		2. ILI definition 1; 3. ILI definition 2.	
DiVita 2011 (conference abstract) RCT Bangladesh	Hand-washing stations with soap and motivation vs none	1. SAR for laboratory-confirmed influenza 2. SAR for ILI	1. SAR higher in intervention group (11.0% vs 7.5%) 2. SAR higher in intervention group (14.2% vs 11.9%)
Feldman 2016 cluster-RCT Israel	Hand disinfection + soap and water installed vs none	1. Number of respiratory infections 2. Number of off-duty days	1. 11 in each group 2. 112 in intervention; 104 in control
Gwaltney 1980 RCT USA	Virucidal hand wash vs placebo	1. Number with illness after immediate exposure 2. Number with illness after 2-hour delay in exposure	1. 0 of 8 in intervention; 7 of 7 in control 2. 1 of 10 in intervention; 6 of 10 in control
Hubner 2010 RCT Germany	Hand disinfection provided vs none	Odds ratios (95% CI) (intervention:control) 1. Influenza 2. Common cold 3. Sinusitis 4. Sore throat 5. Fever 6. Cough	1. 1.02 (0.20 to 5.23) 2. 0.35 (0.17 to 0.71) 3. 1.87 (0.52 to 6.74) 4. 0.62 (0.31 to 1.25) 5. 0.38 (0.14 to 0.99) 6. 0.45 (0.22 to 0.91)
Ladegaard 1999 RCT Denmark	Hand hygiene and education vs none	Sick days during the "effect period"	22 days/child in the intervention group vs 36 days/child in the control group
Larson 2010 cluster-RCT USA	Education vs education with alcohol-based hand sanitiser vs education with hand sanitiser and face masks	Incidence rate ratios (episodes per 1000 person-weeks) for: 1. URI; 2. ILI; 3. influenza; Secondary attack rates for: 4. URI/ILI/influenza; 5. ILI/influenza.	1. HS 29; HS + masks 39; control 35 2. HS 1.9; HS + masks 1.6; control 2.3 3. HS 0.6; HS + masks 0.5; control 2.3 4. HS 0.14; HS + masks 0.12; control 0.14 5. HS 0.02; HS + masks 0.02; control 0.02
Little 2015 RCT England	Bespoke automated web-based hand hygiene motivational intervention with tailored feedback vs none	Number of participants with 1 or more episodes of URI	Risk ratio for intervention to control 0.86 (95% CI 0.83 to 0.89; P < 0.001)

Table 2. Results from trials of hand hygiene compared to control *(Continued)*

Luby 2005 RCT Pakistan	Antibacterial soap and education about hand-washing vs plain soap and education vs none	1. Cough or difficulty breathing in children < 15 yrs (episodes/100 person-weeks) 2. Congestion or coryza in children < 15 yrs (episodes/100 person-weeks) 3. Pneumonia in children < 5 yrs (episodes/100 person-weeks)	All outcomes significantly lower than control 1. 4.21 in antibacterial soap group; 4.16 in plain soap group; 8.50 in control group 2. 7.32 in antibacterial soap group; 6.87 in plain soap group; 14.78 in control group 3. 2.42 in antibacterial soap group; 2.20 in plain soap group; 4.40 in control group
Millar 2016 cluster-RCT USA	Standard educational promotion of hand-washing vs enhanced promotion vs promotion plus a once-weekly application of chlorhexidine-based body wash	Incidence rates of ARI over 20 months	37.7 enhanced + body wash; 29.3 enhanced; 35.3 standard; RR for enhanced + body wash to standard 1.07 (95% CI 1.03 to 1.11); RR for enhanced to enhanced + body wash 0.78 (95% CI 0.75 to 0.81)
Morton 2004 cluster-RCT Cross-over study USA	Alcohol gel plus education vs regular hand-washing	Absence due to infectious illness	Results not stated numerically
Nicholson 2014 cluster-RCT India	Combination hand-washing promotion with provision of free soap vs none	Target children: 1. Episodes of ARI (per 100 person-weeks) 2. School absence episodes (per 100 person-days) Families: 3. Episodes of ARI	1. 16 in intervention; 19 in control 2. 1.2 in intervention; 1.7 in control 3. 10 in intervention; 11 in control
Priest 2014 cluster-RCT New Zealand	Hand hygiene education and hand sanitiser vs education alone	1. % absence days due to respiratory illness 2. % absence days due to any illness	1. 0.84% in intervention group; 0.80% in control (P = 0.44) 2. 1.21% in intervention group; 1.16% in control (P = 0.35)
Ram 2015 RCT Bangladesh	Education to promote intensive hand-washing in households plus soap provision vs none	1. Secondary attack ratio for intervention to control for ILI 2. Laboratory-confirmed influenza	1. 1.24 (95% CI 0.93 to 1.65) 2. 2.40 (95% CI 0.68 to 8.47)
Roberts 2000 cluster-RCT Australia	Hand-washing programme with training for staff and children vs none	Incidence rate ratio for ARI	IRR 0.92 for intervention to control (95% CI 0.86 to 0.99)
Sandora 2008 cluster-RCT USA	Hand sanitiser and education vs none	Incidence rates for ARI (episodes per person-month)	0.43 in intervention; 0.42 in control

