of suspected COVID-19 cases in March 18, 2020; Log flights—log-transformed number of arriving flights in 2020; density—inhabitants by km^2; elderly—proportion of elderly people (≥ 60 years old); income—mean citizen income (R$); temperature—mean daily temperature (°C) with a 15-day lag; radiation—mean daily solar radiation (kJ/m^2) with a 15-day lag; humidity—mean daily air humidity (%) with a 15-day lag.

Predictor	SD	Coefficient	z	P
Intercept	–	2.17	–	–
Time	5.72	1.4	67.7	**<0.001**

DISCUSSION

Our results indicate that the number of confirmed COVID-19 cases in Brazil has been higher and has begun to increase earlier in cities receiving more flights, consistent with the expected role of air-transport connections in spreading the virus across the country (*Ribeiro et al., 2020*). Further, there have been more cases in cities with higher population density, consistent with the expected role of host density (*Poole, 2020*). We also have uncovered a temperature response with a lag of 15 days: there have been more confirmed cases in colder cities and days, and confirmed cases have accumulated faster under lower

Table 2 **Results of the generalized linear mixed model (GLMM) testing for interaction effects on daily cumulative counts of confirmed COVID-19 in Brazil (n = 292; R^2_c = 0.98; R^2_m = 0.77).** The model assumed Poisson-distributed errors and log link, and used capital city identity as a random factor to account for autocorrelated errors of time series within cities. Only statistically significant predictors in Table 1 were used, all of which were scaled to zero mean and unit standard deviation. SD indicates predictor standard deviation; numbers in bold represent statistically significant effects ($P < 0.05$). Variables were as follows: time–time elapsed in days; Log flights—log-transformed number of arriving flights in 2020; density—inhabitants by km^2; temperature—mean daily temperature (°C) with a 15-day lag.

Predictor	SD	Coefficient	z	P
Intercept	–	2.13	–	–
Time	5.71	1.45	46.55	**<0.001**
Log flights	1.19	0.96	4.67	**<0.001**
Density	3,057.46	0.31	1.58	0.115
Temperature	3.11	−0.30	−8.91	**<0.001**
Time × log flights	–	−0.08	−2.46	**0.014**
Time × density	–	0.01	0.47	0.641
Time × temperature	–	−0.08	−2.85	**0.004**

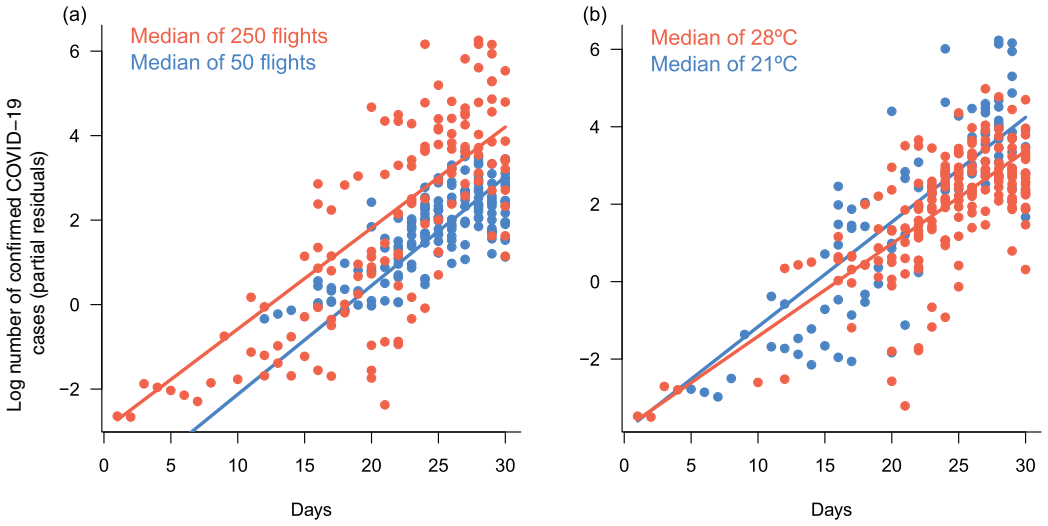

Figure 5 **Response of daily cumulative counts of confirmed COVID-19 cases in Brazil to interactive effects between time an number of arriving flights and mean daily temperature.** Response of daily cumulative counts of confirmed COVID-19 cases across the 27 Brazilian capital cities to interactive effects of (A) time and number of arriving flights, and (B) time and mean daily temperature, based on the Generalized Linear Mixed Model (GLMM) presented in Table 2. The model assumed Poisson-distributed errors and log link, and included capital city identity as a random factor to account for autocorrelated errors in time series within cities. Each point represents a daily observation in a given city (n = 292); lines represent predicted means for each group of observations, as indicated by legends. Group medians were chosen based on their respective predictor ranges (see Fig. 4). Plots use partial residuals of the response variable and thus show the effect of a given interaction while controlling the effects of remaining predictors. Full-size DOI: 10.7717/peerj.9322/fig-5

temperature days. Although correlative, these patterns were independent of several demographic and socioeconomic factors and, thus, are unlikely to be confounded by them. This is disturbing because there is little that authorities can do about this relationship,

whereas the number of arriving flights and population density can be manipulated indirectly by isolation strategies.

The temperature dependance of COVID-19 in Brazil agrees with data from China, where warmer weather also seemed to limit the spread of COVID-19 while controlling for population density and per capita GDP (*Wang et al., 2020*). It also agrees with the thermal dependance of viability and transmission demonstrated experimentally for better-studied viruses, such as influenza (*Lowen et al., 2007*) and other betacoronaviruses, for example, SARS-CoV-1 (*Chan et al., 2011*) and MERS-CoV (*Van Doremalen, Bushmaker & Munster, 2013*). While the precise mechanism underlying this pattern requires further study, it may be related to the lipid bilayer of coronaviruses, which becomes increasingly unstable as temperature increases (*Schoeman & Fielding, 2019*).

Recognizing that we are talking about the rate of spread and not necessarily final mortality rates, the information is still important for authorities trying to predict demands on health services. Our best estimate is that a rise of about 1 °C in mean daily temperature reduces the number of COVID-19 cases by about 8%, independently of other factors. Thus, for instance, our results indicate that Cuiabá, with a mean July temperature of about 23.4 °C, and Porto Alegre, with a mean July temperature of 14.9 °C, may differ up to 50% in the number of COVID-19 cases, all else being equal. It also means that the spread in Porto Alegre might be 41% lower in the middle of March (mean daily temperature of 21.3 °C) than it will be in the middle of July (mean daily temperature of 14.9). At the same time, and contrary to some suggestions (*Poole, 2020*; *Wang et al., 2020*; *Grant et al., 2020*), we found no evidence for effects of solar radiation or humidity. Perhaps such conditions are not limiting for the virus or the disease under the climatic conditions of Brazil. Also, rapid evolution of the climatic niche of SAR-Cov-2 could have a similar effect. Although the mutation rate of SARS-CoV seems to be moderate compared to that of other RNA viruses (*Zhao et al., 2004*; *Yang et al., 2020*), clustering of hundreds of worldwide SARS-CoV-2 genomes based on widely shared polymorphisms suggests 16 subtypes, all of which harbor amino acid replacements which may have phenotypic effects (*Morais et al., 2020*).

Whether the temperature effect is related to the rate of spread of SARS-CoV-2 or to the proportion of persons that suffer reportable symptoms cannot be answered with the data being provided at the moment (*Fasina, 2020*). That would require universal testing for the presence of the virus, which is not presently viable but may be a necessity in the following months. Also, one of the main difficulties we encountered was the lack of systematization of current information, since much of the data generated daily is still scattered and difficult to access. For instance, the number of tests performed, which is the key to estimate the rate of infection and the number of infected patients is not available. The large number of publications on the subject in the last 30 days shows that the scientific community is prepared for a quick response, as long as there is a systematization and transparency of information regarding the number of tests being performed, number of suspected cases, number of infected, number of deaths, etc.

Our models are necessarily simple and have limitations. Most importantly, we need city and state administrations to provide the number of performed tests on a regular basis,

so that this variable can be explicitly accounted for in the model. The data do not allow us to investigate complex nonlinear effects, which likely would require data on temperatures beyond those observed in Brazilian cities in March. Also, it is currently not possible to account for potential interactions between COVID-19 and other diseases, particularly influenza, which is seasonal. It may not be necessary to worry about this in the northern hemisphere because the peaks in COVID-19 will occur after the peaks in seasonal influenza. However, the predicted peaks in COVID-19 in the southern hemisphere will occur concomitantly with peaks in seasonal influenza (*Nelson et al., 2006*; *Viboud, Alonso & Simonsen, 2006*). The effects may just be additive, but it is not known whether the simultaneous infection will increase the severity of COVID-19 and therefore the demand for ICUs, and this interaction also could be temperature sensitive. Further, air pollution is known to increase susceptibility to viral respiratory infections (*Ciencewicki & Jaspers, 2007*), but the extent to which it affects the prevalence of COVID-19 is unclear. As COVID-19 consolidates in different cities, it will be possible to reduce uncertainties in relation to the role of temperature and other factors. Nonetheless, our models still performed well as judged by their predictive power, even when ignoring interactions between predictors.

We stress that the temperature effect does not mean that the northern, warmer regions of Brazil should expect fewer complications in their health care system, because such regions also have poorer socioeconomic and sanitary conditions (*Barreto et al., 2011*), and ICUs are concentrated in southern regions (*Rhodes & Moreno, 2012*). Although we found no evidence for an effect of income on the number of confirmed COVID-19 cases, this variable is related to the capacity of cities to respond to the pandemic. Furthermore, apart from elapsed time, the predictors with the largest standardized coefficients were the number of arriving flights and population density (Table 1). Indeed, Manaus, the largest city in Northern Brazil, was the first Brazilian city to declare the collapse of the health system early in April 2020, which is consistent with its large number of arriving flights and large population density but relatively low number of ICUs (*Rhodes & Moreno, 2012*). By contrast, although southern, colder regions have a higher density of ICUs, their situation could be aggravated if social isolation measures are not effectively adopted before and maintained throughout winter in those regions (from June to September). This should be especially important for "favelas", that is, poorer, highly populated neighborhoods with deficient infrastructure, which are presumably at high risk of infection. Thus, we do not present our results as an indication of how hospital demand should be calculated, but as a warning that models for Brazil need to take into account predicted temperatures.

CONCLUSIONS

Declared as a pandemic by the World Health Organization (WHO), the COVID-19 disease has changed human behavior and strongly affected health systems and the economy worldwide. In an extremely demanding scenario, optimizing the distribution of resources is an essential task. Brazil and other countries are starting to discuss the flexibilization of social distancing policies, as the latter could have important economic costs. However, we need to understand how and when to implement such decisions in

order to prevent new, uncontrolled disease outbreaks that may overcrowd the health care system again and generate even higher economic costs in the near future. Our results suggest that, along with arriving flights and population density, temperature should be taken into account to estimate the number of cases of COVID-19, especially with winter approaching in the southern hemisphere.

ACKNOWLEDGEMENTS

We are grateful to Álvaro Justen and his collaborators for compiling the daily records on COVID-19 cases for Brazilian cities, and Sara Mortara, Andrea Sánchez-Tapia, Karlo Martins and Gustavo Paterno for developing R packages to facilitate obtention of COVID-19 data from the Brazilian Ministry of Health. We thank the Biodiversity Research Program (*PPBio Brasil*) of the Ministry of Science, Technology, Innovation and Communication (MCTIC) of Brazil for providing the contact network that enabled quick collaboration among the researchers involved in this manuscript. We also thank Alexandre Almeida, Daniel Pimenta and Lucas Bandeira for useful suggestions on preliminary analyses, and Elizabeth Franklin, Daniela Bôlla, Fabíola Wieckert, Sérvio Ribeiro and two anonymous reviewers for useful comments on earlier versions of this manuscript.

ADDITIONAL INFORMATION AND DECLARATIONS

Funding

This work was supported by Ministry of Science, Technology, Innovation and Communication (MCTIC) of Brazil, the Brazilian Agency of Higher Education (CAPES) and the Brazilian National Council for Scientific and Technological Development (CNPq). Pedro Pequeno received a postdoctoral fellowship from the Brazilian Agency of Higher Education (CAPES). Clarissa Rosa and Jorge Luiz Souza received a postdoctoral fellowship from the Institutional Training Program of the Brazilian National Council for Scientific and Technological Development (PCI-CNPq). William Magnusson received a productivity grant from CNPq. The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Grant Disclosures

The following grant information was disclosed by the authors:
Ministry of Science, Technology, Innovation and Communication (MCTIC).
Brazilian Agency of Higher Education (CAPES).
Brazilian National Council for Scientific and Technological Development (CNPq).
Brazilian Agency of Higher Education (CAPES).
Brazilian National Council for Scientific and Technological Development (PCI-CNPq).
CNPq.

Competing Interests

The authors declare that they have no competing interests.

Author Contributions

- Pedro Pequeno conceived and designed the experiments, performed the experiments, analyzed the data, prepared figures and/or tables, authored or reviewed drafts of the paper, and approved the final draft.
- Bruna Mendel conceived and designed the experiments, performed the experiments, authored or reviewed drafts of the paper, and approved the final draft.
- Clarissa Rosa conceived and designed the experiments, authored or reviewed drafts of the paper, and approved the final draft.
- Mariane Bosholn conceived and designed the experiments, authored or reviewed drafts of the paper, and approved the final draft.
- Jorge Luiz Souza conceived and designed the experiments, authored or reviewed drafts of the paper, and approved the final draft.
- Fabricio Baccaro conceived and designed the experiments, authored or reviewed drafts of the paper, and approved the final draft.
- Reinaldo Barbosa conceived and designed the experiments, authored or reviewed drafts of the paper, and approved the final draft.
- William Magnusson conceived and designed the experiments, authored or reviewed drafts of the paper, and approved the final draft.

HIGHLIGHTS

- The impacts of meteorological factors on COVID-19 case counts were assessed after controlling population migration.
- The weather with low temperature, mild diurnal temperature range and low humidity likely favor the transmission of COVID-19.
- The epidemic might gradually ease partially due to rising temperatures in coming months.

ABSTRACT

The purpose of the present study is to explore the associations between novel coronavirus disease 2019 (COVID-19) case counts and meteorological factors in 30 provincial capital cities of China. We compiled a daily dataset including confirmed case counts, ambient temperature (AT), diurnal temperature range (DTR), absolute humidity (AH) and migration scale index (MSI) for each city during the period of January 20th to March 2nd, 2020. First, we explored the associations between COVID-19 confirmed case counts, meteorological factors, and MSI using non-linear regression. Then, we conducted a two-stage analysis for 17 cities with more than 50 confirmed cases. In the first stage, generalized linear models with negative binomial distribution were fitted to estimate city-specific effects of meteorological factors on confirmed case counts. In the second stage, the meta-analysis was conducted to estimate the pooled effects. Our results showed that among 13 cities that have less than 50 confirmed cases, 9 cities locate in the Northern China with average AT below 0 °C, 12 cities had average AH below 4 g/

Absolute humidity
Population migration

m^3, and one city (Haikou) had the highest AH (14.05 g/m^3). Those 17 cities with 50 and more cases accounted for 90.6% of all cases in our study. Each 1 °C increase in AT and DTR was related to the decline of daily confirmed case counts, and the corresponding pooled RRs were 0.80 (95% CI: 0.75, 0.85) and 0.90 (95% CI: 0.86, 0.95), respectively. For AH, the association with COVID-19 case counts were statistically significant in lag 07 and lag 014. In addition, we found the all these associations increased with accumulated time duration up to 14 days. In conclusions, meteorological factors play an independent role in the COVID-19 transmission after controlling population migration. Local weather condition with low temperature, mild diurnal temperature range and low humidity likely favor the transmission.

1. Introduction

Wuhan, the capital city of Hubei province, China, was the first major metropolitan region suffering from the coronavirus disease 2019 (COVID-19) outbreak and the epidemic center since December, 2019 (Zhou et al., 2020). COVID-19 is caused by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), a novel coronavirus. Due to the high contiguousness and wide spread, COVID-19 has officially been declared a pandemic by the World Health Organization (WHO) on March 11, 2020 (World Health Organization, 2020b). As of March 21th, more than 170 countries has reported this epidemic, with a total diagnosed cases of about 234,073 causing over 9000 deaths (World Health Organization, 2020b). Europe and the United States have gradually becoming the epicenter of the pandemic (World Health Organization, 2020c) and the world is facing great public health crisis from COVID-19, which is likely more severe than SARS in 2003.

In China, COVID-19 has spread in multiple major cities that have huge numbers of both inbound and outbound passengers (e.g., Beijing, Shanghai, and Guangzhou) (Wu et al., 2020). To block the quick spread of infection and control the severe epidemic, China has conducted strict measures by mobilizing and redistributing nationwide resources, shelter-in-place and quarantining all confirmed cases and close contacts. A study indicated that a series of control measures since January 23, 2020 in China reduced the COVID-19 epidemic size significantly, and the similar measures were expected to remain until the end of April 2020 (Yang et al., 2020). The current daily new COVID-19 cases in China have reached very low level. China has cumulatively reported more than 81,008 confirmed cases and over 3,255 deaths as of March 21, 2020 (National Health Commission of the People's Republic of China, 2020). Among all these effective strategies in controlling this epidemic, locking down Wuhan, a city of 11 million residents, was one of the most dramatic measures. It turned out that the limitation of population migration was effective in controlling epidemic diseases like COVID-19. However, the independent effect of meteorological factors on the transmission of COVID-19 has not been studied systemically while controlling population migration.

Previous studies showed that cold and dry weather is beneficial for the survival and spread of droplet-mediated viral diseases like

influenza (Lowen et al., 2007; Shaman and Kohn, 2009; Li, 2011). The SARS epidemic was gradually faded with the warming weather coming, and was basically ended in July, 2003 (Tan et al., 2005; Wang et al., 2006; Cao et al., 2016), suggesting that the temperature and its variations might have affected the SARS outbreak. Some studies have suggested that the climate change might have contributed to various infectious diseases emergence and spread (Lofgren et al., 2007; Gale et al., 2010; Stott, 2016), including the SARS and COVID-19. In Korea, researchers found that the risk of influenza incidence was significantly increased with low daily temperature and low/high relative humidity (RH), but a positively correlated with diurnal temperature range (DTR) (Park et al., 2020). Absolute humidity (AH) had significant correlations with influenza viral survival and transmission rates (Shaman et al., 2010; Shaman et al., 2011). One important feature of COVID-19 epidemic is that the countries currently suffering most from the disease are most located in the regions with low temperature. Therefore, meteorological factors, such as ambient temperature (AT) and humidity, might play an important role in the spread of the disease.

Many factors might influence the COVID-19 epidemic, including social and political factors, geographical factors, climatic factors, etc. (Casadevall, 2020; Wu et al., 2020). When only considering the temperature in single-factor model in the higher-temperature group, every 1 °C increase in the minimum temperature leads to a decrease of the cumulative number of COVID-19 cases by 0.86 (Wang et al., 2020). Luo etc. reported that weather was related to the spread of COVID-19, but the increase of temperature may not necessarily lead to declines in case counts without the implementation of extensive public health interventions (Luo et al., 2020). In another study, researchers estimated that the weather variables explain 18% of the variation in disease doubling time, and the remaining 82% may be related to containment measures, general health policies, population density, transportation or cultural aspects (Oliveiros et al., 2020). Because of the human to human transmission, the migration should be considered when evaluate the effects of meteorological factors over COVID-19 transmission. However, to

[a] To account for the latent period of COVID-19, for each city, averaged meteorological parameters were calculated during the period of 20th to March 2nd, 2020.

our knowledge, previous studies have not controlled the population migration to examine independent effects of weather conditions on the COVID-19 transmission.

In this study, we first explored non-linear relation between COVID-19 case counts and meteorological factors. Then we used generalized linear models to examine the associations between meteorological factors and COVID-19 daily case counts in 30 provincial capitals except for Wuhan in China while controlling the population migration.

2. Methods

2.1. Data collection

Since the COVID-19 condition was much more complicated compared with other provinces due to government interventions in Hubei, like Wuhan lockdown and mass screening, we chosen to study the relationship in 30 capital cities of China. We obtained daily officially reported confirmed case counts from the Health Commission of the 30 capital cities except Wuhan during the period January 20th to March 2nd 2020 (Fig. 1). The daily meteorological data, including hourly temperature and RH, were obtained from Shanghai Meteorological Bureau and Data Center of Ministry of Ecology from January 5th to March 2nd 2020. Meanwhile, migration scale index (MSI) of the 30 cities was collected from the website of Baidu Migration (https://qianxi.baidu.com/?from=mappc). MSI reflects the population scale of moving in, and MSI of cities can be comparable. The daily average AT and DTR were calculated based on hourly data. AH was calculated according to the method used in the previous study which was measured by vapor pressure (g/m^3) (Shaman et al., 2011; Davis et al., 2016; Liu et al., 2018).

2.2. Statistical analysis

A descriptive analysis was performed to explore the city-specific characteristics of confirmed case counts, AT, DTR, AH and MSI of these 30 cities. For each city, average meteorological data were calculated based on the period of January 20th to March 2nd, 2020 to account for the lag effect and the latent period of COVID-19. Then, a second order polynomial non-linear regression models were fitted between total COVID-19 confirmed case counts and AT, DTR, AH, MSI.

We characterize the disease transmission and case distribution in the 13 cities with less than 50 confirmed cases. Then, a two-stage analysis was conducted for the other 17 cities with more than 50 cases in each city. In the first stage, because of the clustering characteristics of the disease, we adopted generalized linear models with negative binomial distribution to estimate city-specific effects. The analyses were performed with R software version 3.3.2, and the "MASS" package (MASS: Support functions and datasets for venables and Ripley's MASS, 2019) was used to fitting models. The fitted formulas were as follows:

$$\text{Log E}\,(Y_t) = \alpha + \beta_1 \text{AT} + \text{ns}\,(\text{RH}, 3) + \beta_2 \text{MSI} \quad (1)$$

$$\text{Log E}\,(Y_t) = \alpha + \beta_1 \text{DTR} + \text{ns}\,(\text{RH}, 3) + \beta_2 \text{MSI} \quad (2)$$

$$\text{Log E}\,(Y_t) = \alpha + \beta_1 \text{AH} + \beta_2 \text{MSI} \quad (3)$$

where t is the day of the observation; E(Y_t) is the expected number of daily confirmed cases on day t; α is the intercept; β is the regression coefficient. Considering the lag effects and the average latent period of COVID-19, 3-day moving average RH and 3-day moving average MSI were controlled in the models when exploring the effects of AT (1) and DTR (2). As a meteorological factor, natural cubic splines (ns) with 3 *df* was used for controlling RH. Considering the collinearity, only three-day moving average MSI were controlled in the models (3) when dealing with AH. Because of the lag effects, we evaluated the associations in lag 0, lag 03, lag 07 and lag 014 between daily confirmed case counts and these meteorological factors for each city.

In the second stage of the analysis, we conducted a random effects meta-analysis to pool estimates across city-specific associations. The

meta-analysis was performed based on STATA/SE 11.0 (StataCorp LLC, USA).

All results were expressed as the relative risk (RR) in daily confirmed case counts with 95% confidence intervals (95% CI) relative to a fixed change (1 °C or 1 g/m^3) of each factor. Statistical significance was set at p-value < 0.05.

3. Results

3.1. Descriptive analysis

As of March 2nd, 2020, a total of 3,905 cases were officially reported in 30 provincial capital cities in China. Among these cities, 17 cities had more than 50 confirmed cases, accounting for 90.6% of all cases in this study. During our study period, the daily MSI, AT, DTR and AH for these 30 cities were 1.62 ± 1.14, (3.44 ± 7.97) °C, (9.13 ± 3.04) °C and (4.76 ± 3.14) g/m^3. Strong regional differences were observed for meteorological factors and MSI.

Among the 13 cities that have less than 50 cases, 9 cities located in the Northern China with average AT below 0 °C, 12 cities had average AH below 4 g/m^3 and one city (Haikou) had the highest AH (14.05 g/m^3) (Figs. 1, 2 and Table 1). The MSI in these 13 cities were relatively lower than the remaining 17 cities that have more than 50 cases (Fig. 2).

3.2. Temporal and regional characteristics of COVID-19 transmission

The nonlinear regression analysis results (Fig. 3) suggest brief distribution characteristics between confirmed case counts and AT, DTR, AH, MSI. We found an obvious trend association between AT and the confirmed case counts, it seemed that the confirmed case number increased with temperature increasing in the range of −20 °C–20 °C. Like that, similar trend was also found between confirmed case counts and MSI. Well, we found there was an arched shape for the relationship between confirmed case counts and period-average AH, as there were more confirmed cases at the AH of around 6 g/m^3. However, the regression model showed that the confirmed cases counts declined with the increase of DTR in the range of 5 °C–15 °C.

3.3. AT, DTR and AH negatively related to the increase of COVID-19 transmission

Concerning the small sample size in those 13 cities, the fitted city-specific generalized linear models and meta-analysis were only conducted for the 17 cities with 50 and more cases to explore the associations between COVID-19 case counts and meteorological factors (Fig. 4). In city-specific analysis, significant negative associations were found in 9 cities (Beijing, Tianjin, Zhengzhou, Hangzhou, Shanghai, Xian, Nanchang, Fuzhou and Guangzhou) in lag 03. In meta-analysis, the pooled results showed that each 1 °C increase in AT was related to the decline of daily confirmed COVID-19 case counts, the corresponding overall RR was 0.80 (95% CI: 0.75, 0.85) (Fig. 4A). Each 1 °C increase in DTR was associated with decreased patients in lag 03 and the pooled RR was 0.90 (95% CI: 0.86, 0.95). In the city level, it was significant for Hangzhou, Nanchang, Fuzhou, Chengdu and Zhengzhou in lag 03 (Fig. 4B). As showed in Fig. 4C, AH had significant negative effects on confirmed case counts for 4 cities, including Guangzhou, Hangzhou, Nanchang, and Nanjing. Meta-analysis showed that each 1 g/m^3 increase in AH was significantly associated with reduced confirmed case

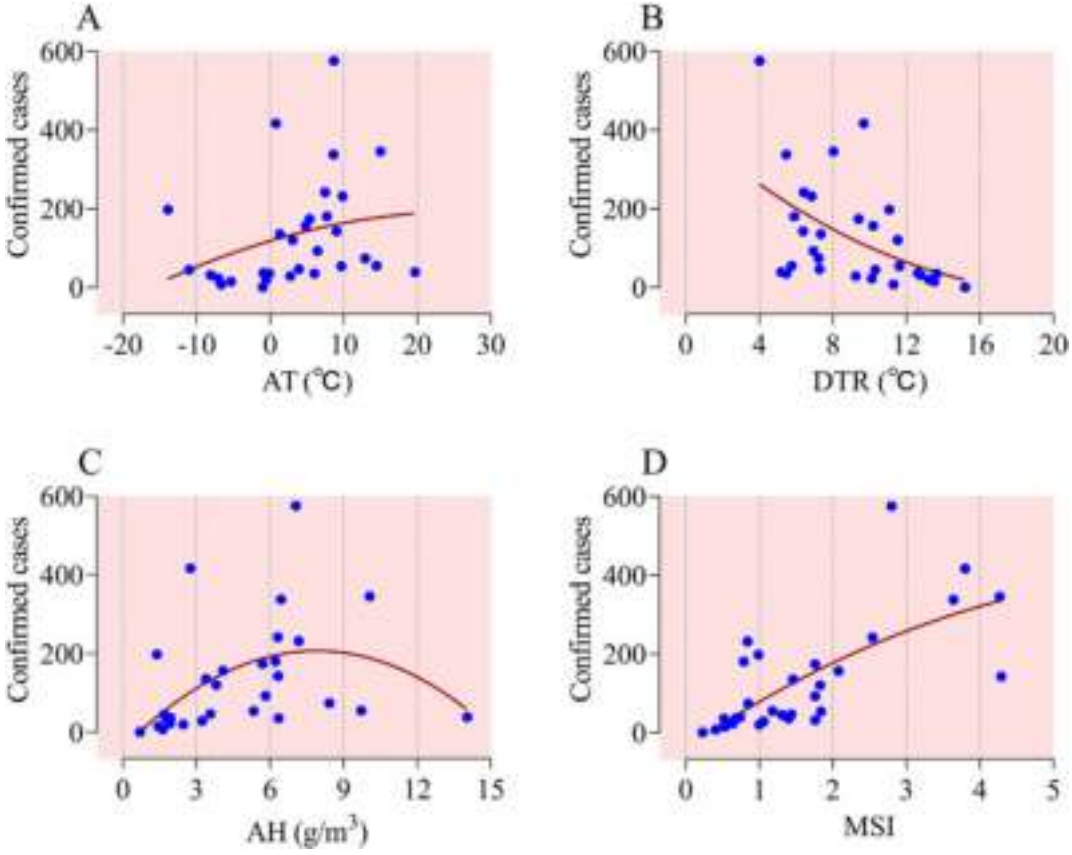

Fig. 3. Associations between COVID-19 confirmed case counts and meteorological factors, MSI in 30 provincial capital cities of China. Note: (A) AT, Curve formula: Y = 118.5 + 5.552 * X-0.1022 * X^2, R^2 = 0.08776; (B) DTR, Curve formula: Y = 408.5–40.24 * X + 0.9651* X^2, R^2 = 0.2379; (C) AH, Curve formula: Y = –40.20 + 62.59* X-3.957 * X^2, R^2 = 0.2291; (D) MSI: Y = –38.21 + 125.7 * X-8.973 * X^2, R^2 = 0.4953. The brown lines in figures represent second order polynomial curves. The blue dots represent the 30 cities. AT: Ambient temperature; DTR: Diurnal temperature range; AH: Absolute humidity; MSI: Migration scale index.

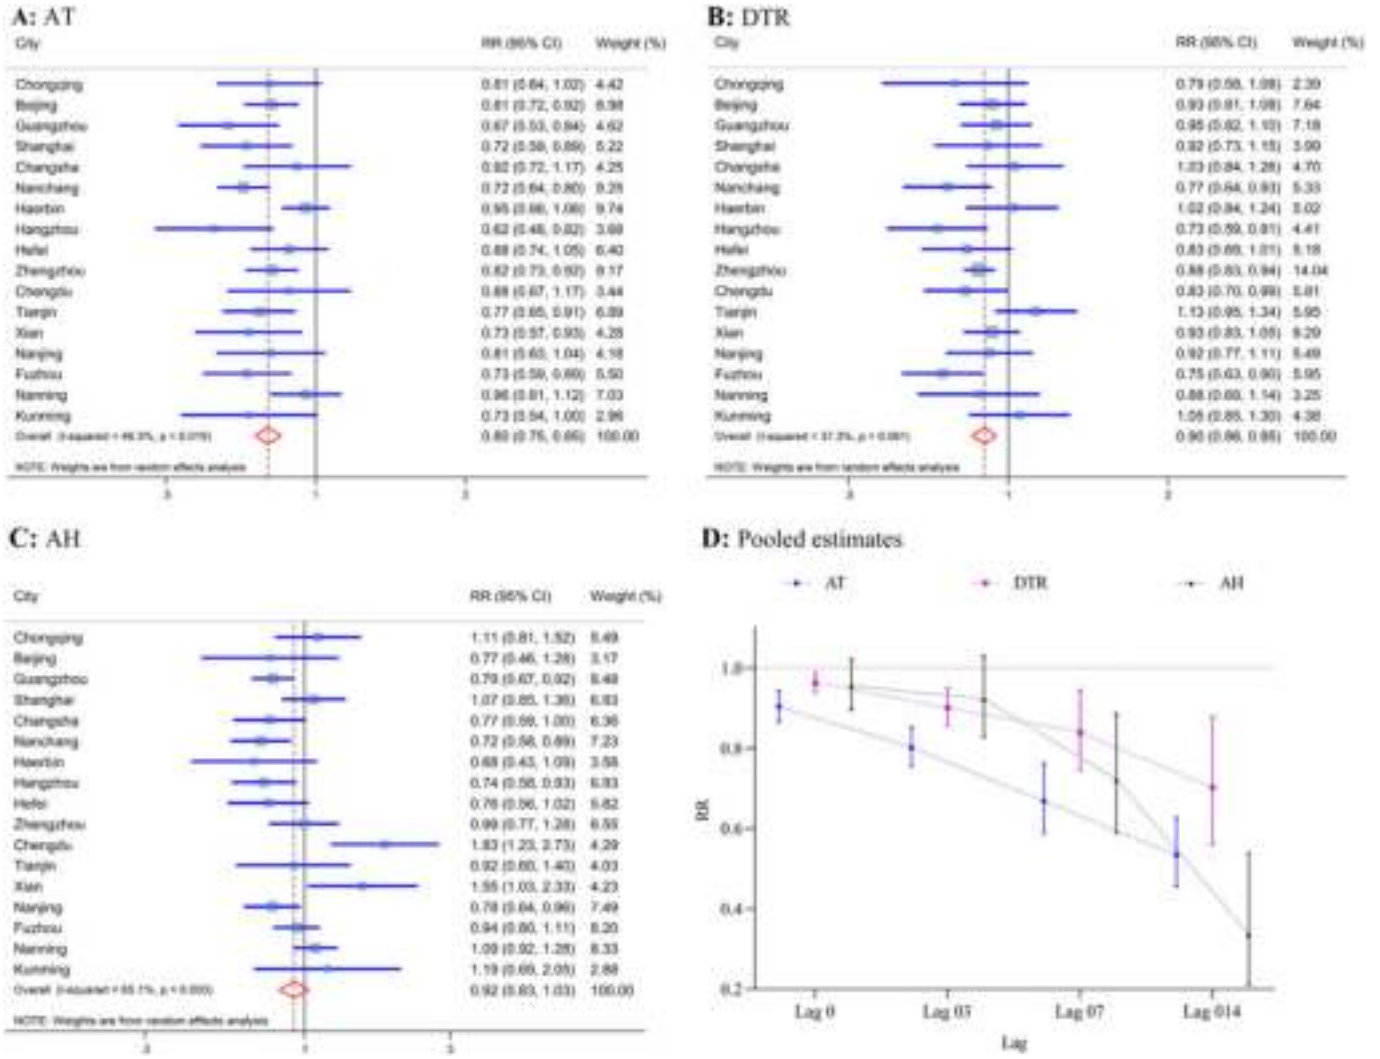

Fig.ure 4. Meta-analysis for effects of meteorological factors on COVID-19 case counts in 17cities during the period of January 20th to March 2nd 2020. Note: (A) AT; (B) DTR; (C) AH; (D) Pooled estimates in lag 0, lag 03, lag 07 and lag 014. The associations of COVID-19 case counts with AT, AH and DTR in each city was evaluated by fitting generalized linear models respectively (Lag 03). The meta-analysis was conducted to combine the city-specific results. AT: Ambient Temperature; DTR: Diurnal Temperature Range; AH, Absolute Humidity.

counts for 17 cities cities in lag 07, lag 014 and the combined RR was 0.72 (95% CI: 0.59, 0.89) and 0.33 (95% CI: 0.21, 0.54).

Fig. 4D showed associations between confirmed case counts and AT, DTR and AH in lag 0, lag 03, lag 07 and lag 014. The pooled effects of AT, DTR and AH became stronger with the increase of cumulative lag days.

4. Discussions

As of March 2nd, China has reported 80, 302 COVID-19 cases. This is the first study to examine the impact of meteorological factors on COVID-19 after controlling population migration. Our results indicated that COVID-19 transmission may be affected by meteorological factors, and a weather with low temperature, mild diurnal temperature range and low humidity likely favor its transmission.

Our findings on the impact of meteorological conditions over the transmission of COVID-19 are consistent with previous studies on the transmission of SARS or other infectious diseases (Tan et al., 2005; Lin et al., 2006; Liu et al., 2018; Park et al., 2020). Some studies suggested that global climate change might be accompanied by the changes to the outbreak of infectious diseases (Bezirtzoglou et al., 2011; Anwar et al., 2019; Casadevall, 2020). As we know, viruses are completely dependent on their hosts for replication and survival. It is possible that as virus has adapted to gradually higher global AT, some new and previously unknown infectious diseases are likely to emerge and spread (Casadevall, 2020), such as SARS-CoV and Ebola virus, and poses a threat to human health. The emergence and spread of novel coronavirus since December 2019 might be related to the ongoing climate change. In winter and spring, a decrease in resistance to respiratory diseases in a colder environment for population might be easier to accelerate the spread velocity. Lin etc. showed that in days with a lower air temperature during the epidemic, the risk of increased daily incidence of SARS was 18.18-fold (95% CI: 5.6, 58.8) higher than in days with a higher temperature (Lin et al., 2006). Tan etc. found a close association between temperature, its variations and the SARS outbreak in the four cities in China, suggesting that SARS more likely outbreaks in spring (Tan et al., 2005). Consistent with these results, we also found that each 1 °C increase in AT was related to the decline of daily confirmed case counts, the corresponding overall RR was 0.80 (95% CI: 0.75, 0.85). In addition, Lambrechts etc. has found that a large DTR might impede dengue virus infection of the mosquito midgut and reduce transmission risks compared to a small DTR or constant temperature. Intensity of dengue virus transmission can be influenced by the specific combination of mean and range in temperature fluctuations (Lambrechts et al., 2011). In our study, each 1 °C increase in DTR was associated with decreased

patients in lag 03 and the pooled RR was 0.90 (95% CI: 0.86, 0.95). This suggests that novel coronavirus might be also more suited to survive in an environment with small DTR or constant temperature.

AH is an indicator describing the mass of water vapor per volume of air (g/m^3). Shaman et al. found that 50% of influenza virus transmission variability and 90% of influenza virus survival variability could be explained by AH variation, whereas, only 12% and 36% could be explained by relative humidity (Shaman and Kohn, 2009), and the epidemic influenza typically peaks in the winter when low AH maximizes R0 (Shaman et al., 2011). A previous study found that AH was one of most important weather parameters in predicting heat-related mortality among a spectrum of weather parameters (Zhang et al., 2014). These studies indicated that AH may be a better indicator of humidity in acute health effects. The COVID-19 outbreak in China happened in winter and early spring with lower AH. Our results indicated that there might exist an optimum low humidity for COVID-19 to spread. Because those 12 cities with AH below 4 g/m^3 confirmed fewer case counts than other cities. For the 17 cities with more than 50 cases, results showed that every 1 g/m^3 increase in AH was significantly associated with declined confirmed case counts in lag 07, lag 014 and the combined RR was 0.72 (95% CI: 0.59, 0.89) and 0.33 (95% CI: 0.21, 0.54). Consistent with our results, Liu et al. has explored the effects of AH on H7N9 infection risks in China and found significantly higher effects of low AH on risks of H7N9 infection (Liu et al., 2018). Possible explanation is that low AH might increase the stability of coronavirus and favor its transmission like influenza did (Lowen et al., 2007). Our results are somewhat different from a previous study about early COVID-19 outbreak, which reported that the changes in temperature and humidity as spring and summer months arriving might not lead to decline of confirmed case counts without the implementation of extensive public health interventions (Luo et al., 2020). Although public health control measures play a major role in controlling pandemic like COVID-19, our results indicate an independent role of weather conditions on the transmission. Unlike this study, we used data over a longer period and controlled the population migration in our models. Therefore, we are optimistic that this epidemic will be faded to a large degree in the coming warmer season with the enforcement of public health interventions in China.

As we know, the COVID-19 in China firstly confirmed in Wuhan and a considerable proportion of confirmed cases in other cities of China were imported from Wuhan, which may confuse the relation of meteorological environment and COVID-19. However, we controlled its effect with MSI and estimated a significant association between the meteorological environment and COVID-19 transmission. The most important environmental implication is that, AT, DTR and AH are critical factor for COVID-19 transmission, which also deserve to be better studied in other regions during this pandemic.

In conclusions, our study implicates that meteorological factors play an independent role in the COVID-19 transmission. A weather with low temperature, mild diurnal temperature range and low humidity favors the transmission. This study indicates that the epidemic might gradually ease as a result of rising temperatures in coming months as well as the implementation of public health control measures.

Absolute humidity
Population density
Multivariable analysis

ABSTRACT

In this study, we analyzed the spread and decay durations of the COVID-19 pandemic in several cities of China, England, Germany, and Japan, where the first wave has undergone decay. Differences in medical and health insurance systems, as well as in regional policies incommoded the comparison of the spread and decay in different cities and countries. The spread and decay durations in the cities of the four studied countries were reordered and calculated based on an asymmetric bell-shaped model. We acquired the values of the ambient temperature, absolute humidity, and population density to perform multivariable analysis. We found a significant correlation ($p < 0.05$) of the spread and decay durations with population density in the four analyzed countries. Specifically, spread duration showed a high correlation with population density and absolute humidity ($p < 0.05$), whereas decay duration demonstrated the highest correlation with population density, absolute humidity, and maximum temperature ($p < 0.05$). The effect of population density was almost nonexistent in China because of the implemented strict lockdown. Our findings will be useful in policy setting and governmental actions in the next pandemic, as well as in the next waves of COVID-19.

1. Introduction

The outbreak of the coronavirus disease (COVID-19) has been reported worldwide, and it has reached more than 200 countries [1,2]. Numerous studies on COVID-19 have investigated meteorological factors, clinical factors, and public health interventions that affect infection and morbidity [3–6]. Commonly, the morbidity and mortality rates of COVID-19 differ by one or more orders of magnitude in each country. Some hypotheses for this observation have been presented but remain controversial, such as the effects of the Bacillus Calmette–Guérin vaccine [7,8], age structure [9,10], and race [11,12].

Another factor that policies should consider is the duration of the lockdown [13–15]. However, proper comparison is not straightforward because of various cofactors, such as human behavior and regional policies; a similar problem occurs with the determination of the morbidity and mortality rates.

During the constraint, the public was stressed because of the lack of information on potential risk factors. Several restrictions negatively impact different life aspects, including employment rate and education progress. Therefore, it is important to determine which social and environmental factors may influence the morbidity and mortality rates in different societies. Thus, the analysis of COVID-19 data will ensure the appropriate policy setting and governmental actions during the pandemic. The establishment of effective policies is closely related to the available medical resources and the required duration of restrictions (e.g., city lockdown). Different lockdown and restriction measures have been applied worldwide. A summary of the lockdown policies in China, England, Germany, and Japan is listed in Appendix.

Among the other cofactors, ambient temperature and humidity have been extensively investigated worldwide [16,17]. Ma et al. [18] discussed the effects of the ambient temperature on mortality in Wuhan, China. Liu et al. [19] and Xie and Zhu [20] discussed the effects of the

ambient temperature and absolute humidity on the number of confirmed cases in Chinese cities. Tosepu et al. [21] discussed the effect of weather on the number of confirmed cases in Jakarta, Indonesia. Briz-Redón and Serrano-Aroca [22] performed a spatiotemporal analysis of temperature during the early evolution of COVID-19 in Spain. A similar analysis was conducted using data from Oslo, Norway [23]. Furthermore, recent studies have evaluated the effects of temperature and relative humidity on the morbidity rates in Brazil [24,25]. A numerical study on the spread of COVID-19 in Croatia has also been reported [26]. Studies using global data have discussed how temperature and humidity are correlated with the infection and fatality rates of COVID-19 [27,28]. However, the timeframe of the spread in each country may be different and difficult to define.

Our previous study [29] conducted with data from Japan suggested that the population density, which is somewhat indicative of social distancing, was more significant than the meteorological factors. The effect of population density on the morbidity rate was also discussed in a case study of Iran [30]. These studies suggested that several cofactors introduce uncertainty. When discussing the effects of policies, a multi-city analysis representing different countries may be imperative. In multi-country analyses, the number of conducted tests may add uncertainty because this number depends on medical resources and regional

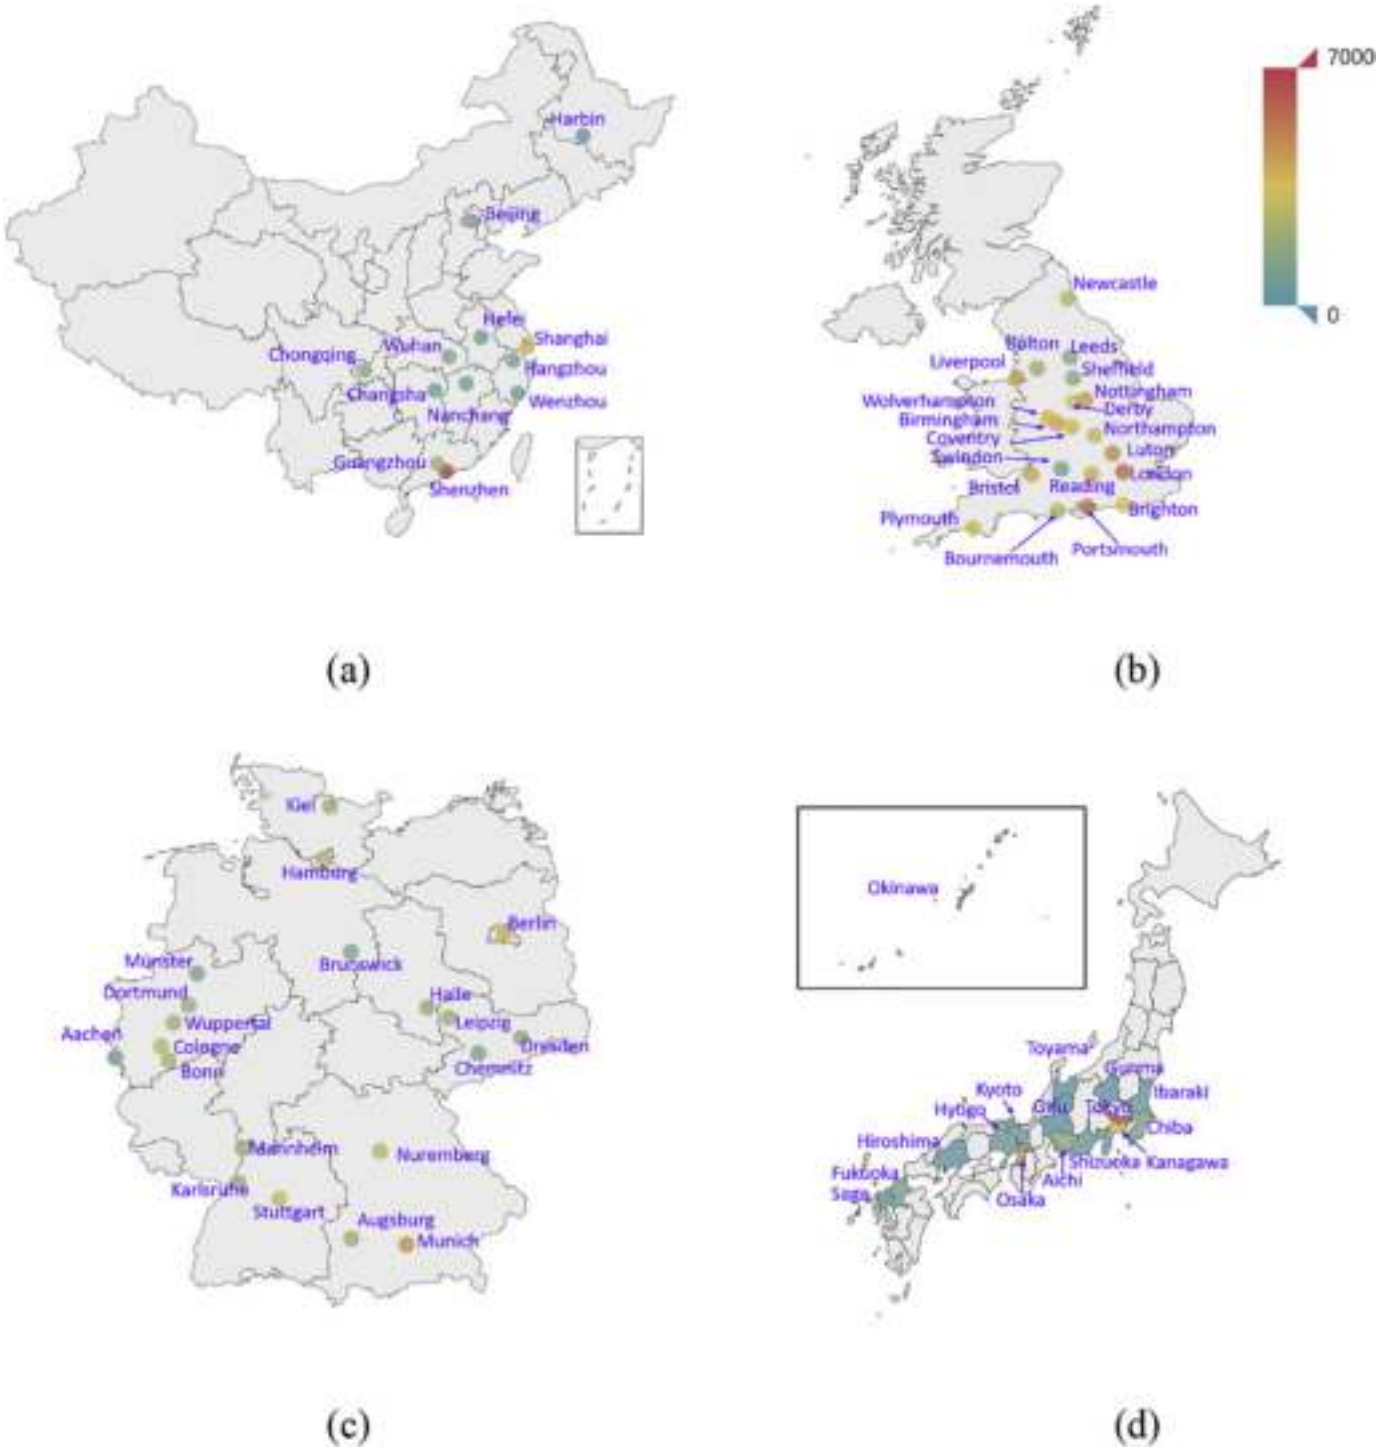

Fig. 1. Map of studied cities or prefectures and population density (people per km^2) in color scales in (a) China, (b) England, (c) Germany, and (d) Japan.

policies.

Unlike the morbidity and mortality rates, the duration of the pandemic may be less affected by different factors; e.g., it may not depend on the available medical resources. The understanding of the pandemic durations will be helpful for developing protection policies and governmental actions, to soften the potential damages to economy and social fabrics. In our recent study on 19 Japanese prefectures [31], the duration of the pandemic was discussed for the first time, and population density, absolute humidity, and temperature were found to be well-correlated in the spread stage. Conversely, the decay stage was predominantly affected by population density. The case study of COVID-19 in Japan provided insights into several environmental factors owing to the consistency and uniformity in data recording, healthcare quality, and social behavior. One open question is whether the findings obtained for one country can be applied globally.

The purpose of this novel study was to evaluate the effects of population density and meteorological factors on the pattern of spread and decay durations in cities or prefectures in four countries, including China, England, Germany, and Japan. To the best of our knowledge, a multi-country analysis focusing on the population, temperature and humidity factors of the COVID-19 duration has been hardly explored.