Table 2. Results from trials of hand hygiene compared to control *(Continued)*

Savolainen-Kopra 2012 cluster-RCT Finland	Hand hygiene with soap and water (IR1 group) vs with alcohol-based hand rub (IR2 group) vs control (none); intervention groups also received education	1. Number of respiratory infection episodes/week 2. Number of reported infection episodes/week 3. Number of reported sick leave episodes/week	1. 0.076 in IR1; 0.085 in IR2; 0.080 in control, NS 2. 0.097 in IR1; 0.107 in IR2; 0.104 in control, NS 3. 0.042 in IR1; 0.035 in IR2; 0.035 in control. Significantly higher in IR1 compared with control
Simmerman 2011 cluster-RCT Thailand	Hand-washing (HW) vs hand-washing plus paper surgical face masks (HW + FM) vs control (none)	Odds ratios for secondary attack rates for influenza	OR for HW: control 1.20 (95% CI 0.76 to 1.88) OR for HW + masks: control 1.16 (95% CI 0.74 to 1.82) OR for HW + masks: HW 0.72 (95% CI 0.21 to 2.48)
Stebbins 2011 cluster-RCT USA	Training in hand and respiratory (cough) hygiene + hand sanitiser vs none	Incidence rate ratios for intervention to control for: 1. laboratory-confirmed influenza (RT-PCR); 2. influenza-A; 3. absence.	1. IRR 0.81 (95% CI 0.54 to 1.23) 2. IRR 0.48 (95% CI 0.26 to 0.87) 3. IRR 0.74 (95% CI 0.56 to 0.97)
Talaat 2011 cluster-RCT Egypt	Mandatory hand-washing intervention + education vs none	1. Number of absence days due to ILI 2. Number of absence days	1. 917 in intervention; 1671 in control (P < 0.001) 2. 13,247 in intervention; 19,094 in control (P < 0.001)
Temime 2018 cluster-RCT France	Hand hygiene with alcohol-based hand rub, promotion, staff education, and local work groups vs none	Incidence rate of ARI clusters (5 or more people in same nursing home)	2 ARI clusters in intervention; 1 in control
Turner 2012 RCT USA	Antiviral hand treatment vs no treatment	1. Number of rhinovirus infections 2. Common cold infections 3. Rhinovirus-associated illnesses	1. 49 in intervention; 49 in control, NS 2. 56 in intervention; 72 in control, NS 3. 26 in intervention; 24 in control, NS
White 2001 DB-RCT USA	Hand rub with benzalkonium chloride (hand sanitiser) vs placebo	ARI symptoms Laboratory: testing of virucidal and bactericidal activity of the product	30% to 38% decrease of illness and absenteeism (RR for illness absence incidence 0.69; RR for absence duration 0.71)
Yeung 2011 cluster-RCT Hong Kong	Alcohol-based hand gel + materials + education vs control (basic life support workshop)	Difference between pre-study period and poststudy in pneumonia infections recorded in residents	0.63/1000 reduction in intervention group; 0.16/1000 increase in control
Zomer 2015 cluster-RCT Netherlands	4 components: 1. Hand hygiene products, paper towel dispensers, soap, alcohol-based hand sanitiser,	Incidence rate ratio for intervention to control for common cold	IRR 1.07 (95% CI 0.97 to 1.19) 8.2 episodes per child-year in intervention; 7.4 episodes per child-year in control

Table 7. Results from trials of virucidal tissues compared to control

Study	Comparison	Reported outcomes	Results
Virucidal tissues compared with placebo or no tissues			
Farr 1988a and Farr 1988b cluster-RCT USA Trial 1 and Trial 2	Trial 1. Virucidal nasal tissues vs placebo vs none Trial 2. Virucidal nasal tissues vs placebo	Respiratory illnesses per person over 24 weeks Trial 1 Trial 2	Trial 1: 3.4 in tissues group; 3.9 in placebo group; 3.6 in no-tissues group Trial 2: 3.4 in tissues group; 3.6 in placebo group NS
Longini 1988 DB-PC RCT USA	Virucidal nasal tissues vs placebo	Secondary attack rate of viral infections (number of infections in household members of index case)	10.0 in intervention; 14.3 in placebo; NS

cluster-RCT: cluster-randomised controlled trial
DB-PC: double-blind, placebo-controlled
NS: non-significant
RCT: randomised controlled trial
vs: versus

Table 8. Summary of main results of the review for the primary outcomes

Interventions	RCT/cluster-RCT (N = 67)
Medical/surgical masks	**Masks (medical/surgical) compared to no masks** 9 trials no effect on ILI (RR 0.99, 0.82 to 1.18) (Aiello 2010; Barasheed 2014; Canini 2010; Cowling 2008; Jacobs 2009; MacIntyre 2009; MacIntyre 2015; MacIntyre 2016; Suess 2012); 6 trials no effect on laboratory-confirmed influenza 95% CI RR 0.84 (0.61 to 1.17) (Aiello 2012; Cowling 2008; MacIntyre 2009; MacIntyre 2015; MacIntyre 2016; Suess 2012); 2 trials in HCWs no effect on ILI (RR 0.37, 0.05 to 2.50) (Jacobs 2009; MacIntyre 2015). **Medical/surgical masks vs other (non-N95) masks:** 1 trial more ILI with cloth mask (RR 13.25, 1.74 to 100.97) (MacIntyre 2015); 1 trial no effect of catechin-treated masks on influenza (adjusted OR 2.35, 0.40 to 13.72) (Ide 2016).
N95 respirator	**N95 respirators compared to medical/surgical masks** 3 trials no difference for clinical respiratory illness (RR 0.70, 0.45 to 1.10) (MacIntyre 2011; MacIntyre 2013; Radonovich 2019); 4 trials no difference for ILI (95% CI RR 0.81, 0.62 to 1.05) (Loeb 2009; MacIntyre 2009; MacIntyre 2011; Radonovich 2019); 4 trials no difference for laboratory-confirmed influenza (95% CI RR 1.06, 0.81 to 1.38) (Loeb 2009; MacIntyre 2009; MacIntyre 2011; Radonovich 2019). 4 studies conducted in HCWs, 3 trials no difference for clinical respiratory illness (RR 0.70, 0.45 to 1.10) (MacIntyre 2011; MacIntyre 2013; Radonovich 2019); 3 trials no difference for ILI (RR 0.64, 0.32 to 1.31) (Loeb 2009; MacIntyre 2011; Radonovich 2019); 3 trials no difference for laboratory-confirmed ILI (RR 1.02, 0.73 to 1.43) (Loeb 2009; MacIntyre 2011; Radonovich 2019).
Hand hygiene	**Hand hygiene compared to control** 16 trials found effect on combined outcome (ARI or ILI or influenza) (RR 0.89, 0.84 to 0.95) (Azor-Martinez 2018; Biswas 2019; Correa 2012; Cowling 2008; Cowling 2009; Hubner 2010; Larson 2010; Little 2015; Millar 2016; Nicholson 2014; Ram 2015; Roberts 2000; Sandora 2005; Simmerman 2011; Stebbins 2011; Zomer 2015); 7 trials effect on ARI (RR 0.84, 0.82 to 0.86) (Azor-Martinez 2018; Correa 2012; Larson 2010; Little 2015; Millar 2016; Nicholson 2014; Sandora 2005); 10 trials no effect on ILI

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Table 8. Summary of main results of the review for the primary outcomes *(Continued)*