2. Material and methods

2.1. Study population

Data were collected for cities or prefectures from four countries, China, England, Germany and Japan, where medical resources collapse was not experienced (except for Wuhan, China). In our previous study [31], the correlation of population and meteorological factors with the spread and decay durations in Japan was studied. China is the first country reported the COVID-19 cases and imposed strict lockdown policies. England and German implemented restriction policies from March. The restrictions in all four countries have been eased before June. Moreover, the choice of the countries also depended on the data availability, the public accessibility of the statistics in city or prefecture level in the four countries allows the analyses to consider the effect of population and meteorological factors in fine resolution.

First, we selected the primate cities of each country, or those in which the pandemic began (Fig. 1). Wuhan was the first and most significant pandemic location in China. Data for municipalities directly under the central government and provincial capitals were collected. Those with a maximum daily increase in cases (7-day average) of less than 10 were excluded from the analysis. Wenzhou exhibited the largest daily increase outside Hubei Province, and it was also included. In England and Germany, we initially selected the cities with the highest population. However, several cities were excluded from the analysis if their daily case curves contained multiple peaks and did not decrease to 10% of the maximum 7-day average because the curves diverged from the bell-shaped model used. Finally, 20 cities in England and Germany were included in the analysis. In Japan, 16 prefectures had more than 10 confirmed daily positive cases; the data for these prefectures were included in the analysis.

2.2. Data sources

Three datasets were utilized in this study (shown in Table 1). The first dataset was the number of confirmed positive cases in each city. The data of the cities in China were collected from the dataset "China COVID-19 Daily Cases with Basemap" [32]. The data of the cities in England and Germany were collected from the referenced webpage [33] and NPGEO Corona Hub [34], respectively. The data of the prefectures in Japan were obtained from Toyo Keizai Online [35] and are based on a report by the Ministry of Health, Labour and Welfare [36]. The last date of data was June 23. Before June, the policies concerning the emergency in the four countries were eased. The number of confirmed positives may be influenced by the day of the week and latency, which is affected by the doctors' judgment. Therefore, we considered a moving average over 7 days (± 3 days in addition to the corresponding day) to reduce the effect of potential singularities.

The second dataset was population and population density in each city, as shown in Table 1. The population data of China were collected from the Statistical Yearbook for each municipality or province. The population data of England were collected from the Office for National Statistics [37]. The population data of Germany were collected from the Statistical Offices of the Federal Government and the Federal States [38]. The data of the prefectures in Japan were obtained from the Statistics Bureau of Japan [39].

The third dataset focused on weather information. The maximum and minimum temperature and relative humidity in China, England, and Germany were obtained from the National Centers for Environmental Information [40]. The weather data of each Japan prefecture were obtained from the Japan Meteorological Agency [41] during the time of the pandemic. The absolute humidity was derived from the relative humidity and ambient temperature data. The meteorological factors for the selected cities are shown in Table S1.

2.3. Outcome variables

In our previous study [31], the number of days required for spreading from 10 to 90% and those for decaying from 90% to 10% of the peak of the confirmed positives (7-day average), namely the spread duration (D_S) and decay duration (D_D), were established as metrics for evaluation of the time span of the pandemic outbreak. An illustration of the definition of the spread and decay durations are shown in Fig. 2 a). Fig. 2 b) shows the relationship between the two durations, *K*-means clustering ($n = 2$) was first applied to separate the data into two major groups. The red group mainly contained cities in China and Japan, whereas the green group contained cities in England and Germany. In the latter clustering, Birmingham and Wolverhampton (England), Berlin and Stuttgart (Germany), and Aichi and Saga (Japan) were excluded as outliers because they were not in the clustering circle. This tendency might have been caused by an overlap of repetitive smaller waves or cluster infections, which do not follow the theoretical spread curves. For example, dual peaks were observed in Aichi during the spread and decay stages.

2.4. Statistical analysis

Statistical analysis was then conducted to determine the correlation between different factors and the spread and decay durations. A multivariable analysis using linear regression was then conducted with the following model:

$$y = \beta_0 + \beta_1 \cdot PD + \beta_2 \cdot AH + \beta_3 \cdot T_{min} + \beta_4 \cdot T_{max} + \beta_5 \cdot T_{avg} + \epsilon \quad (1)$$

where β_0 is intercept, $\beta_1 - \beta_5$ are regression coefficients, ϵ is residual, y is the output variable i.e. D_S or D_D. In the equation, y linearly depends on a combination of independent variables of population density and meteorological factors. Statistical significance was accepted at $p < 0.05$, with test of null hypothesis that $\beta_i = 0$, $i = 1, \ldots, 5$.

3. Results

Fig. 3 shows the dependence of the spread and decay durations on the population density (also see Table S2). The overall correlation of the spread durations with the population densities of four countries was statistically significant ($p < 0.0001$); however, only Japan exhibited a statistical significance ($p < 0.05$) when each country was considered individually. A similar tendency was observed for the decay duration; the correlation with the population density was statistically significant ($p < 0.0001$) when data from all countries were included in the

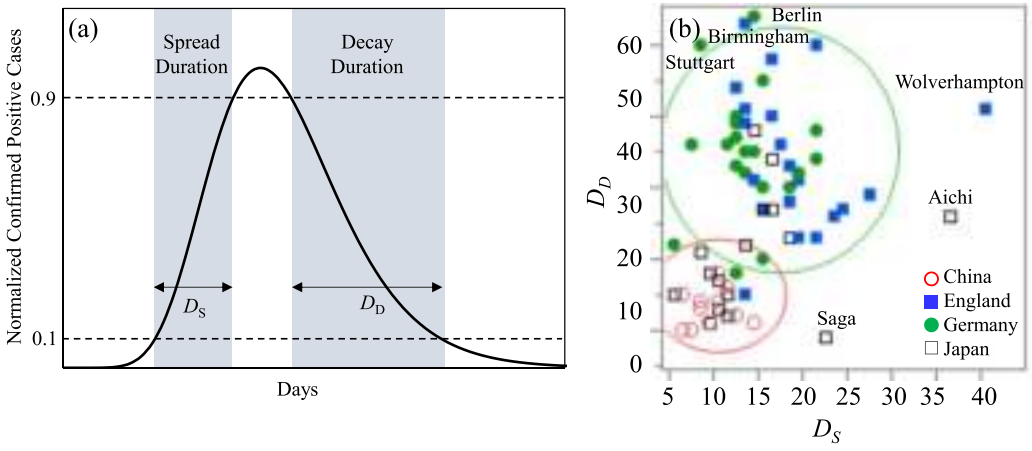

Fig. 2. (a) Definition of the spread (D_S) and decay durations (D_D) in days along the curve of daily normalized confirmed positive cases of COVID-19 [31]. (b) Relationship between D_S and D_D in days. The red and green ellipses mainly contain cities in China and Japan and those in England and Germany. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

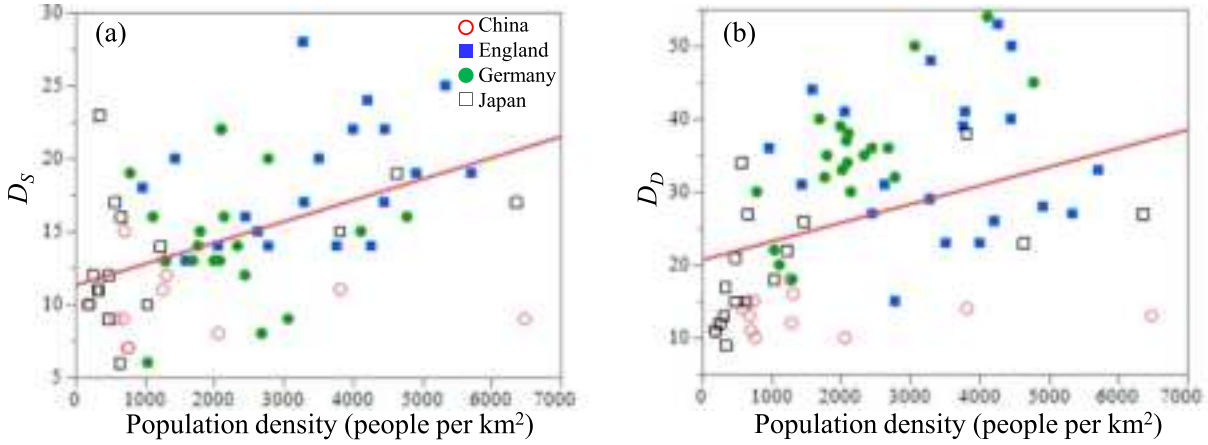

Fig. 3. Relationship of (a) spread and (b) decay durations (D_S and D_D, respectively) with population density.

evaluation. However, only Germany ($p < 0.005$) exhibited statistically significant correlations. The durations of the spread and decay stages were not influenced by the population density in China.

A multivariable analysis was conducted to investigate the relationship between the spread and decay durations of the pandemic with the absolute humidity and ambient temperature measured during the corresponding periods, as well as with the population density. As shown in Fig. 4 and Table 2, the duration of the spread period was characterized with respect to population density and absolute humidity, and the decay period was characterized with respect to population density, absolute humidity, and daily maximum temperature ($p < 0.0001$ for both the spread and decay durations). The maximum temperature was related to the maximum absolute humidity. Thus, multicollinearity was evaluated based on the variance inflation factors (VIFs). We used the threshold value of the VIF to differentiate between low and high contributions, which is commonly taken as 10 [42]. The higher the maximum temperature and absolute humidity, the shorter the spread and decay periods in the analysis of the four countries. The contributions of the population density were 64% and 28% in the spread and decay durations, respectively, and the remaining proportions were explained by the absolute humidity and temperature.

The decay duration in Germany exhibited statistical significances with population density, average temperature, and absolute humidity, the spread duration in England with population density and daily minimum temperature, and the spread period in Japan with population density and absolute humidity. The *p*-value of the decay period in Japan with respect to the daily maximum temperature was 0.063. As listed in Table 2, the residual spread and decay durations were 2.77 days and 6.60 days for all four countries, whereas the average residuals were 2.18 days and 3.84 days for the individual countries, respectively. The effect of population density was nonexistent in China, as shown in Fig. 3.

4. Discussion and conclusion

Understanding the potential risks during the pandemic is essential for managing medical resources. Furthermore, a model that can be used to estimate the potential spread and decay durations of the pandemic enables the implementation of evidence-based government policies.

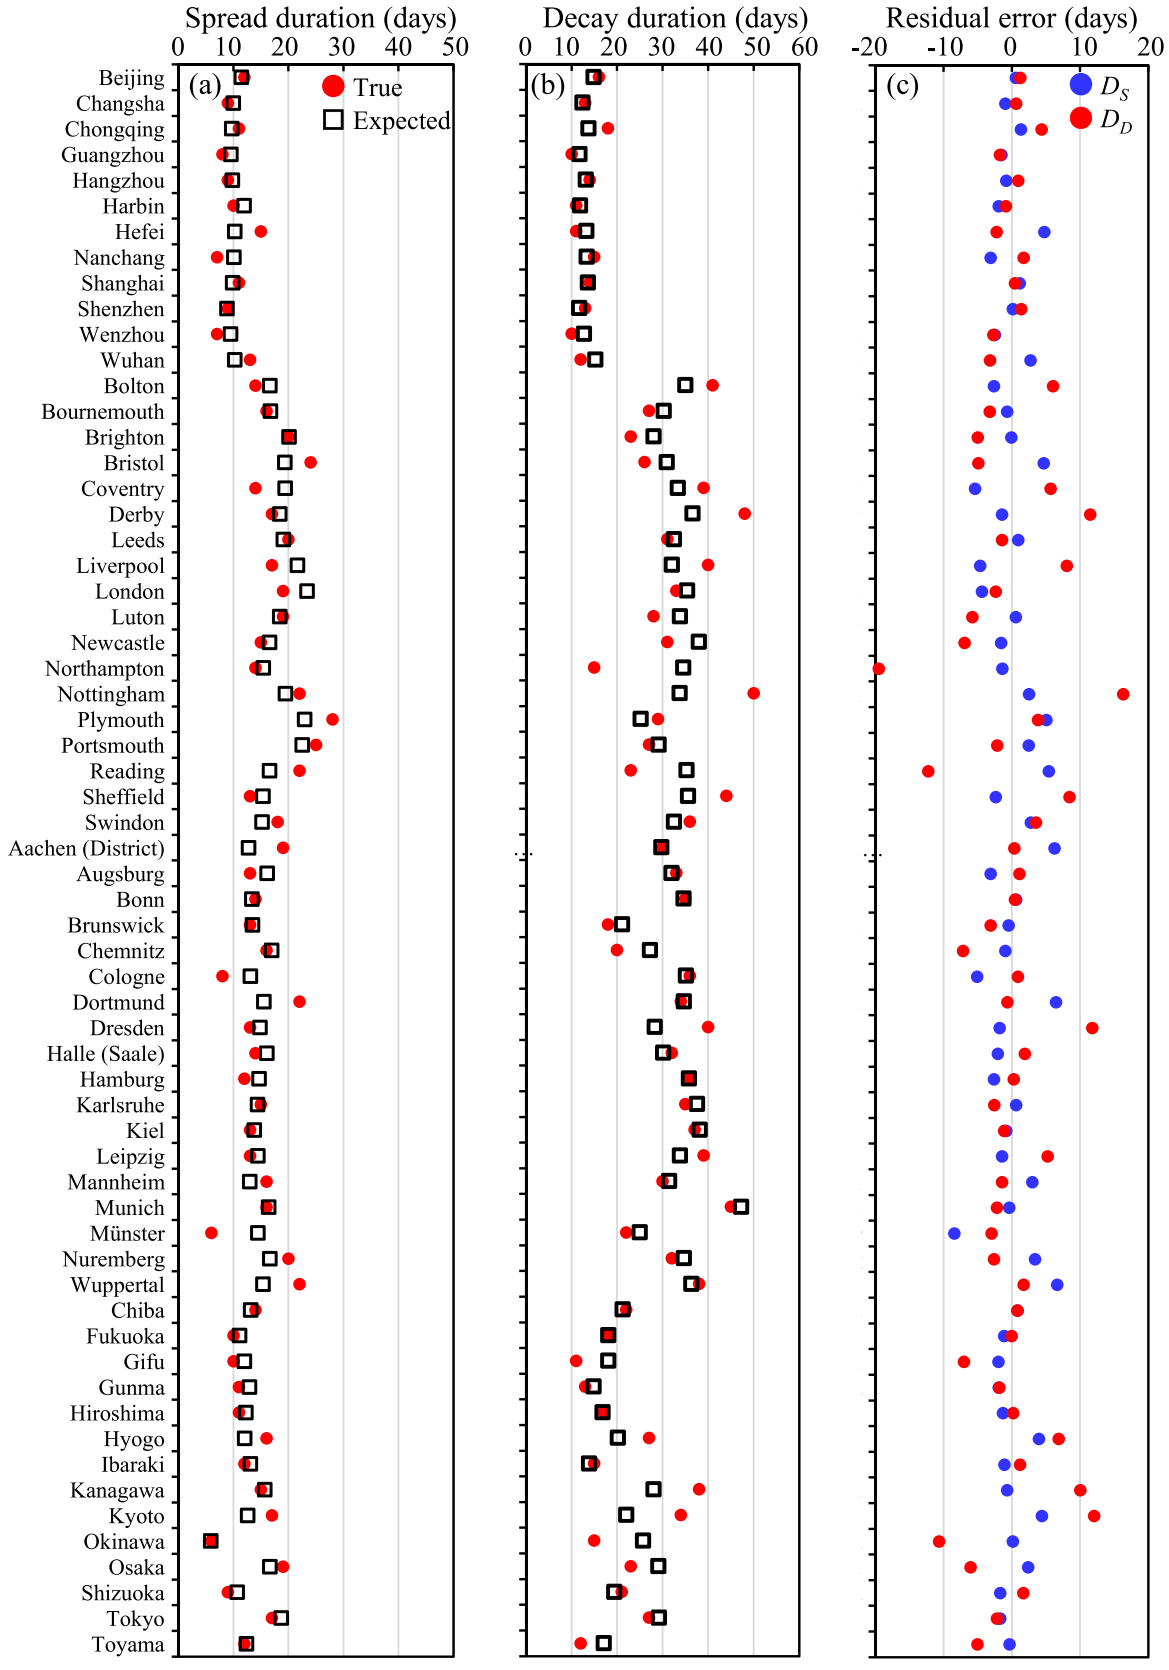

Fig. 4. Multivariable analysis with the variables listed in Table 2(b) for each country. The number of days of (a) spread duration, (b) decay duration, and (c) residual error.

Table 2
Multivariable analysis for spread (D_S) and decay (D_D) durations for (a) all countries and (b) individual countries. *PD* represents the population density. T_{ave}, T_{max}, and T_{min} represent the daily average, maximum, and minimum temperatures, respectively. *AH* represents the daily average absolute humidity values.

(a)	Variables	R^2	adj. R^2	*p*-value	VIF	Residual
D_S	PD, AH	0.32	0.30	<0.0001	1.00	2.77
D_D	PD, T_{max}, AH	0.35	0.32	<0.0001	1.74	6.60
(b)	Variables	R^2	adj. R^2	*p*-value	VIF	Residual
China						
D_S	AH	0.12	0.03	0.27	1.00	1.79
D_D	T_{max}, AH	0.21	0.03	0.35	7.88	1.78
England						
D_S	PD, T_{min}	0.39	0.30	<0.05	1.12	2.45
D_D	AH	0.12	0.06	0.16	1.00	6.34
Germany						
D_S	T_{min}	0.10	0.04	0.20	1.00	2.71
D_D	PD, T_{ave}, AH	0.68	0.61	<0.001	2.44	2.37
Japan						
D_S	PD, AH	0.66	0.60	<0.005	1.02	1.47
D_D	PD, T_{max}	0.40	0.29	0.06	1.20	4.10

This may reduce the potential damage to the economy, education, and various daily activities that have suffered during the lockdown restrictions. This study presented a data analysis of how meteorological factors and population density are correlated to the spread and decay durations of the COVID-19 pandemic in four countries, in some cities of which, the first wave has already decayed. Specifically, both durations exhibited a high correlation with the population density. Longer durations were expected in cities with higher population densities, implicitly suggesting the importance of social distancing [43]. This has been confirmed in cities of England and Germany, which was observed in Japan [31]. The opposite tendency found in China can be explained by the fact that the strict lockdown imposed social distancing despite the high population density.

Direct evaluation of the polices across different countries is difficult, owing to the differences in the testing rates, public response, culture etc. From the collected dataset and the analysis, the effect of policy may be implicitly inferred. In China, short durations and insignificant correlations of durations with population and meteorological factors were observed owing to the broadly strict lockdown policies. In England, mixed signals (such as "herd immunity") was sent out in the beginning, and criticism appeared for the government of not acting quickly in March. In Germany, in the beginning of the pandemic, the government responded with actions such as contact tracing and testing, followed by prohibition of gathering with strict punishment for violation. The multivariable regression analysis revealed significant correlations between spread duration and factors in UK, but not in Germany. The opposite trend observed for decay duration. In Japan, unlike many other countries where city lockdowns were enforced, citizens self-isolated during this state of emergency; stronger correlations for spread and decay durations observed. From these finding, it may be suggested that the strict restriction and its implementation may be related to less correlation of the durations of the pandemic waves with the population and meteorological factors.

Both temperature and absolute humidity were less correlated with the durations than with the population density. This study conducted a multivariable analysis considering population density, maximum and minimum temperature, and absolute humidity. The adjusted R^2 values were 0.30 and 0.32 for the durations of the spread and decay stages, respectively, and they were statistically significant. The spreading and decay durations were sufficiently estimated from the multivariable analysis; the residual spread and decay durations were 2.77 days and 6.60 days for all countries, whereas the average residuals were 2.18 days and 3.84 days for the individual countries. This suggested that we can estimate the durations based on these parameters. One limitation of the analysis in this study is that the daily-increase curves in some cities diverge from the bell-shape used for defining the spread and decay durations, owing to the repetitive sub waves and cluster infections.

In conclusion, the durations of the spread and decay stages of the COVID-19 pandemic were correlated with absolute humidity, temperature, and population density in four countries that did not experience a collapse of their medical systems. The contributions of these factors were different in each country, which could be attributed to regional policies. Although the morbidity and mortality rates differed by one to two orders of magnitude, these parameters were sufficient to estimate the durations. The higher population density tends to lead to prolonged spread and decay durations, while less correlations with the population and meteorological factors. The contribution rate of population density for multivariable are 30–50% in each country. The tendency of shortening duration with higher temperature and humidity reported by [31] was not clearly observed in Germany and England. These durations were affected by the policies and human behavior. With strict lockdown policies imposed (China), durations are shortened and their correlations with the population density and meteorological factor become insignificant. These findings will be useful in policy setting and governmental actions, such as determining the necessary shutdown length. This factor should be considered in another potential pandemic or next waves of COVID-19, in addition to the results of the multi-city comparison.

Appendix A. Policies in different countries

The rapid spread of the virus in China in early 2020 lead several countries to adopt drastic measures at different scales. China [44] enforced a strict lockdown, which started in Wuhan and expanded to the whole province. On February 10, Beijing and Shanghai, two of China's largest cities, restricted the movement of residents and vehicles, made wearing masks compulsory, and shut down leisure and other non-essential community services [45].

The first transmission of COVID-19 in England was confirmed in February. Initially, the government decided not to shut down large gatherings or introduce restrictions. On March 20, the Prime Minister announced in a television broadcast that all pubs, cafes, restaurants, bars, and gyms were to close. On March 23, a nationwide lockdown was announced. At this point, there were 2433 confirmed cases in London. The closure of pubs, restaurants, and indoor sports and leisure facilities was imposed via the Health Protection (Coronavirus, Business Closure) (England) Regulations 2020 [46]. On May 10, plans to ease lockdown restrictions were announced [47].

In Germany, authorities shut down schools and stopped major sports events on March 13, 2020, which was closely followed by further decisions regarding restaurants, shops, and other services [48]. The government banned gatherings in churches, mosques, and synagogues, and ordered the closure of non-essential shops, playgrounds, and schools. Moreover, regional trains were curtailed in an effort to reduce travel. On

May 6, Chancellor announced steps to ease the coronavirus lockdown in Germany [49].

In Japan, a state of emergency was declared nationwide on April 16 after being implemented to only seven prefectures on April 7 [50]. During this state of emergency, people self-contained voluntarily instead of a government-enforced lockdown of the prefectures. This state of emergency was discontinued on May 23.

Abstract: This study analyzed the spread and decay durations of the COVID-19 pandemic in different prefectures of Japan. During the pandemic, affordable healthcare was widely available in Japan and the medical system did not suffer a collapse, making accurate comparisons between prefectures possible. For the 16 prefectures included in this study that had daily maximum confirmed cases exceeding ten, the number of daily confirmed cases follow bell-shape or log-normal distribution in most prefectures. A good correlation was observed between the spread and decay durations. However, some exceptions were observed in areas where travelers returned from foreign countries, which were defined as the origins of infection clusters. Excluding these prefectures, the population density was shown to be a major factor, affecting the spread and decay patterns, with $R^2 = 0.39$ ($p < 0.05$) and 0.42 ($p < 0.05$), respectively, approximately corresponding to social distancing. The maximum absolute humidity was found to affect the decay duration normalized by the population density ($R^2 > 0.36$, $p < 0.05$). Our findings indicate that the estimated pandemic spread duration, based on the multivariate analysis of maximum absolute humidity, ambient temperature, and population density (adjusted $R^2 = 0.53$, p-value < 0.05), could prove useful for intervention planning during potential future pandemics, including a second COVID-19 outbreak.

Keywords: COVID-19; temperature; absolute humidity; population density; spread and decay durations

1. Introduction

Outbreaks of the infectious coronavirus disease of 2019 (COVID-19) have been reported worldwide [1,2]. In response, numerous studies on COVID-19 have been conducted on different aspects, including disease prevention, control, diagnosis, causes, and epidemiology [3]. A state of emergency was declared in 7 of Japan's 47 prefectures on 7 April 2020. This state of emergency was extended nationwide on 16 April and ended on 25 May 2020. During this state of emergency, people voluntarily self-isolated and no government-enforced lockdown of the prefectures (districts) was implemented.

Many epidemic modeling approaches exist [4] and various mathematical models have been used to demonstrate different aspects related to COVID-19, including serial intervals [5], transmission in China [6], and case studies in Wuhan, China [7], Italy [8], and Spain [9]. Comparisons among different countries have also been made [10] and the importance of different models in developing policies has

been discussed in [11]. Regarding the COVID-19 spread in Italy, a multivariate analysis study was conducted to evaluate the effect of different environmental factors on confirmed positive cases [12]. Three regions in Italy with high national infection rates were considered. In a time-series analysis, different factors were evaluated within each region. Strong correlations were found with different environmental factors, such as the average temperature, humidity, and wind speed. Although this study addressed how these factors were correlated with confirmed COVID-19 cases, it does not discuss their influence on disease spread and decay durations. However, it does provide a parameter fitting model based on local data within each region. Being able to estimate the duration of the epidemic in different prefectures would be useful for developing lockdown policies.

The duration and morbidity rates of COVID-19, however, are not easy to compare because different co-factors affect them. The number of polymerase chain reaction (PCR) tests, a simple and cost-effective test conducted in Japan was limited because of its reliability; therefore, chest computed tomography imaging was performed to obtain highly accurate diagnoses [13]. In addition, to avoid nosocomial infections and medical resource shortages, it was suggested that people with symptoms (e.g., fever > 37.5 °C for no more than four consecutive days) stay home and not seek immediate medical attention unless they had been in close contact with infected people or had recently visited a foreign country. Some patients have been reported to be asymptomatic [14], making the statistical study of COVID-19 more complex.

The statistics of confirmed deaths and COVID-19 positive patients are being updated every day in each prefecture of Japan. Furthermore, the Japanese medical system did not collapse during the outbreak, and the health insurance system provides COVID-19 medical care for free. However, the percentage of positive coronavirus tests ranges from 2.2 to 34.8% (Table 1) throughout Japan, making morbidity estimations in different areas more challenging. Assuming that the criteria for conducting a test are the same in each prefecture, the estimation of the epidemic duration provides a useful parameter.

Table 1. Population, area, and population density data of 19 prefectures where daily maximum cases of COVID-19 exceeded 10. Total cases of COVID-19 and mean percentages of the positive test cases are also listed.

	Population (×1000)	Population Density (People Per km^2)	Total Cases (Through 25 May)	Daily Max Cases	Percentage of Positive Test Results (%)

Environmental co-factors potentially influencing COVID-19 morbidity, including ambient temperature, absolute humidity, and air pollution, have been studied [15–22]. However, neither these studies nor the above-mentioned modeling studies have considered the impact of population density and ambient conditions on both the spread and decay duration [23]. In fact, the durations were not discussed at all. The necessity of population density scaling in epidemic transmission models has been suggested for infectious diseases in general [24], indicating that the factors characterizing the spread and decay durations might be different. Recent studies have confirmed the effect of temperature and relative humidity on morbidity rates in Brazil [22,25] and the morbidity/mortality rates in Japan [26]. Studies with wider scopes include global data analysis—discussion on how temperature and humidity are correlated with the infection and fatality rates of the COVID-19 pandemic [27,28]. Both studies focus on the morbidity and mortality rates in their respective study area and globally, but neither of them discusses the effect of environmental factors on the duration of COVID-19, which is an essential factor for policymaking. Its effect on the mortality and morbidity rates is still controversial; for example, no correlation with weather data was found in a study of 122 cities in China [19], whereas a correlation was reported in [15]. A report highlighting the duration of the pandemic spread may lead to better management of medical resources and protective gear, which is a well-known life-threatening factor during the evolution of COVID-19.

In this study, we evaluate the effect of different ambient conditions and population densities on the spread and decay durations of COVID-19 in different prefectures of Japan. To the best of our knowledge, this is the first study to discuss the effect of environmental factors during COVID-19 in Japan. Japan provides an interesting case study for environmental factors, because medical services and social reactions are similar nationwide and high-quality data were properly recorded.

2. Materials and Methods

2.1. Data Source

Three datasets were utilized in this study. The first dataset contains the number of confirmed positive cases in each prefecture that was obtained from Toyo Keizai Online [29] and is based on a report by the Ministry of Health, Labour and Welfare [30].

Because the state of emergency was terminated on 25 May 2020, this study utilized data from 15 March 2020, to that date. COVID-19 started spreading in mid-February in the Aichi Prefecture, which is the only prefecture where the spread started earlier than 15 March. As such, additional data were obtained from the Aichi Prefecture website [31] and included in this study.

The second dataset consists of population and prefecture area data that were obtained from the Statistics Bureau of Japan [32] (Table 1). Several prefectures are classified as geographically adjacent to primary prefectures (Tokyo, Osaka, Aichi, and Fukuoka; Table 1). In adjacent prefectures, several people were found to commute to the primary prefectures, thus potentially affecting the prefecture data, and should, therefore, not be neglected.

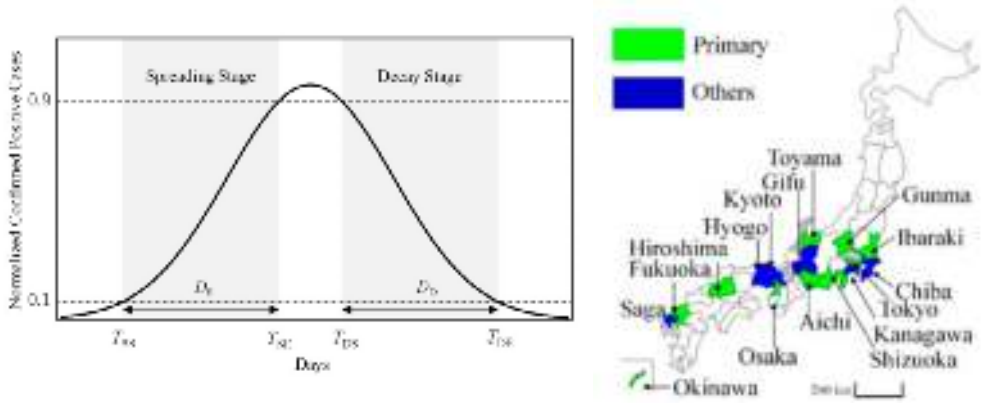
The third dataset contains weather data obtained from the Japan Meteorological Agency for each prefecture during the time of the pandemic. The absolute humidity was derived from the relative humidity and ambient temperature data [33].

2.2. Data Processing

The number of confirmed positive tests may be influenced by diagnostic data, based on Japanese guidelines, serial intervals, and latency, which is affected by each doctor's judgment; therefore, the moving average over 7 days (± 3 days in addition to the corresponding day) was considered to reduce the effect of potential singularities. This duration was used in the trajectory analysis of COVID-19 as well [34], also considering its incubation time (mean value of 5.1 days) [35]. Additional small peaks were still observed, which were attributed to clusters of patients (e.g., nosocomial infections, nursing home patients, and people returning from foreign countries). Similar to other countries, the number

of confirmed positives may depend on the day of the week (see [34]); in general, the number of tests conducted on weekends is lower than on weekdays.

This tendency prevents the direct fitting of the observed cases for comparison with a computational model (typically expressed as a bell-shape or a log-normal distribution, similar to the trend in theoretical models [36,37]). Therefore, our study introduces the criteria of days required for spreading from 10% to 90% and for decaying from 90% to 10% of the peak [38] of the confirmed positives (7-day average [34]), as metrics for the evaluation, as shown in Figure 1a. This metric is particularly useful for cases where the noise effect should not be neglected. A limitation of this metric is that a certain minimum number of samples is needed because if the number of samples is small, one or two new patients would significantly influence the results. Therefore, as a pre-processing step, prefecture data were excluded if the daily maximum number of confirmed positive cases was less than 10. In addition, the percentage of morbidity/mortality in nosocomial infections and nursing home patients should not be significant. In Ishikawa, however, 75% of the confirmed deaths were nosocomial infections. Two prefectures (Saitama and Shiga) were excluded from the analysis due to a lack of humidity data, which are essential for discussing the effect of ambient conditions on the spread and decay durations (see the data source in the next subsection). Based on this criterion, 16 prefectures met the minimum number of confirmed positive cases, as shown in Figure 1b.



(**a**) (**b**)

Figure 1. (**a**) Proposed definition of the spread and decay durations along the curve of the COVID-19 pandemic, which has been applied to the 7-day moving average of original data. Time parameters extracted from the definition are T_{SS} (start of spread), T_{SE} (end of spread), T_{DS} (start of decay), T_{DE} (end of decay), D_S (spread duration), and D_D (decay duration). (**b**) Map of Japan with 16 prefectures under study classified as primary prefectures and adjacent prefectures (others).

2.3. Statistics

A statistical analysis was conducted to determine the correlation between different factors and both the spread and decay periods of the pandemic using the software JMP (SAS Institute, Cary, NC, USA). To assist the pairwise correlations, we calculated the Spearman's rank correlation between the spread and decay durations normalized to the population density and different environmental parameters. The correlation matrix with partial correlation probabilities was also calculated. Subsequently, a multivariate analysis using linear regression was conducted using the same software. Statistical significance was accepted at $p < 0.05$.

3. Results

Table 2 lists the starting and terminating dates of the spread and decay stages (using moving averages) as well as the date of the peak value of daily confirmed cases (without averaging) observed for each prefecture. Figure 2 shows the time-series of the confirmed new positive cases for the spread and decay durations based on the data presented in Table 2.

Table 2. Starting and terminating dates of the spread and decay stages of the COVID-19 pandemic and the date (year 2020) when the highest daily peak value of confirmed cases was reported.

	T_{SS}	T_{SE}	Daily Peak *	T_{DS}	T_{DE}	D_S	D_D
Tokyo	17-Mar	3-Apr	17-Apr	10-Apr	7-May	17	27

* Moving average is not applicable for daily peak values.

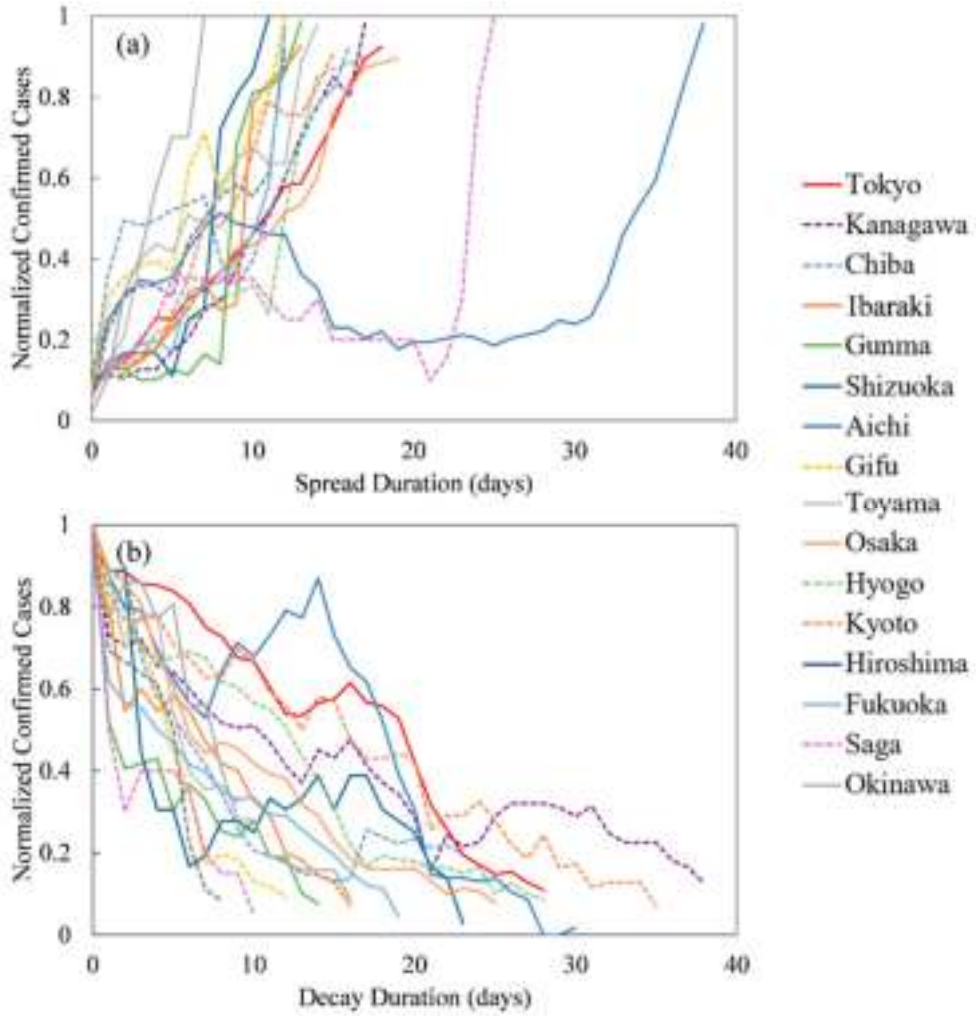

Figure 2. (**a**) Spread and (**b**) decay durations (in days) of 16 prefectures in Japan. Dashed lines represent the prefectures that are adjacent to primary prefectures (Tokyo, Osaka, Aichi, and Fukuoka).

As shown in Figure 2a, the number of normalized confirmed cases increased in most prefectures, and multiple peaks are observed in some prefectures. In Aichi, the start of the spread period, T_{SS}, was three weeks earlier than in the other studied prefectures (Table 2), and in mid-March, when traveling residents returned home from foreign countries in response to a call from the Japanese government, two large peaks are visible in the spread graph. A similar tendency is observed in Saga, while in Chiba, and Gifu, only small peaks are observed.

As shown in Figure 2b, which illustrates the pandemic decay timeline, the number of normalized confirmed cases decreased over time in most prefectures. Similar to Figure 2a, multiple peaks are observed in some prefectures, including Kanagawa and Hyogo. In Aichi, the second peak, whose magnitude is approximately 0.9 times the maximum value, occurred on 15 April 2020, and was caused by travelers returning from foreign countries [39].

Figure 3 illustrates the relationship between the durations of the spread and decay stages. These relationships are separated into two groups based on hierarchical clustering. The red group consists of metropolitan regions with a relatively high population density compared to the more rural blue group. Hereafter, the Aichi and Saga are considered to be outliers. Based on Figure 3, we hypothesize that population density is an important factor, and further investigation is required.

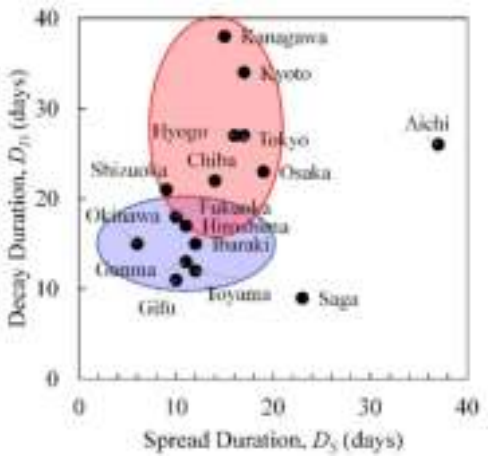

Figure 3. Relationship between the durations of spread and decay (in days). The red ellipse highlights prefectures with relatively high population densities, while the blue ellipse highlights those with lower population densities.

Figure 4 shows the relationship between the spread and decay durations (D_S and D_D) and the population density. The data of Aichi and Saga prefectures were excluded due to their outlier status. The resulting curves confirm the correlation between the spread and decay durations and the population density. The coefficients of determination of the spread and decay stages are 0.390 and 0.424 ($p < 0.05$), respectively.

For environmental factors, the mean daily temperature and humidity values listed in Table 3 were obtained for the two durations listed in Table 2. Figure 5 shows the effect of the ambient parameters on the spread and decay durations. The daily mean, maximum, and diurnal change values were selected based on previous studies on the influenza virus [40,41] and suggest that the temperature and humidity variations are likely correlated with the COVID-19 mortality rate [15]. As seen in Figure 5, such a correlation was observed for the data analyzed in this study. If the adjacent prefectures and those prefectures with multiple peaks in the curves are excluded, a mild correlation is observed for the maximum absolute humidity ($R^2 > 0.2$) with the spread and decay durations (see also Table 4). In both cases, including and excluding adjacent prefectures, the maximum absolute humidity is the parameter that correlates significantly with duration. A brief discussion on how maximum ambient temperature and maximum absolute humidity are correlated can be found in Appendix A.

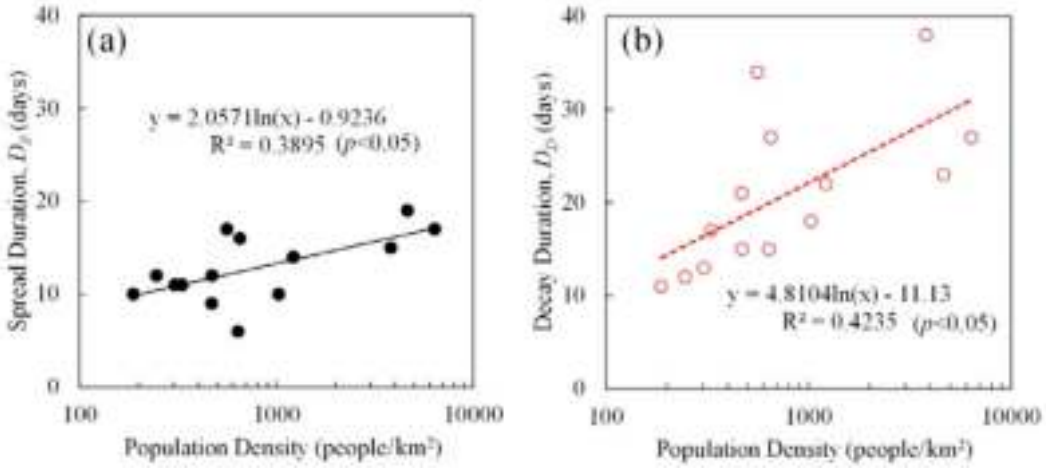

Figure 4. Relationship of the (**a**) spread and (**b**) decay durations (D_S and D_D) with population density.

Table 3. Daily average, maximum and minimum temperature, and absolute humidity values. The values are averaged during the spread and decay stages as listed in Table 2. T_{ave}, T_{max}, and T_{min} represent the daily average, maximum, and minimum temperatures, respectively. H_{ave}, H_{max}, and H_{min} represent the daily average, maximum, and minimum absolute humidity values, respectively.

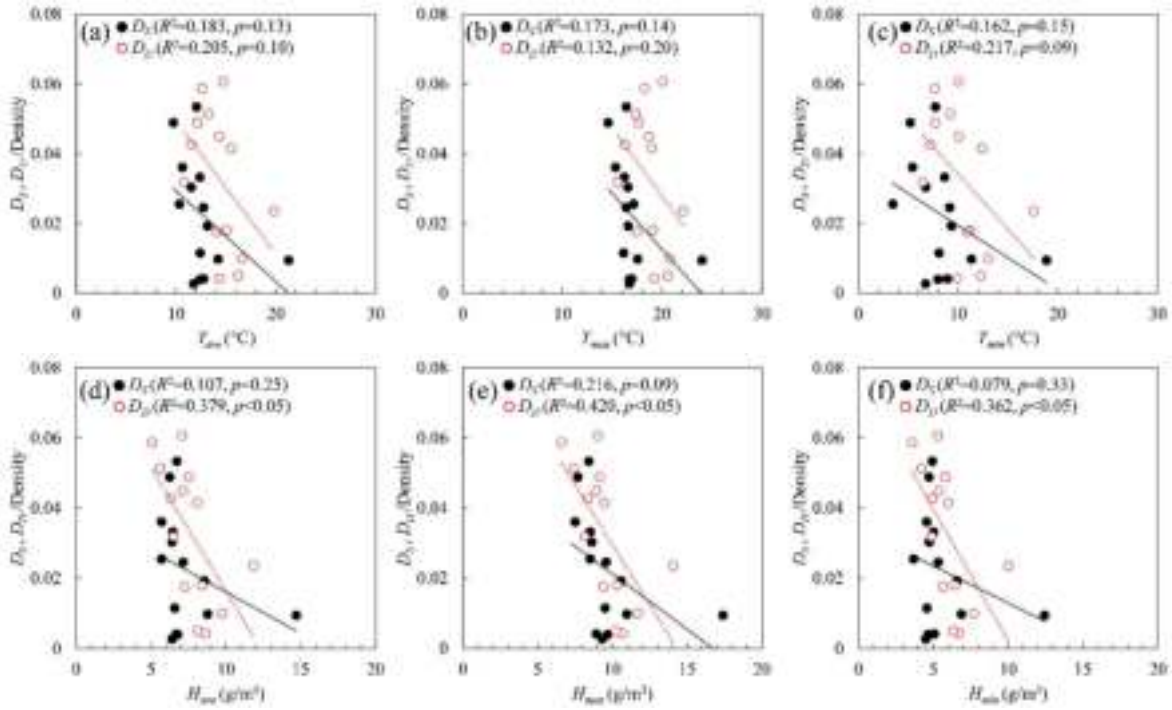

Figure 5. Relationship of the spread and decay durations (D_S and D_D) with (**a**) daily average temperature (T_{ave}), (**b**) daily maximum temperature (T_{max}), (**c**) daily minimum temperature (T_{min}), (**d**) daily average absolute humidity (H_{ave}), (**e**) daily maximum absolute humidity (H_{max}), and (**f**) daily minimum absolute humidity (H_{min}).

A multivariate correlation analysis was conducted to examine the relationship between the daily maximum temperature and absolute humidity values measured during the study period (pandemic spread and decay) and the population density (Figure 6). The data of Aichi and Saga prefectures were excluded due to their outlier status. The results yield adjusted R^2 values of 0.53($p < 0.05$) and 0.24($p = 0.130$) in the spread and decay stages, respectively, indicating variability within some prefectures, as shown in Table 5. The standardized partial regression coefficients of population density, daily maximum temperature, and absolute humidity are 0.611, 0.203, and −0.682, respectively, for the spread duration, while they are 0.388, 0.544, and −0.219, respectively, for the decay duration (Figure 6).

Table 5. Coefficients of determination R^2, adjusted R^2 values and p-values for the multivariate linear regression.

	R^2	adj. R^2	p-Value
D_S	0.641	0.533	<0.05
D_D	0.416	0.240	0.130

4. Discussion

The effect of temperature and humidity on morbidity and mortality has long been investigated in research on health problems caused by different environmental factors (e.g., [42,43]). Even for COVID-19, as reviewed in the introduction, their influence has been discussed extensively in different countries. A case study of COVID-19 in Japan highlights the environmental factors in view of the consistency of data recording, healthcare quality, and social response to the outbreak of the disease. The limitation of data, which is partly attributable to different policies in Japan, as in Section 2, is one factor hampering the analysis of available COVID-19 data. A further challenge is the large variation in data reliability, consistency, and uniformity.

In this study, the durations of the spread and decay stages were evaluated, for the first time, to assist with the setting of policies and action plans. Although the results obtained in this study cannot be directly implemented in all cases, it provides valuable insight into how environmental factors influence the transmission phase during a pandemic in a more general framework.

The COVID-19 spread and decay durations of 16 prefectures in Japan that had a daily maximum of confirmed positive cases exceeding 10 were compared. A definition of the metrics for both durations from 10–90% of the normalized confirmed cases has been introduced. Normalization was performed to avoid potential differences in the absolute number of cases reported among prefectures due to different regulations. One difficulty in handling the data was the lower number of cases in Japan compared to most other countries; for example, the number is one to two orders of magnitude smaller than that of most European countries (e.g., see [34]). As mentioned above, a time-series analysis of COVID-19 cases in Japan is not feasible due to the Japanese COVID-19 policy combined with the incubation period.

The results of this study show that the number of confirmed cases generally increased and then decreased, forming bell-shaped or log-normal curves [36,37]. However, significant dual peaks are

observed in Aichi and Saga during the spread stage and in Aichi, Saga and Tokyo during the decay stage. According to reports of each prefecture, this is mainly caused by patient clusters, which are attributed to nosocomial infections, nursing home patients, and travelers returning from foreign countries. In Aichi, at least one peak is caused predominantly by individuals who returned from foreign countries. The duration of such peaks is relatively short compared to the prefecture durations and generally shorter than the estimated ones. The total spread and decay durations in Aichi were shorter than 20 days for the first bell-shaped curve, whereas the estimated duration from the multivariate analysis was 35 days and thus may not be considered as a second outbreak. If the duration defining threshold is changed (e.g., 0.05. to 0.95), the tendency does not change for distributions following a bell-shape and the duration increases by 30%. However, some differences are apparent in prefectures where small peaks (i.e., cluster infections) are observed. In general, such prefectures have been excluded or treated separately, thus not influencing our conclusions.

Most noteworthy is the evaluation of the effect of population density on the spread and decay durations. The results for the primary prefectures show a good correlation between these parameters, indicating that population density functions as a rough proxy for social distancing [44]. Our data indicate that it significantly influences the formation of the bell-shape of the curve describing the pandemic. By normalizing our data using population density, we found good correlations between the temperature and absolute humidity, and the identified durations. This is surprising because the ambient conditions in the real world vary significantly with time (e.g., [45–47]). Regarding ambient condition parameters, the daily maximum absolute humidity had the greatest effect.

The parameters obtained with multivariate linear regression analysis were applied for the predictions: adjusted R^2 values are 0.53 ($p < 0.05$) and 0.24 ($p = 0.13$) for the spread and decay durations, respectively; that is, the decay duration is not statistically significant. The small peaks observed in the prefectures adjacent to the primary prefectures (Figure 2b) could be the potential reason for this.

This demonstrates that in adjacent prefectures the influence of the primary prefectures may not be neglected because residents commuting between the prefectures influence the spread and/or decay durations. For example, Hyogo prefectural governor decided to match the end of state emergency with that in Osaka; they are adjacent with each other.

Therefore, additional constraints were defined to exclude prefectures located adjacent to primary prefectures to avoid the influence of infections caused by neighboring major pandemic clusters. A set of nine prefectures demonstrated a strong correlation of the average absolute humidity and population density, yielding adjusted R^2 values of 0.896 ($p < 0.05$) and 0.681 ($p < 0.05$) in the spread and decay stages, respectively.

The importance of absolute humidity was suggested in previous studies on the morbidity/mortality rate of the influenza virus [48,49] and also in a preliminary study of COVID-19 [22]. Note that the differences in other parameters, including maximum and average temperatures, and average absolute humidity, show comparable correlations. In [22] the role of the ambient parameters could not be adequately constrained, and controversies and inconsistencies remained (see the review in "Introduction").

A straightforward comparison of our findings with those of different countries is not feasible because the data is measured based on different closure policies, testing rates, validation measures, etc., which would introduce several biases. Further factors influencing data accuracy are lockdown restrictions, social distancing, and public response. Recently, the effect of air-conditioning units on COVID-19 transmission has also been suggested [50]. This case study on the pandemic duration in Japan nevertheless provides a highly consistent result that may lead to a better understanding of this correlation.