	(RR 0.98, 0.85 to 1.13) (Biswas 2019; Cowling 2008; Cowling 2009; Hubner 2010; Larson 2010; Little 2015; Ram 2015; Roberts 2000; Simmerman 2011; Zomer 2015); 8 trials no effect on laboratory-confirmed influenza (RR 0.91, 95% CI 0.63 to 1.30) (Biswas 2019; Cowling 2008; Cowling 2009; Hubner 2010; Larson 2010; Ram 2015; Simmerman 2011; Stebbins 2011)
Hand hygiene + medical/surgical masks	**Hand hygiene + medical/surgical masks compared to control** 7 trials no effect on ILI (95% CI RR 0.97, 0.80 to 1.19) (Aelami 2015; Aiello 2010; Aiello 2012; Cowling 2009; Larson 2010; Simmerman 2011; Suess 2012); 4 trials no effect on laboratory-confirmed influenza (RR 0.97, 0.69 to 1.36) (Cowling 2009; Larson 2010; Simmerman 2011; Suess 2012). **Hand hygiene + medical/surgical masks compared to hand hygiene** 3 trials no effect on ILI (RR 1.03, 0.69 to 1.53) or laboratory-confirmed influenza (RR 0.99, 0.69 to 1.44) (Cowling 2009; Larson 2010; Simmerman 2011).
Soap + water compared to sanitiser, and comparisons of different types of sanitiser	**Soap + water compared to sanitiser, and comparisons of different types of sanitiser** 1 trial hand sanitiser was more effective than soap and water (Azor-Martinez 2018); 1 trial there was no difference (Savolainen-Kopra 2012). 2 trials in children antiseptic was more effective (Morton 2004; White 2001); 1 trial in children antiseptic = soap (Luby 2005). 1 trial hand sanitisers were better than placebo, but no difference between sanitisers (Turner 2004a); 1 trial no difference between different wipes (Turner 2004b).
Surface/object disinfection (with or without hand hygiene) compared to control	**Surface/object disinfection compared to control** 2 trials were effective on ARI (Ban 2015; Carabin 1999); 1 trial was effective for viruses detected on surface (Ibfelt 2015); 2 trials showed no difference in ARIs (Kotch 1994; McConeghy 2017).
Disinfection of living quarters	-
Complex interventions	**Complex interventions compared to control** 4 trials in low-income countries found no effect on respiratory viral illness (Chard 2019; Hartinger 2016; Huda 2012; Najnin 2019).
Physical interventions (masks, gloves, gowns combined)	-
Gloves	-
Gowns	-
Physical distancing	-
Quarantine in the community	**Quarantine compared to control** 1 trial effective for influenza (Cox hazard ratio 0.799, 95% CI 0.66 to 0.97) (Miyaki 2011).
Eye protection	-
Gargling	**Gargling compared to control** 1 trial gargling with tap water was effective, povidone-iodine was not effective (Satomura 2005); 1 trial gargling with green tea was not more effective than tap water (Ide 2014); 1 trial gargling with water was not effective (Goodall 2014); pooling of 2 trials no effect of gargling (RR 0.91, 95% CI 0.63 to 1.31) (Goodall 2014; Satomura 2005).
Virucidal tissues	**Virucidal tissues compared to control**

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Table 8. Summary of main results of the review for the primary outcomes *(Continued)*

	1 trial had a small effect (Farr 1988a) ("The study authors conclude that virucidal tissues have only a small impact upon the overall rate of natural acute respiratory illnesses"); 2 trials non-significant difference (Farr 1988b; Longini 1988).
Nose wash	-

ARI: acute respiratory infection

ILI: influenza-like illness
OR: odds ratio
RCT: randomised controlled trial
RR: risk ratio