5. Conclusions

This study investigates the correlation of the durations of the spread and decay stages of COVID-19 with ambient conditions and population density in 16 prefectures of Japan. Although the number of

cases reported in Japan is limited, the uniformity of the data provides a fairly consistent conclusion; the population density is dominant, and higher absolute humidity and temperature may result in shorter durations. Some exceptions exist, especially in prefectures where travelers returned from foreign countries. In addition, the durations in adjacent prefectures were influenced by the primary prefectures (e.g., Tokyo, Osaka, Aichi, and Fukuoka), resulting in longer durations. For a potential pandemic, especially a potential second wave of COVID-19, this factor should be considered as well as the multi-city comparison for developing different protection policies.

Author Contributions: Conceptualization, A.H.; Data curation, E.A.R. and S.K.; Formal analysis, S.K., J.G.-T. and A.H.; Investigation, E.A.R., S.K. and J.G.-T.; Methodology, A.H.; Project Administration, A.H.; Resources, E.A.R.; Software, E.A.R. and S.K.; Validation, E.A.R.; Visualization, S.K.; Writing—original draft, A.H.; Writing—review and editing, E.A.R., S.K., J.G.-T. and A.H. Funding: This research received no external funding.

Conflicts of Interest: The authors declare no conflicts of interest.

Appendix A

The relationship between the different ambient condition metrics and morbidity is often discussed (e.g., [51]). For the COVID-19 duration analyzed in this study, the correlation between the maximum temperature and maximum absolute humidity in the spread duration presented in Figure A1 are significant ($p < 0.05$). The duration of COVID-19 was generally limited to two months; thus, the metrics considered in the discussion of Figure 6 are correlated unlike the discussion of their annual impact on influenza (e.g., [49]).

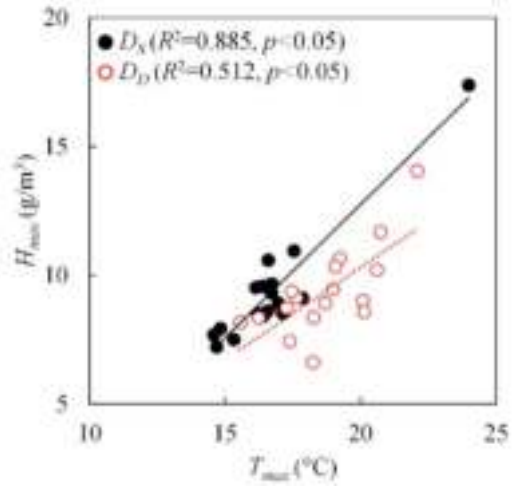

Figure A1. Relationship between maximum humidity and maximum temperature.

Meteorologic factors
Seasonality

ABSTRACT

Coronavirus disease (COVID-19) has infected more than 50 million people and killed more than one million, worldwide, during less than a year course. COVID-19, which has already become the worst pandemic in the last 100 years, is still spreading worldwide. Since the beginning of the outbreak, it has been of particular interest to understand whether COVID-19 is seasonal; the finding might help for better planning and preparation for the fight against the disease. Over the past 12 months, numerous empirical and epidemiological studies have been performed to define the distinct diffusion patterns of COVID-19. Thereby, a wealth of data has accumulated on the relationship between various seasonal meteorological factors and COVID-19 transmissibility at global and local scales. In this review, we aimed to discuss whether COVID-19 exhibits any seasonal features in a global and local perspective by collecting and providing summaries of the findings from empirical and epidemiological studies on the COVID-19 pandemic during its first seasonal cycle.

1. Introduction

Seasonality is a common feature of viral infections in humans and various animals (Dowell and Ho, 2004; Moriyama et al., 2020). For example, while human influenza virus, coronaviruses (HCoVs), and orthopneumoviruses exhibit an annual increase in incidence during winter (Shaman and Kohn, 2009), some non-polio enteroviruses have seasonal peaks in summer (Pons-Salort et al., 2018). As common HCoVs show seasonality, it is plausible to believe that severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), a member of the same family, could also exhibit seasonal features (Killerby et al., 2018; Ye et al., 2020).

SARS-CoV-2, the virus that causes coronavirus disease (COVID-19), was first identified in Wuhan, China, in December 2019. Since then, the virus has rapidly spread worldwide. As of November 9, 2020, more than 50,000,000 confirmed cases with more than 1,250,000 deaths have been reported (case fatality rate [CFR] of approximately 2.5%). During the first months of the outbreak, COVID-19 has shown an interesting diffusion pattern, as the transmission was restricted to a certain range of latitude, temperature, and humidity (Sajadi et al., 2020; Sarmadi et al., 2020). As COVID-19 is a novel disease, it has been challenging so far to corroborate its seasonality because of its short existence. However, statistical data on SARS-CoV-2 transmission have accumulated over the past 12 months, and this new information could provide clues that may explain the distinct diffusion patterns of COVID-19 in the pandemic.

The restricted pattern of spread of COVID-19 has been of great interest. This is because identifying the cause of the disparate diffusion pattern could prove useful in predicting how the COVID-19 situation might unfold. Although vaccine administrations have already begun, there have been reports of new variants of SARS-CoV-2, against which the already developed vaccines may be ineffective (Callaway, 2021). Furthermore, how long the antibody response will be sustained following a natural infection with SARS-CoV-2 is questionable as recent studies suggest that the humoral immunity against SARS-CoV-2 may be short-lived (Anna et al., 2020; Ibarrondo et al., 2020). In line with this, it was recently found that naturally infected individuals, especially those with mild symptoms, are prone to a reinfection (Ibarrondo et al., 2020; Seow et al., 2020). In fact, mounting evidence suggests that COVID-19 has the potential to become a seasonal illness like seasonal influenza (Lavine et al., 2021). This emphasizes the importance of understanding the transmission patterns of SARS-CoV-2, that is, whether it is a seasonal virus. While human-to-human interactions play a great role in viral diffusion, temperature and humidity can still alter human behavioral

SH	specific humidity

patterns, immune system functioning/response, and viral survivability in the external environment; these all ultimately contribute to high SARS-CoV-2 transmission (Al Huraimel et al., 2020; Bontempi et al., 2020; Bontempi, 2020, 2021; Courtemanche et al., 2020; Tammes, 2020). If the development of new vaccines will be constantly required, as with the yearly flu vaccine, establishing whether COVID-19 has seasonality will play a crucial role in future planning of vaccine development.

Here, we aimed to provide a synthesized summary of the findings of empirical and epidemiological studies on the impact of seasonal meteorological factors (e.g., temperature; absolute [AH], relative [RH], and specific humidity [SH]; precipitation; solar radiation/ultraviolet [UV]; wind speed; latitude; and air pollution) on COVID-19 transmissibility during the first seasonal cycle of the pandemic. Of note, we explicitly evaluated the findings of global and local studies separately; this is because sample size and regional disparities may have impacted the findings. By "global study", we refer to cross-country analysis with a dataset comprising data from 50 or more countries. Conversely, by definition, "local study" refers to cross-category analysis in a single country or cross-country analysis with a dataset of fewer than 50 countries.

2. Temperature forms an inverse relationship with the global transmission of SARS-CoV-2

Since the first COVID-19 case was reported in December 2019, the disease has now completed a full seasonal cycle. Between the time when COVID-19 transitioned from being an epidemic to being declared a real pandemic of global significance, regions with higher temperatures (>20°C) still reported lower numbers of COVID-19 cases than those with lower temperatures. Notably, 90% of SARS-CoV-2 transmission occurred within temperatures ranging between 3°C and 17°C in February and March 2020 (Bukhari and Jameel, 2020). Interestingly, the first few countries and cities with a rapid spread of COVID-19 (Italy, Iran, South Korea, and the US cities such as New York and Washington) exhibited a climate similar to the original hotspots of SARS-CoV-2 (Hubei and Hunan) with average temperatures between 3°C and 10°C (Bukhari and Jameel, 2020). In line with these observations, cities with substantial community spread (≥10 deaths as of March 10, 2020) showed average temperatures between 5°C and 11°C, which is indicative of a direct relationship between temperature and the transmission of SARS-CoV-2 (Sajadi et al., 2020). Comprehensively, the preferential distribution of SARS-CoV-2 globally is along the inverse latitudinal gradients (Bajaj and Arya, 2020); SARS-CoV-2 initially spread less prominently around the equator, but more prominently in regions with moderate and cold climates. Overall, these descriptive analyses from the early studies on COVID-19 raised the possibility that SARS-CoV-2 could be temperature-sensitive.

In congruence with these observations, empirical and epidemiological studies have corroborated an inverse relationship between temperature and global distribution of COVID-19 (Table 1). Correlation studies reported that the average temperature is negatively associated with both the proportion of deaths ($r = -0.5$, $p < 0.01$) and cases ($r = -0.5$, $p < 0.01$) per 10^5 population (Sarmadi et al., 2020). Pearson correlation analysis in another study revealed that average temperature negatively correlates with the attack rate, a similar concept as the CFR in terms of infectivity ($r = -0.36$, $p = 0.02$) (Hassan et al., 2020). This result is consistent with that of a study that used Spearman correlation analysis (Bezabih et al., 2020).

A simple linear regression (LR) model found that the air temperature at 2 m above the surface (2 m temperature) forms an inverse relationship with the log of the total number of cases in 50 different countries ($R^2 = 0.26$, $p < 0.001$) (Sajadi et al., 2020). In another simple LR analysis, average high temperature was reciprocally related to both total deaths ($\beta = -0.0377$, $R^2 = 0.4192$) and total cases per million population ($\beta = -0.0037$, $R^2 = 0.5875$) (Iqbal et al., 2020). A stepwise LR model fitted with R_0 displayed a negative relationship between temperature and SARS-CoV-2 infectivity (Metelmann et al., 2020). Fitting a simple LR on the exponential spread rate with the average temperature again exhibited a decreasing slope ($\beta = -0.0035$, $R^2 = 0.18$) (Notari, 2021). Equivalently, in studies using multiple meteorological variables, temperature showed a negative relationship with the total number of cases of SARS-CoV-2 infection ($\beta = -6.40$, $p < 0.01$) (Sobral et al., 2020). Accordingly, the Gutenberg-Richter law equation showed that a 1 °C increase in temperature results in decreased number of COVID-19 infections by 13–16 cases per day (Sil and Kumar, 2020). In addition, a generalized additive model (GAM), with a penalized spline function on the time variable, resulted in a negative trend between average temperature and the number of daily new cases in 166 countries ($\beta = -2.85\%$, $p < 0.01$) (Wu et al., 2020b). In accordance with all these studies, a micro-analysis of 9 locations across the globe (Italy, the United Kingdom, France, Sweden, Iran, the USA, South Korea, and Australia) showed a similar pattern, where regions with higher atmospheric temperature exhibited higher growth rates in the daily number of new cases with a median lag of 10 days (Rouen et al., 2020).

Whereas there was also a small number of studies showing no correlation between temperature and COVID-19 transmissibility (Islam et al., 2020; Jamil et al., 2020; Jüni et al., 2020) (Table 1), most studies showed an inverse relationship between temperature and the transmission of SARS-CoV-2 (Fig. 1).

3. Consistent with the global data, temperature forms an inverse relationship with local transmission of SARS-CoV-2

As COVID-19 was first reported in Wuhan, China, initial research regarding the effects of meteorological factors on SARS-Cov-2 transmission was heavily based toward China. Analysis of data collected from multiple Chinese provinces between December 2019 and February 2020 revealed that temperature and COVID-19 infection rates formed a negative relationship (Jiang et al., 2020; Wang et al., 2020). A parameterization analysis revealed that Chinese provinces with temperatures ranging from −9.41 to −13.87 °C experienced higher SARS-Cov-2 transmission rates (Lin et al., 2020a). Pearson correlation analyses on data collected from 31 Chinese provinces identified 14 provinces with a significant correlation ($p < 0.05$). Out of those 14 provinces, 12 showed a negative correlation between daily temperature and the number of infected cases (Rahman et al., 2020). A group of studies reported that with regression and correlation analysis, increment in temperature resulted in a decrease in the daily number of confirmed cases (Li et al., 2020a, 2020b; Liu et al., 2020b; Luo et al., 2020; Rouen et al., 2020; Oliveiros et al., 2020; Qi et al., 2020; Xie and Zhu, 2020). Several other studies analyzed variables from the Susceptible-Exposed-Infectious-Recovered (SEIR)

model with regression analysis and showed that the transmission rate was negatively related to temperature (Guo et al., 2020; Lin et al., 2020b). Similarly, a stepwise LR model, used to analyze data collected up to May 2020, when the COVID-19 spread was largely under control in China, displayed a negative relationship between the temperature and COVID-19 infectivity (Metelmann et al., 2020).

Studies showed that the acceleration of transmission dynamics of COVID-19 throughout Europe had a strong association with temperature (Benedetti et al., 2020; Ozyigit, 2020; Sanchez-Lorenzo et al., 2021). A simple LR analysis of the relationship between average temperature and COVID-19 case growth in EU-15 area countries (Austria, Belgium, Denmark, Finland, France, Germany, Greece, Ireland, Italy, Luxembourg, Netherlands, Portugal, Spain, Sweden, and the United Kingdom) following each country's 100th reported case, confirmed the coefficient for temperature effect on the COVID-19 case growth rate as −0.009 ($p < 0.01$). Therefore, a 0.9% decrease in SARS-CoV-2 transmission was expected following a 1 °C increase in the average temperature (Ozyigit, 2020). A model analysis of 25 locations from Europe and the USA suggested that the average monthly high temperature is inversely associated with COVID-19 deaths per million population (Benedetti et al., 2020). For Spain, an exponential regression model indicated that the temperature of a region (between 5°C and 11°C) determined the total number of cases and deaths due to COVID-19 (Sanchez-Lorenzo et al., 2021).

For Brazil, the dose-response relationship shown by a GAM suggested that temperature and the total number of daily cumulative confirmed cases of COVID-19 forms a negative relationship (Prata et al., 2020). Each 1°C rise in temperature led to a decrease in the cumulative daily number of COVID-19 confirmed cases by 5.18%. Likewise, Spearman correlation test results demonstrated that the average and maximum temperatures correlated negatively ($p < 0.01$) with the number of COVID-19 cases (Rosario et al., 2020). Not only in Brazil, but also in Latin America and the Caribbean (LAC), a negative relationship was shown between temperature and COVID-19 cases (Bolaño-Ortiz et al., 2020).

In the USA, from January 20, 2020, COVID-19 spread across its states at exponential rates (Holshue et al., 2020). In the US, states with maximum daily temperature above 52 °F (11 °C) showed an inverse relationship with the rate of new cases (incidence rate ratio = 0.85, 95% confidence interval (CI) = [0.76, 0.96], $p = 0.009$) (Sehra et al., 2020). A Gaussian function model demonstrated that deaths per million population in the largest cities of each state in the US peaked between 4 °C and 12 °C (Scafetta, 2020). Similar results were obtained in Mexico, where high temperatures established harsh conditions for SARS-CoV-2 survival and led to lower local transmission ratio and confirmed cases for a month (Méndez-Arriaga, 2020).

Although most data indicated an inverse association of viral spread with temperature, few findings were inconsistent with these. From March to April 2020, New York City experienced increasing new COVID-

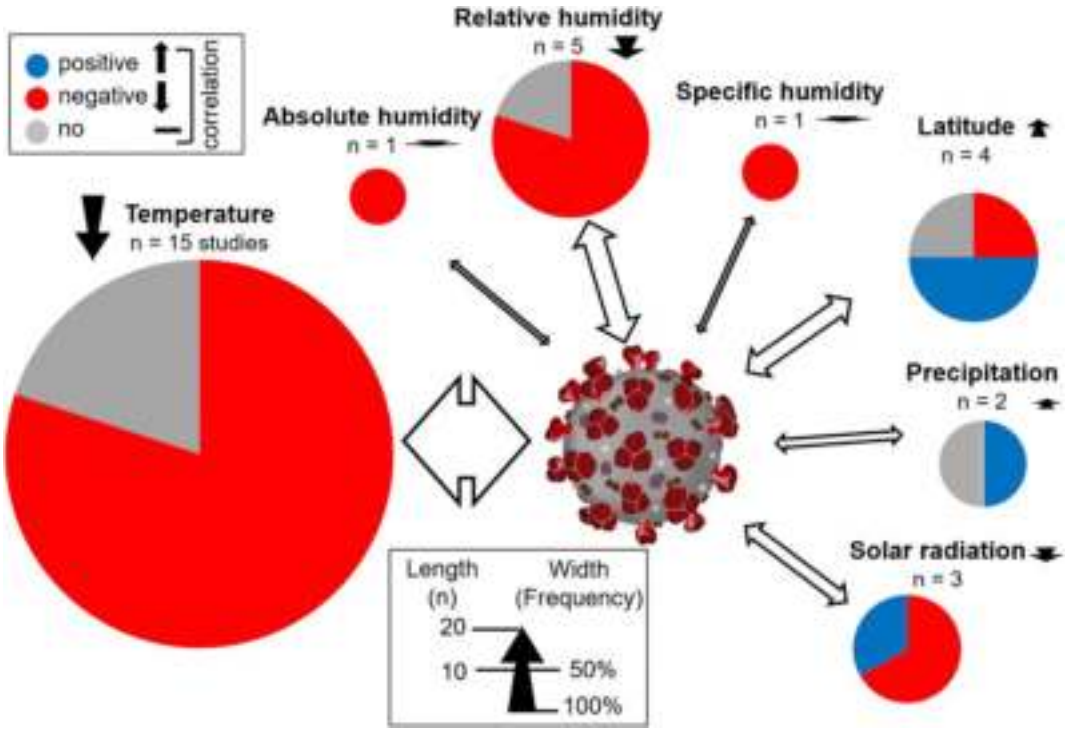

Fig. 1. The impact of meteorological factors on COVID-19 incidence at global scopes.

19 confirmed cases and mortality rates along with increasing city temperatures that ranged between 0°C and 18°C (Bashir et al., 2020). Similarly, Brazil and China also reported a positive relationship between temperature and the number of COVID-19 cases. Five state capitals in Brazil showed a higher case rate at elevated temperatures (Auler et al., 2020). As for China, 112 cities located on the northeast side of mainland China as well as 31 major cities across China followed the positively associated tendency (Xie and Zhu, 2020; Yao et al., 2020a). Besides, positive correlation between temperature and COVID-19 was observed in India, Norway and Singapore studies (Das and Chatterjee, 2020; Gupta et al., 2020; Mangla et al., 2020; Menebo, 2020; Pani et al., 2020). Notably, although SARS-CoV-2 first spread in the temperate zone (Chennakesavulu and Reddy, 2020; Huang et al., 2020; Sajadi et al., 2020; Sarmadi et al., 2020), India and Singapore are located outside the temperate zone, while Norway is at the most northern edge of the temperate zone. Interestingly, some studies also reported no correlation between temperature and the local transmission of SARS-CoV-2 (Briz-Redón and Serrano-Aroca, 2020; Chetty et al., 2020; Harbert et al., 2020; Wu et al., 2020a; Yao et al., 2020b) (Table 1).

Nevertheless, in the analysis of the association of temperature with

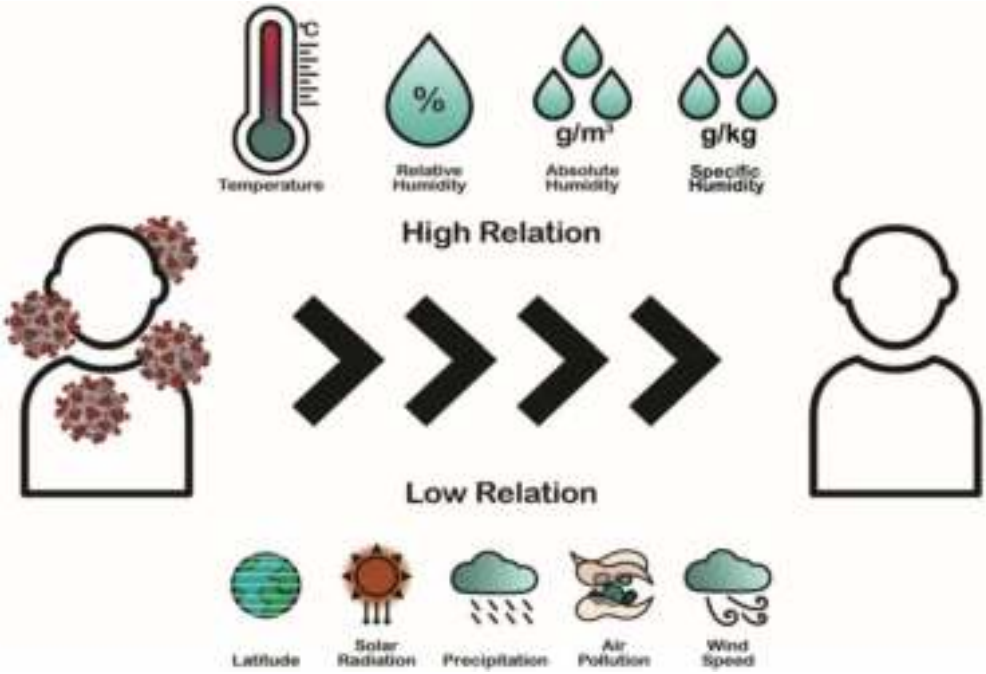

Fig. 2. Meteorological factors highly related with COVID-19 incidence at global scopes.

the local transmission of SARS-CoV-2, most studies reported, overall, an inverse relationship (Table 1 and Fig. 2). This is consistent with the general pattern observed for the global transmission of SARS-CoV-2 (Table 1).

4. Humidity tends to negatively correlate with the global transmission of SARS-CoV-2

Humidity, which is the concentration of water vapor present in the air is a decisive factor that determines the formation and size of aerosol droplets, which the virus can use as a medium to infect new hosts. Thus, humidity is an important meteorological variable that could affect the transmission of SARS-CoV-2 (Harper, 1961; Yang and Marr, 2011).

Pearson correlation analysis showed that RH is negatively correlated with the log of cases per million population ($r_H = -0.23$ with $P_{151}[-1 \leq r \leq r_H] = 0.2\%$) and the log of deaths per million population ($r_H = -0.31$, $P_{151}[-1 \leq r \leq r_H] \leq 0.01\%$) (Scafetta, 2020). When the effect of RH on daily new cases and daily new deaths was log-linearly analyzed using a GAM, a 1% increase in RH was associated with a 0.85% (95% Cl = [0.51%, 1.19%]) reduction in the daily new cases and a 0.51% (95% Cl = [0.34%, 0.67%]) reduction in daily new deaths (Wu et al., 2020b). A weighted random-effects regression analysis was concluded and showed that the epidemic growth of COVID-19 was reciprocally associated with both RH (ratios of rate ratios [RRR] per 10% = 0.91, 95% CI = [0.85, 0.96]) and AH (RRR per 5 g/m^3 = 0.92, 95% CI = [0.85, 0.96]) (Jüni et al., 2020). Congruently, studies using a LR model revealed a negative correlation between humidity and SARS-CoV-2 transmission (Metelmann et al., 2020; Sajadi et al., 2020). Only one study showed no correlation of humidity with global transmission of SARS-CoV-2 at all (Islam et al., 2020) (Table 2).

Overall, a fairly unequivocal effect of humidity on the global transmission of SARS-CoV-2 is observed (Table 2). Mounting evidence suggests that humidity negatively affects the global transmission of SARS-CoV-2 (Fig. 1).

5. Humidity may be a lesser determinant factor for local transmission of SARS-CoV-2

Till date, some studies have shown that humidity is negatively associated with SARS-CoV-2 transmission in China. In four major cities of China, RH correlated negatively with the reproductive rate (R_0) of SARS-CoV-2 ($r = -0.391$, $p = 0.000$) (Guo et al., 2020). Similar patterns were reported for AH, because a 1 g/m^3 increase in AH resulted in a decrease of 0.92 in the overall relative risk in 17 capital cities of China (Liu and Zhang, 2020).

Besides China, in some countries such as Spain, Italy, Turkey, LAC, and India, RH and SH were found to be inversely associated with local COVID-19 cases (Table 2). A polynomial regression analysis of cumulative data showed that SH is negatively associated with SARS-CoV-2 transmission in Spain (Sanchez-Lorenzo et al., 2021). A Pearson correlation analysis of regions in Italy revealed that RH is negatively correlated with the log of deaths per million population ($r_H = -0.37$, $P_{20}[-1 \leq r \leq rH] = 5.4\%$) (Scafetta, 2020). The same study showed, using a Gaussian function model, that states in the US with RH levels between 60 and 75% were the most affected by COVID-19, accounting for 80% of deaths in the USA. Studies that analyzed the association of humidity with COVID-19 cases using Spearman correlation analysis also drew consistent results. In New Delhi, RH was negatively associated with the number of daily COVID-19 infections between March 4 and June 24, 2020 ($r_s = -0.63$, $p < 0.05$) (Mangla et al., 2020). In addition, the number of COVID-19 infections was found to be negatively associated with SH in India (Gupta et al., 2020). In agreement, analysis of the data collected from 9 cities in Turkey between March 10 and April 5, 2020, revealed a negative relationship between RH and SARS-CoV-2 transmission ($r_s = -0.317$) (Şahin, 2020).

Contrarily, other studies indicated that humidity has no or a positive effect on the transmission of SARS-CoV-2 in China. In 31 Chinese provinces, a negative relationship between RH and doubling time of cumulative COVID-19 cases was shown; meaning that RH was positively associated with the rate of local COVID-19 progression (Oliveiros et al., 2020). Another analysis of data from 16 Chinese provinces concluded that RH and SARS-CoV-2 transmission rates have no significant spatial correlation ($R = -0.17$, $p = 0.48$) (Lin et al., 2020a). Similarly, multiple other studies did not find a significant association between RH and SARS-CoV-2 transmission in China (Li et al., 2020b; Metelmann et al., 2020; Rahman et al., 2020; Yao et al., 2020b).

Humidity was also observed to have a positive relationship with local SARS-CoV-2 transmission rates in the USA, Singapore, and the Netherlands (Table 2). When the relationship between RH and SARS-CoV-2 transmission in the USA was investigated using a distributed lag non-linear model with data collected from California, high RH was a

risk factor; RH of around 98% was related to an increased risk of SARS-CoV-2 transmission (RR = 1.703, 95% CI = [1.049, 2.765]) (Fang et al., 2020). In Singapore, both RH and AH were positively correlated to new COVID-19 cases, when analyzed using Spearman (RH: $r_s = 0.21$, $p < 0.05$; AH: $r_s = 0.59$, $p < 0.01$) and Kendall rank correlation analyses (RH: $\tau = 0.15$, $p < 0.05$; AH: $\tau = 0.45$, $p < 0.001$) (Pani et al., 2020). The average RH was 91% and the average AH was 22 g/m^3 over the period of the data collection. In the Netherlands, from March to July 2020, a spatiotemporal disease model affirmed that SH was strongly correlated with the number of daily COVID-19 cases ($r = 0.701$, $p = 0.000$; $r_s = 0.838$, $p = 0.000$) (Ravelli and Gonzales Martinez, 2020).

Overall, humidity may be a lesser determinant factor for local SARS-CoV-2 transmission (Fig. 3). Nevertheless, we cannot exclude the possibility that these inconsistent findings in the relationship between humidity and local transmission of SARS-CoV-2 may be attributed to sample size differences. Further studies are needed to clearly address the relationship between (absolute, relative, and specific) humidity and COVID-19 transmissibility.

6. Other meteorological factors related to SARS-CoV-2 transmission: Air pollution, wind speed, latitude, precipitation and solar radiation

Air pollution, wind speed, latitude, precipitation, and solar radiation are influential factors in determining seasonality in other respiratory viral infections (Domingo et al., 2020; du Prel et al., 2009; Price et al., 2019). However, whether there is a link between COVID-19 transmissibility and the aforementioned meteorological factors remains unclear (Table 3). As compared to temperature or humidity, fewer results are published regarding their possible contribution to SARS-CoV-2 transmission (Table 3). Additionally, the studies included in this review did not report cohesive results to indicate a distinct relationship between each of the factors and the transmission of SARS-CoV-2 (Figs. 2 and 3).

7. Discussion

Meteorological factors play a vital role in the transmissibility of HCoVs. In general, human and animal CoVs show a much higher persistence under low temperature and low RH (Aboubakr et al., 2020). Similarly, the spread of SARS-CoV-2 could be seasonally associated with the colder months. This phenomenon may be closely related to the increased persistence of airborne aerosols under a low temperature and low humidity environment, which increase the chance of infection of a new host (Harper, 1961). The amount of water vapor that a unit of air can hold diminishes at lower temperatures, and a reduction in the size of aerosol droplets occurs at lower humidity due to evaporation (Yang and Marr, 2011).

Higher persistence of SARS-CoV-2 resulting from low temperature could also be explained by the effects of temperatures on the structure of viruses. In high-temperature environments, the order of phospholipids in the viral envelope is disrupted, thus hindering the stability of the viral envelope (Polozov et al., 2008). Higher infectivity in low-temperature conditions could also be attributed to the changes in the receptor-binding motif (RBM) conformation. At temperatures between 10 and 30°C, the RBM is in an open conformation, which is more favorable for host cell receptor recognition and binding (Rath and Kumar, 2020).

It is also evident that meteorological factors have a strong impact on host susceptibility (Dowell, 2001; Fisman, 2007). A typical example would be the effects of temperature and humidity on the mucosal layer lining of the host respiratory tract (Moriyama et al., 2020). Prior studies found that both lower temperature and humidity trigger mucus hypersecretion, which impede the appropriate removal of viruses or foreign substances by the host mucociliary mechanisms, leading to increased virion stability in the host upper respiratory mucosa (Lowen et al., 2007;

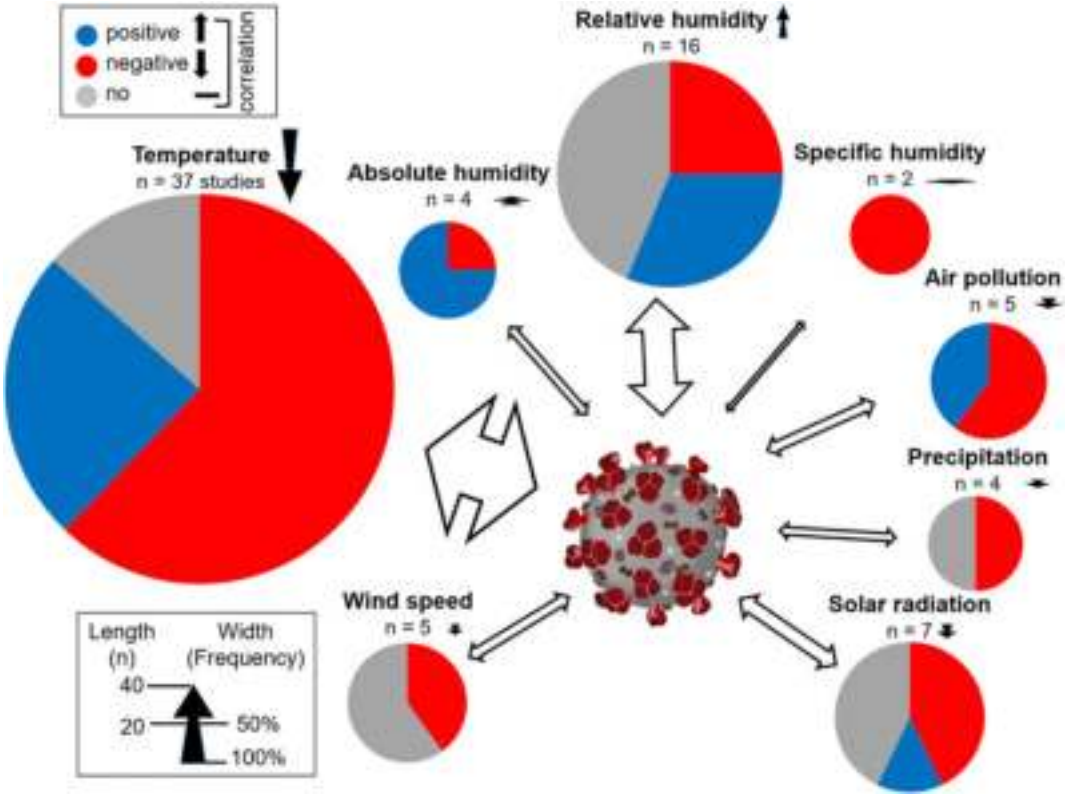

Fig. 3. The impact of meteorological factors on COVID-19 incidence at local scopes.

Tian and Wen, 2015; Wise et al., 2018). Reduced humidity also damages epithelial cell integrity and impairs the re-epithelialization process, allowing easier opportunities for the transmission of infection (Kudo et al., 2019). Furthermore, decreased body temperature is linked with lower expression of interferon-stimulated genes that are actively involved in the primary antiviral defense mechanisms (Foxman et al., 2015; Ivashkiv and Donlin, 2014).

Factors such as solar radiation may alter the seasonal perceptions of the human body by inducing changes in the melatonin mediated circadian rhythm (Nelson and Drazen, 1999). Such shifts in the seasonal perception leads to fluctuations in certain gene expression levels (Dopico et al., 2015; Goldinger et al., 2015). About 147 genes in our immune system are affected by meteorological changes; they are also associated with the processes involving B-cell receptor signaling, Fc receptor-gamma-associated processes, lysosomes, chemokine signaling, and phagosomes (Dopico et al., 2015). The same study proposed that the immune system-related genes are observed in a higher inflammatory status during winter months. This raises the likelihood of cardiovascular, autoimmune, and neurological diseases, further leading to human immune system susceptibility to viral infection.

Population density is another possible contributing factor to a high SARS-CoV-2 transmission rate (Diao et al., 2021; Li et al., 2018; Randolph and Barreiro, 2020; Sil and Kumar, 2020; Tarwater and Martin, 2001). A positive correlation between the population density of an area and the transmission rate has also been observed for viruses other than SARS-CoV-2, emphasizing the importance of taking population density into account when studying the seasonality of SARS-CoV-2 (Vanden Broecke et al., 2019). Mounting evidence suggests that population density has a high impact on the spread of COVID-19 by affecting contact rates (de Lusignan et al., 2020; Han et al., 2021; Kodera et al., 2020; Rocklöv and Sjödin, 2020; Tammes, 2020). The differences in the targeted region's population density could be a possible reason for the contradictory reports on the effect of various meteorological factors. Studies that collected data from cities with higher population densities reported a positive relationship between meteorological factors and SARS-CoV-2 transmission and vice versa (Bashir et al., 2020; Das and Chatterjee, 2020; Menebo, 2020; Pedrosa, 2020). Besides population density, variability in population behavior, air pollution, sewage, natural water has been proposed as other factors that may contribute to the different transmission rates of SARS-CoV-2 (Al Huraimel et al., 2020; Bontempi et al., 2020; Bontempi, 2020, 2021; Courtemanche et al., 2020; Liu et al., 2020a; Tammes, 2020). Behavioral measures such as wearing of masks have been proven to effectively prevent the spread of other known viruses like the influenza virus (Greenhalgh et al., 2020; Liu and Zhang, 2020). Such results indicate that other social factors should be considered when looking into the possible seasonality of COVID-19.

It is important to mention that this review could not have avoided a few methodological limitations. Firstly, most studies included in this review only considered the effects of meteorological factors on SARS-CoV-2 transmission, while neglecting the effects of factors that are dependent on human-to-human interaction. Such factors include social and economic factors such as population density, population behavior, lockdown policies and telecommuting. Certainly, there is a consensus on the fact that virus transmission is mainly caused by human-to-human interaction. Thus, any analysis claiming to find strong correlations without considering human-to-human interaction cannot establish a definite causal explanation (Bontempi, 2020). Secondly, each study included different types of data and utilized different methods in their analysis; these could possibly bring about contradictory findings amongst studies. For example, while some researchers used the absolute number of confirmed/death cases in their analysis, others employed a wide range of metrics such as the number of cumulative confirmed/death cases, R_0 and incidence rate. Coupled with the disparity in the use of a consistent metric of viral transmission, the variability in data collection, data screening approaches and statistical procedures renders the comparison amongst studies as an arduous task. This is especially true when comparing studies from a wide range of locations, where elements other than meteorological factors such as socioeconomic, geographic factors and spatiotemporal patterns are involved in the COVID-19 contagion. Indeed, considering the aforementioned limitations, we are not making a hasty claim that meteorological conditions are the only causative factors or the dominant factor of SARS-CoV-2 transmission. However, we conclude that a clear pattern can be observed, which is an inverse forcing of temperature and humidity on the spread of COVID-19 on a global scale.

8. Conclusion

Several empirical and epidemiological studies have indicated that temperature and humidity are the most significant factors affecting SARS-CoV-2 transmission. Studies collectively agree with the inverse forcing of temperature and humidity (AH, RH, and SH) on the global transmission of SARS-CoV-2. These general tendencies observed for SARS-CoV-2 transmission is consistent with the survivability of other HCoVs in various environmental conditions. Based on the studies presented here, COVID-19 appears to be temperature-sensitive and, therefore, seasonal. Along with the other meteorological factors, such as air pollution, wind speed, etc., analyses on local regions drew ambiguous conclusions on the effect of humidity on SARS-CoV-2 transmission. These discrepancies could be the product of other social and biological factors, such as population density, population behavior, social distancing, and host susceptibility. Nevertheless, as the coronavirus pandemic has just completed a full seasonal cycle, further studies are desirable to corroborate the negative correlation of AH, RH, and SH with the SARS-Cov transmissibility at local scales, if possible, with increased sizes of datasets.

The novel severe acute respiratory syndrome coronavirus type 2 (SARS-CoV-2) emerged in December 2019 and made a huge impact on human society. Different countries and regions have made different policies in control and prevention of the spread of SARS-CoV-2. It is known that the spread rate of a virus, i.e. SARS-CoV-2, heavily depends on population density.[1] Besides, population density has large impacts on the basic reproduction number (R_0) of SARS-COV-2.[2] It is also observed that patients in high-transmission areas have a higher incidence of severe coronavirus disease outcomes when compared with patients in low-transmission areas.[3] To this end, this study investigates the spread rates of SARS-CoV-2 in different regions with different population densities.

We calculated the spread rates of SARS-CoV-2 in different regions of the USA. The counties of the USA are categorized into four regions: the first region consisting of counties with a population density <50 persons/km^2, and the second, third and fourth regions consisting of counties with population densities between 50 and 200, between 200 and 800, and >800 persons/km^2. In this way, the population of the USA is roughly evenly categorized into the four regions, which include 72.3, 91.2, 102.2 and 61.3 million persons, respectively.

The spread rates of SARS-CoV-2 are calculated for each of the four regions. The calculations are based on the data collected by the data hub at the Johns Hopkins University from 1 March 2020 to 30 June 2020.[4] The spread rate of SARS-CoV-2 in a region is defined as the average number of new deaths in last 7 days per 1 million persons as follows:

$$\text{Rate} = \frac{\#\text{of new deaths in last 7 days}}{7} * \frac{1\,000\,000}{\text{Population}}$$

The rates are normalized to a million persons to ensure they are comparable among different regions with different populations. We employ the number of new deaths rather than the number of new infections because the latter number is very inaccurate due to two reasons. First, many people have little or no symptom after infection of SARS-CoV-2,[5] these people are not likely included in the number of infections. Second, number of infections heavily depends on the sufficiency of test facilities and reagents. When more tests are performed, the number of infections gets larger.

By analysis of the spread rates of SARS-CoV-2 in different regions, we have two observations. First, SARS-CoV-2 has higher spread rates in regions with high population densities than regions with low population densities. Before mid-April, when the spread rates of SARS-CoV-2 achieve maximal values for the four regions, the spread rate of SARS-CoV-2 in region 4 is higher than the spread rate in region 3, followed by the spread rates in region 2, which exceeds the spread rates in region 1 (Figure 1). On average, the spread rates in region 4 are 8.0 times as the spread rates in region 1 before 15 April 2020. Similarly, the spread rates in region 3 and region 2 are 3.9 and 1.7 times as the spread rates in region 1 before 15 April 2020. We note that SARS-CoV-2 achieves the maximal spread rates around mid-April in the four regions. However, control and prevention measures are adopted as early as 22 March 2020 when the residents of New York were required to stay home.[6] It was reported that the median time from illness onset to death is 18.5 days for SARS-CoV-2 infection.[7] Since the spread rate in this study is defined on number of new death, the spread rates achieve the maximal values at least 18.5 days after the control and prevention measures are adopted.

Second, we note that the control and prevention measures for SARS-CoV-2 have better effects in regions with high population density. From mid-April (11 April–20 April) to June (20 June–30 June), the spread rate of SARS-CoV-2 in region 4 is reduced to 8.1%. However, the spread rates of SARS-CoV-2 in regions 3,

Figure 1. The spread rates of SARS-CoV-2 in four regions from 1 March 2020 to 30 June 2020. The four regions are categorized by population density from low to high.

2 and 1 are reduced to 46.1, 73.3 and 100.6%, respectively, in the same time period. In other words, the control and prevention measures have very significant effects in region 4 (counties with very high population densities), i.e. the spread rate of SARS-CoV-2 is reduced for >10 times. On the other hand, the control and prevention measures have almost no effect in region 1 (counties with very low population densities), i.e. the spread rate of SARS-CoV-2 retains at the same level. In addition, the control and prevention measures have limited effect to reduce the spread rate of SARS-CoV-2 for region 3 as well.

Since region 1 and region 2 account for 50% of the population of the USA, it is worthy of discussion that should a standard control and prevention measure be made or how to make multiple-layer control and prevention measures, which are flexible for different regions. This study has proved that the spread rate of SARS-CoV-2 is strongly associated with population density, and diversified control and prevention measures should be made for different regions according to population density.

Estimating and explaining the spread of COVID-19 at the county level in the USA

Anthony R. Ives [1]✉ & Claudio Bozzuto [2]

The basic reproduction number, R_0, determines the rate of spread of a communicable disease and therefore gives fundamental information needed to plan public health interventions. Using mortality records, we estimated the rate of spread of COVID-19 among 160 counties and county-aggregates in the USA at the start of the epidemic. We show that most of the high among-county variance is explained by four factors ($R^2 = 0.70$): the timing of outbreak, population size, population density, and spatial location. For predictions of future spread, population density and spatial location are important, and for the latter we show that SARS-CoV-2 strains containing the G614 mutation to the spike gene are associated with higher rates of spread. Finally, the high predictability of R_0 allows extending estimates to all 3109 counties in the conterminous 48 states. The high variation of R_0 argues for public health policies enacted at the county level for controlling COVID-19.

[1] Department of Integrative Biology, University of Wisconsin-Madison, Madison, WI 53706, USA. [2] Wildlife Analysis GmbH, Oetlisbergstrasse 38, 8053 Zurich, Switzerland. ✉email: arives@wisc.edu

The basic reproduction number, R_0, is the number of secondary infections produced per primary infection of a disease in a susceptible population, and it is a fundamental metric in epidemiology that gauges, among other factors, the initial rate of disease spread during an epidemic[1]. While R_0 depends in part on the biological properties of the pathogen, it also depends on properties of the host population, such as the contact rate between individuals[1,2]. Estimates of R_0 are required for designing public health interventions for infectious diseases such as COVID-19: for example, R_0 determines in large part the proportion of a population that must be vaccinated to control a disease[3,4]. Because R_0 at the start of an epidemic measures the spread rate under "normal" conditions without interventions, these initial R_0 values can inform policies to allow life to get "back to normal."

The estimates of R_0 before intervention determine the intensity with which public health interventions must be applied, and the risk and magnitude of potential resurgent outbreaks. In these contexts, R_0 is a reference against which the success or failure of public interventions can be assessed. Using R_0 estimates to design public health policies is predicated on the assumption that the R_0 values at the start of the epidemic reflect properties of the infective agent and population, and therefore predict the potential rate of spread of the disease. Estimates of R_0, however, might not predict future risks if (i) they are measured after perceived risks have generated government actions or pre-emptive personal measures to reduce the spread rate[5–7], (ii) they are driven by stochastic events, such as super-spreading[8,9], or (iii) they are driven by social or environmental conditions that are likely to change between the time of initial epidemic and the future time for which public health interventions are designed[10,11]. To address these potential limitations for using R_0 to design public health policies and future risks of spread, we investigated possible underlying causes for variation in estimates of R_0 among counties: if the causes are unlikely to change in the future, then so too are values of R_0 unlikely to change.

Policies to manage for COVID-19 in the USA are set by a mix of jurisdictions from state to local levels. We estimated R_0 at the county level both to match policymaking and to account for possibly large variation in R_0 among counties. To estimate R_0, we performed the analyses on the number of daily COVID-19 deaths[12]. We used death count rather than infection case reports, because we suspected that the proportion of reported deaths due to COVID-19 is less sensitive to variation in testing rates and methods. We recognize that some deaths due to COVID-19 will go unreported (e.g., the growing evidence from "excess deaths"[13,14]) and that different counties and states may use different criteria for determining the cause of death as COVID-19. Nonetheless, due to the mathematical structure of our estimation procedure, unreported deaths due to COVID-19 and differences among counties in reporting criteria will have little effect on our estimates of R_0; specifically, the estimates of R_0 for a given county will not change provided the proportion of unreported deaths in a county does not change through time. We analyzed data for counties that had at least 100 reported cumulative deaths by 23 May, 2020 ("Methods"), and for other counties we aggregated data within the same state, including deaths whose county was unknown. This led to 160 final time series representing counties in 39 states and the District of Columbia, of which 36 were aggregated at the state level. Some states, even after aggregating data from all counties, did not reach the 100-threshold of cumulative deaths, and therefore the spread rate for these states was not estimated.

We found high variance in the spread rate of COVID-19 among counties, most of which is explained by four factors: the timing of the county-level outbreak, population size, population density, and spatial location. Population density is likely an indicator of the average contact rate among people, and its explanatory power in the statistical model makes it an important predictor of future spread. Spatial location is also important, and we show that some of the effect of spatial location could be caused by differences among strains of SARS-CoV-2 that dominated in different parts of the USA. Using the statistical model, we estimated R_0 at the county level for the entire conterminous USA, giving information to design public health policies for controlling COVID-19.

Results

Estimates of the spread rate. Before estimating R_0, we first estimated the rate of spread of the virus-caused COVID-19 as the rate of increase of the daily death counts, r_0. Although this approach is not typically used in epidemiological studies, it has the advantage of being statistically robust even when the data (death counts) are few, and it makes the minimum number of assumptions that could affect the estimates in unexpected ways (Supplementary Methods: Overview of Statistical Methods). We applied a time-varying autoregressive state-space model to each time series of death counts[15,16]. In contrast to other models of COVID-19 epidemics[17–19], we do not incorporate the transmission process and the daily time course of transmission, but instead we estimate the time-varying exponential change in the number of deaths per day, $r(t)$[20]. Detailed simulation analyses (Supplementary Methods: Simulation model) showed that estimates of $r(t)$ generally lagged behind the true values. Therefore, we analyzed the time series in forward and reverse directions, and averaged to get the estimates of r_0 at the start of the time series (Supplementary Fig. 1); this approach counterbalances the lag in the forward direction with the lag in the backward direction, thereby reducing the lag effect. The model was fit accounting for greater uncertainty when mortality counts were low, and confidence intervals of the estimates were obtained from parametric bootstrapping which is the most robust approach for low counts. Thus, our strategy was to use a parsimonious model to give robust estimates of r_0 even for counties that had experienced relatively few deaths, and then calculate R_0 from r_0 after the fitting process using well-established methods[21].

Our r_0 estimates ranged from close to zero for several counties to 0.33 for New York City (five boroughs); the latter implies that the number of deaths increases by a factor of $e^{0.33} = 1.39$ per day. There were highly statistically significant differences between upper and lower estimates (Fig. 1). Although our time series approach allowed us to estimate r_0 at the start of even small epidemics, we anticipated two factors that could potentially affect our estimates of r_0 that are not likely to be useful in explaining future spread rates. The first factor is the timing of the onset of county-level epidemic: 35% of the local outbreaks started after the declaration of COVID-19 as a pandemic by the WHO on 11 March, 2020[22]. Therefore, we anticipated estimates of r_0 to decrease with the Julian date of outbreak onset due to changes in human behaviors caused by public awareness about COVID-19[7]. Because our goal was to estimate disease spread under "normal" conditions, we wanted to factor out the effect of timing. We used the second factor, the size of the population encompassed by the time series, to factor out statistical bias from the time series analyses. Simulation studies showed that estimates for time series with low death counts were downward biased (Supplementary Fig. 2). Because for a given spread rate $r(t)$ the total number of deaths in a time series should be proportional to the population size, we used population size as a covariate to remove bias. In addition to these two factors that we do not think have strong predictive value for the future rate of spread, we also anticipated effects of population density and spatial autocorrelation. Therefore, we regressed r_0 against outbreak onset, population size,

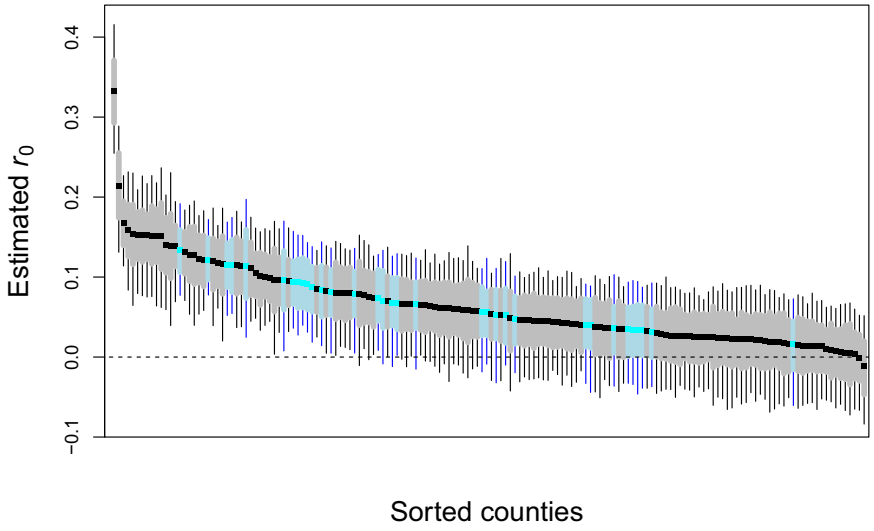

Fig. 1 Estimates of initial spread rate, r_0. The figure shows r_0 point estimates (in black), sorted by magnitude, for 124 counties (gray) and 36 county-aggregates (blue), with 66% (bars) and 95% (whiskers) bootstrapped confidence intervals.

and population density, and included spatially autocorrelated error terms.

Explaining variation in r_0. The regression analysis showed highly significant effects of all four factors (Table 1), and each factor had a substantial partial R^2_{pred}[23]. The overall R^2_{pred} was 0.70, so most of the county-to-county variance was explained. We calculated corrected r_0 values, factoring out outbreak onset and population size, by standardizing the r_0 values to 11 March 2020, and to the most populous county (for which the estimates of r_0 are likely best). Counties with low to medium population density never had high corrected r_0 values, suggesting that population density sets an upper limit on the rate of spread of COVID-19 (Fig. 2a), in agreement with expectations and published results[1,24]. Nonetheless, despite the unequivocal statistical effect of population density ($P < 10^{-8}$, Table 1), the explanatory power was not high in comparison to the entire model (partial $R^2_{pred} = 0.14$), probably because population density at the scale of counties will be only roughly related to contact rates among people. The contact rates will likely depend on a wide variety of additional factors, such as transmission through social gatherings, colleges, and nursing homes.

Spatial autocorrelation had strong power in explaining variation in r_0 among counties (partial $R^2_{pred} = 0.48$, Table 1) and occurred at the scale of hundreds of kilometers (Fig. 2b). This spatial autocorrelation might reflect differences in public responses to COVID-19 across the USA not captured by the variable in the regression model for outbreak onset. For example, Seattle, WA, reported the first positive case in the USA, on 15 January 2020, and there was a public response before deaths were recorded[25]. In contrast, the response in New York City was delayed, even though the outbreak occurred later than in Seattle[26]. Spatial autocorrelation could also be caused by movement of infected individuals. However, movement would only lead to autocorrelation in our regression analysis if many of the reported deaths were of people infected outside the county; while some deaths were likely caused by infections from outside counties, privacy restrictions on case data make these data hard to obtain, and we assume that such deaths are a small proportion of the total. A further possibility is that spatial variation in the rate of spread of COVID-19 reflects spatial variation in the occurrence of different genetic strains of SARS-CoV-2.

To investigate whether spatial autocorrelation could potentially be caused by different strains of SARS-CoV-2 differing in transmissibility, we analyzed publicly available information about genomic sequences from the GISAID metadata[27]. Scientific debate has focused on the role of the G614 mutation in the spike protein gene (D614G) to increase the rate of transmission of SARS-CoV-2[28]. We, therefore, asked whether the proportion of strains containing the G614 mutation was associated with higher rates of COVID-19 spread. Because the genomic samples are only located to the state level, we performed the analysis accordingly, for each state selecting the r_0 from the county or county-aggregate with the highest number of deaths (and hence being most likely represented in the genomic samples). We further restricted genomic samples to those collected within 30 days following the outbreak onset we used to select the data for time-series analyses, and we required at least five genomic samples per state. This data handling resulted in 28 states available for analysis. We again used our regression model (Eq. 3), now including the proportion of strains having the G614 mutation instead of spatial location. The proportion of samples containing the G614 mutation had a positive effect on r_0 ($P = 0.016$, Table S1). The low proportion of strains containing the G614 mutation in the Pacific Northwest and the Southeast were associated with lower values of r_0 (Fig. 3).

Before analyzing the full GISAID data, we analyzed a subset from Nextstrain[29] naïvely, without engaging the specific hypothesis that the G614 mutation increased transmission. This naïve analysis

Table 1 Factors explaining the initial spread rate of COVID-19 for 160 county and county-aggregates in the USA.

	Coefficient	SE	t	P	partial R^2_{pred}
Onset	−0.0019	0.0004	−4.59	10^{-4}	0.11
Log(size)	0.0247	0.0028	8.92	$<10^{-8}$	0.36
Density$^{1/4}$	0.025	0.0028	8.92	$<10^{-8}$	0.14
Space	Range = 5.71 Nugget = 0.33		$\chi^2_2 = 73$	$<10^{-8}$	0.48

Results of the regression of the estimates of the initial spread rate, r_0, against (i) the date of outbreak onset, (ii) total population size and (iii) population density, in which (iv) spatial autocorrelation is incorporated into the residual error. Transforms of population size and density were selected to best-fit the data and satisfy linearity assumptions. The coefficient column contains the estimate of the regression parameters with their associated t-tests; spatial autocorrelation is characterized by a range and nugget for regional and local sources of variation, and their joint significance is given by a likelihood ratio test. For the overall model, $R^2_{pred} = 0.70$, and the residual standard error is 1.19.

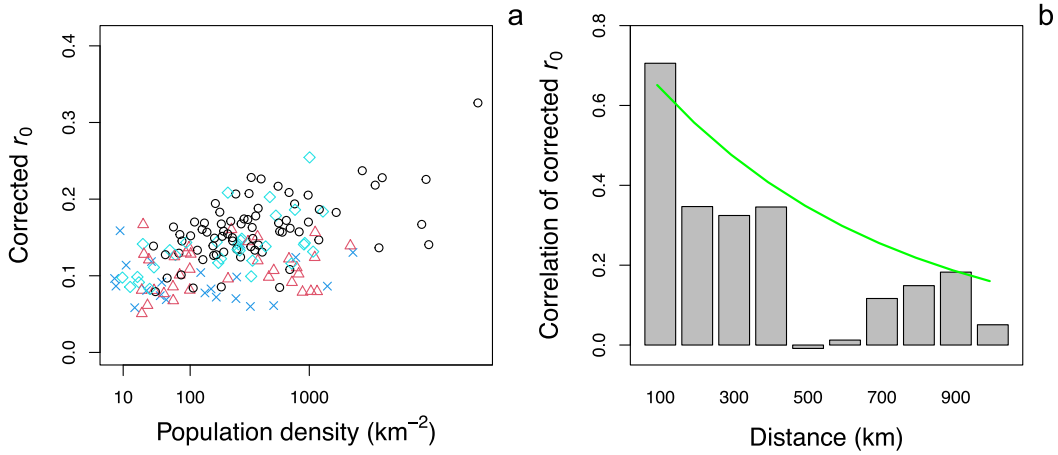

Fig. 2 Estimates of initial spread rates, r_0, after correcting for the effects of outbreak onset and population size. a Effect of population density: Northeast, black circles; Midwest, cyan diamonds; South, blue x's; West, red triangles. **b** Effect of spatial proximity depicted by computing correlations in bins representing 0–100 km, 100–200 km, etc. The line gives the spatial autocorrelation of the residuals from the fitted regression (Eq. 3).

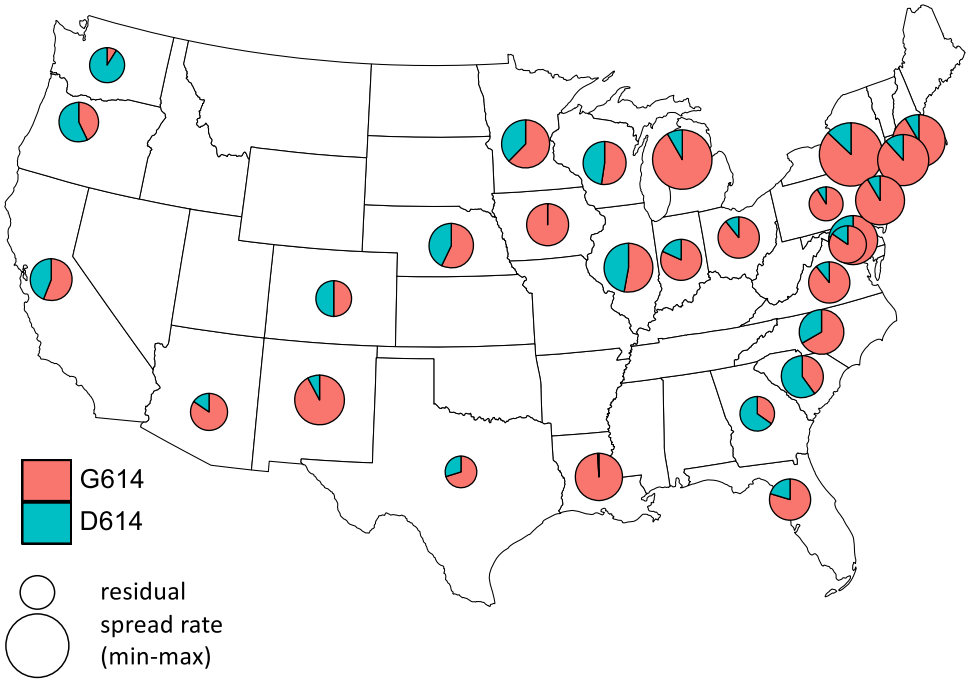

Fig. 3 Spatial distribution of strains of SARS-CoV-2 having the G614 mutation in the spike gene at the outbreak onset among states. Pie charts give the proportion of samples in states collected within 30 days following the outbreak onset that are in the G clades (red)[27]. The size of the pie is proportional to the residual values of r_0 after removing the effects of the timing of outbreak onset, population size represented by the time series, and population density. For each state, we used the estimate of r_0 corresponding to the county or county-aggregate that had the greatest number of deaths.

considered strains from Nextstrain clades 19A, 19B, 20A, 20B, and 20C; clades 19A and 19B do not contain the G614 mutation, but the other clades do. We found that the proportion of samples within clade 19B had a negative effect on r_0 ($P = 0.019$, Supplementary Table 2). Strain 19A, however, did not have a negative effect on r_0. This suggests possible differences among strains separate from or in addition to the G614 mutation[30]. A consensus on the potential impact of SARS-CoV-2 mutations is still lacking[28]: some studies present evidence for a differential pathogenicity and transmissibility[31,32], while others conclude that mutations might be mostly neutral or even reduce transmissibility[33]. Because our analyses only associate strains with spread rates, they give no information about possible mechanisms explaining differences among strains. Nonetheless, our analyses are suggestive of the potential link between viral genomic variation and its impact on transmission and mortality[34].

To check whether there are other factors that might explain variation in our estimates of r_0 among counties, we investigated additional population characteristics[35–42] that might be expected to affect the initial spread rate of COVID-19: (i) proportion of the population over 65, (ii) adult obesity, (iii) diabetes, (iv) education, (v) income, (vi) poverty, (vii) economic equality, (viii) race, and (ix) political leaning (Supplementary Table 3). The first three characteristics likely affect morbidity[43], although it is not clear how higher morbidity could affect the spread rate. The remaining characteristics might affect health outcomes and responses to public health interventions; for example, education, income, and poverty might all affect the need for individuals to work in jobs

that expose them to greater risks of infection. Nonetheless, because we focused on the early spread of COVID-19, we anticipated that these characteristics would have minimal effects. Despite the potential for all nine characteristics to affect estimates of r_0, we found that none was a statistically significant predictor of r_0 when taking the four main factors into account (all $P > 0.1$). We also repeated the main analyses (without the nine additional characteristics) on estimates of $r(t)$ after COVID-19 was broadly established in the USA (5 May 2020, assuming an average time between infection and death of 18 days) (Supplementary Table 4). The R^2_{pred} was 0.40, largely driven by a large positive effect of the date of outbreak onset. The absence of significant effects of the nine additional population characteristics on r_0, and the lower explanatory power of the model on $r(t)$ at the end of the time series, underscore the importance of population density and spatial autocorrelation in predicting county-level values of r_0.

Extrapolating R_0 to all counties. In the regression model (Table 1), the standard deviation of the residuals was 1.19 times higher than the average standard error of the estimates of r_0. This implies that the uncertainty of an estimate of r_0 from the regression is only slightly higher than the uncertainty in the estimate of r_0 from the time series itself; the fixed terms (ignoring spatial autocorrelation) in the regression model explain 71% ($= 1/1.19^2$) of the explainable variance in r_0. Therefore, using estimates from death count time series from other counties will give estimates of r_0 for a focal county (lacking reliable estimates) that are almost as precise as the estimate from the county's time series. We used the regression to extrapolate values of R_0 for all 3109 counties in the conterminous USA (Fig. 4, Supplementary Data 1). The high predictability of r_0, and hence R_0, from the regression is seen in the comparison between R_0 calculated from the raw estimates of r_0 (Fig. 4a) and R_0 calculated from the corrected r_0 values (Fig. 4b). Extrapolation from the regression model makes it possible not only to get refined estimates for the counties that were aggregated in the time-series analyses; it also gives estimates for counties within states with so few deaths that county-aggregates could not be analyzed (Fig. 4c, d). The end product is a map of estimated R_0 values for the conterminous USA (Fig. 4e).

Discussion

It is widely understood that different states and counties in the USA, and different countries in the world, have experienced COVID-19 epidemics differently. Our analyses have put numbers on these differences in the USA. The large differences argue for public health interventions to be designed at the county level. For example, the vaccination coverage in the most densely populated area, New York City, needed to prevent future outbreaks of COVID-19 will be much greater than for sparsely populated counties. Therefore, once vaccines are broadly available to the public, they should be distributed first to counties with high R_0 to have the greatest impact in reducing community spread. Similarly, if non-pharmaceutical public health interventions have to be increased during resurgent outbreaks, then counties with higher R_0 values will require stronger interventions. As a final example, county-level R_0 values can be used to assess the practicality of contact-tracing of infections, which become impractical when R_0 is high[44,45].

Estimating county-level values of R_0 at the start of the epidemic faces statistical challenges that our analyses have tried to address. We used death counts, rather than cases reported from testing, because particularly at the start of the epidemic, testing was limited and heterogeneous among states and counties. Nonetheless, death counts are not perfect, because different criteria could be used by different counties to ascribe deaths to SARS-CoV-2. Furthermore, evidence suggests that "excess deaths" have occurred in comparison to historical data[13] and that these excess deaths are likely due to the mis-attribution to causes other than SARS-CoV-2. Nonetheless, we estimated R_0 from the spread rate of the disease (Eq. 1), which depends on the change in the number of recorded deaths from one day to the next. This change in death counts should be insensitive to the criteria used to ascribe death to SARS-CoV-2, and although there are undoubtedly mistakes and omissions, our statistical methods account for this measurement error.

We present our county-level estimates of R_0 as preliminary guides for policy planning, while recognizing the myriad other epidemiological factors (such as mobility[46–48]) and political factors (such as legal jurisdictions[49]) that must shape public health decisions[3,50–52]. Although we have emphasized the high predictability of R_0 among counties in the USA, our estimates of R_0 will be under-estimates for some regions if there are changes in the transmissibility of strains (Fig. 3). This uncertainty underscores the need for more information about strain differences affecting SARS-CoV-2 transmission[28,30].

We recognize the importance of following the day-to-day changes in death and case rates, and short-term projections used to anticipate hospital needs and modify public policies[53–55]. Looking back to the initial spread rates, however, gives a window into the future and what public health policies will be needed when COVID-19 is endemic.

Methods

Data selection and handling: death data. For mortality due to COVID-19, we used time series provided by the New York Times[12]. We selected the New York Times dataset because it is rigorously curated. We analyzed separately only counties that had records of 100 or more deaths by 23 May, 2020. The threshold of 100 was a balance between including more counties and obtaining reliable estimates of $r(t)$. Preliminary simulations showed that time series with low numbers of deaths would bias $r(t)$ estimates (Supplementary Fig. 2). However, we did not want to use the maximum daily number of deaths as a selection criterion, because this could lead to selection of counties based on data from a single day. It would also involve some circularity, because the information obtained, $r(t)$, would be directly related to the criterion used to select datasets. Therefore, we used the threshold of 100 cumulative deaths. The District of Columbia was treated as a county. Also, because the New York Times dataset aggregated the five boroughs of New York City, we treated them as a single county. For counties with fewer than 100 deaths, we aggregated mortality to the state level to create a single time series. For thirteen states (AK, DE, HI, ID, ME, MT, ND, NH, SD, UT, VM, WV, and WY), the aggregated time series did not contain 100 or more deaths and were therefore not analyzed.

Data selection and handling: explanatory county-level variables. County-level variables were collected from several public data sources[36–42]. We selected socio-economic variables a priori in part to represent a broad set of population characteristics.

Time series analysis: time series model. We used a time-varying autoregressive model[15,56] designed explicitly to estimate the rate of increase of a variable using nonlinear, state-dependent error terms[16]. We assume in our analyses that the susceptible proportion of the population represented by a time series is close to one, and therefore there is no decrease in the infection rate caused by a pool of individuals who were infected, recovered, and were then immune to further infection.

The model is

$$x(t) = r(t-1) + x(t-1) \quad (1a)$$

$$r(t) = r(t-1) + \omega_r(t) \quad (1b)$$

$$D(t) = \exp(x(t) + \phi(t)) \quad (1c)$$

Here, $x(t)$ is the unobserved, log-transformed value of daily deaths at time t, and $D(t)$ is the observed count that depends on the observation uncertainty described by the random variable $\phi(t)$. Because a few of the datasets that we analyzed had zeros, we replaced zeros with 0.5 before log-transformation. The model assumes that the death count increases exponentially at rate $r(t)$, where the latent state variable $r(t)$ changes through time as a random walk with $\omega_r(t) \sim N(0, \sigma^2_r)$. We assume that the count data follow a quasi-Poisson distribution. Thus, the expectation of counts at time t is $\exp(x(t))$, and the variance is proportional to this expectation.

We fit the model using the extended Kalman filter to compute the maximum likelihood[57,58]. In addition to the parameters σ^2_r and σ^2_ϕ, we estimated the initial

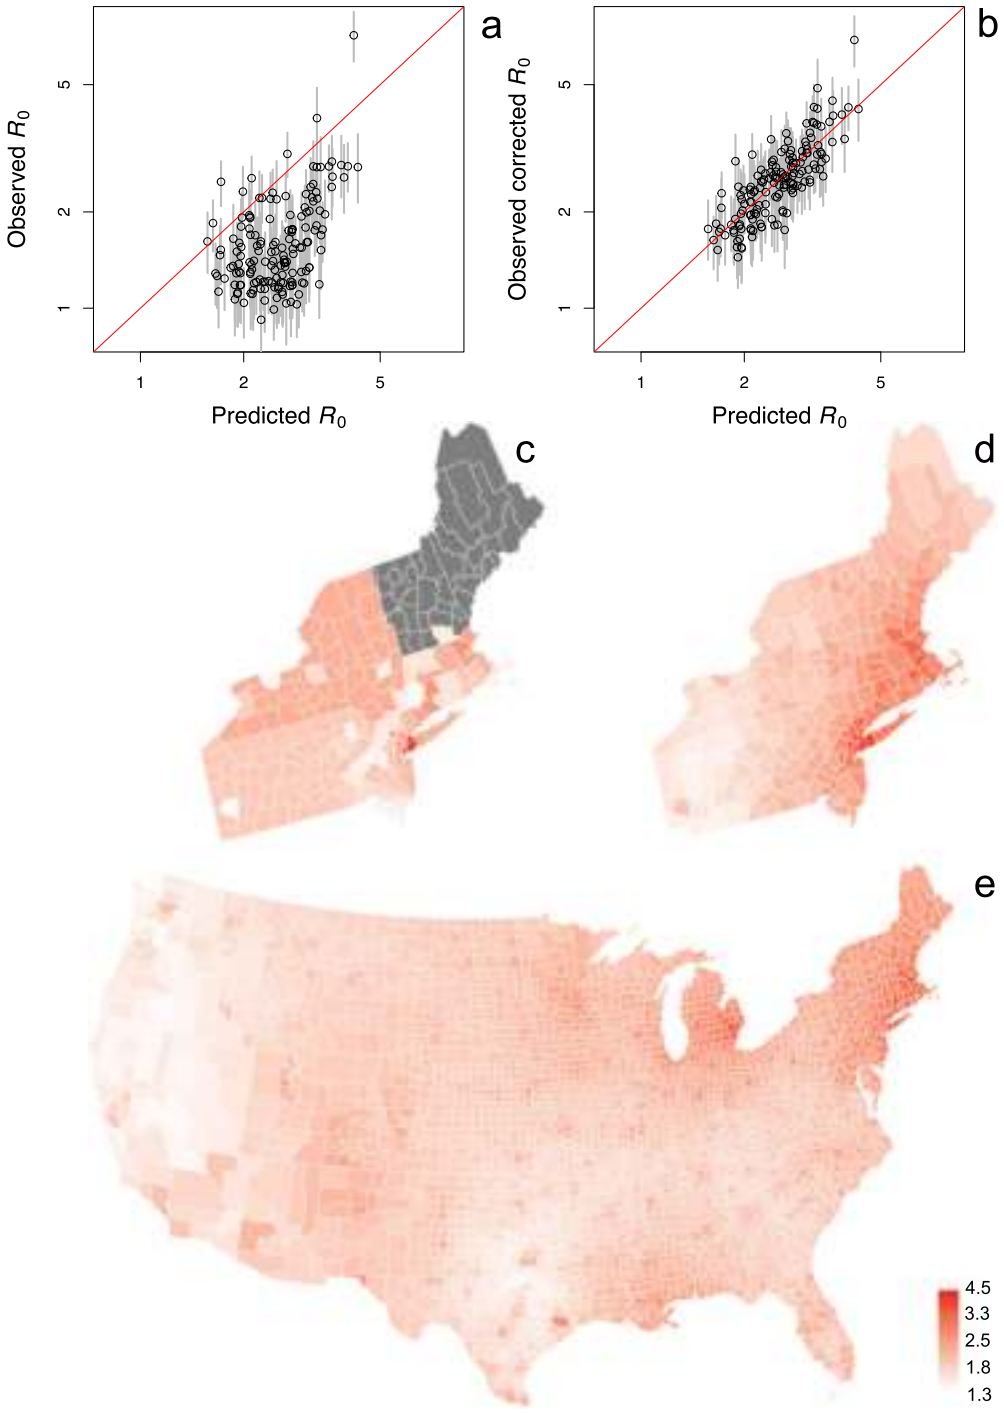

Fig. 4 Prediction of R_0 values for all 3109 counties in the conterminous USA. a, **b** Raw and corrected estimates of R_0 for 160 counties and county-aggregates. The predicted R_0 values are obtained from the regression model, with corrections to standardize values to an outbreak onset of 11 March 2020, and a population size equal to the most populous county. Comparing the raw estimates of R_0 (**a**) and the corrected R_0 values (**b**) shows the predictive power of the regression analysis. We thus used the regression model to predict R_0 for all counties. **c**, **d** To illustrate the prediction process for the northeastern states, the raw estimates (**c**) are all the same for county-aggregates and could not be made for some states (gray). In contrast, the predictability of R_0 in the regression model allows for better estimates (**d**). **e** This makes it possible to extend estimates of R_0 to all 3109 counties in the conterminous USA.

value of $r(t)$ at the start of the time series, r_0, and the initial value of $x(t)$, x_0. The estimation also requires terms for the variances in x_0 and r_0, which we assumed were zero and σ^2_r, respectively. In the validation using simulated data (Supplementary Methods: Simulation model), we found that the estimation process tended to absorb σ^2_r to zero too often. To eliminate this absorption to zero, we imposed a minimum of 0.02 on σ^2_r.

Time series analysis: parametric bootstrapping. To generate approximate confidence intervals for the time-varying estimates of $r(t)$ (Eq. 1b), we used a parametric bootstrap designed to simulate datasets with the same characteristics as the real data that are then refit using the autoregressive model. We used bootstrapping to obtain confidence intervals, because an initial simulation study showed that standard methods, such as obtaining the variance of $r(t)$ from the Kalman filter, were too

conservative (the confidence intervals too narrow) when the number of counts was small. Furthermore, parametric bootstrapping can reveal bias and other features of a model, such as the lags we found during model fitting (Supplementary Fig. 1a, b).

Changes in $r(t)$ consist of unbiased day-to-day variation and the biased deviations that lead to longer-term changes in $r(t)$. The bootstrap treats the day-to-day variation as a random variable while preserving the biased deviations that generate longer-term changes in $r(t)$. Specifically, the bootstrap was performed by calculating the differences between successive estimates of $r(t)$, $\Delta r(t) = r(t) - r(t\text{-}1)$, and then standardizing to remove the bias, $\Delta r_s(t) = \Delta r(t) - \mathrm{E}[\Delta r(t)]$, where E[] denotes the expected value. The sequence $\Delta r_s(t)$ was fit using an autoregressive time-series model with time lag 1, AR(1), to preserve any shorter-term autocorrelation in the data. For the bootstrap, a new time series was simulated from this AR(1) model, $\Delta\rho(t)$, and then standardized, $\Delta\rho_s(t) = \Delta\rho(t) - \mathrm{E}[\Delta\rho(t)]$. The simulated time series for the spread rate was constructed as $\rho(t) = r(t) + \Delta\rho_s(t)/2^{1/2}$, where dividing by $2^{1/2}$ accounts for the fact that $\Delta\rho_s(t)$ was calculated from the difference between successive values of $r(t)$. A new time series of count data, $\xi(t)$, was then generated using equation 1 with the parameters from fitting the data. Finally, the statistical model was fit to the reconstructed $\xi(t)$. In this refitting, we fixed the variance in $r(t)$, σ^2_r, to the same value as estimated from the data. Therefore, the bootstrap confidence intervals are conditional of the estimate of σ^2_r.

Time series analysis: calculating R_0. We derived estimates of $R(t)$ directly from $r(t)$ using the Dublin-Lotka equation[21] from demography. This equation is derived from a convolution of the distribution of births under the assumption of exponential population growth. In our case, the "birth" of COVID-19 is the secondary infection of susceptible hosts leading to death, and the assumption of exponential population growth is equivalent to assuming that the initial rate of spread of the disease is exponential, as is the case in equation 1. Thus,

$$R(t) = 1/\sum\nolimits_{\tau} \mathrm{e}^{-r(t)}\tau p(\tau) \tag{2}$$

where $p(\tau)$ is the distribution of the proportion of secondary infections caused by a primary infection that occurred τ days previously. We used the distribution of $p(\tau)$ from Li et al.[59] that had an average serial interval of $T_0 = 7.5$ days; smaller or larger values of T_0, and greater or lesser variance in $p(\tau)$, will decrease or increase $R(t)$ but will not change the pattern in $R(t)$ through time. Note that the uncertainty in the distribution of serial times for COVID-19 is a major reason why we focus on estimating r_0, rather than R_0: the estimates of r_0 are not contingent on time distributions that are poorly known. Computing $R(t)$ from $r(t)$ also does not depend on the mean or variance in time between secondary infection and death. We report values of $R(t)$ at dates that are offset by 18 days, the average length of time between initial infection and death given by Zhou et al.[60].

Time series analysis: Initial date of the time series. Many time series consisted of initial periods containing zeros that were uninformative. As the initial date for the time series, we chose the day on which the estimated daily death count exceeded 1. To estimate the daily death count, we fit a Generalized Additive Mixed Model (GAMM) to the death data while accounting for autocorrelation and greater measurement error at low counts using the R package mgcv[61]. We used this procedure, rather than using a threshold of the raw death count, because the raw death count will include variability due to sampling small numbers of deaths. Applying the GAMM to "smooth" over the variation in count data gives a well-justified method for standardizing the initial dates for each time series.

Time series analysis: validation. We performed extensive simulations to validate the time-series analysis approach (Supplementary Methods: Simulation model).

Regression analysis for r_0. We applied a Generalized Least Squares (GLS) regression model to explain the variation in estimates of r_0 from the 160 county and county-aggregate time series:

$$r_0 = b_0 + b_1 start.date + b_2 log(pop.size) + b_3 pop.den^{0.25} + \varepsilon \tag{3}$$

where *start.date* is the Julian date of the start of the time series, log(*pop.size*) and $pop.den^{0.25}$ are the log-transformed population size and 0.25 power-transformed population density of the county or county-aggregate, respectively, and ε is a multivariate Gaussian random variable with covariance matrix $\sigma^2\mathbf{\Sigma}$. We used the transforms log(*pop.size*) and $pop.den^{0.25}$ to account for nonlinear relationships with r_0; these transforms give the highest maximum likelihood of the overall regression. The covariance matrix contains a spatial correlation matrix of the form $\mathbf{C} = u\mathbf{I} + (1\text{–}u)\mathbf{S}(g)$ where u is the nugget and $\mathbf{S}(g)$ contains elements $\exp(-d_{ij}/g)$, where d_{ij} is the distance between spatial locations and g is the range[62]. To incorporate differences in the precision of the estimates of r_0 among time series, we weighted by the vector of their standard errors, **s**, so that $\mathbf{\Sigma} = \mathrm{diag}(\mathbf{s}) * \mathbf{C} * \mathrm{diag}(\mathbf{s})$, where * denotes matrix multiplication. With this weighting, the overall scaling term for the variance, σ^2, will equal 1 if the residual variance of the regression model matches the square of the standard errors of the estimates of r_0 from the time series. We fit the regression model with the function gls() in the R package nlme[63].

To make predictions for new values of r_0, we used the relationship

$$\hat{e}_i = \bar{e} + \mathbf{v_i} * \mathbf{V}^{-1}(\epsilon_i - \bar{e}) \tag{4}$$

where ε_i is the GLS residual for data i, $\hat{e}_i$ is the predicted residual, $\bar{e}$ is the mean of the GLS residuals, **V** is the covariance matrix for data other than i, and $\mathbf{v_i}$ is a row vector containing the covariances between data i and the other data in the dataset[64]. This equation was used for three purposes. First, we used it to compute R^2_{pred} for the regression model by removing each data point, recomputing $\hat{e}_i$, and using these values to compute the predicted residual variance[23]. Second, we used it to obtain predicted values of r_0, and subsequently R_0, for the 160 counties and county-aggregates for which r_0 was also estimated from time series. Third, we used equation (4) to obtain predicted values of r_0, and hence predicted R_0, for all other counties. We also calculated the variance of the estimates from[64]

$$\hat{v}_i = \sigma^2 - \mathbf{v_i} * \mathbf{V}^{-1} * v_i^{\mathbf{t}} \tag{5}$$

Predicted values of R_0 were mapped using the R package usmap[65].

Regression analysis for SARS-CoV-2 effects on r_0. The GISAID metadata[27] for SARS-CoV-2 contains the clade and state-level location for strains in the USA; strains G, GH, and GR contain the G614 mutation. For each state, we limited the SARS-CoV-2 genomes to those collected no more than 30 days following the onset of outbreak that we used as the starting point for the time series from which we estimated r_0; from these genomes (totaling 5290 from all states), we calculated the proportion that had the G614 mutation. We limited the analyses to the 28 states that had five or more genome samples. For each state, we selected the estimates of r_0 from the county or county-aggregate representing the greatest number of deaths. We fit these estimates of r_0 with the weighted Least Squares (LS) model as in equation (3) with additional variables for strain. Figure 3 was constructed using the R packages usmap[65] and scatterpie[66].

Statistics and reproducibility. The statistics for this study are summarized in the preceding sections of the "Methods". No experiments were conducted, so experimental reproducibility is not an issue. Nonetheless, we repeated analyses using alternative datasets giving county-level characteristics, and also an alternative dataset on SARS-CoV-2 strains (Supplementary Methods: Analysis of Nextstrain metadata of SARS-CoV-2 strains), and all of the conclusions were the same.

Reporting summary. Further information on research design is available in the Nature Research Reporting Summary linked to this article.

Data availability

The data that support the findings of this study are available on Figshare[67].

Code availability

R code for the analyses is available on Figshare[67].

Abstract

The basic reproductive number (R_0) is a function of contact rates among individuals, transmission probability, and duration of infectiousness. We sought to determine the association between population density and R_0 of SARS-CoV-2 across U.S. counties. We conducted a cross-sectional analysis using linear mixed models with random intercept and fixed slopes to assess the association of population density and R_0, and controlled for state-level effects using random intercepts. We also assessed whether the association was differential across county-level main mode of transportation percentage as a proxy for transportation accessibility, and adjusted for median household income. The median R_0 among the United States counties was 1.66 (IQR: 1.35–2.11). A population density threshold of 22 people/km^2 was needed to sustain an outbreak. Counties with greater population density have greater rates of transmission of SARS-CoV-2, likely due to increased contact rates in areas with greater density. An increase in one unit of log population density increased R_0 by 0.16 (95% CI: 0.13 to 0.19). This association remained when adjusted for main mode of transportation and household income. The effect of population density on R_0 was not modified by transportation mode. Our findings suggest that dense areas increase contact rates necessary for disease transmission. SARS-CoV-2 R_0 estimates need to consider this geographic variability for proper planning and resource allocation, particularly as epidemics newly emerge and old outbreaks resurge.

Introduction

The COVID-19 pandemic has infected millions of people globally, and there are over 400 thousand reported deaths and 7 million confirmed cases of COVID-19 worldwide [1]. Transmission of airborne and directly transmitted pathogens, such as SARS-CoV-2 (the causative

available publicly (link: https://github.com/nytimes/covid-19-data/blob/master/us-counties.csv).

agent of COVID-19), have been previously shown to be density-dependent [2–4]. Population density facilitates transmission of disease via close person-to-person contact [5–8], and may support sustained disease transmission due to increased contact rates [9–11]. Large urban areas have more opportunities for disease transmission, and hotspots of SARS-CoV-2 have been mostly concentrated in cities [12].

The basic reproductive number (R_0) describes the contagiousness and transmissibility of pathogens, and is a function of contact rates among individuals, transmission probability (probability of transmission per contact), and duration of infectiousness [13]. This is in contrast with the time-varying reproductive number (R_t), defined as the number of people in a population who were infected by an infectious individual at a given point in time, which reflects the changing levels of immunity in the population and the impact of control measures limiting transmission [14]. Control measures include implementation of non-pharmaceutical interventions (NPIs), such as face coverings and social distancing. Thus, R_0 estimates of COVID-19 are not exclusively determined by the pathogen, and variability in R_0 depends on local sociobehavioral and environmental settings, including population density [12].

During the initial phase of the outbreak, or the exponential growth period, we hypothesize that spatial heterogeneity in R_0 occurs primarily due to geographic variability in contact rates, since transmission probability and duration of infectiousness remain constant across settings. During this time frame, transmission probabilities across localities are equivalent, because exponential growth occurs prior to the implementation of NPIs which affect likelihood of transmission during contact. Moreover, contact networks are also affected by transportation systems that facilitate disease spread due to increased interconnectivity and mobility between different geographic areas [15, 16]; thus, we also hypothesize that the association of population density and R_0 may be differential depending on transportation accessibility, and areas that lack access to efficient modes of transportation would not have the same SARS-CoV-2 growth rate, even in high density areas.

In the current COVID-19 pandemic, evidence of the association of population density and disease transmission have been conflicting [17–20]. The estimation of differential R_0 using these area-level factors can assist in more accurate predictions of the rate of spread of SARS--CoV-2 in geographic settings with potential resurgence, where cases have been steadily increasing. In this study, we examine the association of population density with R_0 of COVID-19 across United States counties.

Methods

Data

We obtained publicly available daily COVID-19 cases among United States counties from the New York Times [21]. For each county, we assumed that the exponential growth period began one week prior to the second daily increase in cases. We assumed that the period of exponential growth lasted approximately 18 days, as previous research have shown the COVID-19 exponential period to be around 20–24 days in New York City [22]. These assumptions calibrated the period of exponential growth accordingly and created reasonable curves that approximated exponential growth across the counties for case data (Fig A in S1 Appendix). The algorithm ensured that the virus had taken hold in the area and allowed a sufficient number of days to estimate the exponential growth rate, as R_0 cannot be estimated accurately with sparse data, since it would be uncertain if the county was experiencing a sustained outbreak with community transmission. We restricted our analyses to counties that met a certain threshold of cumulative case counts at the end of the exponential growth period, but including counties with less than 25 cases included daily incidence counts that were insufficient to

calculate R_0 and yielded computational errors. Our final analytic sample included counties with 25 cases or greater at the end of the exponential growth period.

Data on the primary mode of transportation to work and median household income were obtained from the most recent 5-year American Community Survey (ACS) 2014–2018 survey estimates from the United States Census Bureau [23]. Main commuting mode was operationalized as the total percentage of people that use private transportation to work, such as those that own private vehicles (car, truck, van, motorcycle) or use a private taxi. Private transportation is a proxy for transportation accessibility in each county, as we hypothesize that areas that that lack efficient modes of transportation may not have as fast of COVID-19 exponential growth, and we want to assess whether the effect of density on R_0 would differ due to ease of transportation accessibility. Population and land area were obtained from the 2010 census, and density was calculated by population divided by total square km. All census data were extracted using the R package *tidycensus* [24].

Statistical analysis

We first compared the densities of counties included in the final analytical sample to those that did not have sufficient case counts with a two-sample Wilcoxon test. R_0 was estimated from the exponential growth rate method developed by Wallinga and Lipstich [25] and implemented by the R package *R0* [26], assuming a generation interval with a gamma distribution of mean 4.7 and standard deviation of 2.9 [27]. We then conducted a cross-sectional analysis using linear mixed models with random intercepts for each state and fixed slopes for the counties to assess the association of population density and R_0. The linear mixed models allow the intercept to vary among states, which accounts for non-independence among counties within each state, potentially due to variable resource allocation and differing health systems across states.

We also adjusted for county-level main mode of transportation to work percentage and median household income to control for any potential confounding between the association of density and R_0. Therefore, we fit 4 models with R_0 as the outcome and the following factors as covariates: Model 1: population density; Model 2: population density and the percent of individuals reporting private transportation as their main mode of transportation to work; Model 3: population density and the percent of individuals reporting private transportation, and median household income; Model 4: population density, percent of individuals reporting private transportation, median household income, and the interaction of private transportation use with population density. The associated linear mixed model equation for model 4 is

$$\begin{aligned} Y_{ij} = {} & \beta_{0j} + \beta_{1j} ln(density 1\ unit\ increase)_{ij} + \beta_{2j} \%private\ transportation_{ij} \\ & + \beta_{3j} median\ household\ income_{ij} + \beta_{4j} \%private\ transportation_{ij} \\ & * median\ household\ income_{ij} + e_{ij} \end{aligned}$$

where $\beta_{0j} = \gamma_{00} + u_{0j}$, for the i-th county for the j-th state

Sensitivity analyses

We conducted three sensitivity analyses to address the limitations of our approach and assess the robustness of our results. First, we conducted a sensitivity analysis using death counts from the New York Times [21] to estimate R_0 to limit bias due to differential availability of testing by geographic location. We used the same exponential period as the cases, but with a lag of 14 days to account for the delays from symptom onset to deaths of cases [28–30]. Moreover, the analysis of deaths was restricted to counties with greater than 10 deaths and more than 5 daily

increases in incident deaths, in order to appropriately estimate R_0 in counties with sufficient death counts. The daily death data created curves that approximated exponential growth across the counties (Fig B in S1 Appendix). Second, we excluded counties within a radius of 15 miles, the average commuting miles in the United States [31], from counties with densities greater than the 75th percentile. Removing these adjacent counties would demonstrate the extent of biases due to individuals commuting from surrounding counties to cities. If cases are imported from more densely population (i.e. cities) to less dense counties, we could potentially be biasing our estimates downwards. Lastly, we conducted an analysis excluding influential counties with a Cook's distance measure over 4/N for each model. Cook's distance is a commonly used indicator of influence, which measures the extent data points impact the regression parameter estimates [32]. Our sensitivity analysis excluding influential counties ensures that our findings were not driven by these highly influential observations, and that the association holds for other counties.

All analyses was conducted in R version 4.0.0 [33]. The figure and removal of adjacent counties in the sensitivity analyses were done with ArcGIS [34].

Results

The United States has 3,221 counties and county equivalents. When restricting to counties with greater than 25 cases, 1,151 (35.73%) counties were included (Fig 1). The median R_0 among the counties was 1.66 (IQR: 1.35–2.11). The median start and end of the exponential growth period was March 25, 2020 and April 9, 2020 respectively, and differed for each county depending on the start of disease transmission. The median density in counties included and not included in the analysis were 53.8 people/km^2 (IQR: 21.24–144.05) and 11.3 people/km^2 (IQR: 3. 56–23.88) respectively, and the difference was statistically significant ($p < 0.0001$). A

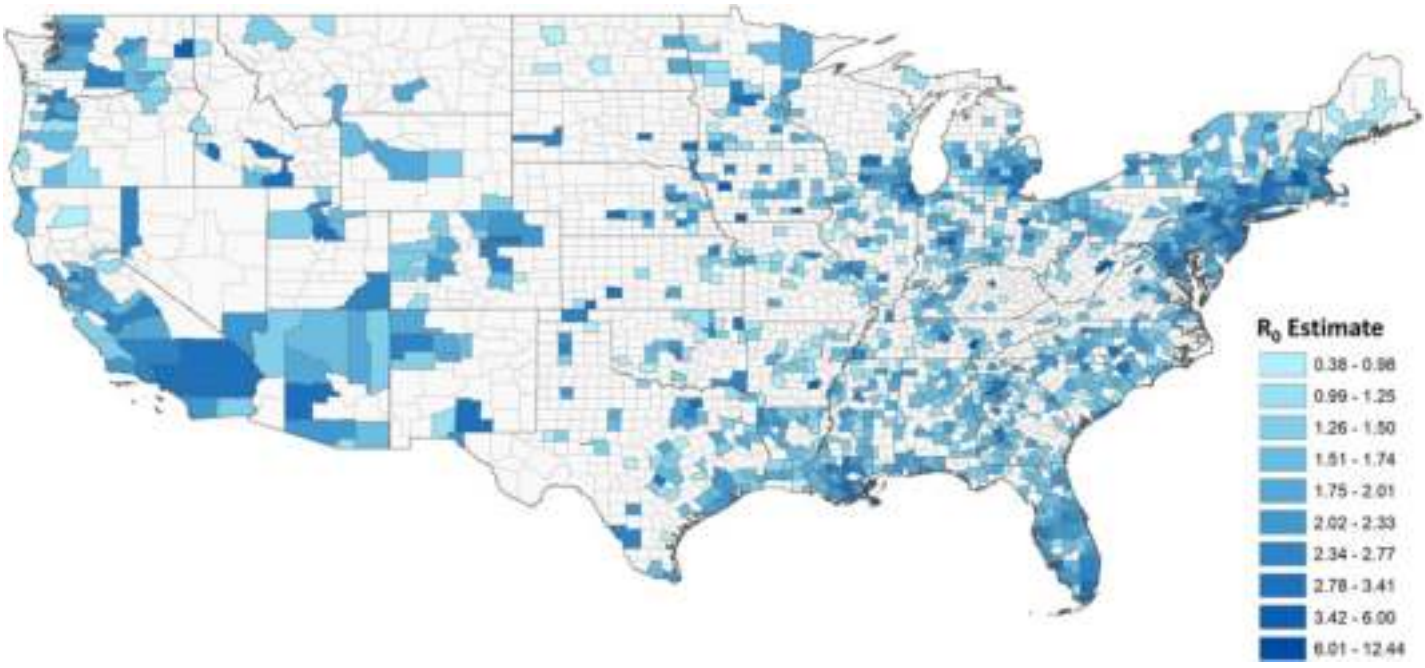

Fig 1. Basic reproductive number (R_0) estimates across United States counties. Larger R_0 indicates greater transmission during the initial phase of the outbreak, or the exponential growth period. We restricted calculation of R_0 to counties with greater than 25 cases at the end of the exponential growth period (n = 1,151), as R_0 cannot be estimated accurately with sparse data and it would be uncertain if the county was experiencing a sustained outbreak with community transmission.

https://doi.org/10.1371/journal.pone.0249271.g001

population density threshold of approximately 22 people/km^2 was needed to sustain an outbreak (Fig 2).

An increase in one unit of log population density increased R_0 by 0.16 (95% CI = 0.13 to 0.19) (Model 1; Table 1), or the doubling of population density increased the R_0 on average by 0.11 (95% CI = 0.09 to 0.13). When adjusted for percent of private transportation and median household income, the association of log population density and R_0 remained unchanged (Model 3; Table 1). There was no significant interaction, and the effect of population density on R_0 was the same among counties with a larger percentage with private vehicles as their transportation to work, but was no longer significant (Model 4; Table 1). Therefore, model 4 should be not be interpreted, since the interaction does not contribute to the model and only serves to decrease the precision (larger confidence intervals) of the measures of association of interest. R_0 decreased by 0.12 (95% CI = -0.02 to -0.04) with an 10% increase in private transportation as the main commute mode, accounting for population density and median household income (Model 3; Table 1).

In all three sensitivity analyses, population density remained positively associated with R_0, demonstrating the robustness of our main analysis. First, death data was used to calculate R_0 from 301 counties. The median R_0 among the counties that had sufficient death counts was 1.40 (IQR: 1.05–1.78). The unadjusted association between population density and R_0 remained consistent (β = 0.18, 95% CI = 0.14 to 0.23) (Model 1a; Table 2), and there were no significant interactions (Model 4a; Table 2). Next, there were 288 counties above the 75th percentile, and 414 counties that were within 15 miles of these counties high-density counties. We removed these 414 counties from the sample, and using the subsample of 737 counties, our findings remained consistent (Table 2). Influential counties were also not driving the

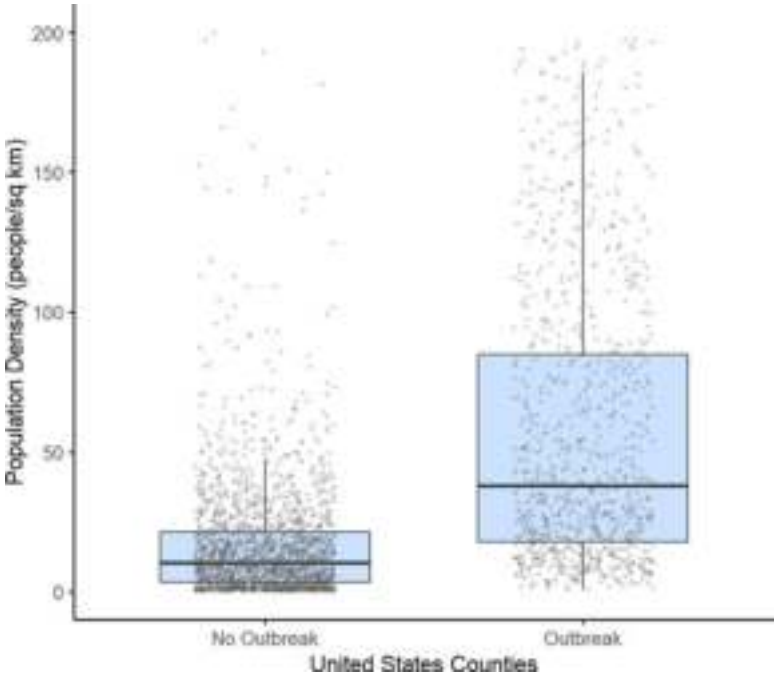

Fig 2. Population density threshold required to establish a sustained outbreak in United States counties. A population density of approximately 22 people/km^2 was needed to sustain an outbreak, which is approximately equal to the lower IQR of the counties with established COVID-19 outbreaks [median = 53.8 population/km^2; IQR = 21.24, 144.05], and a slightly less than the upper IQR of the counties with no COVID-19 outbreaks [median = 11.3 population/km^2; IQR = 3.56, 23.88]. The grey circles represent the individual county population densities.

association of population density and R_0, and our results remained robust (Table 2). For the two sensitivity analyses excluding counties adjacent to highly dense counties and excluding high influence counties, however, the association of private transportation usage and R_0 did not remain (Models 2a, 3a, 2b, 3b; Table 2).

Discussion

Our findings show that the basic reproductive number (R_0) is associated with population density, even when percent of individuals that use private transportation and median income were accounted for. In these settings, greater population density may potentially facilitate interactions between susceptible and infectious individuals in densely-populated networks, which sustain continued transmission and spread of COVID-19. Moreover, we see that population density continues to have an important impact on disease transmission regardless of transportation accessibility and median income, suggesting that the opportunity for effective contacts are mostly driven by crowding in denser areas, increasing the contact rates necessary for disease spread. However, we did not see that density-dependence is differential across transportation accessibility, as demonstrated by the non-significant interaction of population density and transportation. Our findings are consistent with previous research that have demonstrated a strong relationship between population density and other infectious diseases [4, 6, 7, 9, 35]. In the current SARS--CoV-2 pandemic, recent literature has been conflicting, where some research also suggests a density-dependence of COVID-19 transmission [17, 36] and other measures of the severity of the outbreak [19, 37], while other research suggests that there are other factors that can better explain the pandemic [18, 38]. However, to our knowledge, our results are one of the first to show that population density is an important driver of COVID-19 transmission, even in areas where residents rely more on private modes of transportation. Moreover, even though transmission is less in lower density areas (i.e. rural areas), rural settings may eventually disproportionately be more vulnerable to COVID-19 morbidity and mortality. Individuals in rural areas are generally older, have more underlying conditions, have less access to care, and have fewer ICU beds, ventilators, and facilities needed for severe COVID-19 treatment [39–42]. Further research is needed on the overall burden of COVID-19 across the spectrum of population density.

Geographic estimates of R_0 of SARS-CoV-2 need to take into account the specific area's population density, since the R_0 estimate is dependent on both the pathogenicity of the virus as well as environmental influences. In countries where cases are only on the starting to climb, such as countries in Latin America and Southern Africa [1, 43], or there is a resurgence of cases, such as India, Iraq, and Israel [44], area-specific density can assist in predictions of R_0, which is important because epidemiological forecasts and predictive models are sensitive to small changes in R_0 inputs. Accurate estimation of R_0 consequently leads to more precise approximations of the epidemic size, so that governments can appropriately allocate resources and coordinate mitigation strategies. Moreover, as cities and states reopen in the United States, and if there is a second-wave of infections, areas with higher density accessibility will likely have greater SARS-CoV-2 resurgence.

Our study has a number of limitations. While we demonstrate that population density is associated with R_0, the estimation of R_0 can be biased depending on the data and assumptions adopted. However, our main aim in this analysis was to evaluate the association between population density and R_0, and not to accurately estimate R_0. Thus, any biases in estimation of R_0 due to underlying assumptions would likely be non-differential across counties, and would still yield similar results. In addition, we estimated R_0 based on the number of reported cases; therefore, the incidence of COVID-19 across US counties may be underestimated at varying rates due to differential testing. Testing data at the county-level currently do not exist, and we

were unable to adjust for the number of tests performed. Confounding of true epidemic growth by increase in testing could also be a potential constraint to the robustness of the analysis. To mitigate this limitation, we included a random intercept term to adjust for state-level effects, and thus differential testing across states were accounted by our model. Differential testing by local governments within states are less likely to strongly impact our findings, as most funding and budgets for COVID-19 is distributed at the state-level [45, 46]. We also conducted a sensitivity analysis using death data which demonstrates the robustness of our findings. Furthermore, we utilized a number of assumptions based on previous findings to calibrate the exponential growth period, which ensured that the virus had taken hold and allowed a sufficient number of days and case counts to estimate exponential growth. There are potential for biases in our method; for example, there is the possibility that some NPIs were introduced in the initial outbreak stage of COVID-19 in some counties; however, if this was the case, then case counts and subsequently R_0 would even higher than we calculated, and thus our associations of density and R_0 was underestimated. However, we implemented numerous ways to limit the biases. The exponential growth period was restricted to approximately 14 days at the start of the epidemic, where we would expect limited increases in testing and thus would not affect R_0 substantially. Moreover, we plotted the calibrated exponential growth curves of all the counties included in our analysis, which gave us reasonable curves that approximated exponential growth for case and death data. Another limitation is that we had to only include counties that had sufficient case data in order to accurately estimate R_0; however, if we included all counties, the true association between population density and R_0 would likely be greater than what we report in our analysis given our findings that the counties excluded in the analysis had a significantly lower density and expected very low R_0 due to lack of cases. Another limitation is that our model also assumes homogenous mixing, which may can be an oversimplification of the heterogeneity in contact patterns within populations [4, 47]. However, previous research has shown that population structure only changes R_0 estimates slightly [48], and assumptions of well-mixed populations are valid in small-to-medium spatial scales [17]. Moreover, our method loses spatial granularity in assessing R_0 in counties, especially in counties with spatially heterogenous clustering. The aim of our study, however, was to provide a generalizable estimate of the association between population density and R_0, in order to appropriately estimate potential for disease transmission, rather than a microspatial estimate that may not be generalizable to other settings. Finally, an important confounder that we were unable to adjust for is the number of importations of SARS-CoV-2 in these counties, as more urbanized areas are more likely to have links with countries and other states where the virus could have originated from. Even so, we still see that once an area is seeded with COVID-19, the growth rate is greater in denser areas during the time period prior to implementation of NPIs.