Table 9. Trial authors' outcome definitions

	Study	Outcomes definitions
Masks (n = 13)		
1.	Cowling 2008 cluster-RCT Hong Kong	Laboratory: QuickVue Influenza A+B rapid test Viral culture on MDCK (Madin-Darby canine kidney cells) Samples were harvested using NTS, but the text refers to a second procedure from June 2007 onwards with testing for influenza viruses on index participants with a negative QuickVue result but a fever ≥ 38 °C who were also randomised and further followed up. Data on clinical signs and symptoms were collected for all participants, and an additional NTS was collected for later confirmation of influenza infection by viral culture. It is noteworthy that dropout was higher in households of index participants who had a negative result on the rapid influenza test (25/44, 57%) compared to those who had a positive result (45/154, 29%). Effectiveness: secondary attack ratios (SAR): SAR is the proportion of household contacts of an index case who subsequently were ill with influenza (symptomatic contact individuals with at least 1 NTS positive for influenza by viral culture or PCR) 3 clinical definitions were used for secondary analysis: 1. fever ≥ 38 °C or at least 2 of the following symptoms: headache, coryza, sore throat, muscle aches and pains; 2. at least 2 of the following S/S: fever ≥ 37.8 °C, cough, headache, sore throat and muscle aches and pains; and 3. fever of ≥ 37.8 °C plus cough or sore throat. Safety: harms were not mentioned as an outcome in the methods, but it was reported in the results that there were no adverse events.
2.	Jacobs 2009 RCT Japan	Laboratory-confirmation not reported. Effectiveness: URTI is defined on the basis of a symptom score with a score > 14 being a URTI according to Jackson's 1958 criteria ("Jackson score"). These are not explained in text, although the symptoms are listed in Table 3 (any, sore throat, runny nose, stuffy nose, sneeze, cough, headache, earache, feel bad) together with their mean and scores (SD) by intervention arm. Safety: the text does not mention or report harms. These appear to be indistinguishable from URTI symptoms (e.g. headache, which is reported as of significantly longer duration in the intervention arm). Compliance is self-reported as high (84.3% of participants).

Table 9. Trial authors' outcome definitions *(Continued)*

3.	Loeb 2009 cluster-RCT HCW Canada	Clinical respiratory illness, influenza-like illness, and laboratory-confirmed respiratory virus infection. 1. Clinical respiratory illness, defined as 2 or more respiratory symptoms or 1 respiratory symptom and a systemic symptom. 2. Influenza-like illness, defined as fever ≥ 38 °C plus 1 respiratory symptom. 3. Laboratory-confirmed viral respiratory infection. Laboratory confirmation was by nucleic acid detection using multiplex RT-PCR for 17 respiratory viruses. Safety: harms were not mentioned as an outcome in the methods, but it is stated in the results that no adverse events were reported by participants.
4.	MacIntyre 2009 cluster-RCT Australia	Eligibility criteria were stipulated as follows: 1. the household contained > 2 adults > 16 years of age and 1 child 0 to 15 years of age; 2. the index child had fever (temperature > 37.8 °C) and either a cough or sore throat; 3. the child was the first and only person to become ill in the family in the previous 2 weeks; 4. adult caregivers consented to participate in the study; and 5. the index child was not admitted to the hospital. Definitions used for outcomes: 1. ILI defined by the presence of fever (temperature > 37.8 °C), feeling feverish or a history of fever, > 2 symptoms (sore throat, cough, sneezing, runny nose, nasal congestion, headache), or 1 of the symptoms listed plus laboratory confirmation of respiratory viral infection. 2. Laboratory confirmation: multiplex RT-PCR tests to detect influenza A and B and RSV, PIV types 1–3, picornaviruses (enteroviruses or rhinoviruses), adenoviruses, coronaviruses 229E and OC43, and hMPV plus ≥ 1 sym Effectiveness: presence of ILI or a laboratory diagnosis of respiratory virus infection within 1 week of enrolment. Safety: harms not mentioned as an outcome in the methods, but it is reported in the results that more than 50% of participants reported concerns with mask wearing, mainly that wearing a face mask was uncomfortable, but there were no significant differences between the P2 (N95) and surgical mask groups. Other concerns were that the child did not want the parent wearing a mask.
5.	Aiello 2010 cluster-RCT USA	Laboratory details are described in appendix. Effectiveness: ILI, defined as cough and at least 1 constitutional symptom (fever/feverishness, chills, headache, myalgia). ILI cases were given contact nurses phone numbers to record the illness and paid USD 25 to provide a throat swab. 368 participants had ILI, 94 of which had a throat swab analysed by PCR. 10 of these were positive for influenza (7 for A and 3 for B), respectively by arm 2, 5 and 3 using PCR, 7 using cell culture. Safety: no outcomes on harms planned or reported.
6.	Canini 2010 cluster-RCT USA	The primary endpoint was the proportion of household contacts who developed an ILI during the 7 days following inclusion. Exploratory cluster-level efficacy outcome, the proportion of households with 1 or more secondary illness in household contacts. A temperature over 37.8 °C with cough or sore throat was used as primary clinical case definition. The authors also used a more sensitive case definition based on a temperature over 37.8 °C or at least 2 of the following: sore throat, cough, runny nose, or fatigue.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Table 9. Trial authors' outcome definitions *(Continued)*