Conclusions

Counties with greater population density have greater rates of transmission of SARS-CoV-2, likely due to increased contact rates in areas with greater population density. Population density affects the network of contacts necessary for disease transmission, and SARS-CoV-2 R_0 estimates need to consider this variability for proper planning and resource allocation, particularly as epidemics newly emerge and old outbreaks resurge.

The Geography of the Covid-19 Pandemic: A Data-Driven Approach to Exploring Geographical Driving Forces

Frederik Seeup Hass and Jamal Jokar Arsanjani *

Department of Planning, Geography and Surveying, Aalborg University Copenhagen, A.C. Meyers Vænge 15, 2450 Copenhagen, Denmark; frederiksh@plan.aau.dk
* Correspondence: jja@plan.aau.dk

Abstract: The Covid-19 pandemic emerged and evolved so quickly that societies were not able to respond quickly enough, mainly due to the nature of the Covid-19 virus' rate of spread and also the largely open societies that we live in. While we have been willingly moving towards open societies and reducing movement barriers, there is a need to be prepared for minimizing the openness of society on occasions such as large pandemics, which are low probability events with massive impacts. Certainly, similar to many phenomena, the Covid-19 pandemic has shown us its own geography presenting its emergence and evolving patterns as well as taking advantage of our geographical settings for escalating its spread. Hence, this study aims at presenting a data-driven approach for exploring the spatio-temporal patterns of the pandemic over a regional scale, i.e., Europe and a country scale, i.e., Denmark, and also what geographical variables potentially contribute to expediting its spread. We used official regional infection rates, points of interest, temperature and air pollution data for monitoring the pandemic's spread across Europe and also applied geospatial methods such as spatial autocorrelation and space-time autocorrelation to extract relevant indicators that could explain the dynamics of the pandemic. Furthermore, we applied statistical methods, e.g., ordinary least squares, geographically weighted regression, as well as machine learning methods, e.g., random forest for exploring the potential correlation between the chosen underlying factors and the pandemic spread. Our findings indicate that population density, amenities such as cafes and bars, and pollution levels are the most influential explanatory variables while pollution levels can be explicitly used to monitor lockdown measures and infection rates at country level. The choice of data and methods used in this study along with the achieved results and presented discussions can empower health authorities and decision makers with an interactive decision support tool, which can be useful for imposing geographically varying lockdowns and protectives measures using historical data.

1. Introduction

According to the World Health Organization (WHO), there have been more than 79.2 million confirmed cases of Covid-19 globally and 1.7 million people are reported to have died hereof by the end of 2020 [1]. The Covid-19 pandemic has had and will continue to have life-changing effects on our lives around the world. Therefore, there is an urgent need for interdisciplinary studies to support health authorities and decisions makers with data-driven approaches for more effective recommendations and regulations for better management of such situations [2,3]. The Covid-19 outbreak has proven to be largely associated with geography, geographical information, and the geographical constellation of our cityscapes, land use information and transportation means, among others [4,5]. While epidemiologists and virologists and medics are trying to develop the right medicines, vaccines and medical solutions, an investigation of the geographical patterns of the pandemic and their relationship with geographical space with respect to

the outbreak's characteristics such as outbreak hot spots and cold spots, proximity of relevant urban elements, e.g., bars and restaurants, can help decision makers to impose more effective protective measures. These analyses help them to understand the nature and magnitude and severity of outbreak up to a certain timeframe and plan the future actions according to the historical development of the outbreak. Once such knowledge is gained, they can optimize daily societal activities more efficiently while lowering the infection risk. Thus, the aim of this study is to propose a data-driven approach for harvesting open geographic data (socio-economic data, biophysical data, mobility network, climatological data) released by open data initiatives and earth observation missions in order to (a) extract meaningful information about the geography of the pandemic such as hot- and cold spots in a temporal manner, i.e., weekly basis, that allow us to identify regions that have been constantly exposed to high infection rates or wise versa, (b) uncover the relationship between the outbreak and its geographical dimension. To do so, an application of statistical models and machine learning techniques will be tested allowing to explore what geographical settings support the outbreak. Finally, we will present appropriate open-source geospatial tools for achieving the aforementioned outputs.

The reminder of the paper is structured as follows: The introduction is followed by a literature review in Section 1.1. The data and methods used in the study will be presented in Section 2, while Section 3 presents our results. Section 4 presents discussions on our results and leads to conclusive remarks.

1.1. Related Work

Since the Covid-19 virus spread throughout the world causing a global pandemic, several studies have been conducted on the causes and factors that are essential to the spread of the virus. In this section, we present the state of the art on the studies focusing on geographic features and their correlation to the spread of virus together with machine learning techniques used in prediction spread and infection rates. The early studies related to the geography of Covid-19 focused on mapping the space and time of proven incidences and also to correlate these to geographic factors such as climate indicators and measures population density, population composition and human travel patterns. For instance, a study by Kim, Sun, and Castro [6] found a strong spatial autocorrelation and with the use of space-time scan identified clusters of Covid-19. Their findings proved that the disease initially spread in the densely and heavy populated capital region and over time moved to more distant regions of the country, furthermore single events of large spread and counter measures of these showed a space-time ripple effect in decreasing infection rates, which is also confirmed by the study of Giachino, et al. [7].

Investigating how climate indicators affect the spread, Briz-Redón and Serrano-Aroca [8] found no significant correlation between spring temperatures of Spain and Covid-19 cases, whereas Malki et al. [9] found Covid-19 was positively correlated to temperature and humidity, but also that these factors alone are not sufficient alone to predict infection rates. Briz-Redón and Serrano-Aroca [8] found that population density and number of visitors to a city had high correlations ($p > 0.85$) to infection rates, and Sannigrahi et al. [10] also found that total population, population income and poverty rates are strongly correlated to infection rates ($p = 0.75, 0.68, 0.69$ respectively). Mollalo, Behzad and Rivera [11] investigated demographic data across the United States and found that income inequality, household income, percentage of nurses and percentage of female black population, to be the most relevant explanatory demographic variables of countrywide infection numbers.

Studying the very first wave of Covid-19 in Wuhan China, Kraemer et al. [12] showed that by using positioning data of citizens, future infection hotspots can be accurately predicted. The study found an $R^2 = 0.89$ between people travelling out of Wuhan and towards nearby cities and hereby causing spread of virus. Likewise, Kapoor et al. [13] was able to predict next-day cases within a single county in the United States with very high accuracy (RMSLE = 0.0109); this was done by plotting mobility data of people's

movement between counties on a graph neural network. It has, however, proven difficult for researchers to use geographic variables to predict the spread of virus through machine learning techniques. Wang et al. [14] were able to predict and forecast infection rates during the first wave of the pandemic in the spring of 2020 using a logistic growth model with a s-shaped curve, but they also found that the nature of the pandemic in the long term cannot be fitted to such a curve, and thus concluded that such a model can only poorly account for the fluctuations of infection seen over time. Besides being capable of predicting infection rates, studying them with machine learning techniques can provide knowledge about the importance and relationship between the included variables. Using machine learning, Gupta and Gharehgozli [15] showed that population density and pollution levels are closely correlated to virus spread.

Pollution levels and air-quality have indeed been seen to also change rapidly over the course of the pandemic, mainly due to the measures imposed on citizens' ability to move and travel, and restrictions imposed on how businesses to run. Bao and Zhang [16] studied pollution levels across 44 Chinese cities, and found that across all pollution measures, the general Air Quality Index increased by 7.76% while the pollution indicators of SO_2, $PM_{2.5}$, PM_{10}, NO_2 and CO decreased by 6.76%, 5.93%, 13.66%, 24.67% and 4.58%, respectively. Collivignarelli et al. [17] similarly found that the early lockdown measures imposed in Milan (Italy) caused nitrogen dioxide and nitrogen oxide levels to fall by 61% and 74%, respectively, during the time of the lockdown.

Since the beginning of the Covid-19 pandemic, studies has been made to find factors that impact the spread of the virus, and we have presented some of the most relevant within the field of geographical analysis. Based on these, we aimed to implement novel techniques to map the spread of the virus within the European Union across space and time, examine explanatory variables and use them to predict infection rates. By including variables used in different studies presented, we can gain a deeper understanding of geographic driving factors in the Covid-19 pandemic. Within the geographic medium, our study additionally adds points of interest (POIs) data as a new set of variables that reflects the location of social hubs within urban areas. With the findings of the significant changes in pollution levels over the pandemic, these will also be included, allowing us to further investigate the correlation and explanatory factors between a large set of indicators for climate, pollution, population density, and POIs and the infection rate of Covid-19.

2. Data and Methods

2.1. Data

Covid-19 data was obtained from the European Centre for Disease Prevention and Control (ECDC), an agency under the European Union. The ECDC tracks and publish Covid-19 case numbers for the whole globe on a country level, within the European Union Covid-19 infection rates are also published at subnational regional levels. The dataset used is the *"Data on the weekly subnational 14-day notification rate of new COVID-19 cases"*, which contains weekly infection rates since week 13 (effectively week 14, since the data is based on bi-weekly reports) for each of the European subnational regions.

The subnational regions should be in accordance with the European Nomenclature of territorial units for statistics (NUTS) Regions, but it varies from country to country as per on what NUTS level the data is being recorded at. It has therefore been necessary to create a shapefile that consists of both NUTS 2 and NUTS 3 regions, and manually validate that each region matches the NUTS code provided by ECDC. This does, inevitably, results in countries being divided in an uneven amount of regions, with countries towards east such as Hungary, Estonia, Romania reporting cases at a municipal level, and the larger central European countries such as Germany, France, Spain reporting at a larger regional level. Cases reported in Wales UK, could not be identified at either NUTS 2 or 3 level, so the case data for Wales has been averaged in to a single region. The Covid-19 infection rate for each region are summed to a total infection rate covering the period of week 13 to week 45 (23 March 2020—8 November 2020), these can be seen in Figure 1.

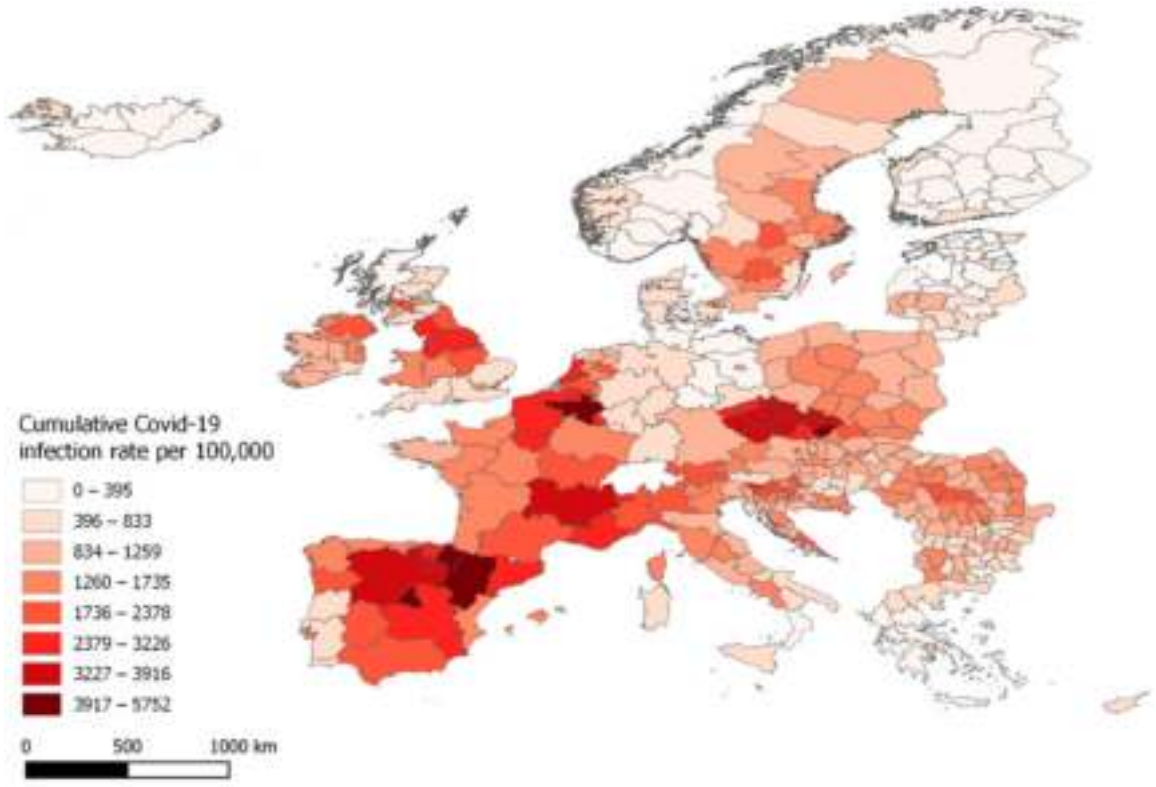

Figure 1. Cumulative Covid-19 infection rates per 100,000 inhabitant, from 23 March until 8 November 2020.

POI data was gathered from OpenStreetMap (OSM), where all amenities for each country was collected through the overpass API and merged into a complete amenity point dataset. The number of amenities within each region were counted per capita by the 10 most abundant amenity types, i.e., restaurants, bars, cafés, gas stations, etc.

The amenities contained in OSM are crowdsourced data, which naturally raises the question of data quality. Since the amenity data is implemented as counts within the individual European regions, only the quality of completeness of the amenities are of concern. The quality of positional accuracy of points is not a cause for concern when working on a European scale. Unfortunately, completeness of amenities in the European countries was mostly studied a decade ago when the use and data contained in OSM was rising [18,19], and since then, most studies on accuracies of OSM amenities has been made with the focus of positional accuracy, and not completeness. A recent study on completeness of road and OSM's POIs data in Europe found general high levels of quality in amenities and road data across major European cities [20]. The overall quality of OSM data in developed countries around the world is generally at a very high level [21], providing data in comparable quality to those of official data sources [22]. Places that has a high degree of tourism, i.e., most major European cities, also has a high completeness of the mapped amenities, whereas the data quality in rural areas remains to be tested [20].

Daily surface temperatures are available from Copernicus Climate Change Services (C3S) who monitor temperatures from ground stations across Europe. The daily mean temperature of 2019 was downloaded from the E-OBS database as a 0.1 degree regular gridded raster, and averaged in to an annual mean temperature. The annual mean temperature for each region is derived by using zonal statistics.

The Copernicus Atmosphere Monitoring Service (CAMS) monitors a set of variables related to air-quality and pollution levels across Europe, and distributes these as 0.1 degree rasters. Based on availability and documented cause for each pollutant, we chose "Non-methane VOCs" (volatile organic compounds), "Particulate matter < 2.5 μm ($PM_{2.5}$)", "Nitrogen dioxide" and "Particulate matter < 10 μm (PM_{10})" as indicators for air-quality and pollution levels. The four indicator data sets were downloaded as daily levels in the

period of February through October for both 2019 and 2020 and the average year over year difference was calculated for each indicator and through zonal statistics transferred to the study regions.

The results is a data set covering 401 European regions with total Covid-19 infections a dependent variable (x0) and 17 independent geographic variables. All variables are listed in Table 1.

Table 1. Regions, Covid Infection rates and related variables.

Variable	Argument
Total infected [dependent variable]	X0
Population Density	X1
Restaurants per cap.	X2
Cafes per cap.	X3
Fast Food Places per cap.	X4
Pubs per cap.	X5
Bars per cap.	X6
Gas Stations per cap.	X7
Schools per cap.	X8
Doctors' Offices per cap.	X9
Kinder gardens per cap.	X10
Annual mean temperature	X11
Nitrogen dioxide, year-over-year change	X12
Particulate matter < 2.5 μm ($PM_{2.5}$, year-over-year change	X13
Non-methane VOCs (volatile organic compounds), year-over-year change	X14
Particulate matter < 10 μm (PM_{10}), year-over-year change	X15

2.2. Methods

2.2.1. Exploratory Data Analysis

Initially, an exploratory data analysis is carried out using the global Moran's I statistics to determine spatial autocorrelation. The Moran's statistic is a measure of how a variable of a region is correlated variable values of its surrounding regions, under the assumption that variable values are normally distributed across space. Moran's I follows a normal distribution curve and tests whether clustering is appearing by calculating a z-score and *p*-values, which are measures for standard deviation values and level of significance. Moran's I is a product of these values ranging from −1 to 1, where −1 is clustering of dissimilar values, 0 is perfect distribution of values and 1 is clustering of similar values and hereby showing spatial autocorrelation [23]. A predefined measure of neighbors are set, and each individual regions and its surrounding areas are tested for spatial autocorrelation against the complete data set. We used the *k* nearest neighbors to define neighborhoods, with differentiated k values for the two scales of the study. For the European spatial autocorrelation analysis we set $k = 6$ and for the Danish one we set $k = 4$.

The result of the analysis is grouped into four categories: hotspot, coldspot, doughnuts and diamonds. The hot- and coldspots are showing clusters of high infection rates and clusters of low infection rates, and the doughnuts and diamonds are showing regions with low infection rates surrounded by high infection rates and regions with high infection rates surrounded by low infection rates.

The data for the analysis are the total infection rates for each region gathered by accumulating the bi-weekly infection rates since week 14. The spatial autocorrelation is therefore a measure of clusters over the pandemic as a whole.

2.2.2. Space Time Patterns

As an addition to the exploratory data analysis, an emerging hotspot analyses was made based on the results of spatial autocorrelation. The emerging hotspot analysis is a method that utilize a three-dimensional data set to locate clusters through both time and space. By doing a spatial autocorrelation analysis for each time slot of the available data (34 weeks) and adding these as layers on top of each other, it is possible to analyze how hot and coldspots change in space over time. The analysis was carried out as an extension to the spatial autocorrelation analysis done with the Pysal library in Python where we implemented space time patterns categorization inspired by the Esri tool for the same purpose [24]. The analysis look for 13 different scenarios for each region, these are seen in Table 2. The standard implementation of space time categories include an upper time interval threshold (t_{max}) of 90% and a lower time interval threshold (t_{min}) at opposite l0% in some of the categories. To better account for the changes in infection clustering in space it was decided to do multiple analysis with t_{max} and t_{min} at 75%, 25% and 55%, 45% for those categories.

Table 2. Regions, Covid Infection rates and related variables (modified from [24]).

Space Time Category	Definition (t_{max} = 90%, t_{min} = 10%)
New Hotspot	Region identified as hotspot in the last time step that has not been a hotspot before
Sporadic Hotspot	Region identified as a hot spot at least once but in less than 10% of the time steps that also has not been a cold spot
Oscillating Hotspot	Region identified as hotspot in the last time step and been a hotspot in less than 90% of the time steps that also been a coldspot at least once
Historical Hotspot	Region that is not identified as hot spot in the last time step but has been a hot spot in more than 90% of the time steps
Intensifying Hotspot	Region identified as a hotspot in the last time step that has also been a hotspot in more than 90% of the time steps
Persistent Hotspot	Region identified as a hotspot in at least 90% of the time steps
New Coldspot	Region identified as a coldspot in the last time step that has not been a coldspot before
Sporadic Coldspot	Region identified as a coldspot at least once but in less than 10% of the time steps that also has not been a hotspot
Oscillating Coldspot	Region identified as a cold spot in the last time step and been a coldspot in less than 90% of the time steps that also been a hotspot at least once
Historical Coldspot	Region that is not identified as coldspot in the last time step but has been a coldspot in more than 90% of the time steps
Intensifying Coldspot	Region identified as a coldspot in the last time step that has also been a coldspot in more than 90% of the time steps
Persistent Coldspot	Region identified as a coldspot in at least 90% of the time steps
Not Significant	None of the above

The classifications are based on assessments of the results of spatial autocorrelation outputs stacked as layers through time, and these are then categorized by looking through the layers vertically. This is considered a simplified emerging hot spot analysis, as the analyses of the individual layers does include the layers above or below.

2.2.3. Statistical Models: OLS & Geographically Weighted Regression

OLS

The ordinary least squares is a global regression model that seeks to investigate the relationship between a dependent variables (indicators) and a number of independent variables. The model is explained by the following equation [25]:

$$y = \beta_0 + B_1 X_1 + \beta_2 X_2 + \cdots \beta_n X_n + \varepsilon \quad (1)$$

where y is the dependent variable, in our case Covid-19 infection rates, β is the ordinary least squares estimated coefficients and ε is the residuals of the predicted values. The OLS is a global model since the equation assume the relationship between the dependent variable and the indicators to be constant for the whole data set. This is however a simplification of the investigated relationship, as this will often vary from location to location.

GWR

The geographically weighted regression (GWR) model is a similar regression model with the addition of adding geography to the equation by estimating local coefficients for local areas. GWR is thereby a local OLS model that varies over space. GWR is described by the OLS equation with the addition of coordinates for each location [25]:

$$y = \beta_0(u_i, v_i) + B_1(u_i, v_i) X_1 + \beta_2(u_i, v_i) X_2 + \cdots \beta_n(u_i, v_i) X_n + \varepsilon \quad (2)$$

The local regression area is defined by a spatial kernel function and a bandwidth that can be defined as either distance (fixed bandwidth) or a neighborhood size (adaptive bandwidth). Only areas that are within the kernel are included in the GWR model. We used an adaptive bandwidth size defined by automatic model calibration and a Bi-square kernel.

GWR is capable of mapping how variable relationships vary across space and hereby to tell which variables best describes the variation seen in the dependent variable at different regions. We included all the variables seen in Table 1 in the GWR analysis. The model is evaluated by mapping local R^2 values, variables coefficients and model residuals.

2.2.4. Machine Learning Prediction

The geographic variables collected are a mix of static elements and dynamic climatic indicators. The population density, amenity counts and annual temperatures are elements that both reflects the geography and cityscapes, while at the same time, also tells something about the culture and local habits of the people living in a certain area. Meanwhile the air quality and pollution indicators are variables that change on the short term as a direct consequence of the level of activity and movement of people within a region. The year over year change should be a good indicator of how far from normal the activity level in a region has been, and thereby reflect the different lockdown policies implemented in the different countries and regions, a measure that elsewise is difficult to quantify.

By incorporating all these values in a prediction model, we aim at reflecting different aspects of geography, culture and level of activity in the regions across Europe. However, with lockdown measures being one of the key components in preventing the spread of virus, a pan European prediction model that does not directly include lockdown measures is very unlikely to outperform a model that does include such measures.

We therefore aim at carrying out the prediction at different levels of scale, with the broadest being all the 401 European regions where cases are reported. Narrowing down, the prediction is performed on the identified hot- and cold spots identified in the spatial autocorrelation analysis, reflecting the clusters of regions who did worst and best in terms of total Covid-19 infections. Lastly, the prediction is carried at a municipal level for the country Denmark, where the implemented policies have almost been uniform since the beginning of the pandemic.

We chose three different prediction models, all capable of predicting quantity values, and set out to predict the infection rate based on the 16 independent variables. The predictors of choice are random forest regressor [26], lasso regression [27] and support vector regression (SVR) [28,29]. The models were each chosen because they are widely used in similar prediction tasks.

3. Results

By November 2020, all European countries were affected by the Covid-19 pandemic, but the infection rates varied greatly between the individual countries and regions. Belgium, Spain and the Czech Republic are over the course of the whole period the countries with the highest infection rates. The regions of Wallone and Brussels in Belgium are the two worst hit, with total infection rates of 11,504 and 10,832 per 100,000 population. Iceland and Finland are the two countries with least infected regions. Five out of six regions in Iceland have less than 100 infected per capita and its capital region have had a total of 115 infected per 100,000 population. In Figure 2, bi-weekly infection rates for the included regions are visualized at three different weeks of 2020.

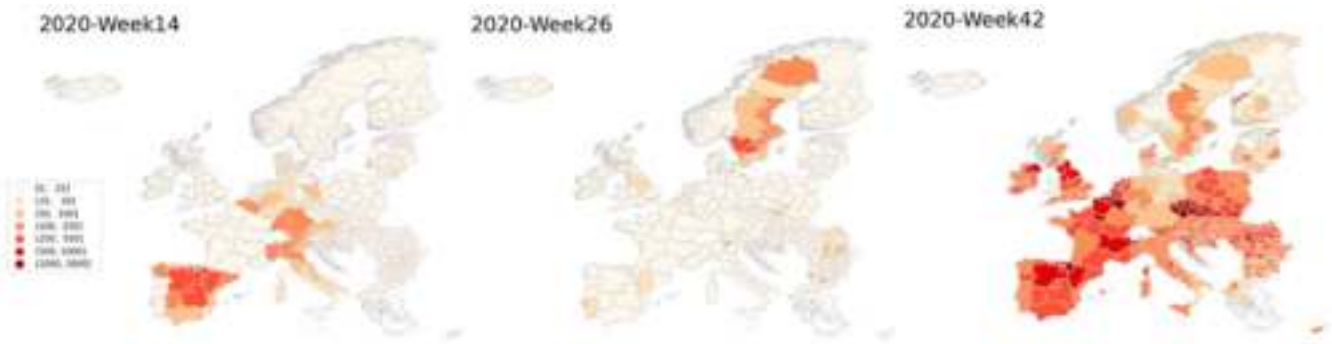

Figure 2. Bi-weekly infection rates at week 14, week 26 and week 42.

Over the whole time period of March to November, peak infection rates has occurred at different countries. In the spring of 2020 northern Italy and Spain were the worst affected, whereas in the summer Sweden was the only country with overall high infections, in the fall of 2020 the majority of countries were seeing surges in infections far higher than those observed in the spring.

3.1. Spatial Autocorrelation, EU and DK

The spatial autocorrelation analysis was carried out at the levels of all European Regions and for the municipalities in Denmark. The analysis covers a period of 32 weeks, from the start of April until start of November 2020, for which the infection rates has been accumulated.

The spatial autocorrelation analysis seen in Figure 3 successfully identified clusters of hot- and coldspots together while also locating some doughnuts and diamonds. For Europe as a whole it is clear that the identified hotspots over the whole pandemic is the majority of Spain, France and Belgium and some parts of The Netherlands, the Czech Republic is also identified as a hotspot resulting in the surrounding regions of south Germany and Poland being doughnuts, i.e., low infection areas surrounded by high infected areas. Low infection areas, coldspots, are seen to mostly in the Nordic regions of Norway, Finland, the Baltic countries and Iceland, while Greece and Cyprus are the only southern regions reporting low infection rates.

For the municipalities of Denmark, high-infection areas are centered around the capital region of Copenhagen and its surrounding municipalities. High infection rates are also seen in the second largest city of Denmark, Aarhus, as this is identified as a diamond, i.e., having high infection rates while its surrounding municipalities have not seen similar high rates. The coldspot are seen to be the less populated areas of southern Denmark and

central-north Jutland. The third largest city of Denmark, Odense in central Fyn, are within the large cold spot towards south and hereby not having significant higher infection rates than its surrounding municipalities.

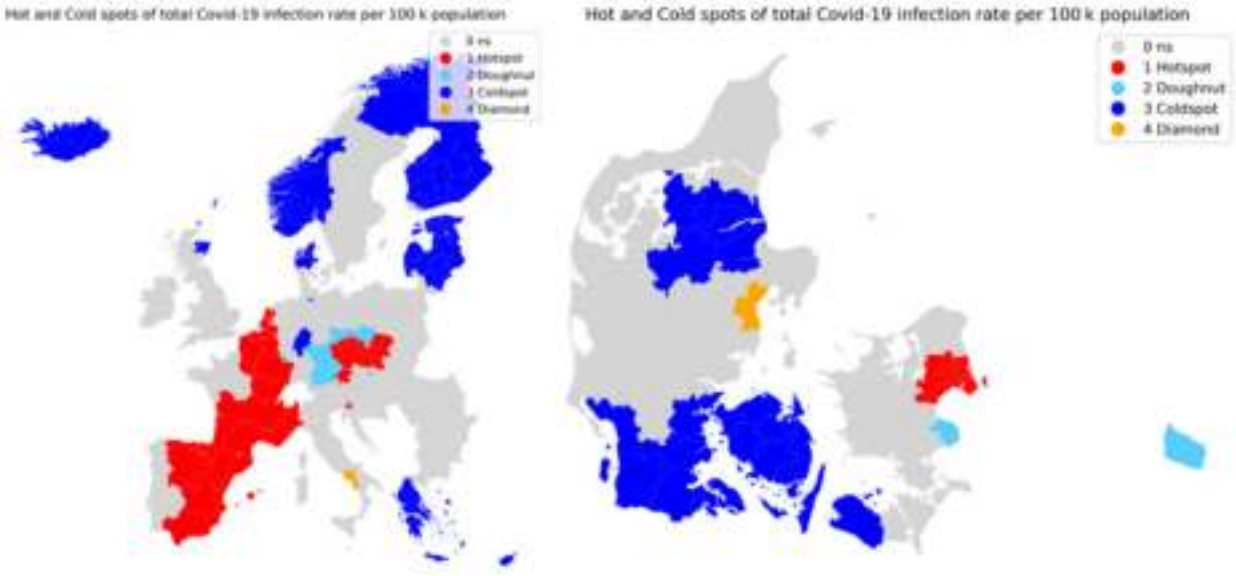

Figure 3. Hot and cold spots of total accumulated Covid-19 cases in the EU regions (left) and the municipalities of Denmark (right).

As the spatial autocorrelation is based on accumulated infection rates, it does not show how infection rates has fluctuated over time in the individual regions, for this purpose we can assess the results of emerging hotspot analysis.

3.2. Space Time Patterns—Emerging Hotspot Analysis

The emerging hotspot analysis is a product of spatial autocorrelation over time, where each classification bin is a measure of how many times a regions has been either a hot- or coldspot or having no significance. As described in Section 2.2.2, two analyses are carried out each with a different threshold for how many times a region must be of a category that falls under one of the space time pattern categories.

3.2.1. Emerging Hotspots—Europe

In Figure 4, the results of the emerging hotspot analysis for the EU regions are seen. Both at the 90% time interval setting and the 70% time interval setting, the majority of regions are seen to fall under the 'not significant' class, meaning that they did fall under any of the categories specified in Table 2. At the 90%-time interval map, new hotspots are seen to appear in northern Italy, parts of Austria (including Vienna), Croatia and the capital region of Poland. The sounding regions, that is mostly Austria and Croatia, are classified as oscillating hotspots, which are new hotspots that has in fact been a coldspot at an earlier time. Oscillating coldspots are centered on Ireland, Northern Ireland and some regions in Scotland, while some regions in Finland are seen to be intensifying coldspots which are regions that has generally have low infection rates and keep on doing so.

As seen in Figure 5, when lowering the time setting from 90% to 75%, more regions are expectedly classified in to the hot and coldspot categories. Especially the sporadic hot and coldspots are seen to be greater in number, with most of Romania, eastern France and northern Italy covered, and also Luxembourg, Wales and parts of The Netherlands (including its capital region) being sporadic hotspots. Sporadic coldspots are also seen to be greater in number, covering northern Germany, southern Denmark, eastern Hungary and Poland, and southern Italy. A larger part of Finland and all of Iceland is now classified as intensifying hotspots, and the regions of and around Ireland not changing their classification.

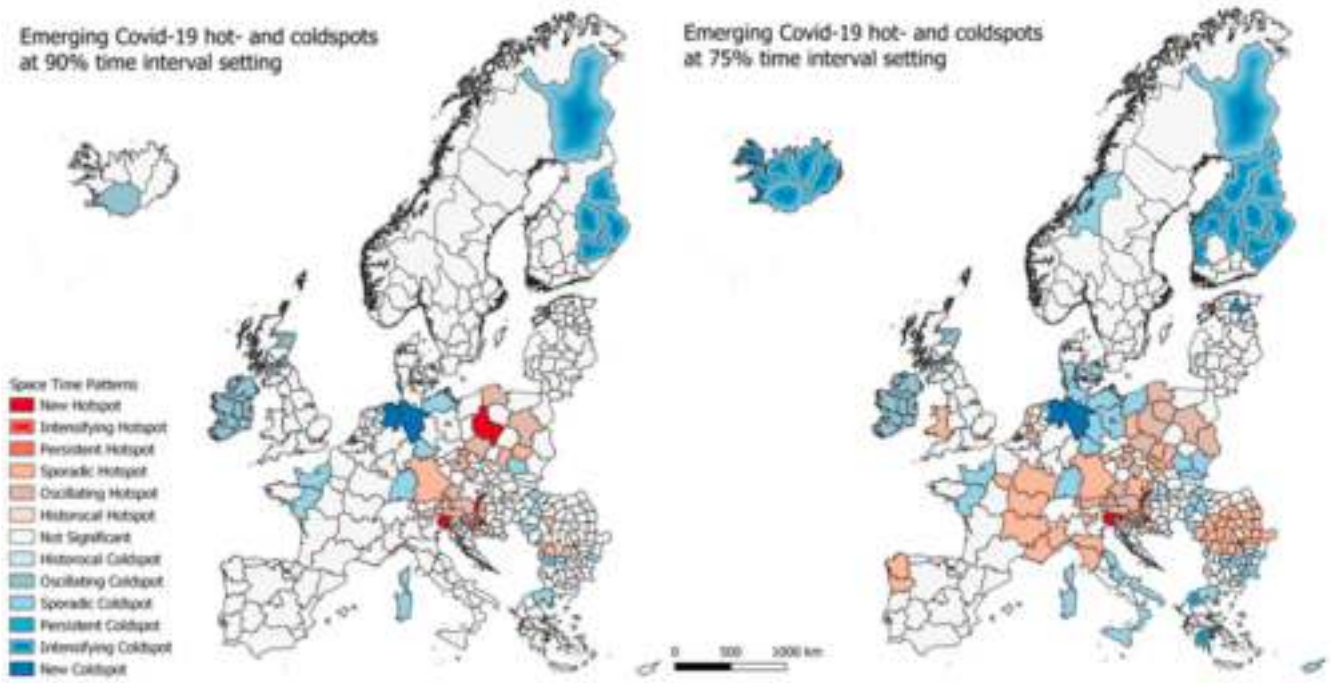

Figure 4. Emerging hotspot results for total cumulative infection rates from week 13 to week 45 in Europe at 90% (left) and 75% (right) time interval setting.

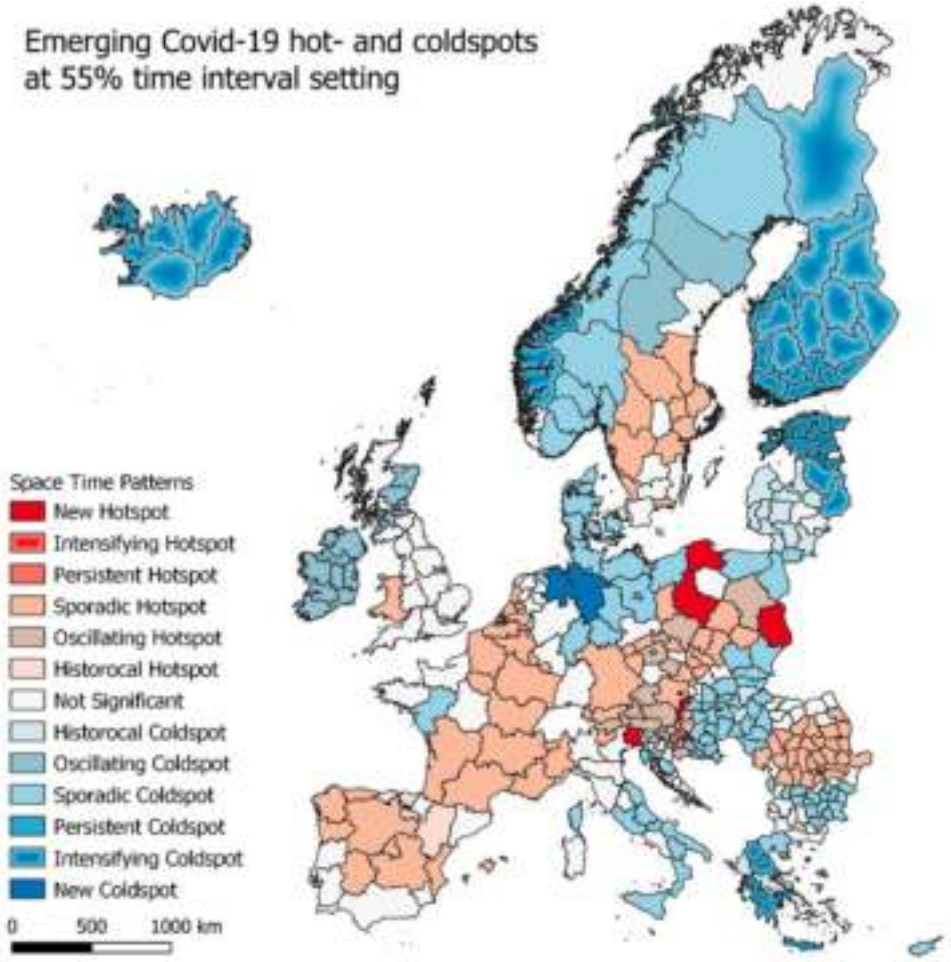

Figure 5. Emerging hotspot results for total cumulative infection rates from week 13 to week 45 at 55% time interval setting.

3.2.2. Emerging Hotspots—Denmark

A similar emerging hotspot analysis was carried out for the municipalities of Denmark, the results are seen in Figure 6. Interestingly, only the sporadic coldspots are seen to be greater in number when the time interval threshold is lowered from 90% to 75%. At the lower threshold, these sporadic coldspots covers large parts of mid- and western Jutland together with the municipalities towards south for the islands Lolland and Falster. For both the analysis, the outcome is otherwise roughly the same. In close proximity to Copenhagen, we see four oscillating hotspots and going a bit further away from the capital we see the sporadic hotspots. The oscillating coldspots are meanwhile seen to be at the opposite end of the country, in the very north of Jutland, where the 4th largest city of Denmark, Aalborg in also placed. Interestingly, neither the capital of the second and third largest cities of Denmark are categorized as any kind of hotspot. In Figures 7 and 8, the emerging hotspot analysis is implemented on a monthly basis, showing in which parts of the country infection rates where increasing and decreasing at the given times.

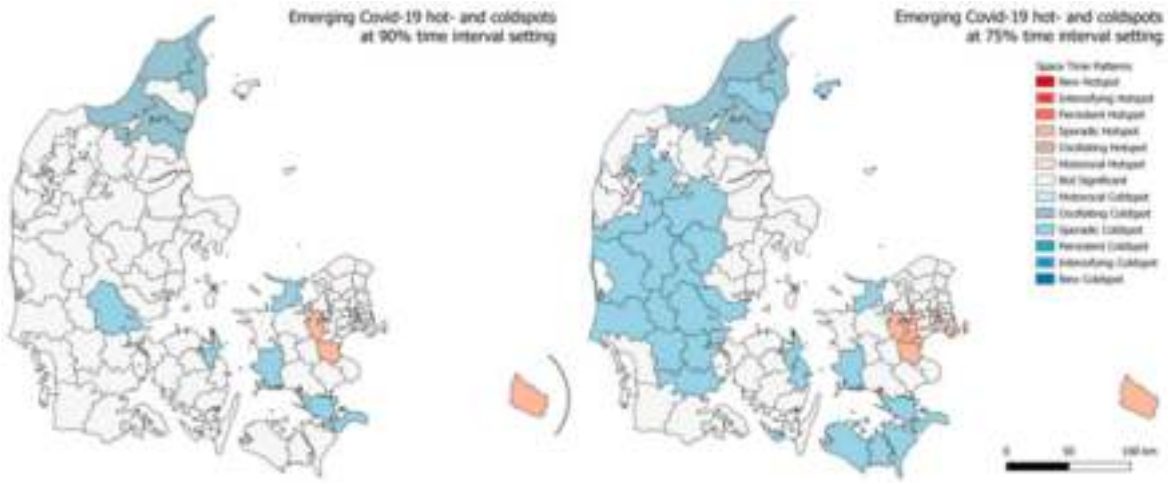

Figure 6. Emerging hotspot results for total cumulative infection rates from week 13 to week 45 in Denmark at 90% (left) and 75% (right) time interval setting.

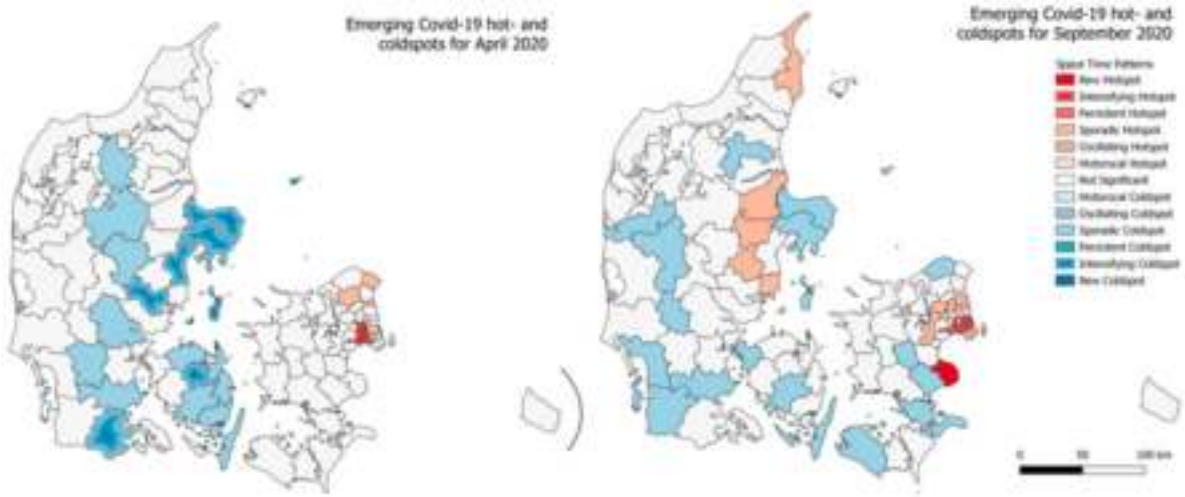

Figure 7. Emerging hotspot results for total cumulative infection rates in Denmark for April 2020 (left) and September 2020 (right) at 75% time interval setting.

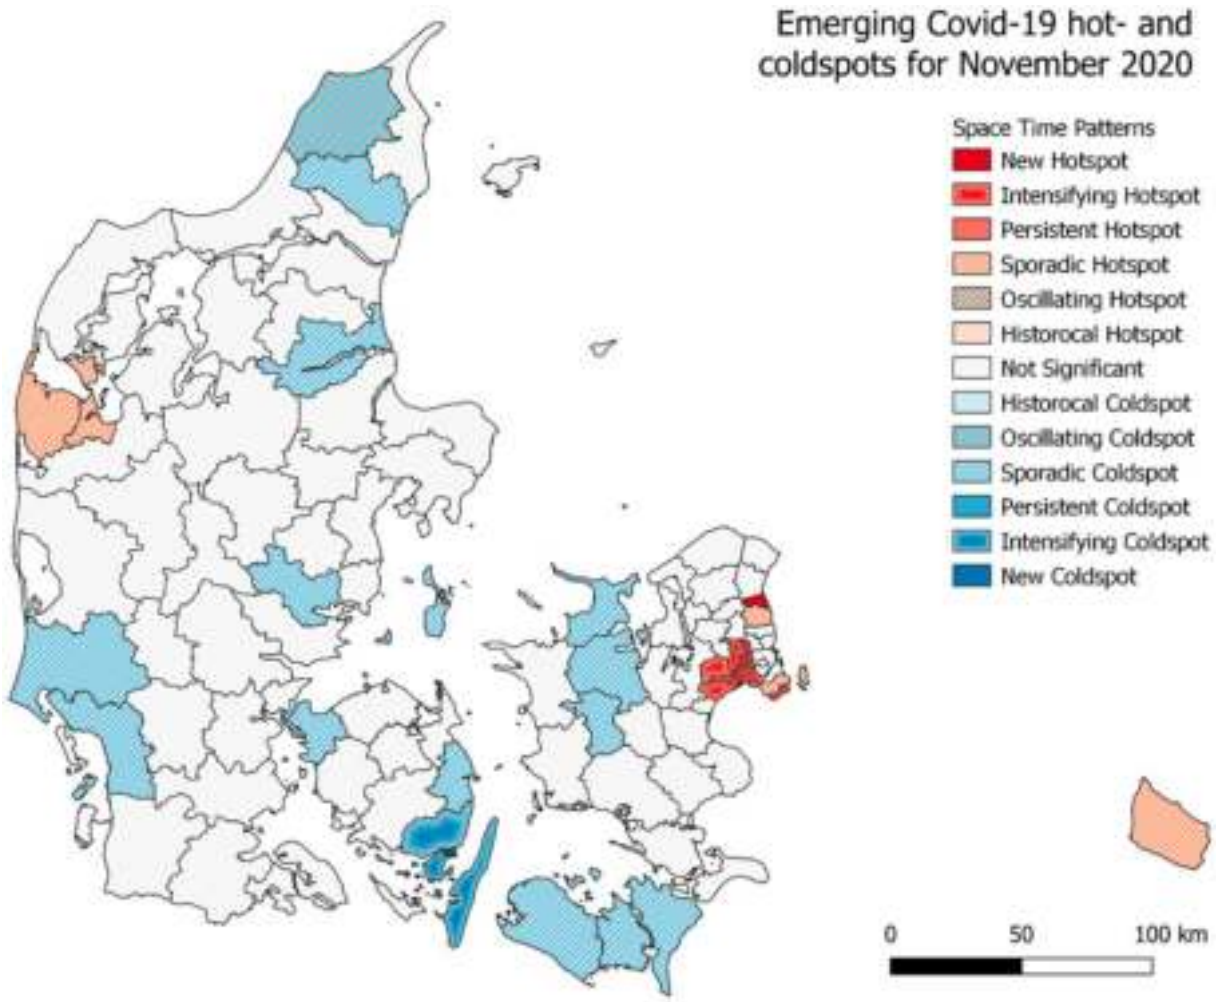

Figure 8. Emerging hotspot results for total cumulative infection rates in Denmark for November 2020 at 75% time interval setting.

3.3. Geographically Weighted Regression—EU

The GWR model was used to analyze how the 16 variables affected the total infection rate over the 401 European regions, the results consist of both the global regression model (OLS) and as local regression model. An automatic calibrated adaptive bi-square kernel [25] was used, with a bandwidth size of 104. See the global result statistics in Table 3 and local regression model results in Table 4.

Table 3. The global regression model (OLS) and the local regression model (GWR) results.

Model	Res Sum Squares	AIC	AICc	R^2	Adjusted R^2
OLS	219.230	927.850	931.448	0.453	0.432
GWR	66.922	654.585	752.719	0.833	0.765

Table 4. Variable statistics for OLS and GWR model. Est = Estimate, SE = Standard Error.

Variable	OLS		*p*-Value	GWR			
	Est	SE		STD	Min	Median	Max
X0	0.000	0.038	1.000	0.380	−0.909	−0.010	0.805
X1	0.111	0.043	0.009	0.137	−0.110	0.113	0.676
X2	0.109	0.063	0.084	0.222	−0.246	0.167	1.122
X3	−0.264	0.056	0.000	0.412	−1.612	−0.184	0.279
X4	0.007	0.049	0.893	0.306	−0.784	0.119	0.683
X5	−0.071	0.045	0.116	0.197	−0.761	−0.113	0.487
X6	0.195	0.054	0.000	0.359	−0.598	0.112	1.312
X7	0.011	0.051	0.828	0.441	−0.629	−0.018	1.487
X8	0.048	0.046	0.297	0.208	−0.568	−0.028	0.355
X9	−0.102	0.044	0.021	0.306	−1.074	−0.200	1.349
X10	−0.087	0.045	0.056	0.225	−0.610	0.010	0.780
X11	−0.134	0.052	0.010	0.322	−1.135	−0.280	0.640
X12	−0.115	0.049	0.019	0.353	−1.257	−0.022	0.794
X13	0.144	0.057	0.011	0.298	−0.997	0.039	0.500
X14	0.506	0.050	0.000	0.279	−0.124	0.372	0.956
X15	−0.142	0.050	0.004	0.376	−0.697	−0.069	1.360

Comparing the global regression model (OLS) with the local regression model (GWR) in Table 3, the residual sum of squares is seen to drop significantly from 219 to 66, and the AIC dropped from 931 to 752. The adjusted R^2 value almost got a twofold increase from 0.432 to 0.765, indicating that the GWR model is able to account for 76.5% of the variation in Covid-19 infections. These results confirm the superiority of GWR in a case where we expect spatial variably in the relationship between the variables [30]. We can further investigate the statistics results for each of the variables included in the model, these are shown in Table 4.

Inspecting the *p*-values of the individual variables in Table 4, the five variables having the greatest significance (*p*-value) on the dependent variable are X1 (Population Density), X3 (Cafes), X6 (Bars), X14 (Non-methane VOC) and X15 (PM_{10}). The mapped coefficients for these five variables are shown in Figure 9. In the mapped coefficients, a similar pattern is seen between café and PM_{10} levels that the variables are of most influence in central Scandinavia, i.e., central Norway and Sweden, Denmark and Northern Germany. The other three variables do to some degree also share the same pattern, with the greatest influence on Covid-19 infection rates seen in eastern Europe, France, and to some degree Scandinavia and Italy.

X14 (Non-methane VOC) and X15 (PM_{10}) are both measures of air pollution, so these could be expected to have similar estimate coefficients, whereas the coefficients calculated in the OLS model in Table 4 show that X14 is positive and X15 is negative. The mapped coefficients in Figure 9 shows that the variable coefficients geographically are very different from each other, and similarly in Figure 10 where the two variables are seen to have significance in areas directly opposite to each other. Even though X14 and X15 are measures of air pollution, they each represent different emission sources and thus, do not follow the same geographic pattern.