		Safety: adverse reactions due to mask wearing were reported, with 38 (75%) participants in the intervention arm experiencing discomfort with mask use due to warmth (45%), respiratory difficulties (33%), and humidity (33%). Children wearing children face masks reported feeling pain more frequently than other participants wearing adult face masks (P = 0.036).
7.	Aiello 2012 cluster-RCT in halls of residence in the USA	Clinically verified ILI - case definition (presence of cough and at least 1 or more of fever/feverishness, chills, or body aches) Laboratory-confirmed influenza A or B. Throat swab specimens were tested for influenza A or B using real-time PCR. Safety: no outcomes on harms planned or reported.
8.	Barasheed 2014 cluster-RCT Saudi Arabia	Laboratory: 2 nasal swabs from all ILI cases and contacts. 1 for influenza POCT using the QuickVue Influenza (A+B) assay (Quidel Corporation, San Diego, USA) and 1 for later NAT for influenza and other respiratory viruses. However, there was a problem with getting POCT on time during Hajj. Effectiveness: to assess the effectiveness of face masks in the prevention of transmission of ILI. ILI was defined as subjective (or proven) fever plus 1 respiratory symptom (e.g. dry or productive cough, runny nose, sore throat, shortness of breath). Safety: no outcomes on harms planned or reported.
9.	MacIntyre 2011 cluster-RCT China	Clinical respiratory illness Influenza-like illness Laboratory-confirmed viral respiratory infection Laboratory-confirmed influenza A or B 1. Clinical respiratory illness, defined as 2 or more respiratory or 1 respiratory symptom and a systemic symptom. 2. Influenza-like illness, defined as fever ≥ 38 °C plus 1 respiratory symptom (i.e. cough, runny nose, etc.). 3. Laboratory-confirmed viral respiratory infection (detection of adenoviruses, human metapneumovirus, coronavirus 229E/NL63, parainfluenza viruses 1, 2, and 3, influenza viruses A and B, respiratory syncytial virus A and B, rhinovirus A/B and coronavirus OC43/HKU1 by multiplex PCR). 4. Laboratory-confirmed influenza A or B. 5. Adherence with mask/respirator use. Safety: adherence and adverse effects of mask wearing were collected at exit interviews 4 weeks' poststudy. Significantly higher adverse events with N95 respirator compared to medical mask for discomfort, headache, difficulty breathing, nose pressure, trouble communicating, not wearing, and unspecified "other" side effects. Over 50% of those wearing N95 respirators reported adverse events. Of those wearing medical masks versus N95 respirators, 85.5% (420/491) versus 47.4% (447/943) reported no adverse events (P < 0.001), respectively.
10.	MacIntyre 2013 cluster-RCT China	Laboratory: 1. Laboratory-confirmed viral respiratory infection in symptomatic participants, defined as detection of adenoviruses; human metapneumovirus; coronaviruses 229E/NL63 and OC43/HKU1; parainfluenza viruses 1, 2, and 3; influenza viruses A and B; respiratory syncytial viruses A and B; or rhinoviruses A/B by NAT using a commercial multiplex PCR (Seegen, Inc., Seoul, Korea). 2. Laboratory-confirmed influenza A or B in symptomatic participants.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Table 9. Trial authors' outcome definitions *(Continued)*

		3. Laboratory-confirmed bacterial colonisation in symptomatic participants, defined as detection of *Streptococcus pneumoniae*, *Legionella*, *Bordetella pertussis*, *Chlamydia*, *Mycoplasma pneumoniae*, *or Haemophilus influenzae* type B by multiplex PCR (Seegen, Inc.). Effectiveness: clinical respiratory illness defined as 2 or more respiratory symptoms or 1 respiratory symptom and a systemic symptom. ILI defined as fever (38 °C) plus 1 respiratory symptom. Safety: adverse effects measured using a semi-structured questionnaire. Investigators stated that there was higher reported adverse effects and discomfort of N95 respirators compared with the other 2 arms. In terms of comfort, 52% (297 of 571) of the medical mask arm reported no problems, compared with 62% (317 of 512) of the targeted arm and 38% (217 of 574) of the N95 arm (P < 0.001).
11.	MacIntyre 2015 cluster-RCT Vietnam	Clinical respiratory illness, influenza-like illness, and laboratory-confirmed respiratory virus infection. 1. Clinical respiratory illness, defined as 2 or more respiratory symptoms or 1 respiratory symptom and a systemic symptom. 2. Influenza-like illness, defined as fever ≥ 38 °C plus 1 respiratory symptom. 3. Laboratory-confirmed viral respiratory infection. Laboratory confirmation was by nucleic acid detection using multiplex RT-PCR for 17 respiratory viruses. Safety: adverse events associated with face mask use were reported in 40.4% (227/562) of HCWs in the medical/surgical mask arm and 42.6% (242/568) in the cloth mask arm (P = 0.45). The most frequently reported adverse events were: general discomfort (35.1%; 397/1130) and breathing problems (18.3%; 207/1130). The rate of ILI was higher in the cloth mask arm compared to medical/surgical masks (RR 13.25, 95% CI 1.74 to 100.97).
12.	MacIntyre 2016 cluster-RCT China	Clinical respiratory illness, influenza-like illness, and laboratory-confirmed viral respiratory infection. 1. Clinical respiratory illness, defined as 2 or more respiratory symptoms (cough, nasal congestion, runny nose, sore throat, or sneezes) or 1 respiratory symptom and a systemic symptom (chill, lethargy, loss of appetite, abdominal pain, muscle or joint aches). 2. Influenza-like illness, defined as fever ≥ 38 °C plus 1 respiratory symptom. 3. Laboratory-confirmed viral respiratory infection, defined as detection of adenoviruses, human metapneumovirus, coronaviruses 229E/NL63 and OC43/HKU1, parainfluenza viruses 1, 2, and 3, influenza viruses A and B, respiratory syncytial virus A and B, or rhinovirus A/B by NAT using a commercial multiplex PCR. Safety: no outcomes on harms planned or reported.
13.	Radonovich 2019 cluster-RCT USA	Laboratory. Primary outcome: incidence of laboratory-confirmed influenza, defined as: 1. detection of influenza A or B virus by RT-PCR in an upper respiratory specimen collected within 7 days of symptom onset; 2. detection of influenza from a randomly obtained swab from an asymptomatic participant; and 3. influenza seroconversion (symptomatic or asymptomatic), defined as at least a 4-fold rise in haemagglutination inhibition antibody titres to influenza A or B virus between pre-season and postseason serological samples deemed not attributable to vaccination. Effectiveness. Secondary outcomes: incidence of 4 measures of viral respiratory illness or infection as follows:

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Table 9. Trial authors' outcome definitions *(Continued)*