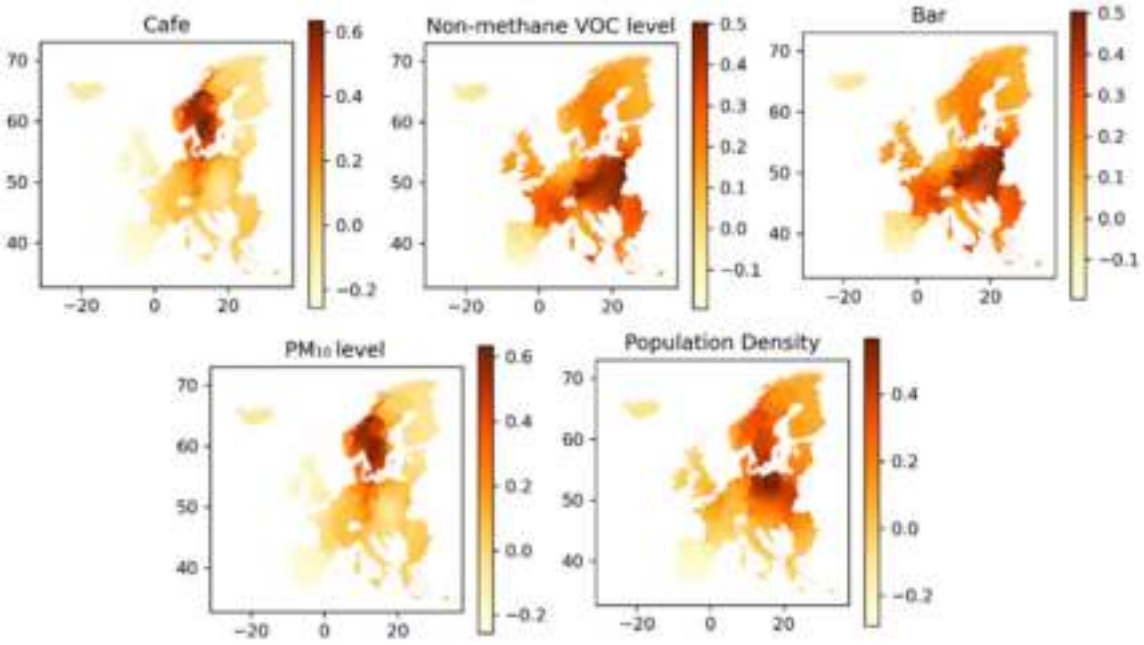

Figure 9. The coefficients of the 5 most significant variables in explaining total Covid-19 infections.

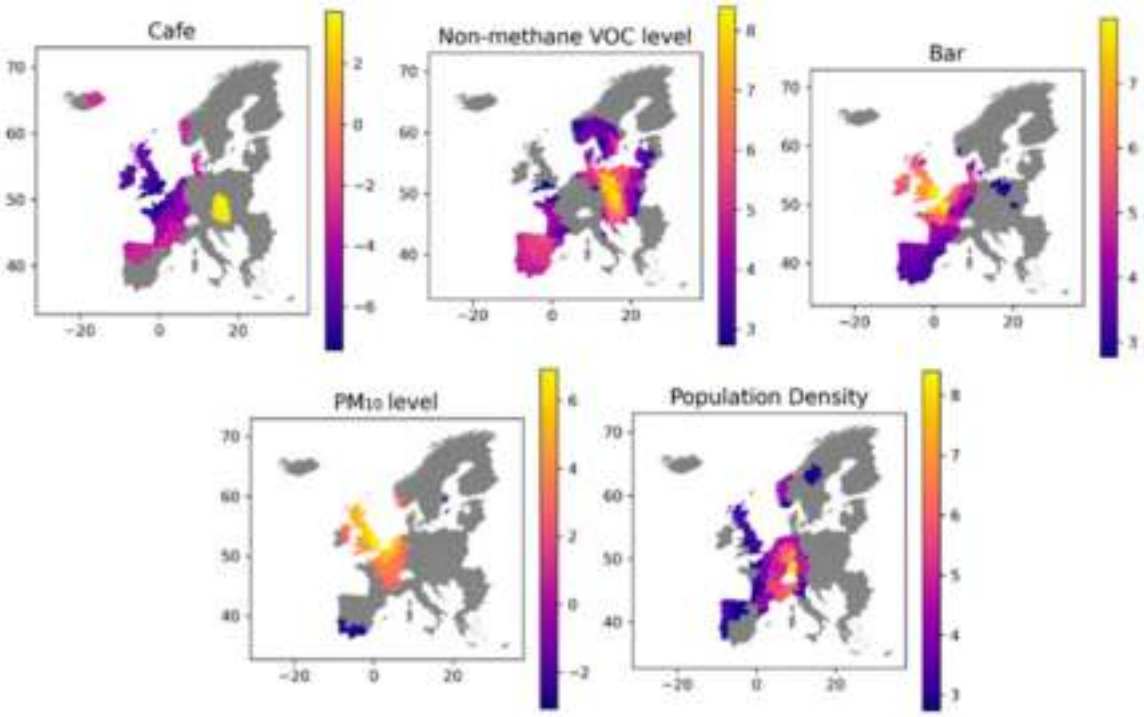

Figure 10. The significance of the 5 most significant variables in explaining total Covid-19 infections.

The charts in Figure 10 are showing in which regions each variable is having a significance towards the infection rate, this can both be a positive (high rates) and negative (low rates) impact on the rate. In the regions coloured in grey the variable did show any significance toward infection rates.

The population density is seen to have an overall positive effect on infection rates, with the greatest effect seen in the central European regions, covering Germany, France, Belgium, The Netherlands and England. Looking at cafes as bars, they seem to have effect in roughly the same area of western Europe, but interestingly each of these variables are affecting infection rates in opposite directions. Areas with a high number of bars per capita

are having high infection rates, where the opposite is the case with cafes per capita in roughly the same areas. Since the two pollution level indicators, Non-methane VOC and PM_{10}, are measured as year-over-year changes, higher values equal to a higher percentage yearly change. While we see the pollution indicators having impact at different geographic regions, the impact of them is highly positive. This indicates that regions that did not have a decrease in their pollution levels also had high Covid-19 infection numbers.

Figure 11 shows the geographic distribution of the condition numbers, local R^2 values, and standardized residuals. The condition number checks for redundancy in the variables used in the local regression task, and values above 30 are a cause for concern and results within these regions are not to be trusted [31]. For the most part, the condition numbers do not cause reasons for concern except at the very red regions of Romania and Greece. The levels here are in fact so high that the model output is not of any use in these regions. The R^2 values are indicators of how well the model can fit the regression locally. The highest R^2 values are in the regions around East Germany, Poland and Czech Republic, together with some parts of Scandinavia and Spain. The lowest R^2 values are seen in Italy, parts of France and the North of Romania. Lastly the residuals are mapped to investigate if these appear to be clustered, to have a properly fitted model the residual should be evenly distributed in space. The residual map in Figure 11 does not indicate any spatial clustering of residuals.

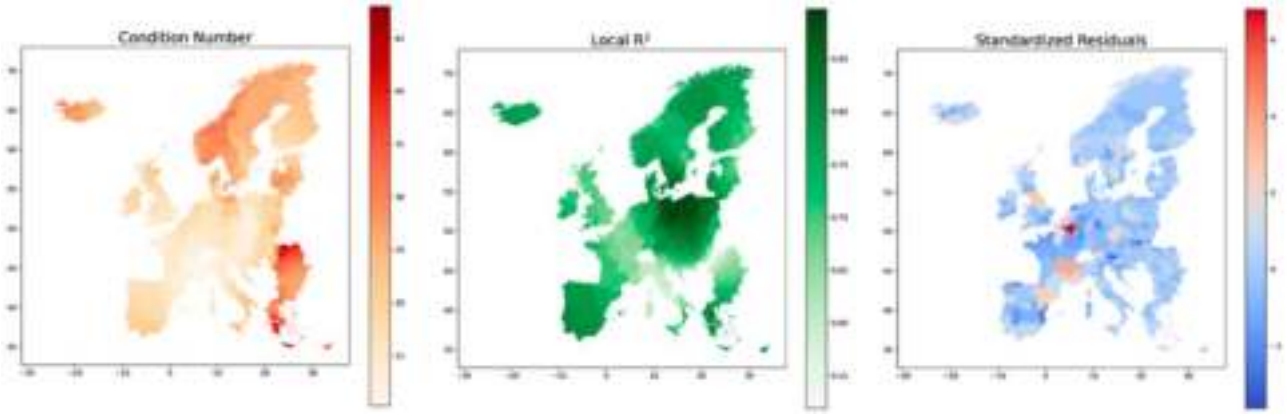

Figure 11. Geographic distribution of Condition Number, Local R^2 values and Standardized Residuals for the GWR model of total Covid-19 infections.

3.4. Machine Learning Prediction

The machine learning prediction aimed at predicting the total infection rate for the included regions based on the variables described in Section 2.1 and Table 1. We tested three different models at four different scale levels, ranging from all of Europe, to selected regions of Europe and down to the individual municipalities of Denmark. All data included in the model are normalized and split into training and test data at a ratio of 70/30. The models are evaluated using the accuracy and mean absolute error (MAE) metrics, the accuracy should be as high as possible and MAE as low as possible. All models across all regions are ran over 10 iterations each and the evaluation scores are the average of the result of each iteration. The results of the models are seen in Table 5.

Across the included prediction models, the random forest is the best performing in both accuracy and MAE. The random forest prediction of all European regions is seen to have an accuracy of 52%, where, when only including the hot- and cold-spots, the same predictor is achieving 76% accuracy. The latter is of course a selection of the regions performing best and worst in terms of infection number, so a higher accuracy is expected here. However, the lowest MAE of all predictions is seen to be the pan European random forest prediction. The random forest prediction for the municipalities of Denmark showed 61% accuracy and a MAE of 0.095. This is finest level of scale for the predictions and also within a single country, so the policies for infection counter-measures are much more uniform across the regions.

Table 5. Machine Learning Prediction Results, MAE = Mean Absolute Error.

Area	Nr. of Regions	Model	Accuracy	MAE
Europe	401	Random Forest	**52%**	**0.079**
		Lasso	36%	0.153
		Support Vector Regression	51%	0.151
Europe—Hot- & Coldspots	128	Random Forest	**76%**	**0.099**
		Lasso	74%	0.285
		Support Vector Regression	73%	0.256
Europe—Hotspots	56	Random Forest	19%	**0.177**
		Lasso	- %	0.217
		Support Vector Regression	- %	0.221
Denmark	98	Random Forest	**61%**	**0.095**
		Lasso	35%	0.233
		Support Vector Regression	41%	0.232

Numbers marked in bold are the best achieved accuracy measures for the given area.

The importance of the 10 most significant variables in the random forest pan Europe prediction is shown in the plot in Figure 12. It is clear that the year over year change of Non-methane VOCs are by far the most importance variable in this model, secondly comes population density, a variable that is also expected to be of significance importance to the spread of the virus. These variables are the only ones with a significance greater than 10%, and following them comes gas stations and other measures for air quality and pollution levels. This is according well to the results found in the geographic weighted regression models, where both Non-methane VOC and Population density showed great significance in explaining total infection rates.

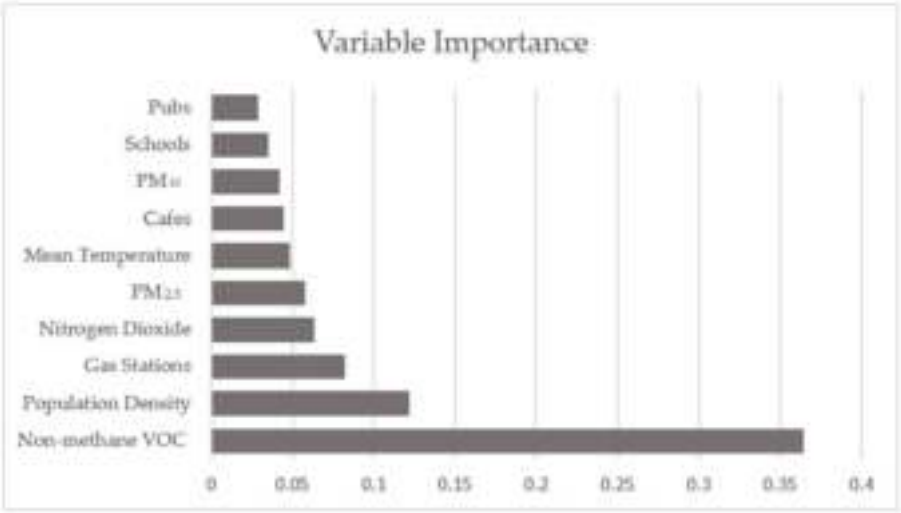

Figure 12. Variable Importance for Random Forest Regression of all EU regions.

4. Discussion

Throughout the paper, we have presented and implemented a number of tools that can be used to help understand how the spread of Covid-19 has evolved over time, where it is currently most active and what are the factors that affect this spread. For the most part of 2020 and continuing into 2021, Europe has been severely hit by the global pandemic with the first wave seen in the spring of 2020 followed by a summer with generally low infection rates and into the fall and winter of 2020 where the second, and in many cases, even more severe wave of infection raging over Europe. By the end of 2020, no country in Europe has remained safe and unaffected by the virus.

Our spatial autocorrelation analysis identified the central European regions as the hotspot of the total pandemic, and the more isolated and less populated Nordic regions

as cold spots. This finding confirms our general understanding of how viruses spread, where densely populated and interconnected areas are at higher risk for a fast spread of pandemic [32,33]. As this analysis does not reflect the spread of virus over time, we used the finding of the spatial autocorrelation in an emerging hotspot analysis. This analysis is a powerful tool in mapping the pandemic in its current status and still factoring in how the individual regions have been affected in the past. The analysis can be implemented at many different scales of time and can hereby be used to study the spread of virus over long periods of time and down to monthly or even bi-weekly status of individual regions. The emerging hotspot maps are great tools for authorities to help deciding on where measures must be tightened or relieved while also serving as a great communication tool for the citizens to understand the basis of such decisions.

Our further analysis revolves around investigating what geographic factors affects the infection rate of Covid-19 in Europe, for this purpose we carried out a geographically weighted regression analysis. We found that the number of bars and cafes are significantly correlated to infection rates, confirming that places for social aggregation serve as infection source. Further analysis could be done at finer scales, to provide more in-depth knowledge of how the virus spread locally throughout cities and hereby help decision making regarding if such places should have restrictions imposed. Furthermore, we found that the air-quality and pollution indicators of Non-methane VOC and PM_{10} levels are also correlated with infection rates. This proves as an indication towards the level of activity in the society as lockdown measures expectedly have an effect on pollution levels [16], and indeed regions that had lower reduction in pollution levels have higher infection rates. Moreover, the GWR analysis showed a positive correlation between population density and infection rates, a finding that confirms the hypothesis that population density is associated with higher Covid-19 infection rates [15,34–37].

Finally, we implemented all the variables in a machine learning framework including random forest, support vector regression and lasso with the goal of assessing the predictability of infection rate solely based on the included variable features. Our pan European model was able to predict the infection rate with 52% accuracy and the single country model of Denmark resulted in 61% accuracy. A key component in predicting infection rates is naturally to which degree a country has introduced lockdown measures, a variable that is difficult to quantify and that was not introduced in the model. To achieve better prediction results, such a variable is highly recommended to include in the future works. The variable importance showed that pollution measures have a great importance in the prediction and given the fact that pollution levels and lockdown measures are closely correlated, we suggest that future research use pollution measures as one potential proxy of countrywide lockdowns. Certainly, while moving towards electric vehicles and renewable energies, such a proxy will not function. Actual levels of lockdown could also be quantified, but that is a challenging task since policies and their implementation are subject to human interpretation and behaviour. Due to the fact of dissimilar policies implemented, we found that implementing a single model across multiple countries is challenging, this is further concluded by result of the same model performing 10% better within a single country, i.e., Denmark, where policies are more uniform. This is largely due to a number of reasons such as (a) dissimilar number of COVID tests per capita rooted in the cost of Covid-19 tests from being free of charge (e.g., Denmark) or expensive (e.g., Greece, Romania), (b) not applying a universal standard for reporting infection numbers, (c) diversity of geodemographic distribution across each country, (d) dissimilar health services across Europe and, (e) wide diversity of cultures, behavioural factors, dominant background health issues in Europe.

5. Conclusions

This study presented a series of useful geospatial methods for studying the geography of Covid-19 and what factors facilitate the pandemic's spread. We located European hot- and cold spots of infection rates and used this to further investigate and visualize how individual regions and municipalities have progressed over time. The emerging

hot spot analysis is especially a powerful tool in understanding and visualizing where case numbers are rising and falling and hereby contribute to decision-making and raise understanding in the general public. We further examined the drivers of the pandemic through a pan European statistical GWR model and in a machine learning environment. The GWR model shows the most significant points of interest in explaining infection rates, while also showing that population density and air pollution are also strong explanatory factors. Our machine learning model, i.e., the random forest method, reached prediction accuracies of 52% and 61% for Europe and Denmark and confirmed that pollution data can be used as a relevant variable in predicting infections. In order to develop better prediction models in the future, we suggest including further variables that reflects lockdown levels of individual regions over time. Such a variable could be made from close examination of adopted policies, but could as well be derived from pollution levels.

Abstract

Objective: Since the identification of COVID-19 in December 2019 as a pandemic, over 4500 research papers were published with the term "COVID-19" contained in its title. Many of these reports on the COVID-19 pandemic suggested that the coronavirus was associated with more serious chronic diseases and mortality particularly in patients with chronic diseases regardless of country and age. Therefore, there is a need to understand how common comorbidities and other factors are associated with the risk of death due to COVID-19 infection. Our investigation aims at exploring this relationship. Specifically, our analysis aimed to explore the relationship between the total number of COVID-19 cases and mortality associated with COVID-19 infection accounting for other risk factors. **Methods**: Due to the presence of over dispersion, the Negative Binomial Regression is used to model the aggregate number of COVID-19 cases. Case-fatality associated with this infection is modeled as an outcome variable using machine learning predictive multivariable regression. The data we used are the COVID-19 cases and associated deaths from the start of the pandemic up to December 02-2020, the day Pfizer was granted approval for their new COVID-19 vaccine. **Results**: Our analysis found significant regional variation in case fatality. Moreover, the aggregate number of cases had several risk factors including chronic kidney disease, population density and the percentage of gross domestic product spent on healthcare. **The Conclusions**: There are important regional variations in COVID-19 case fatality. We identified three factors to be significantly correlated with case fatality.

1. Introduction

Coronavirus disease 2019 (COVID-19) is now a considered a pandemic by the World Health Organization. The main objective of this study is to report on the association between regional case fatality of COVID-19, kidney diseases mortality, diabetes, population density and the Gross Domestic Product (GPD). This cross-sectional historical data was constructed by combining data from several sources [1]-[6].

The above sited data sources were accessed on December 2-2020. We included in the study the cumulative number of COVID-19 cases and the associated death counts by country as of December 2-2020. We excluded countries that had cumulative count less than 10,000 cases. The data base has 120 countries, and we divided them into regions according to the classification given in data source number 2, resulting in 15 regions. This classification is shown in **Table 1**. This table has in the first column the names of the countries, the second column is the name of the region they belong to, within brackets, the number of countries in that region, and the third column is a code given to each region.

Basically, we have two outcome variables of interest: 1) The aggregate number of cases per country over the period ending December 2-2020 (AC). 2) The COVID-19 Case Fatality (CF). This is calculated as:

AC = Count of COVID-19 cases analyzed at the regional level.

CF = Count of deaths attributed to COVID-19/(Count of COVID-19 cases) × 100,000.

This paper has three objectives. Firstly, we quantify the degree between regions variation in both AC and CF. The second objective is to identify the important factors associated with AC and CF. We use machine learning algorithm to build a regression models with the entire data set divided into learning set and validation test to quantify the predictive accuracy of the constructed models.

2. Selected Risk Factors

2.1. Chronic Kidney Diseases

Chronic Kidney Disease (CKD) is an important contributor to morbidity and mortality from noncommunicable diseases, and this disease should be actively addressed to meet the UN's Sustainable Development Goal target to reduce premature mortality from non-communicable diseases by a third by 2030 [2]. We extracted the CKD prevalence and the associated mortality from the countries listed in table. The rationale was that there are many published articles

highlighting the importance of CKD as a possible risk factor for COVID-19 mortality.

A recent meta-analysis [7] outlined several reasons urging investigators to emphasize the importance of CKD during the COVID-19 infection. It was also noted in [7] that CKD has not attracted enough awareness due to its inconspicuous course, especially in the early stage. Both diabetes and hypertension are the leading causes of CKD in all developed countries and many developing countries, and the long-term or advanced CKD usually increases the risk of car-

diovascular diseases. To be noted, these conditions accompanying CKD are all risk factors that exacerbate the COVID-19 patients. The present study highlights the importance of CKD as a risk factor for COVID-19 mortality. Some reports either did not include information on CKD or failed to state the definition of CKD used in the study. By contrast, the study by Williamson *et al.* [8] includes data for three subgroups with CKD. These data also demonstrate that patients with severe forms of CKD have a very high risk of COVID-19 mortality, which is even higher than that of other known high-risk groups, including patients with hypertension, obesity, chronic heart disease or lung disease [9] [10] [11]. The CKD data indicate that these patients deserve special attention with regard to COVID-19.

2.2. Population Density

Two studies [12] [13] utilized data from Japan suggested that the population density, which is somewhat indicative of social distancing, was a significant factor associated with COVID-19 infection. The effect of population density on the morbidity rate was also discussed in a case study of Iran [14]. These studies suggested that several cofactors introduce uncertainty. When discussing the effects of policies, a multi-city analysis representing different countries may be imperative. In multi-country analyses, the number of conducted tests may add uncertainty because this number depends on medical and economic resources for each country.

2.3. Diabetes

A recent population-based study from Italy [15] documented that the presence of comorbidities, including diabetes, were associated with a more severe course of COVID-19 and a higher fatality rate. Other studies from the most affected countries, including China, United States and Italy, seem to indicate that prevalence of diabetes among patients affected by COVID-19 is not higher than that observed in the general population, thus suggesting that diabetes is not a risk factor for SARS-CoV-2 infection. However, a large body of evidence demonstrate that diabetes is a risk factor for disease progression towards critical illness, development of acute respiratory distress syndrome, need for mechanical ventilation or admission to intensive care unit, and ultimately death. The mechanisms underlying the relationship between COVID-19 and diabetes remain to be elucidated. In particular, it is still unresolved whether is diabetes per se, especially if poorly controlled, or rather the various comorbidities/complications associated with it that predispose patients with COVID-19 to a worse prognosis. In fact, conditions that cluster with diabetes in the context of the metabolic syndrome, such as obesity and hypertension, or complicated chronic hyperglycemia, such as cardiovascular disease and chronic kidney disease, have also been associated with poor prognosis in these individuals and the available studies have not consistently shown that diabetes predict disease severity independently of them [15].

The estimated global prevalence was 9.3% in 2019 with an upward trend [16] [17]. In the USA alone, more than 34 million adults had known or undiagnosed diabetes in 2018 [18]. In 2017, diabetes was listed as the underlying or contributing cause of death on 270,702 death certificates, which corresponds to a crude rate of 83.1 per 100,000 persons [18]. Infectious diseases are more frequent and can be associated with worse outcomes in patients with diabetes [19]. Therefore, it is not surprising that diabetes has been considered as a possible risk factor or a predictor for worse outcomes in patients with coronavirus disease 2019 (COVID-19) [20] [21] [22]. COVID-19 rapidly reached the level of a pandemic and has caused more than 850,000 deaths worldwide within a few months despite unprecedented mitigation measures [23]. The strength of the association between diabetes and COVID-19 has been investigated in observational cohorts around the world. We aimed to systematically review and conduct a meta-analysis of the available observational studies reporting the effect of diabetes on mortality among hospitalized patients with COVID-19.

We obtained the data of global prevalence of diabetes by country from [24]. The rationale behind including diabetes in the data base of or study is to explore the strength of the country level diabetes prevalence with the CF outcome variable.

2.4. Gross Domestic Product (GDP) and the Percentage of Spending on Health Care (PHSC)

A recent article [25] analyzed data from 88 countries included as a covariate the percentage of government spending on healthcare. This factor is an indicative of the level of preparedness of the healthcare system to face urgent crisis such as the one caused by the COVID-19 pandemic. The authors showed that there is a significant relationship between an increase in health care spending and reduction in the COVID-19 case fatality. The finding that countries with strong healthcare capacity had fewer deaths per confirmed case was unsurprising. In this sense, the [25] study confirms previous research on the association of overall mortality (all causes) and healthcare funding [26].

3. Data Analysis

We divided the data analysis into two sections. In the first section univariate and descriptive statistics are produced with graphics. We also explore the extent of regional variability for the parameters of interest. This is measured by comparing the between regional variation to the within regional variations. A widely used statistic in this regard is the "Intraclass Correlation Coefficient" (ICCC). In the second stage we first identify the risk factors associated with the outcome of interest. Factors that are significantly correlated with the outcome of interest are used in a multivariate analysis model. The model that we used identifies regions as random effects. Using predictive analytic machine learning regression approach to evaluate the joint effect of the selected covariates on the outcome of

interest is done by splitting the data into training data (70% of the entire data) and validation or test set (the remaining 30% of the data).

3.1. Descriptive Measures (Table 2)

The lowest average population density is in region 4, or, HIAP (47267.5 ± 51256.458).

The highest average population density is in region 7, or, West Europe (2628158.14 ± 6383767.55).

The histogram of population density is shown in Figure 1.

In Table 3 we present the summary statistics for the aggregate number of COVID-19 cases.

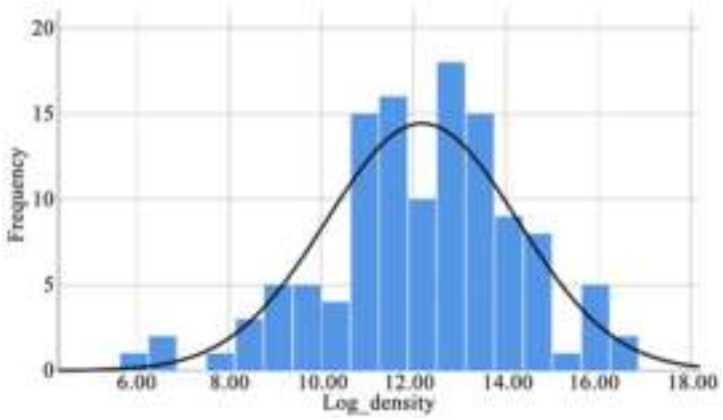

Figure 1. Histogram of log-population density.

Table 2. Summary measures of population density.

11	10	953,104.00	1,947,275.831
12	20	233,409.90	230,576.529
13	8	36,655.00	38,224.367
14	8	39,255.13	34,628.880
15	3	272,281.33	450,353.611
Total	119	530,003.45	1,619,102.721

From Figure 2 we can see that the distribution of the number of cases is highly skewed to the right and the data in Table 1 shows that the variance is much larger than the mean, a phenomenon known as "over dispersion".

In Table 4 we present the mean, standard deviations of CF as defined above. The largest mean CF is in Andean Latin America (5626.36 ± 1685), while the smallest mean number of CF is in Central Asia (1199.95 ± 402.64).

The large variations in CF can better be depicted from the boxplot of the data as shown by the boxplot as given in Figure 3.

It appears from the above boxplot (Figure 3) that there is considerable variation in the distribution of CF. One way to stabilize this variation is to employ a specific transformation. We selected the logarithmic transformation, so that the dependent variable of interest is Y = Log (CF). The histogram of this new outcome variable Y is given in Figure 4. The Q-Q plot of Y is given in Figure 5 and it shows the closeness of the distribution of Y to that of the normal distribution.

The primary predictor of interest is CKD case fatality (Table 5).

As can be seen from Figure 6, there is great amount of variation among the 15 regions with respect to CKD case fatality. The next covariate we examine is the percent of GDP spending on healthcare. The summary measures are shown in Table 6, with the histogram given in Figure 7.

The above histogram (Figure 7) is quite symmetric apart from an extreme outlier. We shall not employ any transformation on this variable.

In Table 7 we present the summary measures of the diabetes prevalence for each of the 15 regions in the data.

The lowest diabetes prevalence is in WSSA (2.95), while the highest is in MENA region (11.965).

3.2. Detection of Regional Clustering

In this section we shall quantify the degree of clustering for any continuous variable.

We assume that we have k regions and that the individual units within each region are the countries as indicated in Table 1. To articulate this concept, we first assume that the quantity of interest measured in the j^{th} country within the i^{th} *region,* y_{ij} is modelled as

$$y_{ij} = \mu + \tau_i + e_{ij} \tag{3.1}$$

where;

τ_i = random regional effect and represents the collective effects of all regional level unmeasured covariates.

e_{ij} = the country within region deviation from the overall mean of the i^{th} *region*

μ is the grand mean of all measurements in the population. It is assumed that the region effects $\{\tau_i\}$ are normally and identically distributed with mean 0 and variance σ_τ^2, the errors $\{e_{ij}\}$ are normally and identically distributed with mean 0 and variance σ_ϵ^2, and the $\{\tau_i\}$ and $\{e_{ij}\}$ are independent. For this model the ICCC, which may be interpreted as the correlation ρ between any two countries belonging to the same region, is defined as:

$$\rho = \frac{\sigma_\tau^2}{\sigma_\tau^2 + \sigma_\epsilon^2} \tag{3.2}$$

It is seen by definition that the ICCC is defined as non-negative in this model, a plausible assumption for the application of interest here. We also note that the variance components σ_τ^2, and σ_ϵ^2 can be estimated from the one-way ANOVA mean squares (see; Shoukri, page 47) [27] given in expectation by

$$E(\text{MSB}) = \sigma_\epsilon^2 + n_0\sigma_\tau^2 \tag{3.3}$$

$$E(\text{MSW}) = \sigma_\epsilon^2 \tag{3.4}$$

The ANOVA estimator of ρ is then given by

$$\hat{\rho}_0 = \frac{\text{MSB} - \text{MSW}}{\text{MSB} + (n_0 - 1)\text{MSW}} \tag{3.5}$$

where MSB and MSW are, obtained from the usual ANOVA table, with corresponding sums of squares

$$\text{SSB} = \sum_{i=1}^{k} n_i (\bar{y}_i - \bar{y})^2$$

$$\text{SSW} = \sum_{i=1}^{k} \sum_{j=1}^{n_i} (y_{ij} - \bar{y}_i)^2,$$

where

$$N = \sum_{i=1}^{k} n_i \quad \text{and} \quad n_0 = \frac{1}{k-1}\left[N - \sum_{i=1}^{k} n_i^2 / N\right].$$

$$\text{MSB} = \text{SSB}/(k-1), \text{ and } \text{MSW} = \text{SSW}/(N-k).$$

Using the delta method, and to the first order of approximation, the variance of $\hat{\rho}_0$ [27] is given by:

$$\operatorname{var}\left(\hat{\rho}_0\right)=\frac{2\left(1-\rho\right)^2\left(1+\left(n_0-1\right)\rho\right)^2}{n_0^2\left(k-1\right)\left(1-\frac{k}{N}\right)} \tag{3.6}$$

In our data, $k = 15$, $N = 120$, and $n_0 = 7.47$.

We now start screening for the potential risk factors using bivariate correlation analysis. **Table 8** provides the Pearson's correlations and the associated p-values. Significant factors (p-value < 0.05) are candidate for entry into the multivariate model. **Table 9** accounts for the regional clustering effect. The clustering parameter (Intra Class Correlation Coefficient) affects the standard errors by a quantity known as the "*Design Effect*" or DEFF. The effect of the clustering is that the standard errors must be multiplied by the corresponding DEFF when we desire to construct confidence limits on the mean of the variable of interest.

It should be noted that the general definition of the "Design Effect" or DEFF is $\left(1+\left(n_0-1\right)\rho\right)^{1/2}$, that is when reporting the standard errors of the means in **Tables 3-6** the standard error reported in these tables must be multiplied by the corresponding DEFF. We note that the between regions variations is quite significant for all the parameters in **Table 8**, except for the COVID-19 cases where the ICCC is quite low for that parameter. This means that there is a large amount of variability between countries within regions with respect to the COVID-19 cases.

Table 8. Bivariate correlations between variables in the data set.

Variable 1	Variable 2	Pearson's correlation	p-value
Log-COVID Case Fatality	Log-CKD Case Fatality (2017)	0.347	0.00001
Log-COVID Case Fatality	Log-Density (2019)	0.567	0.00001
Log-COVID Case Fatality	% of GDP spent on Healthcare (2018)	0.203	0.028
Log-COVID Case Fatality			
Log-COVID Case Fatality	Prevalence of Diabetes (2019)	0.002	0.979
COVID-19 cases	Log (pop. Density)	0.429	0.00001
COVID-19 cases	CKD count	0.508	0.00001
COVID-19 cases	% spending on healthcare	0.331	0.00001

Table 9. Regional clustering of variables of interest. DEFF = $(1 + 6.47 * \text{ICCC})^{1/2}$.

Variable	ICCC	SE	DEFF
1. COVID-19 Cases	0.022	0.060	1.14*
2. COVID Case Fatality	0.190	0.098	1.47
3. CKD Case fatality (2017)	0.461	0.116	2
4. % of GDP spent on Healthcare (2018)	0.480	0.120	1.91
5. Diabetes (2019)	0.410	0.116	2.03

*No regional clustering.

In the next section we develop multiple regression models relating the target outcome variables; COVID-19 cases, and COVID-19 case fatality using the significant predictors.

4. Multivariate Regression Analyses

4.1. Negative Binomial Regression Model (NBRM)

From Table 9, the outcome variable, the number of COVID-19 cases does not exhibit regional clustering. That is one can safely ignore the region as a predictor. However, this variable (which is an integer variable) exhibits large amount of over dispersion, (the variance is much larger than the mean). The commonly used regression models of counts in the presence of over dispersion are constructed using the Negative Binomial Regression Model (NBRM) [28]. For this model we selected number of COVID-19 case as the dependent variable, and the three risk factors that are, in the univariate screening step for potential predictors, significantly correlated with it as shown in Table 8. It is interesting to see that in the NBRM multiple regression model the three covariates are jointly significantly associated the number of COVID-19 cases. The results are shown in Table 10. For this type of models, the "Scaled Deviance" is taken as a measure of goodness of fit of the NBRM. An optimal model should have a scaled deviance very close to unity. The scaled deviance for our model is 1.417. In our opinion this value is not substantially higher than unity, and the results based on the NBRM are quite useful. As the brilliant statistician ***George Box*** once said: *All models are wrong, some of them are useful.*

4.2. Linear Mixed Effects Modeling of COVID-19 Case Fatality

Before we proceed with the data analysis of COVID-19 Case fatality we should emphasize the hierarchical structure of the data. Basically, the data have two levels; the higher level consists of regions and the lower level consists of countries nested within regions. The results of the fitted model are summarized in Table 11 and Table 12. In Table 11 we have the results of the F-statistic to test the significance of all effects. In Table 12, we have the estimated regression coefficients.

Table 10. Results of the negative binomial regression of the aggregate number of COVID-19 cases.

Parameter	Regression coefficient estimate	Standard Error	p-value
Intercept	7.844	0.5027	0.00001

[Region = E.Europe]	0.321	0.286	1.125	0.263
[Region = HIAP]	0.267	0.370	0.721	0.473
[Region = MENA]	0.435	0.226	1.923	0.057
[Region = S.Asia]	−0.111	0.324	−0.342	0.733
[Region = S.Latin]	0.258	0.573	0.450	0.654
[Region = SSA]	0.339	0.358	0.948	0.345
[Region = W.Europe]	0.994	0.302	3.292	0.001
[Region = WSSA]	0[a]			
Log_density	0.212	0.027	7.900	0.000
GDP_PER_CAPITA	−1.001E−5	3.904E−6	−2.565	0.012
CKD_CASE_FATALITY	0.001	0.001	2.026	0.045

All risk factors we included in the model are deemed significant, except diabetes which was not significant neither in the univariate screening stage nor in the multiple regression model. In Note that in Table 12, the region WSSA was

selected as the reference category when the computer program created dummy variables for the 15 regions.

Now the model-based prediction for the random effects model the correlation between observed and predicted outcome is R = 0.765, which is quite high. Moreover, we found no association between the model-based predictions and the residuals indicating that no model assumptions have been violated.

5. Conclusions

The data that we analyzed are two-levels or hierarchical. We used R software [29] and the commercial software SPSS version 25 [30] for the data analyses. The univariate analyses showed that there is strong regional clustering of CKD, population density and percentage of GDP spending on health care. But the variability between regions in the COVID-19 cases was significantly lower than the variability with regions.

The analyses in this paper targeted two important outcome variables. The first is the aggregate number of COVID-19 cases. The NBRM found that CKD count, population density, and the percentage of GDP spent on healthcare were the most significant risk factors associated with this outcome. The second outcome variable is the COVID-19 case-fatality. The predictive analytic procedure showed that regional effect, log-population density, per-capita GDP, and CKD case fatality are the most important predictors of this outcome. The analysis showed that neither diabetes, nor the percentage of GDP spending on healthcare is significant predictors of COVID-19 case fatality.

Since the analyses in this paper are ecological, the conclusions should not be applied at the within region country level. By contrast, there may be several regional area-level environmental factors that we were not able to explore that may explain the correlation we see between regional level prevalence of health-related risk factors and case fatality of COVID-19.

Since these data did not include within country individual subjects' information on the health status of the case patients, conclusions cannot be drawn about within countries individual risk factors. However, this analysis suggests that there are important regional-level variations in COVID-19 infections that are correlated with variations in other chronic conditions, suggesting that the factors that influence health disparities may also be operating on the distribution of COVID-19.

Furthermore, there presently are limitations with overall infection count data. The analyses were conducted with data only in the first wave of the COVID-19 pandemic in the world. This fact may explain the associations observed with both CKD and population density, rather than indicators of who is being infected, and these data continue to reflect those countries with the most severe outcomes after infection. Finally, the implementation of restrictions on travel and in-person activities may also impact overall rates of COVID-19 during this first wave. It should also be noted that several new strains of the virus have

emerged near the end of 2020. Therefore, new and more comprehensive data on the new variant of the COVID virus through the winter of 2021 may clarify the association with other comorbid conditions.

In summary, these analyses found that countries within the fifteen regions estimated CKD case fatality and population density were significant ecologic predictors of case fatality of COVID-19.

Conflicts of Interest

The authors declare no conflicts of interest regarding the publication of this paper.

Association of Social Distancing, Population Density, and Temperature With the Instantaneous Reproduction Number of SARS-CoV-2 in Counties Across the United States

David Rubin, MD, MSCE; Jing Huang, PhD; Brian T. Fisher, DO, MPH, MSCE; Antonio Gasparrini, PhD, MSc; Vicky Tam, MA; Lihai Song, MS; Xi Wang, PhD; Jason Kaufman, MSt; Kate Fitzpatrick, BS; Arushi Jain, BS; Heather Griffis, PhD, MS; Koby Crammer, PhD; Jeffrey Morris, PhD; Gregory Tasian, MD, MSc, MSCE

Abstract

IMPORTANCE Local variation in the transmission of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) across the United States has not been well studied.

OBJECTIVE To examine the association of county-level factors with variation in the SARS-CoV-2 reproduction number over time.

DESIGN, SETTING, AND PARTICIPANTS This cohort study included 211 counties, representing state capitals and cities with at least 100 000 residents and including 178 892 208 US residents, in 46 states and the District of Columbia between February 25, 2020, and April 23, 2020.

EXPOSURES Social distancing, measured by percentage change in visits to nonessential businesses; population density; and daily wet-bulb temperatures.

MAIN OUTCOMES AND MEASURES Instantaneous reproduction number (R_t), or cases generated by each incident case at a given time, estimated from daily case incidence data.

RESULTS The 211 counties contained 178 892 208 of 326 289 971 US residents (54.8%). Median (interquartile range) population density was 1022.7 (471.2-1846.0) people per square mile. The mean (SD) peak reduction in visits to nonessential business between April 6 and April 19, as the country was sheltering in place, was 68.7% (7.9%). Median (interquartile range) daily wet-bulb temperatures were 7.5 (3.8-12.8) °C. Median (interquartile range) case incidence and fatality rates per 100 000 people were approximately 10 times higher for the top decile of densely populated counties (1185.2 [313.2-1891.2] cases; 43.7 [10.4-106.7] deaths) than for counties in the lowest density quartile (121.4 [87.8-175.4] cases; 4.2 [1.9-8.0] deaths). Mean (SD) R_t in the first 2 weeks was 5.7 (2.5) in the top decile compared with 3.1 (1.2) in the lowest quartile. In multivariable analysis, a 50% decrease in visits to nonessential businesses was associated with a 45% decrease in R_t (95% CI, 43%-49%). From a relative R_t at 0 °C of 2.13 (95% CI, 1.89-2.40), relative R_t decreased to a minimum as temperatures warmed to 11 °C, increased between 11 and 20 °C (1.61; 95% CI, 1.42-1.84) and then declined again at temperatures greater than 20 °C. With a 70% reduction in visits to nonessential business, 202 counties (95.7%) were estimated to fall below a threshold R_t of 1.0, including 17 of 21 counties (81.0%) in the top density decile and 52 of 53 counties (98.1%) in the lowest density quartile.[2]

CONCLUSIONS AND RELEVANCE In this cohort study, social distancing, lower population density, and temperate weather were associated with a decreased R_t for SARS-CoV-2 in counties across the United States. These associations could inform selective public policy planning in communities during the coronavirus disease 2019 pandemic.

Key Points

Question How is the instantaneous reproduction number of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) associated with social distancing, wet-bulb temperature, and population density in counties across the United States?

Findings In this cohort study of 211 counties in 46 states, social distancing, temperate weather, and lower population density were associated with a decrease in the instantaneous reproduction number of SARS-CoV-2. Of these county-specific factors, social distancing appeared to have the most substantial association with a reduction in SARS-CoV-2 transmission.

Meaning In this study, the instantaneous reproduction number of SARS-CoV-2 varied substantially among counties; the associations between the reproduction number and county-specific factors could inform policies to reduce SARS-CoV-2 transmission in selective and heterogeneous communities.

Introduction

Coronavirus disease 2019 (COVID-19) is the result of the novel severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). This virus has caused a pandemic resulting in more than 3.2 million cases of COVID-19 by May 1, 2020, with more than 236 000 deaths worldwide. By the same date, there were more than 1 million individuals with COVID-19 in the United States, resulting in more than 64 000 deaths. The rapid evolution of this pandemic led to the widespread implementation of social distancing measures across most of the United States and the world.

The transmissibility of SARS-CoV-2, like other viral pathogens, is estimated by the reproduction number (R). An infectious pathogen's R value represents the number of people that will be infected by an individual who has the infection. An R value that exceeds 1 will result in increasing numbers of incident cases as each individual with the infection transmits it to more than 1 other individual. When the R value is below 1, the transmission of that pathogen will eventually cease as each patient will transmit infection to less than 1 person. Therefore, the R value is an important measure to estimate when attempting to predict the evolution of an outbreak. It is often assumed that R is constant for each pathogen; however, R most certainly varies by location and by time, which is referred to as the instantaneous R (R_t).[1-3] At the individual level, variation in R_t is likely dependent on being in environments where exposure risk is high or of intense duration, such as among high-exposure workers in health care or mass transit settings or for families in densely crowded living conditions. At the community level, variation in R_t may also include population density (as a proxy for increased likelihood of crowded conditions), temperature and/or humidity (given their effects on viral propagation), policies such as social distancing, and the number of susceptible individuals.

Models that rely on fixed assumptions for R_t are unlikely to capture local heterogeneity in transmission. Our objective was to examine how time-varying changes in social distancing and weather within counties of different population densities might be associated with changing R_t values across counties in the United States. Understanding how these time-varying factors might influence the R_t of SARS-CoV-2 could allow policy makers to implement targeted interventions to decrease R_t in heterogeneous communities.

Methods

Using publicly deidentified data, this study was determined to be exempt from institutional review board review[4] and informed consent. This study followed the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) reporting guideline for cohort studies.[5]

Setting and Participants

We selected 211 counties, representing 178 892 208 of 326 289 971 US residents (54.8%), based on the following characteristics: had at least 1 case of COVID-19 as of February 25, 2020, and either contained at least 1 city with population exceeding 100 000 residents or the state capital. For states with no counties containing a city with 100 000 persons, the most populated county in that state was selected. We excluded counties with average daily case rates of less than 5 and counties with fewer than 3 days with daily case rates of more than 5 during the analysis period of February 25 to April 23, 2020. We considered time-0 for each county to be the date on which they achieved the minimum threshold of disease activity. A total of 211 counties, representing 46 states and the District of Columbia, met these criteria.

Outcome

The outcome was the estimated R_t of SARS-CoV-2 in each county. Daily incident case counts of COVID-19 aggregated at the county level were obtained from the *New York Times*.[6]

Downloaded From: https://jamanetwork.com/ on 01/16/2021

Exposures

There were 3 a priori exposure variables: social distancing practice, population density, and daily mean wet-bulb temperatures. Social distancing was measured using a data set of daily cellular telephone movement, provided by Unacast, that allows comparison of the association of social distancing policies with individuals' movement within a county.[7,8] Based on an a priori assumption and confirmed by preliminary analyses that included cellular telephone measurement of overall distance traveled, we used a social distancing variable that measured percentage change in visits to nonessential businesses (eg, restaurants, hair salons) within each county compared with visits in a 4-week baseline period between February 10 and March 8, 2020. We used a rolling average of the percentage of visits 3 to 14 days before time-0, based on the lag observed between change in social distancing and mean R_t estimates across the counties (eFigure 1 in the Supplement) and on an incubation period of at least 3 days.[9]

Population density of each county was obtained from US Census data and is expressed as number of people per square mile. Log transformation was performed to achieve a normal distribution because of substantial skewedness in density for the largest cities.

It has been demonstrated that humidity and temperature both play a role in the seasonality of influenza; viral transmission is most efficient at lower humidity and temperature. It is proposed that colder, drier air damages respiratory mucosa and thickens secretions, impairing the protective capacity of mucociliary clearance, and that higher humidity physically limits the distance respiratory droplets can travel.[10,11] For this reason, the primary weather variable we used was wet-bulb temperature, a metric that captures the complex thermodynamic relationship of temperature and humidity, has been shown to predict human health events with more precision than temperature and humidity separately, and avoids the associated problem of collinearity.[12,13] Wet-bulb temperatures were obtained from the National Oceanic and Atmospheric Administration Local Climatological Data.

Covariates

County-level covariates that may confound the association between the exposures of interest and R_t were considered and included demographic factors (eg, age distribution, insurance status, and socioeconomic status) and health-related factors associated with COVID-19 severity (eg, proportion of individuals with hypertension, obesity, or diabetes and proportion of individuals who smoke).[14] Demographic and health characteristics were abstracted from the US Census, American Community Survey, Behavioral Risk Factor Surveillance System, Esri Business Analyst, and Multi-Resolution Land Characteristics Consortium.[15-18]

From 70 covariates, we examined the correlation between each pair of factors and calculated the variance inflation factor to quantify multicollinearity among variables (eFigure 2 in the Supplement). Among highly correlated variables, we chose covariates based on their potential association with viral transmission and/or the probability of an individual with infection becoming symptomatic and obtaining a diagnostic test. The final covariates included proportion of residents older than 65 years, with incomes less than 200% of the poverty level, and with diabetes. Variables for obesity, smoking, and uninsured population were removed because of collinearity with other variables.

Statistical Analysis

Our analysis followed a 2-step procedure. First, we calculated the R_t for SARS-CoV-2 using the method of Cori et al[1] with a moving average window of 3 days. This method has been applied in the dynamic estimation of R_t from Wuhan, China.[19] The generation time of SARS-CoV-2 was assumed to follow a γ distribution, with mean (SD) of 7.5 (3.4) days according to a previous epidemiological survey of the first 425 cases in Wuhan, China.[9] In the early days of a county's outbreak, when the ratio of cases to tests was unstable, kernel smoothing with a box kernel and bandwidth of 7 days was performed to account for the likelihood that cases from prior days would accumulate when testing capacity increased.[20,21] We stopped smoothing 1 day after the county's ratio of daily cases to tests

Downloaded From: https://jamanetwork.com/ on 01/16/2021

first fell in the interval of 5% to 90% or after March 20, 2020, whichever came first, to avoid overprocessing the data.

Next, we fit a hierarchical linear mixed-effects model with random intercepts for each county and metropolitan area to evaluate the association between exposures and R_t after a log transformation, adjusting for covariates. Population density was standardized after log transformation because of the highly skewed distribution. Temperature associations were estimated using a distributed lag nonlinear model, which considers bidimensional exposure-lag response associations between wet-bulb temperature and log(R_t).[22-24] We considered a lag period of 4 days to 14 days before case identification to reflect the incubation period of SARS-CoV-2 and to reduce bias introduced by daily weather affecting an individual's decision to seek a test. The final cross-basis term included natural cubic splines defined by 3 internal knots at the 10th, 75th, and 90th percentile of temperature ranges observed during the period, corresponding to 1 °C, 13 °C, and 19 °C, and 2 knots in the lag dimension at 7 and 11 days. The number and placement of spline knots were based on an a priori assumption of a relatively simple association between temperature and SARS-CoV-2 transmission and on minimization of the Akaike information criterion. The temperature knots permitted flexibility in the model nonlinearity at higher and lower temperatures, within the moderate range used in this study.[25] We included an interaction term between population density and temperature, assuming that temperatures would influence transmissibility differently in densely populated counties.[26] The relative change in R_t was expressed as the cumulative exposure response relative to 11 °C. Interactions between population density and social distancing were included in the linear mixed-effects model, given the hypothesis that the association of social distancing with the R_t might be greater in highly dense areas. We also controlled for potential time effect using a cubic polynomial of days in outbreak. Statistical significance of the associations was determined using the maximum likelihood ratio test at the nominal level of $P < .05$. All tests were 2-tailed.

We ran 3 sensitivity analyses. First, the model was re-estimated every 2 weeks (a total of 3 times) during a period of 1 month, checking for stability in estimates of associations for primary covariates. Second, the model fit was evaluated by calculating in-sample R^2 in a randomly selected 70% of counties over 100 replicates. Finally, to address concerns regarding potential bias owing to the exclusion of counties with later outbreaks or with less overall population density, we relaxed our inclusion criteria to permit counties with active outbreaks and a total population of at least 100 000 residents (as opposed to having cities with at least 100 000 residents), and we re-estimated the associations of social distancing and wet-bulb temperatures with R_t during the study period. Given concerns regarding limited representation of temperatures at the upper and lower ranges across counties of different population density, we did not include interaction terms between population density and temperature. Analyses were performed with R version 3.6.0 (R Project for Statistical Computing) using the EpiEstim and dlnm packages.[27]

Results

Geographic locations and characteristics of the 211 counties are demonstrated in **Figure 1** and **Table 1**. The 211 counties contained 178 892 208 of 326 289 971 US residents (54.8%). County median (interquartile range [IQR]) population density was 1022.7 (471.2-1846.0) people per square mile, with skewing of the top decile of 21 counties to a median (IQR) of 8916.0 (5381.1-14 475.6) people per square mile. The mean (SD) reduction in visits by people to nonessential business by mid-April was 68.7% (7.9%). Median (IQR) daily wet-bulb temperatures were 7.5 (3.8-12.8) °C. The 21 counties in the top decile for population density had the highest median (IQR) incident case and fatality rate per 100 000 people (1185.2 [313.2-1891.2] cases; 43.7 [10.4-106.7]), nearly 10 times the estimates in the lowest quartile (121.4 [87.8-175.4] cases; 4.2 (1.9-8.0) deaths). Mean (SD) R in the first 2 weeks was 5.7 (2.5) in the top decile compared with 3.1 (1.2) in the lowest quartile. The mean (SD) change in visits to nonessential businesses from April 6 to April 19 was higher among counties in the top decile (−77.9% [7.9%]) compared with those in the lowest quartile (−66.3% [7.8%]). The top decile of

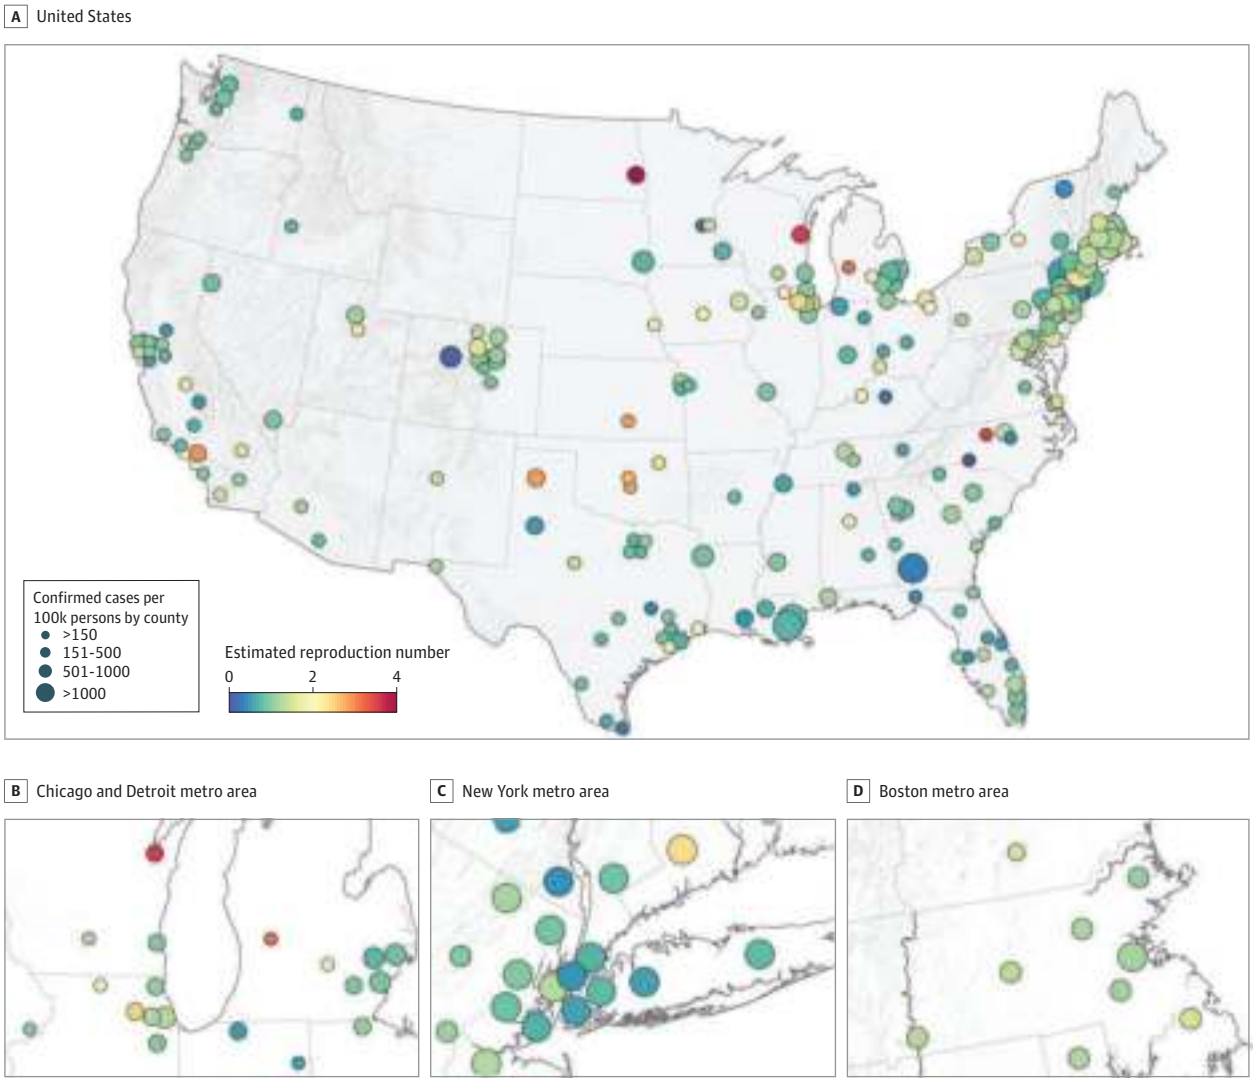
Downloaded From: https://jamanetwork.com/ on 01/16/2021

counties also experienced colder median (IQR) temperatures during the analysis period compared with the counties in the lowest quartile (5.9 [3.4-8.4] °C vs 7.9 [3.1-12.7] °C).

We estimated R_t over a total of 6588 county-days for the 211 counties; 17 outlier county days were removed because of an extremely low estimate of R_t at low case thresholds (ie, $R_t < 0.05$). The estimated R_t by county varied greatly, but it tended to be highest earlier the epidemic, reaching a peak R_t of 7.8 before declining later in the period (eFigure 1 in the Supplement). Adjusting for county-level covariates, social distancing, population density, and temperature were associated with R_t (**Table 2**). The estimated R_t in the context of a 50% decrease in visits to nonessential businesses was 54% (95% CI, 51%-57%; $P < .001$) of the R_t in the setting of normal visit intensity, corresponding to a 46% decrease in the overall R_t. Compared with counties in the bottom quartile of population density, the 21 counties in the top decile of density had a 15% increase (95% CI, 9%-22%; $P < .001$) in relative R_t.

The nonlinear association of lagged temperature between 4 and 14 days is reported in Table 2 and **Figure 2**. Compared with the minimum estimated R_t at 11 °C, relative R_t increased across the coldest temperatures to a relative R_t at 0 °C of 2.13 (95% CI, 1.89-2.40). A smaller peak of the relative

Figure 1. Location and Estimated Instantaneous Reproduction Number of Severe Acute Respiratory Syndrome Coronavirus 2 as of April 26, 2020, in 211 Counties in the United States



Downloaded From: https://jamanetwork.com/ on 01/16/2021

R_t to 1.61 (95% CI, 1.41-1.84) was estimated at 20 °C, before declining again at higher temperatures. These findings were robust to the addition of 183 less densely populated counties with at least 100 000 residents (eTable and eFigure 3 in the Supplement).

The standardized association of social distancing, population density, and temperature on R_t, appears in **Figure 3**. Assuming social distancing of 35% (ie, halfway between estimates during the US shelter-in-place phase and normal activity), 2 counties (0.9%) were estimated to have a R_t less than 1.0 at 2 °C, and 114 counties (54.0%) were estimated to have a R_t of less than 1.0 at 11 °C. When visits to nonessential businesses were reduced to the national mean of 70%, the number of counties estimated to have R_t less than 1.0 increased to 63 (29.9%) and 202 (95.7%) at 2 °C and 11 °C, respectively. At this 70% reduction in visits to nonessential businesses, 28 and 52 of 53 counties

Table 1. Population Characteristics in an Analysis of Instantaneous R for Severe Acute Respiratory Syndrome Coronavirus 2 by Population Density for 211 Counties Across the United States

Characteristic[a]	Population density					
	<25th Percentile (n = 53)	25th-50th Percentile (n = 53)	50th-75th Percentile (n = 53)	75th-90th Percentile (n = 31)	>90th Percentile (n = 21)	All (N = 211)
Population density, median (IQR), people per square mile	298.4 (164.2-376.1)	662.7 (539.1-826.8)	1368.7 (1211.4-1584.9)	2395.4 (2151.2-2860.6)	8916.0 (5381.8-14 475.6)	1022.7 (471.2-1846.0)

Abbreviations: BMI, body mass index (calculated as weight in kilograms divided by height in meters squared); IQR, interquartile range; R, reproduction number.

[a] All characteristics were obtained from the American Community Survey (2018) except health data, which were obtained from the US Centers for Disease Control and Prevention Behavioral Risk Factor Surveillance System (2017); social distancing, which were obtained from Unacast (2020); and wet-bulb temperature, which were obtained from the National Oceanic and Atmospheric Administration (2020).

[b] Regular smoking was defined as adult respondents who reported smoking at least 100 cigarettes in their life and currently smoking at least some days.

[c] Low income was defined as incomes of less than 200% of the poverty level.

[d] Visits to nonessential businesses obtained from Unacast, calculated as the change from mean nonessential business visits during matching days of the week before March 9, 2020.

[e] Daily wet-bulb temperatures were calculated by averaging the hourly recordings from weather stations that contribute to the National Oceanic and Atmospheric Administration Local Climatological Data.

Downloaded From: https://jamanetwork.com/ on 01/16/2021

(52.8% and 98.1%, respectively) in the lowest quartile of density achieved this threshold at 2 °C and 11 °C, respectively, compared with 0 and 17 of 21 counties (81.0%) in the top decile at the same temperatures.

No significant interactions were observed for population density and social distancing. Model estimates were stable over time. The overall R^2 of the mixed-effects model was 0.53 based on the covariate associations; the addition of random county and metropolitan area intercepts increased the R^2 to 0.64. Distribution of the in-sample R^2 in a randomly selected 70% of counties over 100 replicates revealed good model fit (eFigure 4 in the Supplement).

Discussion

In this analysis of 211 US counties, change in social distancing, population density, and wet-bulb daily temperature were associated with the rate of SARS-CoV-2 transmission within a county, as measured by estimated R_t. Our analysis indicates that of these 3 factors, implementation of social distancing has been the most significant in reducing transmission. In addition, the mitigating association of increased social distancing and moderate increases in wet-bulb daily temperature were most

Table 2. Ratios of R_t for Social Distancing and Population Density in 211 United States Counties Between February 25 and April 23, 2020

Variable	R_t ratio estimates with 95% CIs[a]			*P* value
Visits to nonessential businesses, compared with no change[b]	Reduce 25%	Reduce 50%	Reduce 75%	NA
	0.73 (0.71-0.75)	0.54 (0.51-0.57)	0.40 (0.36-0.43)	<.001
Population density, compared with 25th percentile[c]	50th percentile	75th percentile	90th percentile	NA
	1.05 (1.03-1.07)	1.09 (1.05-1.14)	1.15 (1.09-1.22)	<.001
Wet-bulb temperature	0 °C	5 °C	20 °C	NA
	2.13 (1.89-2.40)	1.38 (1.27- 1.50)	1.61 (1.41-1.84)	<.001

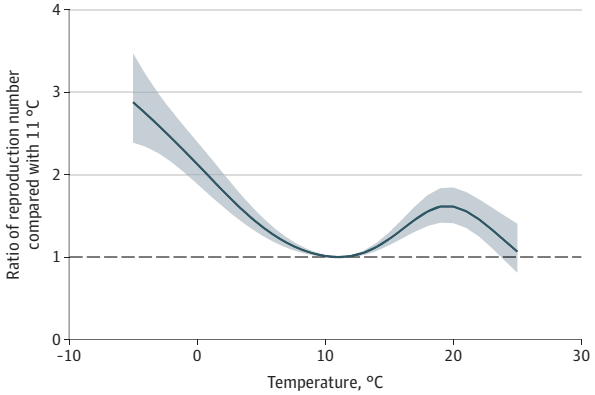
Abbreviations: NA, not applicable; R_t, instantaneous reproduction number.

[a] Estimates and variation obtained through mixed-effects linear models using a log transformed R_t, log population density, and distributed lag nonlinear models to estimate temperature effects. Postestimation was performed to convert variables into meaningful units of change. Ratios of R_t are compared with the reference groups, adjusting for proportion of residents older than 65 years, with incomes less than 200% of the poverty level, and with diabetes. Marginal R^2 was 0.50; conditional R^2 was 0.61.

[b] Visits to nonessential businesses obtained from Unacast. The referent value was the average visits to nonessential business before March 9, 2020.

[c] Population density was categorized at the 25th, 50th, 75th, and 90th percentiles, which corresponded to 471, 1022, 1846, and 3951 people per square mile.

Figure 2. Cumulative Lagged Temperature Dependence of the Instantaneous Reproduction Number of Severe Acute Respiratory Syndrome Coronavirus 2 in 211 US Counties



Cumulative exposure-response association between mean daily wet-bulb temperatures and instantaneous reproduction number using a lag period of 4 to 14 days before case identification. The line represents the estimated instantaneous reproduction number at each point along the temperature range compared with 11 °C. The shaded areas represent the 95% CIs. The wet-bulb temperature range for the counties included in the analysis was −9 °C to 25 °C.

Downloaded From: https://jamanetwork.com/ on 01/16/2021

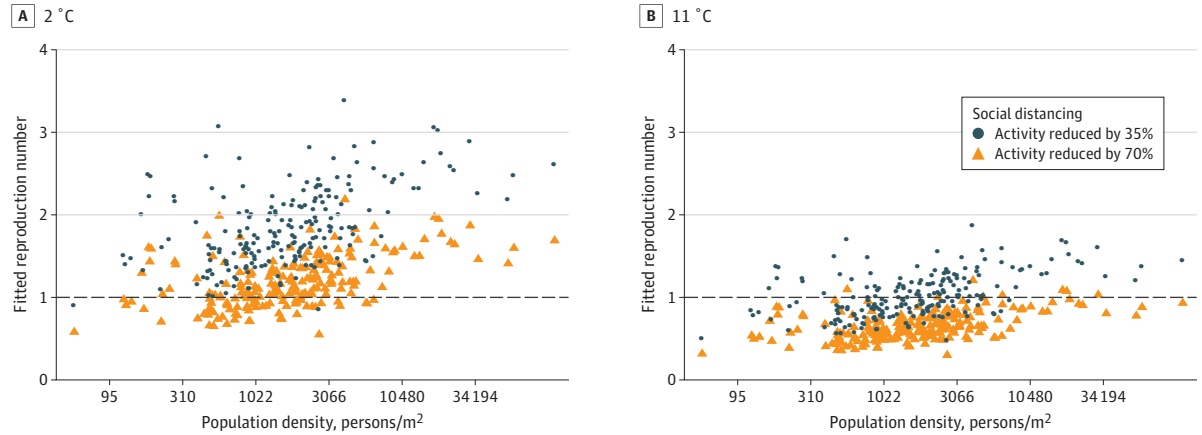
dramatic in counties with higher population density, which had high R_t values, consistent with higher R estimates from around the world.[28]

The underlying mechanism for the associations of social distancing and population density on the estimated R_t for SARS-CoV-2 is likely associated with increased droplet transmission and potentially airborne transmission when individuals are in closer proximity to each other.[29,30] However, the association of population density with COVID-19 outcomes may not be limited to transmission. The densest counties also had the highest number of deaths per 100 000 people. The association of more severe disease in higher density areas is hypothesized to be associated with the inoculum effect. The inoculum effect suggests that individuals exposed to a higher viral load at the time of infection will have more severe illness; this is supported by epidemiologic studies for other viruses,[31,32] in particular for SARS-CoV-1.[33-35] These data support the concept that during a pandemic, people living in highly dense counties are more likely to transmit SARS-CoV-2 and to be exposed to higher inoculums of SARS-CoV-2. This translates not only to more cases of COVID-19 but also to a higher case fatality rate. Data assessing the inoculum effect for SARS-CoV-2 are needed to confirm this hypothesis.

Our analysis, which used well-established methods developed to examine the association of temperature with human health, is also among the first to consider the association of temperature and humidity with SARS-CoV-2 transmission.[22,25] We found that combined temperature and humidity associations (proxied by wet-bulb temperatures) were nonlinear with the R_t and insufficient alone to mitigate R_t values below 1 in the absence of considerable social distancing. The nonlinear associations we observed were such that R_t ratios decreased, as hypothesized, when wet-bulb temperatures increased to 11 °C. Beyond 11 °C, there was a modest increase in relative R_t ratios before the ratios began declining again at higher temperatures.

The nonlinear associations we observed, particularly within the temperate range, are consistent with the inverse relationship of temperature and transmission in animal models for influenza and other coronaviruses.[10,36] Those studies also found that higher humidity was associated with increased viability and transmission of influenza through fomites, even as aerosol transmission was mitigated with warming temperatures. If SARS-CoV-2 has similar properties to influenza at higher humidity, it could explain our association of wet-bulb temperatures higher than 11 °C with a modest increase in R_t.

Figure 3. The Association of Social Distancing, Population Density, and Temperature With the Instantaneous Reproduction Number of Severe Acute Respiratory Syndrome Coronavirus 2 in 211 US Counties



Each point represents the fitted instantaneous reproduction number of an individual county at 2 °C (A) and 11 °C (B), adjusted for the proportion of residents older than 65 years, with incomes less than 200% of poverty level, and with diabetes. Different levels of social distancing are shown for a 35% reduction and 70% reduction in visits to nonessential businesses.

Downloaded From: https://jamanetwork.com/ on 01/16/2021

Beyond the direct association of temperature and humidity with virus stability, viability, and propagation, it is also possible that changes in temperature and humidity alter human activity. For example, at higher temperatures people may be more likely to congregate in public locations, such as beaches and festivals. Therefore, an increase in R_t at higher temperatures could also be explained in part by a decrease in social distancing not measured by our social distancing variable. Regardless of the etiology, we remain cautious in interpreting the association of higher temperature and humidity with R_t beyond the temperate range we observed in this analysis. The coming months will allow for additional assessment of R_t during more prolonged periods of higher temperature and humidity. These additional observations will help to confirm or refute the attenuated associations at higher temperatures observed in this study.

To date, projections of COVID-19 outcomes have considered large areas, such as countries, provinces, and US states. These models have provided useful information to set expectations for deaths in the United States, to identify potential gaps in health services, such as intensive care unit beds and ventilators, and to guide initial wide-ranging social distancing recommendations from federal and state governments. Our county-level analysis has allowed us to better examine relevant contributions of social distancing, population density, and seasonal weather changes on a given county's R_t. This approach gives valuable information on risk of transmission to inform area-specific public policy decisions. It will be important to examine whether the introduction of these associations to models can accurately estimate the likelihood of viral transmission in the future, given that these factors will continue to change. To the degree that predictive modeling efforts are successful, it may demonstrate some validity of using this approach, which incorporates random effects for counties alongside seasonal changes to inform future epidemics.

Limitations

There are always limitations in observational studies. Generalizability remains a concern, particularly given our focus on larger counties. The 45% of US residents not captured in our analysis were residing in smaller, rural counties, and as such, our models are not applicable to these areas. It is reassuring that the inclusion of an additional 183 more geographically dispersed and less densely populated counties replicated our findings. Second, temperature associations we observed might have been confounded by time period in the analysis, given that outbreaks occurred during spring in parallel with changing weather. However, the addition of time to the model did not appreciably change our results. Third, increases in testing capacity might have biased the models by inflating the total cases reported within each county. It is possible that differences in diagnostic test availability could contribute to the variation detected by the random effects across counties. However, our estimate of R_t depended on the rate of change of cases, rather than on the absolute number of cases, and during the period in which this analysis was conducted, test positivity rates, a proxy for testing capacity, were flat.[37] Furthermore, we smoothed early outbreak case incidences to account for early limited access to diagnostic tests. We intentionally did not include testing capacity as a covariate, so as not to overfit the model (eg, controlling for a factor that was also associated with rising viral transmission itself). Fourth, as the random county and metropolitan area intercepts explained additional variation, there are likely other unmeasured county factors that we did not capture. Our proxy for social distancing used cellular telephone records and may not have captured all movement and gathering within a county; it requires further validation as a proxy for the distancing associations we were measuring. Other unmeasured factors might include commuter automobile traffic, public transportation usage, and domestic and international flights, which had decreased during the study period. It is clear that early local epidemics were seeded by international travel that contributed to early transmission in some locations.[38] Further investigation will be needed as communities reopen to examine the association of these additional time-varying factors with risk of SARS-CoV-2 transmission.

Downloaded From: https://jamanetwork.com/ on 01/16/2021

Conclusions

The results of this study suggest that social distancing, population density, and daily weather may account for variation in the R_t for SARS-COv-2 across the United States. These results may guide policy decisions for managing this pandemic more selectively at the local level throughout the country.

Prevalence of SARS-CoV-2 antibodies in a large nationwide sample of patients on dialysis in the USA: a cross-sectional study

Shuchi Anand, Maria Montez-Rath, Jialin Han, Julie Bozeman, Russell Kerschmann, Paul Beyer, Julie Parsonnet, Glenn M Chertow

Summary

Background Many patients receiving dialysis in the USA share the socioeconomic characteristics of underserved communities, and undergo routine monthly laboratory testing, facilitating a practical, unbiased, and repeatable assessment of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) seroprevalence.

Methods For this cross-sectional study, in partnership with a central laboratory that receives samples from approximately 1300 dialysis facilities across the USA, we tested the remainder plasma of 28 503 randomly selected adult patients receiving dialysis in July, 2020, using a spike protein receptor binding domain total antibody chemiluminescence assay (100% sensitivity, 99·8% specificity). We extracted data on age, sex, race and ethnicity, and residence and facility ZIP codes from the anonymised electronic health records, linking patient-level residence data with cumulative and daily cases and deaths per 100 000 population and with nasal swab test positivity rates. We standardised prevalence estimates according to the overall US dialysis and adult population, and present estimates for four prespecified strata (age, sex, region, and race and ethnicity).

Findings The sampled population had similar age, sex, and race and ethnicity distribution to the US dialysis population, with a higher proportion of older people, men, and people living in majority Black and Hispanic neighbourhoods than in the US adult population. Seroprevalence of SARS-CoV-2 was 8·0% (95% CI 7·7–8·4) in the sample, 8·3% (8·0–8·6) when standardised to the US dialysis population, and 9·3% (8·8–9·9) when standardised to the US adult population. When standardised to the US dialysis population, seroprevalence ranged from 3·5% (3·1–3·9) in the west to 27·2% (25·9–28·5) in the northeast. Comparing seroprevalent and case counts per 100 000 population, we found that 9·2% (8·7–9·8) of seropositive patients were diagnosed. When compared with other measures of SARS-CoV-2 spread, seroprevalence correlated best with deaths per 100 000 population (Spearman's ρ=0·77). Residents of non-Hispanic Black and Hispanic neighbourhoods experienced higher odds of seropositivity (odds ratio 3·9 [95% CI 3·4–4·6] and 2·3 [1·9–2·6], respectively) compared with residents of predominantly non-Hispanic white neighbourhoods. Residents of neighbourhoods in the highest population density quintile experienced increased odds of seropositivity (10·3 [8·7–12·2]) compared with residents of the lowest density quintile. County mobility restrictions that reduced workplace visits by at least 5% in early March, 2020, were associated with lower odds of seropositivity in July, 2020 (0·4 [0·3–0·5]) when compared with a reduction of less than 5%.

Interpretation During the first wave of the COVID-19 pandemic, fewer than 10% of the US adult population formed antibodies against SARS-CoV-2, and fewer than 10% of those with antibodies were diagnosed. Public health efforts to limit SARS-CoV-2 spread need to especially target racial and ethnic minority and densely populated communities.

Introduction

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) virus stimulates a rapid antibody response in people with symptomatic[1–5] and asymptomatic[2,6,7] infection. Seroprevalence of SARS-CoV-2 antibodies in a population thus serves as a reasonable measure of exposure and spread. Seroprevalence surveys in the USA, however, have been restricted to single hotspots[8–10] or under-represented high-risk or vulnerable populations.[9,11] Moreover, these studies face challenges to timely repetition and longitudinal follow-up, limiting their utility for surveillance.[8–10]

Patients receiving dialysis might be considered an ideal sentinel population in which to study the evolution of the COVID-19 public health crisis. Patients receiving dialysis in the USA undergo routine monthly laboratory studies to gauge the effectiveness of therapy and to screen for associated complications. In haemodialysis, regular access to the bloodstream abrogates the need for phlebotomy to acquire blood samples. Risk factors for acquisition of SARS-CoV-2 and for severe COVID-19, including advanced age, non-white race, poverty, and diabetes, are the rule rather than the exception in the US dialysis population.[12]

Research in context

Evidence before this study

Measuring the seroprevalence of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) antibodies provides a comprehensive assessment of its community spread. Community seroprevalence surveys require considerable infrastructure and expense, and face implementation challenges during the COVID-19 pandemic due to restricted outreach in the worst-affected communities. Of the two largest seroprevalence surveys in the USA, one was limited only to New York state (n=15 101) and used convenience sampling at grocery stores. A second survey used remainder plasma from people visiting commercial laboratories in six cities (n=11 933), but lacked details on race and ethnicity and other community-level risk factors.

Added value of this study

We tested the remainder plasma of 28 503 patients receiving dialysis throughout the USA, using a chemiluminescence assay with high sensitivity and specificity. To our knowledge, we provide the first nationally representative estimate of SARS-CoV-2 seroprevalence in the US dialysis and US adult population, and estimates for differences in seroprevalence by neighbourhood race and ethnicity, poverty, population density, and mobility restriction. We also evaluate which of the existing measures of COVID-19 incidence most closely correlate with seroprevalence. Most importantly, we show that as patients receiving dialysis have monthly blood draws, without fail and without bias, and are a population with increased representation of racial and ethnic minorities, repeated cross-sectional analyses of seroprevalence within this sentinel population can be implemented as a practical and unbiased surveillance strategy in the USA.

Implications of all the available evidence

Similar to data from other highly affected countries and regions (eg, Spain and Wuhan, China), despite the intense strain on resources and unprecedented excess mortality being experienced in the USA during the COVID-19 pandemic, fewer than 10% of US adults had formed antibodies to SARS-CoV-2 as of July, 2020. There was significant regional variation from less than 5% prevalence in the west to more than 25% in the northeast. Public health efforts to curb the spread of the virus need to continue, with focus on some of the highest-risk communities that we identified, such as majority Black and Hispanic neighbourhoods, poorer neighbourhoods, and densely populated metropolitan areas. A surveillance strategy relying on monthly testing of remainder plasma of patients receiving dialysis can produce unbiased estimates of SARS-CoV-2 spread inclusive of hard-to-reach, disadvantaged populations in the USA. Such surveillance can inform disease trends, resource allocation, and effectiveness of community interventions during the COVID-19 pandemic.

Testing remainder plasma from monthly samples obtained for routine care of patients on dialysis for SARS-CoV-2 antibodies therefore represents a practical approach to a population-representative surveillance strategy,[13] informing risks faced by a susceptible population while ensuring representation from racial and ethnic minorities. In addition, seroprevalence surveys in patients receiving dialysis can be linked to patient-level and community-level data to enable evaluation and quantification of differences in SARS-CoV-2 prevalence by demographic and neighbourhood strata, and thus facilitate effective mitigation strategies targeting the highest-risk individuals and communities.

In partnership with a commercial clinical laboratory, we tested seroprevalence of SARS-CoV-2 antibodies in a randomly selected representative sample of patients. Our goal was to provide a nationwide estimate of exposure to SARS-CoV-2 during the first wave of COVID-19 in the USA, up to July, 2020, with stratification by region, age, sex, and race and ethnicity. We also harnessed population data on SARS-CoV-2 cases and deaths and percentage testing positive using nasal swab testing to assess how seroprevalence estimates correlated with other epidemiological measures of COVID-19 incidence. Finally, to inform preventive strategies for the high-risk dialysis population as well as the general population, we investigated community-level correlates for seropositivity.

Methods

Study design and participants

We did a cross-sectional analysis of adult (≥18 years) patients undergoing monthly laboratory testing at Ascend Clinical using samples obtained for routine clinical care that otherwise would have been discarded. Ascend Clinical is a commercial clinical laboratory based in Redwood City, California, that receives samples from a nationwide network of around 1300 dialysis facilities, serving approximately 65 000 patients. We randomly selected patients from the patient list on June 15, 2020, for seroprevalence testing to be done in July, 2020, using implicit stratification by region, age, sex, and race and ethnicity followed by systematic sampling with fractional polynomials.[14] After sample selection and processing, Ascend Clinical sent anonymised data on patient age, sex, race and ethnicity, and residence and facility ZIP codes to Stanford University investigators for analyses. Stanford University investigators further linked patient geographical information (ZIP code) to census data and publicly available COVID-19 burden and community mobility data. The study received expedited approval from the Stanford University of Medicine Institutional Review Board; informed consent was waived.

Procedures

We used the US Food and Drug Administration-approved Siemens Healthineers SARS-CoV-2 spike protein receptor

binding domain (S1RBD) total antibody (immunoglobulin) chemiluminescence assay, which has 100% sensitivity (≥14 days after a positive PCR test) and 99·8% specificity.[5] We chose this assay on the basis of its Emergency Use Authorization in June, 2020, in the context that S1RBD is also the target of vaccine development efforts.[15] Sample processing is detailed in the appendix (p 3).

We linked patient-level residence data with cumulative and daily cases and deaths per 100 000 population as compiled on a county level by the Center for Systems Science and Engineering at Johns Hopkins University[16] and with nasal swab test positivity rates, as compiled on a state level by the Covid Tracking Project.[17] For Utah, we followed the Utah Department of Health groupings of several smaller counties and extracted data directly.[18] New York City data are not available by county within the Johns Hopkins University dataset; therefore, we directly extracted data from the New York City Dashboard.[19] For county-level mobility restrictions, we used Google Mobility Data that report an average percentage change in the number of workplace visits over the period March 1–15, 2020, before the implementation of shelter-in-place restrictions in the majority of the country. Percentage changes in the Google Mobility data are indexed to a corresponding weekday (eg, Tuesdays are matched to Tuesdays) from Jan 3 to Feb 6, 2020.[20]

We also linked patient-level residence data with ZIP code tabulation area (ZCTA) data from the 2018 American Community Survey (ACS) 5-year estimates[21] to ascertain patient neighbourhood proportion living below the poverty level and race and ethnicity mix, and with American Census Bureau 2010 estimates[22] to ascertain population density. We defined ZCTA majority race and ethnicity as Hispanic, non-Hispanic Black, or non-Hispanic white if the population in the ZCTA was at least 60% Hispanic, non-Hispanic Black, or non-Hispanic white, respectively; where this was not the case, if the Hispanic and Black population combined was at least 60% of the population, the ZCTA majority was defined as Hispanic and Black, otherwise as other. For urban versus rural ZCTA status, we used the 2010 Rural Urban Commuting Area codes by census tract, categorising a ZCTA as dense urban, metropolitan, micropolitan, or small town or rural area if more than 50% of the population in the ZCTA was living in one of these area codes.[23]

See **Online** for appendix

Statistical analysis

We assumed a nationwide prevalence of SARS-CoV-2 antibody of 5%.[8,24] To generate prevalence estimates for patients on dialysis using preselected regional strata with precision within 0·5%, a sample of 27 364 was required (appendix p 2). Based on previous trends, we expected 15% of selected samples to be unavailable in July, 2020, due to death, move to other facilities, or other reasons for missing laboratory data (eg, hospitalisation or non-adherence). Accounting for this potential dropout, we randomly selected 31 509 patients.

We present prevalence estimates with 95% CIs in our sample, standardised to the US adult dialysis population and to the US adult population. For the US adult dialysis

US adult population given is for 2018 and US adult patients dialysis population as of Jan 1, 2017. ZCTA=ZIP code tabulation area. *Computed for total US 2018 population (n=326 274 356). †When excluding people with unknown race and ethnicity, the proportions were 18·6% Hispanic, 38·2% non-Hispanic white, 28·6% non-Hispanic Black, and 14·5% non-Hispanic other. ‡343 people in the US Renal Data System and two people in the sample populations were missing data on ZCTA majority race and ethnicity due to missing ZIP code.

Table 1: **Comparison of sampled population, US adult dialysis population, and US adult population**

For the **United States Renal Data System database** see https://www.usrds.org

population, we used the distribution of all adults receiving maintenance dialysis, excluding those living in the territories, on Jan 1, 2017, identified through the United States Renal Data System database. For the US adult population, we used 2018 ACS 1-year estimates.[21] Based on the test sensitivity range obtained by Schnurra and colleagues in their external validation,[25] we also provide test characteristic-adjusted sample population estimates, ranging sensitivity from 85% to 98%.[10] To compute the percentage of estimated seroprevalent cases that were likely to be diagnosed cases,[10,26] we compared the estimated seroprevalent cases per 100 000 adult population with Johns Hopkins University estimates of cumulative diagnosed cases per 100 000 US adult population as of June 15, 2020.

To standardise estimates, we assigned weights to each person based on their membership to each of 32 strata of census regions (northeast, south, midwest, and west), age (18–44, 45–64, 65–79, and ≥80 years), and sex. We defined post-stratification weights as the proportion of each stratum represented in the US dialysis population or US adult population divided by the analogous proportion in the sample.[27–29] We then computed weighted frequencies and 95% CIs according to four prespecified strata (region, age, sex, and race and ethnicity) with differences evaluated using Rao-Scott χ^2 tests.[30,31] Due to the missingness of race and ethnicity data in the electronic health records, we used the additional measure of ZCTA race and ethnicity distribution with categories adapted from Moore and colleages.[32,33]

Next, we correlated five measures of COVID-19 incidence—cumulative cases on June 15, 2020 (or first available date between June 15 and June 30, 2020); cumulative deaths on June 30, 2020 (or last available date between June 15 and June 30, 2020); 15-day averages of daily cases and daily deaths; and percentage testing positive on nasal swab tests between June 15 and June 30, 2020—with SARS-CoV-2 seroprevalence in patients on dialysis in July, 2020. To do this, we first collapsed all measures to a state level and then assessed the Spearman's correlation coefficient ρ for the association of each measure with seroprevalence. Because of the high density of Ascend Clinical facilities in New York, Texas, and California, we also chose those states to present county-level correlations.

Finally, using logistic regression, we determined the age-adjusted and sex-adjusted correlates of seropositivity for patient ZCTA race and ethnicity distribution, percentage living below poverty level, rural or urban classification, population density, and county mobility restriction.

We assumed statistical significance at $\alpha<0{\cdot}05$. All statistical analyses were done with SAS Enterprise Guide (version 7.1) and Stata (version 15.1).

SARS-CoV-2=severe acute respiratory syndrome coronavirus 2. ZCTA=ZIP code tabulation area. *Standardised to the US dialysis population using all adults receiving dialysis for the treatment of end-stage kidney disease on Jan 1, 2017, identified through the United States Renal Data System database (n=499 150). †Seropositivity per 100 000 people calculated as (standardised count/category count) × 100 000. ‡Different at $\alpha<0{\cdot}05$ by the Rao-Scott χ^2 test. §Different at $\alpha<0{\cdot}0001$ by the Rao-Scott χ^2 test.

Table 2: **Seroprevalence of SARS-CoV-2 antibodies in patients receiving dialysis in the USA**

Role of the funding source

Ascend Clinical Laboratories supported the remainder plasma testing for SARS-CoV-2 antibodies. SA, MM-R, and JH had complete access to all data in the study and SA, MM-R, JH, JP, and GMC were responsible for the decision to submit for publication.

Results

Of the 31 509 people selected for testing on June 15, 2020, 28 503 were tested in July, 2020 (figure 1), with 25 217 (88·5%) tested in the first 2 weeks (appendix p 4). The sampling was representative of the US dialysis patient distribution by age, sex, race and ethnicity (when excluding patients without race and ethnicity data), and region, except sampled patients were less likely to be non-Hispanic Black (table 1). Compared with the US adult population, our sampled patient population was older, had more men, and was more likely to be non-Hispanic Black and living in non-white neighbourhoods

Table 3: **Seroprevalence estimates for the US adult population**

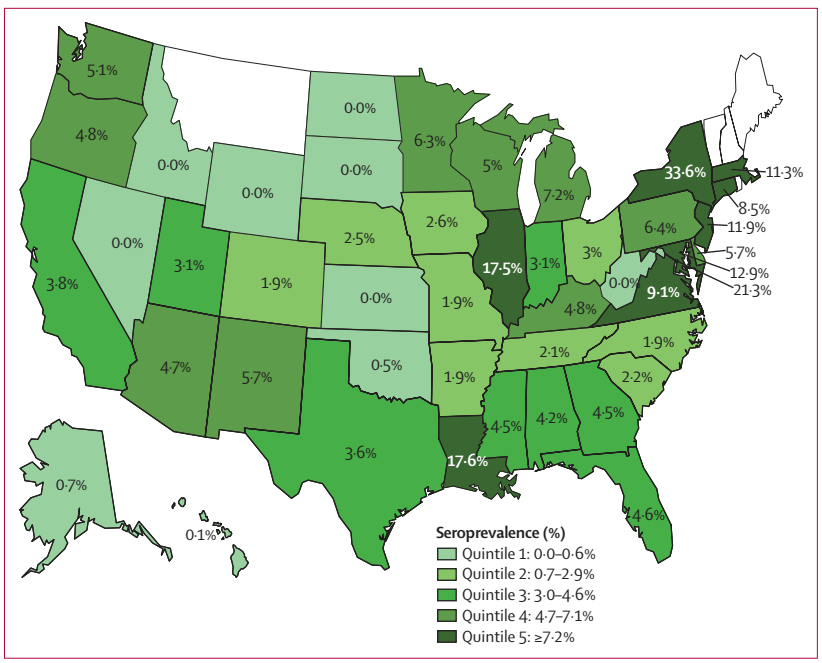

Figure 2: **Prevalence of SARS-CoV-2 antibodies in sampled population, by state**
Bolded borders represent states with more than 100 patients in the sample. The median number of patients sampled by state was 176 (IQR 83–536). States in white were not sampled. SARS-CoV-2=severe acute respiratory syndrome coronavirus 2.

(table 1). A greater proportion of our sampled population and the US dialysis population lived in the west, and a lower proportion lived in the midwest, compared with the US adult population. Patients in our sample lived in 46 states and in 1013 (32%) of 3141 US counties (appendix p 6).

Overall, sample seroprevalence was 8·0% (95% CI 7·7–8·4). Accounting for the externally validated test sensitivity,[25] seroprevalence ranged from 8·2% (7·9–8·5) to 9·4% (9·1–9·8) in our sampled population (appendix p 7). When standardised to the US dialysis population, seroprevalence was 8·3% (8·0–8·6), with high regional variation in seroprevalence (ranging from 3·5% [3·1–3·9] in the west to 27·2% [25·9–28·5] in the northeast; table 2). Seroprevalence was similar by sex and modestly lower in people aged 80 years or older compared with those aged 45–64 years (table 2). Differences in seroprevalence by race and ethnicity were similar using both our patient-level (electronic health record) and neighbourhood-level (ZCTA majority race and ethnicity) measures, with non-Hispanic Black patients having the highest seropositivity, followed by Hispanic patients, and non-Hispanic white patients having the lowest.

We estimated the SARS-CoV-2 standardised seroprevalence in the US population to be 9·3% (95% CI 8·8–9·9; table 3). Based on the Johns Hopkins University cumulative case data as of June 15, 2020, the prevalence of (nasal swab) diagnosed cases was 826 per 100 000 US adult population, compared with our estimate of 8989 seropositive people per 100 000 population, meaning that 9·2% (8·7–9·8) of seropositive people were diagnosed.

Using data from our sampled population, variation by state was high, ranging from 0·0% in seven states to 33·6% (31·7–35·6) in New York, with the highest regional variation occurring in the northeast (figure 2; appendix pp 8–9). When comparing state seroprevalence against cumulative cases and deaths per 100 000 population, deaths correlated best (ρ=0·66 for cases *vs* 0·77 for deaths; figure 3). The percentage of people testing positive by nasal swab test and 15-day average of daily deaths in the latter half of June, 2020, showed a weaker correlation (ρ=0·58 and 0·66, respectively), whereas 15-day average of daily cases did not correlate with seroprevalence (ρ=–0·14). On a county level in California, New York, and Texas, there was even more heterogeneity in the correlation between seroprevalence and other disease measures (ρ≤0·51 for all correlations for all three states' county-level data; appendix p 10).

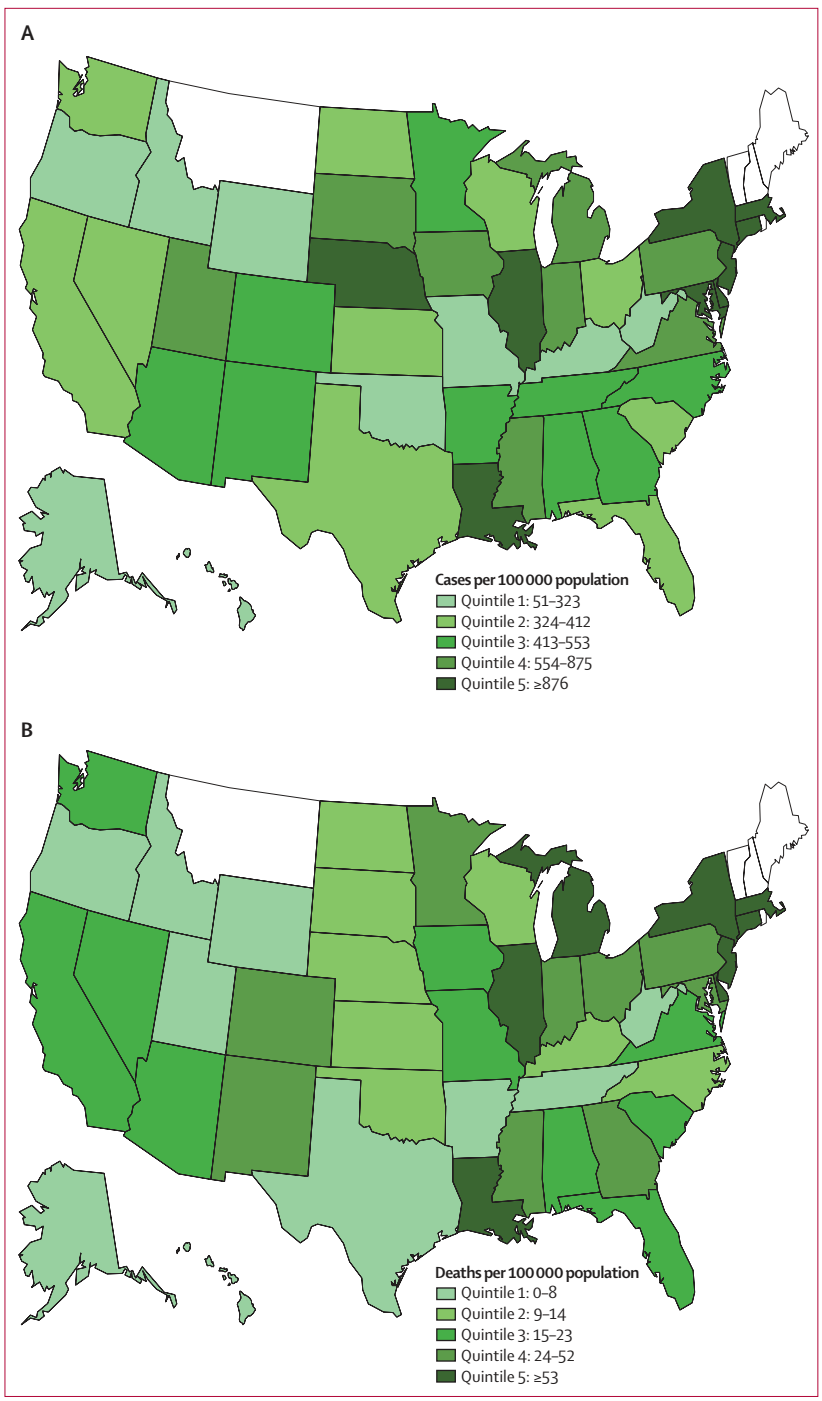

Figure 3: **Cumulative cases (A) and cumulative deaths (B) per 100 000 population, by state**
Data are in the US population as of June 15 (A) and June 30 (B), 2020.[16,18,19,21] States in white were not included in the sample.

Likelihood of SARS-CoV-2 seropositivity was lower among older people (odds ratio 0·8 [95% CI 0·7–0·9] for people aged 80 years or older *vs* people aged 45–64 years), but did not differ by sex (1·0 [0·9–1·1] for women *vs* men). In age-adjusted and sex-adjusted models, neighbourhood racial and ethnic distribution, poverty level, dense urbanisation, population density, and percentage change in workplace visits in early March, 2020, were all strongly associated with seropositivity (figure 4).

Discussion

In our analysis of seroprevalence of SARS-CoV-2 spike protein receptor binding antibodies from a nationwide representative sample of patients receiving dialysis, we find that despite the USA contemporaneously leading the world in the numbers of diagnosed cases, overall, fewer than 10% of US adults had evidence of seroconversion in July, 2020. A vast majority of US adults, including people receiving dialysis who are among the highest risk for mortality upon contracting SARS-CoV-2,[34] do not have evidence of exposure or immune response. Furthermore, we find increased likelihood of SARS-CoV-2 seropositivity in residents of predominantly Black and Hispanic neighbourhoods (two to three times higher), poorer areas (two times higher), and the most densely populated areas (ten times higher). Early reduction in community mobility in March, 2020, was associated with 60% lower likelihood of individual-level seroconversion by July that year.

Unlike most published estimates of SARS-CoV-2 seroprevalence from the USA,[8,10,11] patients included in our study sample had antibodies measured from blood collected as part of routine medical care. Thus, our prevalence estimates should not be subject to selection bias due to presence versus absence of symptoms, availability of testing materials, local or regional testing strategies, geography, income, educational attainment, language proficiency, immigration status, mobility, anxiety, fear, or other factors. Moreover, since end-stage kidney disease qualifies affected patients for Medicare insurance, and since end-stage kidney disease disproportionately affects Black, Hispanic, and other disadvantaged populations,[12,35,36] we are able to determine—with a high level of precision—differences in seroprevalence among patient groups within and across regions of the USA. Of the two larger seroprevalence surveys published from the USA thus far, one was confined to New York state (n=15 101), employed a convenience sampling technique at grocery stores, and relied on a microsphere immunoassay with lower sensitivity.[10] The second, the Centers for Disease Control and Prevention (CDC) Six Sites study (n=11 933), used remainder plasma from people getting testing for undefined clinical indications, and did not have detailed sociodemographic information about the tested people.[11]

Uncertainty exists as to whether seroprevalence estimates in the dialysis population can be extrapolated to the US population more broadly. A recent analysis of SARS-CoV-2 IgG antibodies in two dialysis units in London, UK, reported seroprevalence of 36%, higher than in healthy blood donors (15%) but lower than in healthcare workers (45%) sampled within a similar time frame.[37] Our data might overestimate overall seroprevalence in

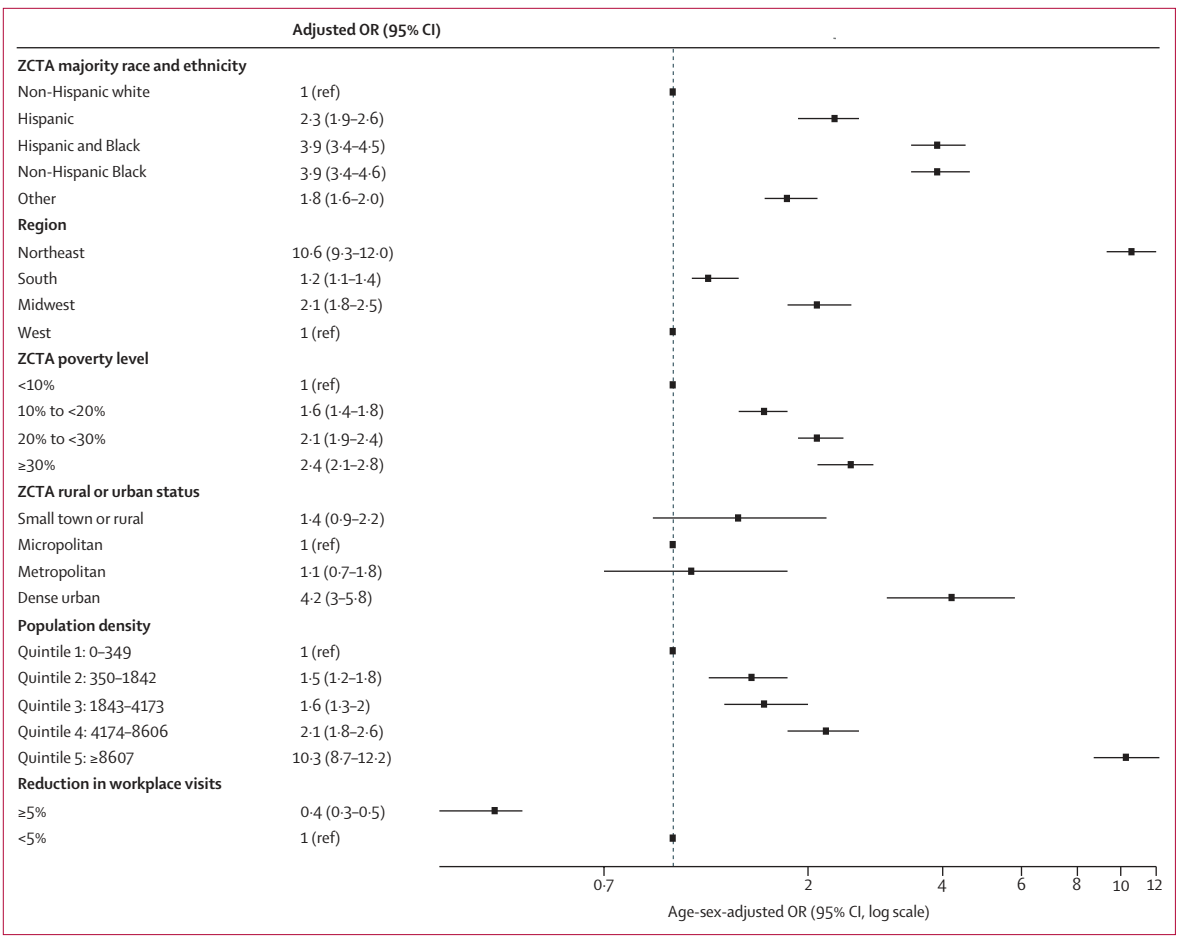

***Figure 4*: Forest plot for odds of SARS-CoV-2 seropositivity**
All variables are at a neighbourhood (ie, ZCTA) level, except for reduction in workplace visits, which is at a county level, and are modelled separately, accounting for age and sex. Poverty level is defined as percentage of people living below the federal poverty level in the ZCTA. Population density quintiles are derived from the ZCTA (median 2884 people per square mile [IQR 603–6800]). Reductions in workplace visits were measured during the first 2 weeks of March, 2020, compared with a baseline in January–February, 2020. OR=odds ratio. SARS-CoV-2=severe acute respiratory syndrome coronavirus 2. ZCTA=ZIP code tabulation area.

the general population since patients on dialysis are disproportionately from racial and ethnic minorities;[38,39] for example, Black Americans have a nearly four-times higher risk of end-stage kidney disease than white Americans.[12] Moreover, the process of undergoing in-centre haemodialysis might include the use of public or non-public shared transportation to and from the facility, and 10–12 h of care delivered in indoor facilities.

Conversely, these data might underestimate overall seroprevalence in the general population. Patients receiving dialysis are less likely to be employed[40] and more likely to restrict their mobility and social activity due to advanced age and frailty;[41] therefore, they might have fewer opportunities to acquire the infection, particularly from asymptomatic individuals. Extrapolating from multiple prospective hepatitis B immunisation studies—in which 50–75% of vaccinated patients receiving dialysis mounted a response compared with 95% or more people from the general population—patients receiving dialysis might mount a weaker immune response and thus be less likely to seroconvert.[42] Finally, patients receiving dialysis might have been more likely to die or have been hospitalised due to complications of SARS-CoV-2 infection. If so, these patients would not have been present for testing in the dialysis facilities, creating a survival bias and yielding lower estimates of exposure.

Nonetheless, the ten-times difference we observed between diagnosed cases per 100 000 population and our estimates of seropositive people per 100 000 has been similarly reported in studies from New York,[10] the CDC Six Sites study,[11] and in a population-representative analysis from Geneva.[26] Thus, our findings comport with other seroprevalence estimates. We confirm that as in other studies from COVID-19 hotspots,[1,26,43] a minority of the population has evidence of exposure and immune response, and a vast majority, including people at high risk for mortality (ie, the population on dialysis), remain vulnerable. In fact, even if the seroprevalence estimates derived from the US dialysis population overestimated true seroprevalence in the overall US adult population,

our data nonetheless support that fewer than 10% of the US population has seroconverted as of July, 2020, and herd immunity remains out of reach, as has been the conclusion from large international surveys from the UK[44] and Spain,[1] where intense outbreaks of COVID-19 occurred during the spring and summer of 2020.

Furthermore, the seroprevalence differences captured by region, age, sex, and community-level risk factors (ie, internal comparisons) are expected to be similar in the US dialysis and US general adult population. Our study provides convincing evidence that the COVID-19 pandemic has dramatically amplified existing health disparities. Data from the CDC highlighting SARS-CoV-2 health disparities evaluate hospitalisations and deaths by race and ethnicity,[45,46] calling into question whether Black and Hispanic populations are experiencing more severe illness versus facing higher likelihoods of exposure. Some US state dashboards also report higher cumulative cases among Black and Hispanic people compared with non-Hispanic white people,[47] but none have as precisely quantified differences on a national level.

Neighbourhood poverty and population density were also highly correlated with seroprevalence, with a possible threshold effect for population density, such that there was a ten-times higher risk in the highest density ZCTAs (>8607 people per square mile). Population density is recognised as a crucial factor, driving the spread in metropolitan areas, in confined spaces (eg, the *Diamond Princess* cruise ship), large gatherings (eg, the New Orleans' Mardi Gras),[48,49] and in populous regions across the world.[50] Rocklöv and Sjödin suggest that the basic reproduction number (R_0) of SARS-CoV-2 increases linearly with population density.[51] Our data also show slightly lower likelihood of seropositivity among older people, as was seen in a recent report from Geneva[26] and attributed to better adherence to physical distancing measures by the authors. A higher competing risk from hospitalisations or mortality after SARS-CoV-2 exposure might be a larger contributing factor in the observed lower seroprevalence in older compared with younger age groups.

In addition to providing an overall estimate of SARS-CoV-2 seroprevalence and quantifying differences by patient and community characteristics, our study puts forth a viable surveillance strategy for SARS-CoV-2 spread in the USA. WHO and other experts[13,52] advocate for repeated cross-sectional analyses of seroprevalence as a disease tracking system able to most completely measure the true incidence of SARS-CoV-2, since these can more likely capture incidence of exposure in both symptomatic and asymptomatic individuals. In fact, we observed substantial heterogeneity in the correlation between seroprevalence and other measures of SARS-CoV-2 that are currently being used—with the exception of deaths per 100 000, which are a late outcome[53]—supporting the use of rapidly instituted seroprevalence surveys as a complementary surveillance tool. Additional public health implications of seroprevalence surveys include assessing testing adequacy. For example, in states where the difference between seropositive and diagnosed cases is decreasing over time, testing capacity is likely to be increasing. Furthermore, following seroconversion rates over time can presage hospitalisations and intensive care unit stays, since the time between exposure and seroconversion is relatively short (median 10 days),[26] and can therefore facilitate resource allocation. Finally, as we show by assessing community mobility restrictions, seroprevalence surveys can measure the effects of interventions to treat or prevent infection with SARS-CoV-2.[13] Repeated serological surveys, if done in a community setting, would require extensive resources and yet remain subject to selection bias. However recurring monthly testing of remainder plasma of randomly selected sets of people—as is practically feasible in patients receiving dialysis—can serve as a representative surveillance system in the USA, with minimal phlebotomy or infrastructure requirement, and as our data show, include traditionally under-represented and socially disadvantaged groups.

This analysis has numerous strengths. We used a highly specific and sensitive immunoassay, one which has been robustly linked to SARS-CoV-2 exposure.[13,25,54,55] The study sample was highly representative of the US dialysis population and, as noted, we used remainder plasma from specimens used in routine clinical care. The sample size and sampling scheme allowed us to estimate with precision prevalence across several patient characteristics. Moreover, linking to US Census and other publicly available data sources assembled during the pandemic provides valuable context when considering the implications of these data to the general population. There are also several important limitations. As noted previously, it is plausible that seroprevalence estimates from the US dialysis population overestimate seroprevalence in the US adult population. We do not have patient-level data on symptoms nor nasal swab testing results, and thus cannot test whether the likelihood of seroconversion differs in patients receiving dialysis from generally healthy adults, although preliminary data from London, UK, suggest no differences.[37] We also do not have patient-level data on health status, employment status, income, household size, living space, and other sociodemographic factors, and so relied on neighbourhood proxies for some of these domains. Dialysis units are more often located in urban areas, and thus we have under-representation of rural areas. Finally, while large, our study was designed for precise regional, not state-level or county-level, estimates.

In conclusion, we present SARS-CoV-2 seroprevalence data in a broadly representative sample of patients receiving dialysis across the USA and show striking differences in seroprevalence by several patient characteristics, with higher seroprevalence in younger patients, Black and Hispanic patients, and patients living in poorer and majority-minority neighbourhoods. These data can help to

inform surveillance and management strategies during the next phase of the pandemic. Serial sampling of dialysis remainder plasma should be used to determine trends in disease prevalence and the effect of various strategies being implemented around the USA to reduce the burden of COVID-19 on the general population.

Contributors

SA assisted with data cleaning and analysis planning, and manuscript writing. MM-R developed the analysis plan, generated census data tables, supervised data analysis, and contributed to manuscript writing. JH undertook data cleaning and analysis, including linkage to external data and figure generation, and contributed to manuscript writing. JB undertook sample processing and data preparation and contributed to manuscript writing. RK selected seroprevalence testing, supervised sample processing, and contributed to manuscript writing. PB co-conceived the study, secured seroprevalence testing, and supervised sample processing and data preparation. JP supervised the study analysis plan, identified relevant external data, contributed to data interpretation, and supervised manuscript writing. GMC co-conceived the study, supervised the study analysis plan, and co-wrote the manuscript.

Declaration of interests

JB, RK and PB are employed by Ascend Clinical Laboratories. GMC is on the Board of Directors of Satellite Healthcare, a not-for-profit dialysis organisation. All remaining authors declare no competing interests.

Data sharing

De-identified cross-sectional data from the analysis can be made available after authors' review of request and might require compilation of specific categories (eg, at the older age groups) to protect patient privacy.

Acknowledgments

Ascend Clinical Laboratories supported the remainder plasma testing for SARS-CoV-2 antibodies. SA was supported by 5K23DK101826. MM-R and GC are supported by National Institutes of Health NIDDK K24 DK085446. We thank Martin Gorfinkel (Mountain View, CA, USA) for his feedback on sampling design.

The COVID-19 pandemic as experienced by the individual

September 30, 2020

Abstract

The ongoing COVID-19 pandemic has progressed with varying degrees of intensity in individual countries, suggesting it is important to analyse factors that vary between them. We study measures of 'population-weighted density', which capture density as perceived by a randomly chosen individual. These measures of population density can significantly explain variation in the initial rate of spread of COVID-19 between countries within Europe. However, such measures do not explain differences on a global scale, particularly when considering countries in East Asia, or looking later into the epidemics. Therefore, to control for country-level differences in response to COVID-19 we consider the cross-cultural measure of individualism proposed by Hofstede. This score can significantly explain variation in the size of epidemics across Europe, North America, and East Asia. Using both our measure of population-weighted density and the Hofstede score we can significantly explain half the variation in the current size of epidemics across Europe and North America. By controlling for country-level responses to the virus and population density, our analysis of the global incidence of COVID-19 can help focus attention on epidemic control measures that are effective for individual countries.

1 Introduction

Since the onset of the COVID-19 pandemic in December 2019, over a million people have died of the disease worldwide [41]. Given the vast human and economic cost, considerable effort has been given to understanding and modelling epidemics by the media and scientific community [37, 6]. At this early stage, the media in particular have performed the role of disseminating mortality data between and within countries, often through data visualizations.

Such visualizations [37] are informally used to assess the responses and interventions of various Governments, or the quality of their health services, and have therefore put pressure on governments to allocate resources based on apparent differences between the performance of countries. We caution against making such judgements based on raw data alone without controlling for factors that may impact the rate of spread of COVID-19 and the severity of any outbreak. These factors may include: demographic variables such as age and ethnicity, pre-existing medical conditions, patterns of mobility (i.e., travel), and cultural factors such as voluntary mask wearing, household age profile, or patterns of social contact. These factors exist independently of the quality of any specific Government coronavirus response, and more formal analysis is beginning to emerge that suggests they are important for the apparent severity of epidemics between countries [3].

Any assessment of a COVID-19 epidemic in any country must be carried out carefully, in the context of these factors. It will be a major statistical exercise to do this properly, considering interactions rigorously. In this article, we make a minor early contribution to such an audit by considering one demographic factor, population density, while controlling for cross-cultural differences that may impact country-level responses to the virus.

Population density plays a significant role in emerging infectious diseases [16, 39, 22]. The basic reproduction number (R_0) for a zoonotic pathogen not yet fully adapted for human-to-human transmission may in fact require sufficiently many interactions, facilitated by population density, for an outbreak to occur [17]. This need for a sufficient density of people susceptible to infection was apparent to those first modelling infectious disease outbreaks nearly 100 years ago ([18]). Contemporary modelling of influenza pandemics have utilised this framework, and subsequently employed it to model COVID-19 epidemics ([5, 6]). Of note in these models is the use of the standard measure of population density (total number of people divided by area) applied to relatively high resolution population data (square kilometre). This prompted us to consider two questions: does weighting high resolution population data by the local density experienced by an average individual improve its ability to predict epidemic growth, and could such a methodology be used to explain the dynamics of epidemics between countries?

Regardless of what demographic variables are chosen to compare COVID-19 epidemics between countries, the same problem will be encountered: individual countries and their governments have responded differently to the virus. Public health interventions have

0417

included: testing, contact tracing, and isolation of positive cases and their contacts; restricting public gatherings, physical distancing, mandated face mask wearing, and closures of schools and nonessential businesses [13]. It is noticeable that such measures appear to have been more effective in East Asian countries than Europe and North America; for example, China has reduced cases by 90% but Italy and the USA have not replicated this performance [29, 26]. This may be partly due to the speed with which control measures have been instigated; and in particularly, when the strongest measure, lockdowns, have been ordered [1, 9]. Any analysis that attempts to compare country-level COVID-19 epidemics will need to control for these differences. The Oxford COVID-19 Government Response Tracker collates these country-level responses into a 'Stringency index' [12]; however, whether these government responses are derived from a more fundamental difference in cultural responses to infectious diseases has not been currently explored.

It has been hypothesised that pathogen exposure puts selection pressure on animals to modify their behaviour, which in humans has been labelled the 'pathogen-stress hypothesis' [8, 7, 21]. Fincher et al. [8] hypothesised that historical pathogen prevalence could explain variation in cross-cultural measures of individualism and collectivism. In particular, historical and contemporary pathogen prevalence was significantly negatively correlated with, for example, the cross-cultural measure of individualism proposed by Hofstede [15], which captures to what extent a country values individual freedom over collective benefit. This axis between individualism and collectivism has been shown to be particularly stark between Western and East Asian countries, with the former more individualistic and the latter more collectivist. Interestingly, countries with high individualism scores also have a greater susceptibility to zoonotic disease outbreaks [21]. Whether these observations can be replicated for the current COVID-19 pandemic and used to control for country-level responses is currently an unanswered question.

We have used publicly available data to examine whether population density can explain the burden of COVID-19 disease between countries. We first explore two methods for rationalising the 'lived density' experienced by an average individual. High resolution population data from the WorldPop data set has allowed us to calculate two measures of population-weighted density (PWD) for multiple countries across East Asia, Europe, North America, and US states. We investigate whether these PWD measures can explain the initial and current stages of the ongoing COVID-19 pandemic. Finally, we examine whether the Hofstede cross-cultural measure of individualism can account for variance between the current size of COVID-19 epidemics, and subsequently use both PWD and the Hofstede score to explain the current size of COVID-19 epidemics across a range of countries. This analysis provides a rationale for controlling two important variables, population density and country-level responses, when comparing epidemics between countries.

0418

2 Methods

2.1 COVID-19 mortality data

We use two sets of data in this paper to measure the extent of COVID-19 in a region, firstly a measure that captures the rate of spread early on, and secondly a measure that captures the size of the epidemic after a period of time has passed.

The first measure examines the rate of spread early in the epidemic by choosing a relatively small threshold value of deaths, and then comparing the number of deaths that have occurred a fixed number of days later. For concreteness, we choose these numbers to be 5 and 5: that is, our metric is "number of deaths that have occurred 5 days after deaths hit 5". In the sense of the classical SIR model [18], we anticipate that this is a phase of unrestricted exponential growth, where we seek to compare the growth exponent. Since this measure seeks to capture the early rate of spread, we do not believe it is appropriate to normalize these figures by total population size, since this corresponds to a situation of a limited number of small localized outbreaks which have not spread to the whole country.

Clearly the choice of these numbers is somewhat arbitrary: we want to choose a threshold that is large enough that daily numbers are not affected too much by random fluctuations, and to wait a long enough period for random daily effects to cancel out. However, waiting too long means that the numbers can be affected by Government actions such as lockdowns. Further, waiting for deaths to hit too high a level may exclude some smaller countries. Some experimentation has shown that our results are robust to the choice of parameters.

An alternative method would be to study the rate of growth of cases. However, such comparison risk being distorted by the significant variation between availability of tests in different countries early in the pandemic.

Our second measure is to consider total deaths per million 120 days after the 1st clinically confirmed case. We are therefore measuring epidemics at a comparable stage of their duration.

The data on COVID-19 deaths itself was obtained online. Data for European countries was taken from [31], which is itself based on ECDC data. Data for US states was downloaded from [23]. Data for East Asian countries was also taken from [31].

2.2 Population data

We studied 30 European countries, using figures of standard population density ρ_S (see Results for notation) taken from Wikipedia [40], and using the values of the non-empty lived density ρ_N for each country calculated by Rae from Eurostat data, and stated in [28]. Some extremely small countries (where the size of the COVID-19 outbreak was too small

0419

to achieve the threshold discussed above) were excluded from the comparison.

Additionally, we used WorldPop population count data [35] to calculate the population-weighted density ρ_W for these countries, using the formula (3). As described in [32, 34] WorldPop distribution datasets are produced by disaggregating administrative-unit based official population estimates into grid cells having a resolution of 3 arc seconds (approximately 100m at the equator) before summarizing them at 30 arc seconds (approximately 1km at the equator). To ensure comparability between countries, 2019 gridded country-based population estimates were adjusted to match the corresponding UNPD country total estimates [38].

We tabulate the resulting values ρ_N, ρ_W, ρ_S and $V = \rho_W/\rho_S$ in Appendix A for completeness. Additionally, in Appendix B we consider a range of other countries of interest and provide values of their standard population density ρ_S (again taken from Wikipedia [40]) and population-weighted density ρ_W calculated from WorldPop data [35] in the same way.

We studied the 50 US States, using figures of standard population density ρ_S taken from Wikipedia, and calculating the population-weighted density ρ_W ourselves, again based on WorldPop data. Values of ρ_N were not available for US states, but since we found a stronger relationship between rate of spread in Europe with ρ_W than with ρ_N (see Figures 3 and 4), in any case we prefer to focus on ρ_W. We tabulate the density values for US states in Appendix C for completeness.

2.3 Hofstede individualism score

We used the values of this measure for a range of countries calculated from questionnaires and tabulated in [15, Table 4.1].

2.4 Nomenclature of regions analysed, data processing and availability

Global regions analysed were: Western/West (Europe, USA, Canada, Israel); East Asia and Oceania (Australia and New Zealand). Countries are listed in appendices A and B

Fits for normal or lognormal (base 10) distributions were generated using a maximum likelihood approach, and the likelihoods compared for statistically significant differences (see [2, Section 6.7.2]). It was observed that the initial rate of spread of COVID-19 and later deaths per million associated with it followed a lognormal distribution, and this was used for regression analysis. The antilog is presented on graphs to aid interpretation. All data is available at: `https://github.com/ptrckgrlnd/COVID-PWD-and-Individualism`

3 Results

3.1 Lived density, or population density as experienced by a random individual

First we motivate and define the various measures of population density that we use in this paper.

Example 3.1. *Consider three countries, each with 100,000 people and an area of 100km^2, and consider the population of each square kilometre grid square. As illustrated in Figure 1:*

1. *Averagia has a uniform spread of population, with 1,000 people living in each grid square.*
2. *Builtupia has ten towns, each consisting of 10,000 people living in a single square kilometre, and the remaining land is uninhabited.*
3. *Citia has one city, where 100,000 people live in a single square kilometre, and the remaining land is uninhabited.*

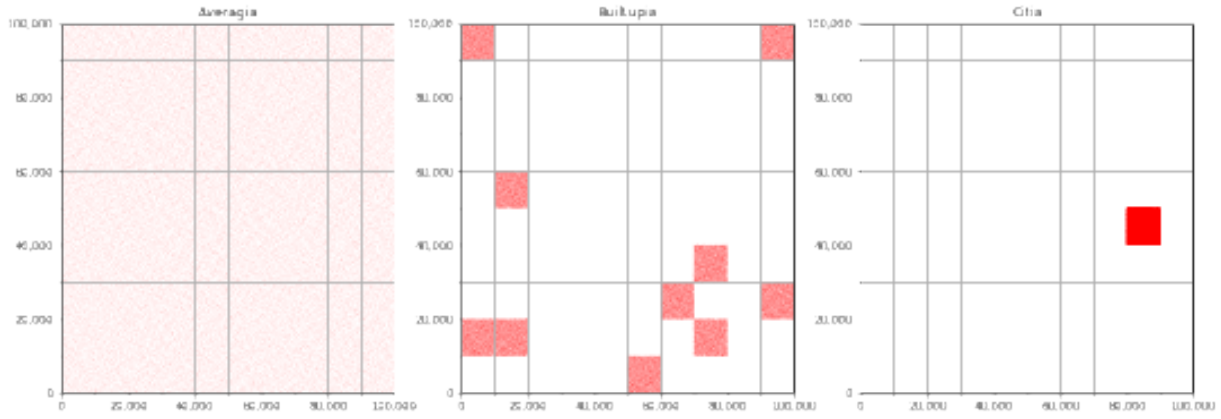

Figure 1: Schematic diagram of population in Averagia, Builtupia and Citia – see Example 3.1.

Since each standard population density is 100000/100 = 1000 people/km^2, we might naively say that each country is equally crowded. However, if we consider the lived experience of a person in each country, it is clear that in everyday life residents of Citia would have daily encounters with more people than in Builtupia, who in turn would have daily encounters with more people than Averagia. Since daily encounters are likely to cause infection events, it seems natural to imagine that COVID-19 would spread more rapidly in

Citia than in Builtupia, and in turn faster in Builtupia than in Averagia. We would like to use a measure of population density that captures this, and here define two such measures.

We will consider a region of total area A, divided into M subareas of area $A_1, \ldots, A_M$ respectively. We will write n_i for the population of the ith subarea, and write $n = \sum_{i=1}^{M} n_i$ for the total population of the region.

Definition 3.2. *In this notation, the* standard population density *is*

$$\rho_S = \frac{n}{A} = \frac{\sum_{i=1}^{M} n_i}{\sum_{i=1}^{M} A_i}. \tag{1}$$

Definition 3.3. *We will refer to the* non-empty lived density *[28] as the same expression normalized by the total area where some people live. That is, we write S for the set of regions with non-zero population, and consider*

$$\rho_N = \frac{\sum_{i \in S} n_i}{\sum_{i \in S} A_i}. \tag{2}$$

Note that in comparison with the expression (1) given for ρ_S, the numerator is unchanged here, since removing terms which are zero does not affect the value of a sum. Indeed, if each subarea contains at least one person then the non-empty lived density ρ_N coincides with the standard population density ρ_S.

Definition 3.4. *We will refer to the* population-weighted density *[4] as the sum*

$$\rho_W = \frac{1}{n} \sum_{i=1}^{M} \frac{n_i^2}{A_i} = \sum_{i=1}^{M} \left(\frac{n_i}{n}\right) \left(\frac{n_i}{A_i}\right). \tag{3}$$

We can think of this as a quadratic measure because if each subarea has $A_i = 1$ then it becomes $\rho_W = \left(\sum_{i=1}^{M} n_i^2\right)/n$. Note that the form of this quantity is somewhat reminiscent of the Herfindahl–Hirschman Index, which is used in economics to measure diversity of market share (see [14] for a history of this quantity).

Remark 3.5. *As described for example in [25]:*

1. *We can think of this population-weighted density ρ_W as follows: select an individual uniformly at random from the population (with probability n_i/n this will be someone from subarea i). Then n_i/A_i is the density of their local subarea. Hence, assuming the subareas are small enough to be reasonably homogeneous, this measure represents the expected local density, sampling by person.*

0422

2. *In contrast, the standard population density corresponds to sampling by area. That is, pick a point uniformly in the region (with probability A_i/A this will be a point in subarea i). Then according to this distribution, the expected local density will be*

$$\sum_{i=1}^{M} \left(\frac{A_i}{A}\right)\left(\frac{n_i}{A_i}\right) = \frac{n}{A}, \tag{4}$$

the standard population density ρ_S.

We return to Example 3.1, where recall that each country had standard population density $\rho_S = 1000$. Considering the square kilometre grid squares as the subareas, note that that the non-empty lived density ρ_N of Averagia, Builtuipia and Citia is $100000/100 = 1000$ people/km^2, $100000/10 = 10000$ people/km^2 and $100000/1 = 100000$ people/km^2 respectively. In fact, calculation shows that the same three values hold for the population-weighted density ρ_W in these cases (though this will not be true in general). For example, for Builtupia, there are 10 non-zero terms in the sum of $\left(\frac{n_i}{n}\right)\left(\frac{n_i}{A_i}\right)$, each equal to $(1/10)(10000/1)$, giving 10000 overall.

Notice that ρ_S, ρ_N and ρ_W are all measured in the same units, namely people/km^2, meaning that it is legitimate to compare them. It turns out that the three measures are always ordered in the same way for every region:

Lemma 3.6. *For any region, the three measures satisfy*

$$\rho_S \leq \rho_N \leq \rho_W,$$

with equality in the first inequality if and only if all the areas have non-zero population, and with equality in the second inequality if and only if all the areas of non-zero population have the same density.

Proof. The fact that $\rho_S \leq \rho_N$ is clear, since the two expressions both have the same numerator n, but the non-empty lived density has a smaller denominator since the sum is taken over a smaller range. Clearly, equality holds if and only if the denominators are equal.

The fact that $\rho_N \leq \rho_W$ is more subtle, but can be proved using the Cauchy-Schwarz inequality. Recall that we write S for the set of areas of non-zero population, then use the fact that

$$n^2 = \left(\sum_{i\in S} \frac{n_i}{\sqrt{A_i}}\sqrt{A_i}\right)^2 \leq \left(\sum_{i\in S} \frac{n_i^2}{A_i}\right)\left(\sum_{i\in S} A_i\right) = (n\rho_W)\left(\sum_{i\in S} A_i\right), \tag{5}$$

and rearrange, using the fact that the value of ρ_W is unchanged if we restrict to a sum over $i \in S$ (since terms with $n_i = 0$ do not contribute to the sum). Equality holds if and only if each populated subarea has the same density, that is if n_i/A_i does not depend on i for each $i \in S$. □

Indeed, a version of the same argument shows that if we partition a subarea into smaller subareas (by obtaining more finely grained population and area data) then the population-weighted density ρ_W does not decrease, and will strictly increase unless all the new subareas have the same density. In other words, the maximum value of ρ_W for a region is obtained by breaking it into small homogeneous subareas.

Definition 3.7. *For a given region we define the* variability coefficient $V = \rho_W/\rho_S$. *Note that this is a dimension-free quantity.*

From Lemma 3.6, we know that $V \geq 1$ for any region. This ratio measures the extent to which population is evenly distributed in a region; returning to the toy Example 3.1, notice that Averagia has $V = 1$, Builtupia has $V = 10$ and Citia has $V = 100$. These values may help calibrate our understanding of the values of V observed for actual regions.

3.2 Population density analysis of Western countries

First, since we have values for all three measures ρ_S, ρ_N and ρ_W for a range of European countries, we compare how well each measure explains the rate of spread of COVID-19.

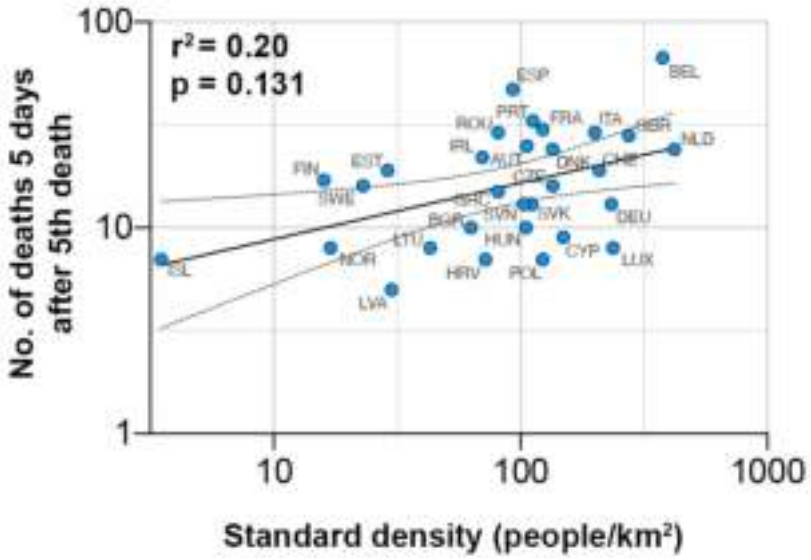

Figure 2: Simple linear regression analysis of rate of COVID-19 spread against standard population density ρ_S for European countries. Both axes are on a log scale. $n = 30$, dashed lines represent 95% CI.

In Figure 2 we plot the correlation between the rate of COVID-19 spread and the standard population density ρ_S for European countries. However, the r^2 of 0.20 is relatively

low and the p-value of 0.131 means a lack of statistical significance. In contrast, for the rate of spread and the respective lived density measures, the effect is stronger than for the corresponding plot for ρ_S. In Figure 3 we see a significant correlation between rate of spread and ρ_N for Europe ($r^2 = 0.26$ and $p < 0.004$), and in Figure 4 we see an even stronger effect in terms of ρ_W ($r^2 = 0.53$ and $p < 0.0001$). Therefore, we conclude that in each case using non-standard measures of population density reveals statistically significant effects compared with those arising from the standard population density ρ_S. It appears that the population-weighted measure ρ_W is of the most value in this sense, explaining over half the variation in the rate of spread of COVID-19 across Europe.

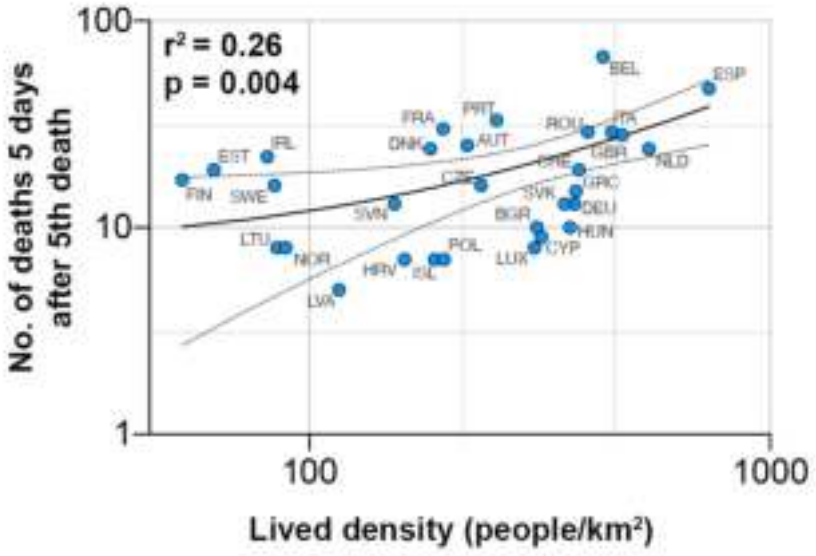

Figure 3: Simple linear regression analysis of rate of COVID-19 spread against non-empty lived population density ρ_N for European countries. Both axes are on a log scale. $n = 30$, dashed lines represent 95% CI.

Having established that ρ_W works well to explain the variation in rates of spread among European countries, we can perform a similar analysis for a wider range of countries.

First, we add the United States, Canada and Israel to the range of countries considered, to emphasise that the correlation observed is not restricted to European countries. As before, the standard density ρ_S does not explain a significant fraction of the correlation, achieving $r^2 = 0.13, p = 0.0378$ (figure not shown here for brevity).

However, in Figure 5, we show that adding these further countries still leaves a good fit between ρ_W and the number of deaths 5 days after the 5th death. Further, we show that this early rate of spread is crucial in determining the ultimate scale of the epidemic, by shading each point according to the number of deaths per million 120 days after the 1st case. It is striking that generally the countries with the highest final death tolls are positioned to the right-hand side of the graph, indicating that they are typically those with

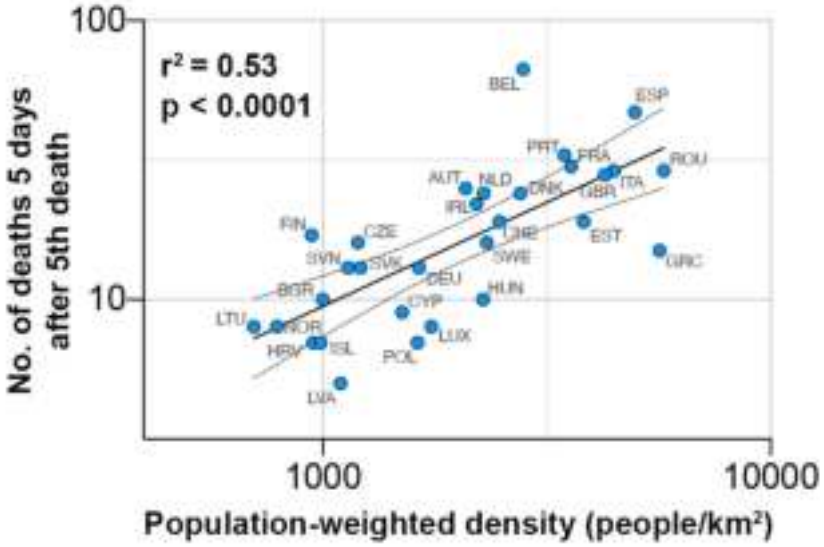

Figure 4: Simple linear regression analysis of rate of COVID-19 spread against population-weighted density ρ_W for European countries. Both axes are on a log scale. $n = 30$, dashed lines represent 95% CI.

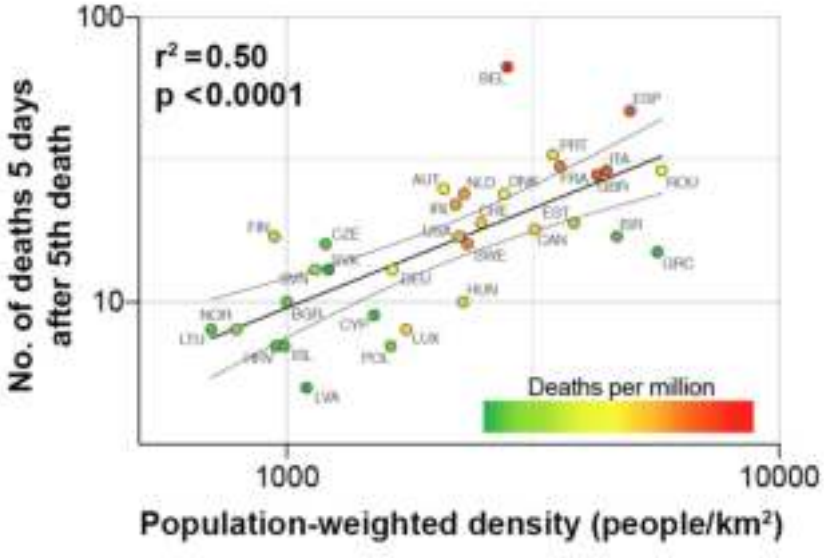

Figure 5: Simple linear regression analysis of rate of COVID-19 spread against population-weighted density ρ_W for a range of Western countries. Plot is on a log-log scale. $n = 33$, dashed lines represent 95% CI. Deaths per million are 120 days after the 1st confirmed case for each country.

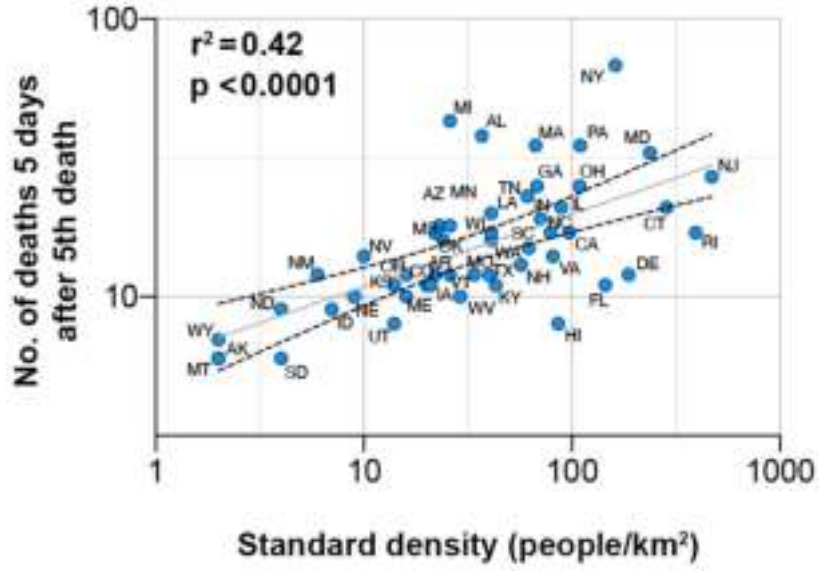
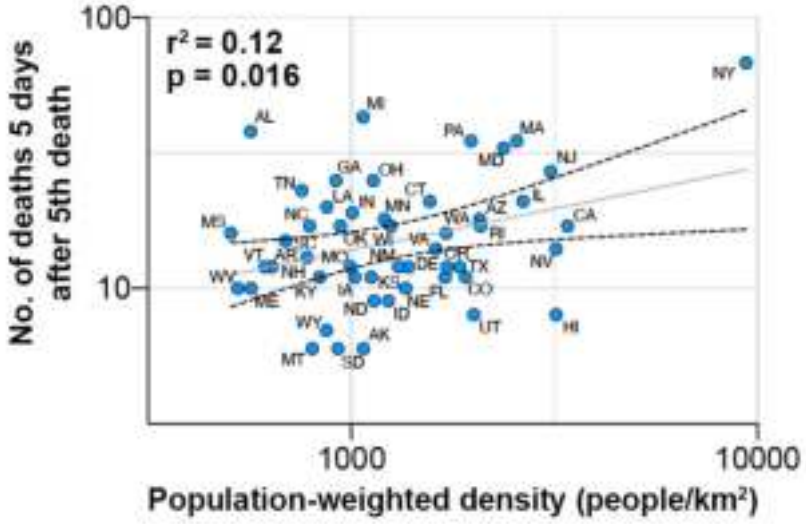
large population-weighted densities.

3.3 Limitations of population density: US states

Next, we perform a similar analysis for the US states, to confirm analysis of [30] who found a statistically significant effect for population-weighted density ρ_W.



a)



b)

Figure 6: Simple linear regression analysis for US states of rate of COVID-19 spread against a) standard density ρ_S b) population-weighted density ρ_W. Plots are on a log-log scale. $n = 50$, dashed lines represent 95% CI.

As shown in Figure 6, the population-weighted density does indeed provide a statistically significant effect ($r^2 = 0.12$, $p = 0.016$). However it is striking that in this case, in contrast to the case of European countries, the standard density ρ_S explains more of the

variation ($r^2 = 0.42$, $p < 0.0001$).

In particular, we can observe from Figure 6 that there is surprisingly little variability in the values of ρ_W calculated. For example, even extremely sparsely-populated states such as Alaska and Wyoming (with standard density $\rho_S \leq 2$) have a population-weighted density ρ_W between 800 and 1100, comparable with denser states such as Georgia ($\rho_S = 68$) and Indiana ($\rho_S = 71$).

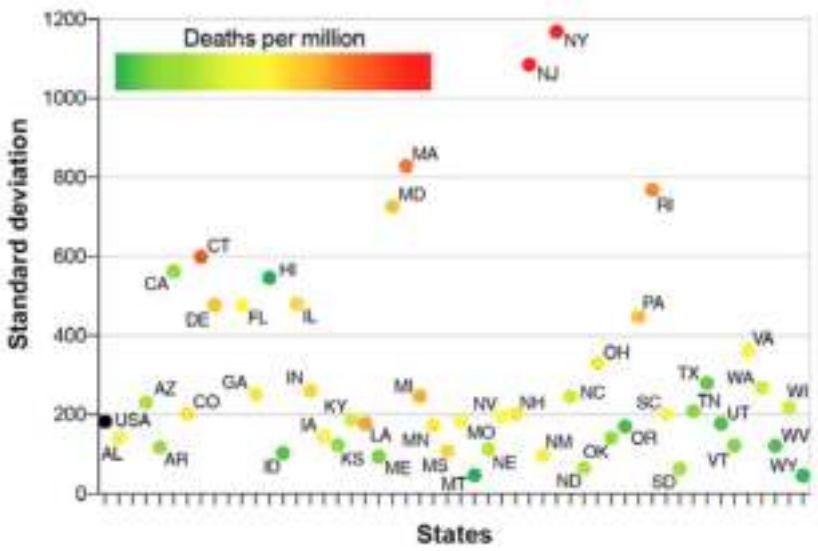


Figure 7: Values of standard deviation observed for US states, shaded according to the deaths per million 120 days after the 1st confirmed case in each state

We can understand this better by studying the standard deviation of the population values n_i within grid squares in a state. If the squares all have area of one square kilometer, then calculation in the spirit of Remark 3.5 shows that since the expected value of n_i is ρ_S, the variance of n_i satisfies

$$\mathrm{Var}(n_i) = \rho_S \rho_W - \rho_S^2,$$

so that the standard deviation is $\rho_S \sqrt{V - 1}$, meaning it captures a combination of standard density and variability.

In Figure 7 we plot the values of standard deviation for each state in alphabetical order, with points shaded according to their deaths per million 120 days after the first confirmed case in each state. It is striking to observe that high values of this standard deviation measure correctly identify the states with highest numbers of deaths - with the majority, however, having similar values for standard deviation and deaths per million.

3.4 The Hofstede measure of individualism can control for country-level differences in the response to COVID-19

Population-weighted density could not explain variation in the early or late stages of COVID-19 epidemics between multiple East Asian countries (data not shown). However, population-weighted density was able to significantly explain the number of deaths per million 120 days after the 1st confirmed case across a global collection of countries including both Western and East Asian countries but the variance explained was relatively low ($r^2 = 0.14$, $p = 0.0075$). This lack of explanatory power for population density (either ρ_S or ρ_W) is particularly noticeable as multiple East Asian countries have very high population densities. For example, Singapore with a population-weighted density of 21,925 and Hong Kong with 46,301 are far in excess of any Western country. As both pre- and peri-pandemic responses to new and emerging infectious diseases could be affected by cultural differences we investigated the explanatory power of the Hofstede individualism score, which has been correlated with historical pathogen exposure [8, 7, 21]

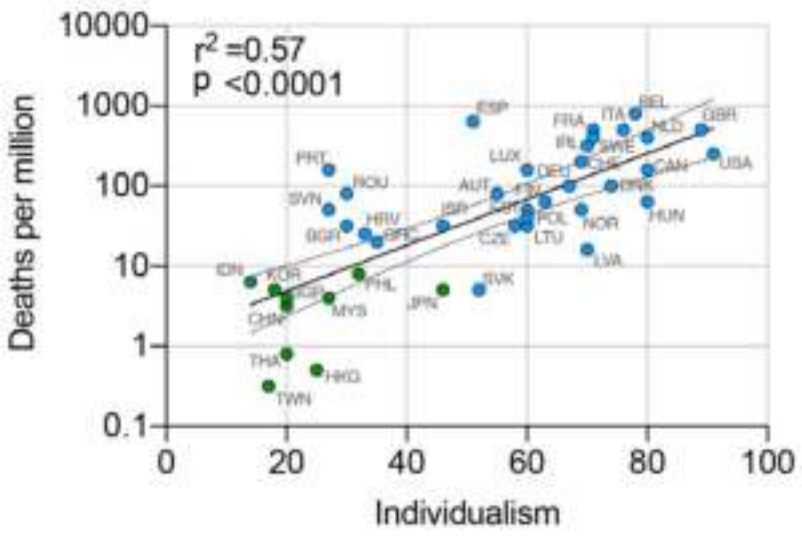

Figure 8: Simple linear regression analysis shows the Hofstede measure of individualism explains the global variation in deaths per million 120 days after the 1st confirmed COVID-19 case (green = Asian countries, blue = Western). $n = 41$, dashed lines represent 95% CI.

As can be seen in Figure 8, the Hofstede measure of individualism significantly explains variation in the number of deaths 120 days after the 1st clinically confirmed COVID-19 case across multiple Western and East Asian countries.

One possible criticism of the individualism measure in this context is that the green and blue points are somewhat separated in Figure 8, and so this score may be serving as a

proxy for other factors that give the difference between Western and East Asian countries. However, we observed that the Hofstede individualism score can control for country-level responses when examining the role of population density in explaining variation in COVID-19 epidemic sizes across Western countries late in the ongoing pandemic. For example, Figure 9 shows that individualism can improve the fit of deaths per million across Western countries. A multiple linear regression based on both population-weighted density ρ_W and the Hofstede individualism score shows that both these variables are statistically significant in this context, and together give $R^2 = 0.46$ when considering deaths per million 120 days after the 1st confirmed COVID-19 case (which is considerably higher than the $r^2 = 0.27$ achieved in this context by ρ_W alone).

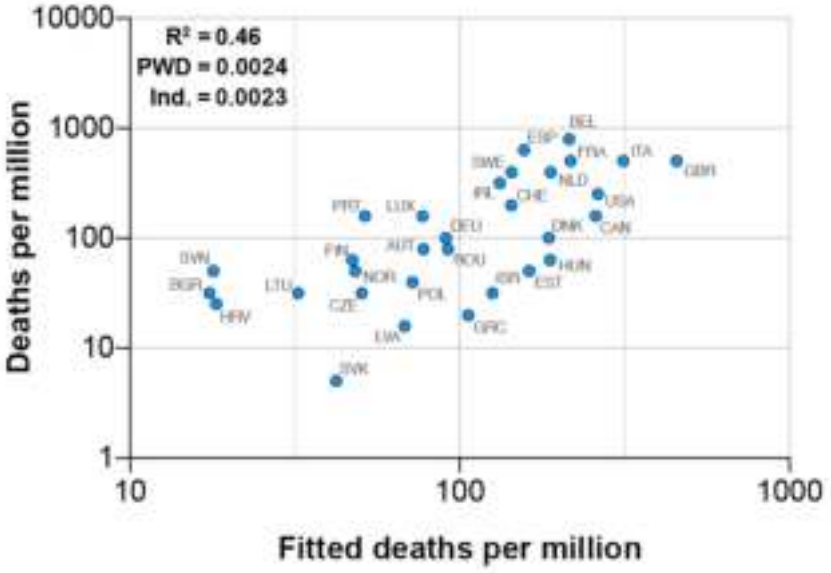

Figure 9: Multiple linear regression between deaths per million 120 days after the 1st confirmed COVID-19 case and a combination of the Hofstede individualism score (Ind) and population-weighted density ρ_W (PWD) for Western countries. $n = 33$.

4 Discussion

Country-level comparisons have been used to assess government responses to the COVID-19 pandemic. For these comparisons to be useful, they must be done using carefully controlled analysis. This study is an early contribution to this effort which focuses on population density. We find that the initial rate of spread of COVID-19 across Western countries can be readily explained by their population-weighted density. PWD does not appear to be as crucial for the spread of COVID-19 in East Asia, or for explaining the size of current epidemics recorded across multiple countries. However, controlling for country-level responses using the Hofstede cross-cultural measure of individualism allows a substantial

proportion of the variance in the size of current COVID-19 epidemics across Western countries to be explained.

PWD can be seen to more readily explain the initial rate of COVID-19 spread by examining individual countries as plotted in Figure 4. For example, Spain has one of the quickest rates of COVID-19 spread yet its standard population density $\rho_S = 93$ people/km^2 is relatively low; in contrast, Spain has one of the highest lived non-empty population densities in Europe, with a value of $\rho_N = 737$ people/km^2, and one of the highest PWD, with $\rho_W = 4980$ people/km^2. As discussed in detail in [28], much of Spain is unpopulated, with very high density populations in Barcelona and Madrid. As a result, other than three very small countries (Monaco, Andorra and Malta, not studied here because of the size of their epidemics), Spain is one of the most densely populated countries in Europe, which our measure of population density captures.

Also of note, are countries whose rate of spread is as predicted by their PWD despite popular perception about their relative performance. For example, Germany has a population-weighted density $\rho_W = 1641$ people/km^2 — lower than Sweden or Ireland (see Appendix A) — reflecting the fact that its population is fairly evenly distributed across the country (giving its relatively low value $V = 7$). Considering Germany's PWD, it may be unnecessary to postulate the existence of an 'immunological dark matter' to explain the current size of its epidemic [33]. In fact, from Figure 4 the European country which stands out for having a significantly slower spread than expected is Greece, which has a very high population-weighted density. This may be due to its high stringency national response [12], which is particularly interesting as it has one of the lowest Hofstede individualism scores within Europe [15, Table 4.1].

Our observation that standard population density ρ_S but not PWD ρ_W predicts the rate of COVID-19 spread across US states was unexpected. We can observe from Figure 6b that there is surprisingly little variability in the values of ρ_W calculated. The fit observed in Figure 6a due to standard population density ρ_S comes through sparsely-populated states such as Alaska and Wyoming, with the remainder of the states forming a relatively homogenous cluster. It is striking that New York, the state with the fastest rate of spread, has a significantly higher value of ρ_W than any other state, whereas is not an outlier in terms of ρ_S, indicating the importance of ρ_W in this context. These observations combined suggest that the lived population density experienced by many Americans is similar; this hypothesis is supported by the observation that the standard deviations for population density within US states as plotted in Figure 7 are also similar. It may be possible that other factors such as mobility (i.e., travel between states) affect the rate of COVID-19 spread within the USA; as has been observed, for example, in China [19]. Although, for epidemic management, there is still value in observing that US states with the highest PWD, like New York, are, as predicted, those with quickest rate of COVID-19 spread. For the USA as a whole, the Hofstede measure of individualism was found to accurately predict its current epidemic size relative to other less individualistic countries. Why might this cross-cultural axis between individualism and collectivism explain variation in COVID-19?

0431

As argued by Fincher and Thornhill [7], collectivism has a two-fold benefit in protecting societies against pathogens. The first is greater attention to in-group vs out-group members, which can limit contact with out-group members either in general or during disease outbreaks; and the second is increased social pressure to conform to group priorities over individual rights. These are culture-wide attitudes and we hypothesise that the Hofstede score can be used as a proxy for both government-level responses and everyday social pressure to perform prosocial behaviour. At the level of government, these differences in cultural values may have impacted how quickly and strongly control measures were put in place to limit the spread of COVID19 [12]. For example, limiting travel within and between countries for both nationals and non-nationals, widespread population surveillance to identify infected individuals and their contacts, and quarantining infected individuals and anyone they have come into contact with; in contrast, in more individualistic countries governments have been slow to restrict individual rights and less comprehensive [12, 13]. At the level of everyday individual conduct the ability of a society to enforce prosocial behaviour (e.g., symptom vigilance and self isolation, mask wearing, hand hygiene) may impact the probability of outbreaks; for example, where they are dependent on superspreader events [20].

We have focused on population density as a default, stable variable that may impact differences in the dynamics of epidemics between countries. What other variables might also play a role?

Advanced age is a risk factor for severe disease and mortality following infection with SARS-CoV-2 [24, 42]. Considering immunosenescence and 'inflamm-aging' are known features of advanced age, it is possible that industrialised countries with aging populations may have sufficient densities of immunocompromised people to promote outbreaks of zoonotic pathogens initially ill adapted to human-to-human transmission [10, 11, 39]). And in terms of country comparisons, age has been a factor impacting relative differences in mortality [3].

At the country-level and in the absence of physical distancing measures, mobility has a significant impact on the spread of COVID-19 ([19]). The degree to which this factor has impacted the international spread of COVID-19 has yet to be formally investigated. However, two countries noticeably absent from our analysis may give possible insight to this question. Although Australia and New Zealand only marginally reduce the variance explained for the initial rate of spread of COVID-19 amongst Western countries ($r^2 = 0.47$, $p < 0.0001$), these two highly individualistic countries are outliers in the global comparison of deaths per million using the Hofstede score ($r^2 = 0.41$, $p < 0.0001$). Compared to the UK, for example, AUZ and NZ have 4-fold and 10-fold less international arrivals, respectively, per year [36]. Therefore, it may be the case that the international connectivity of countries such as the UK has played an important role in the size of its epidemic [27].

0432

5 Conclusion