		1. acute respiratory illness with or without laboratory confirmation; 2. laboratory-detected respiratory infection, defined as detection of a respiratory pathogen by PCR or serological evidence of infection with a respiratory pathogen during the study surveillance period(s), which was added to the protocol prior to data analysis; and 3. laboratory-confirmed respiratory illness, identified as previously described (defined as self-reported acute respiratory illness plus the presence of at least PCR–confirmed viral pathogen in a specimen collected from the upper respiratory tract within 7 days of the reported symptoms and/or at least a 4-fold rise from pre-intervention to postintervention serum antibody titres to influenza A or B virus). Influenza-like illness, defined as temperature of at least 100 °F (37.8 °C) plus cough and/or a sore throat, with or without laboratory confirmation. Safety: 19 participants reported skin irritation or worsening acne during years 3 and 4 at 1 site in the N95 respirator group.
Hand and hygiene (n = 32)		
14.	Alzaher 2018 cluster-RCT Saudi Arabia	Episode of URI was defined as having 2 of the following symptoms for a day or 1 of the symptoms for 2 or more consecutive days: 1) a runny nose, 2) a stuffy or blocked nose or noisy breathing, 3) sneezing, 4) a cough, 5) a sore throat, and 6) feeling hot, having a fever or a chill.
15.	Arbogast 2016 cluster-RCT USA	ICD-9 used: 46611: acute bronchiolitis due to respiratory syncytial virus, 46619: acute bronchiolitis due to other infectious organisms, 4800: pneumonia due to adenovirus, 4809: viral pneumonia, unspecified, 4870: influenza with pneumonia, 07999: unspecified viral infection, 4658: acute upper respiratory infections of other multiple sites, 4659: acute upper respiratory infections of unspecified site, 4871: influenza with other respiratory manifestations.
16.	Azor-Martinez 2016 RCT Spain	Upper respiratory illness was defined as 2 of the following symptoms during 1 day, or 1 of the symptoms for 2 consecutive days: (1) runny nose; (2) stuffy or blocked nose or noisy breathing; (3) cough; (4) feeling hot or feverish or having chills; (5) sore throat; or (6) sneezing.
17.	Azor-Martinez 2018 RCT Spain	Respiratory illness (RI) was defined as the presence of 2 of the following symptoms during 1 day or the presence of 1 of the symptoms for 2 consecutive days: (1) runny nose, (2) stuffy or blocked nose or noisy breathing, (3) cough, (4) feeling hot or feverish or having chills, (5) sore throat, or (6) sneezing. ICD-10 and ICD-9 diagnosis codes used: nonspecific upper respiratory tract infection (465.9), otitis media (382.9), pharyngotonsillitis (463), lower respiratory tract infections (485 and 486), acute bronchitis (490), and bronchiolitis (466.19). Study authors combined the bronchopneumonia code (485) and pneumonia code (486) under the label "lower respiratory tract infections." If > 1 antibiotic was prescribed during an episode, they used the first prescription for analysis. The final diagnosis was done by the medical researchers on the basis of the symptoms described above and a review of the medical history of children with RIs.
18.	Biswas 2019 cluster-RCT Bangladesh	Influenza-like illness: an ILI episode was defined as measured fever > 38 °C or subjective fever and cough. Laboratory-confirmed influenza Nasal swabs for real-time RT-PCR.
19.	Correa 2012	Acute respiratory infection was defined as 2 or more of the following symptoms for at least 24 hours, lasting at least 2 days: runny, stuffy, or blocked nose or noisy

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Table 9. Trial authors' outcome definitions *(Continued)*

	cluster-RCT Colombia	breathing; cough; fever, hot sensation, or chills; and/or sore throat. Ear pain alone was considered ARI alternately.
20.	Cowling 2009 cluster-RCT Hong Kong	Laboratory-confirmed of influenza virus infection by RT-PCR for influenza A and B virus. Clinical influenza-like illness: used 2 clinical definitions of influenza based on self-reported data from the symptom diaries as secondary analyses. The first definition of clinical influenza was at least 2 of the following signs and symptoms: temperature 37.8 °C or greater, cough, headache, sore throat, and myalgia; the second definition was temperature 37.8 °C or greater plus cough or sore throat.
21.	DiVita 2011 (conference abstract) RCT Bangladesh	Influenza-like illness was defined as fever in children < 5 years old and fever with cough or sore throat in individuals > 5 years old.
22.	Feldman 2016 cluster-RCT Israel	Infectious diseases grouped into diarrhoeal, respiratory, and skin infection. Based on ICD-9, but no supplementary material was accessible for further definition (Supplementary Material C lists all ICD-9 diagnoses tallied in this "outcome").
23.	Gwaltney 1980 RCT USA	Viral cultures and serology if rhinovirus in laboratory-inoculation
24.	Hubner 2010 RCT Germany	Assessing illness rates due to common cold and diarrhoea. Collecting data on illness symptoms (common cold, sinusitis, sore throat, fever, cough, bronchitis, pneumonia, influenza, diarrhoea) and associated absenteeism at the end of every month. Definitions of symptoms were given to the participants as part of the individual information at the beginning of the study. Whilst most symptoms are quite self-explanatory, "influenza" and "pneumonia" are specific diagnoses that were confirmed by professional diagnosis only. Similarly, (self-) diagnosis of "fever" required objective measurement with a thermometer.
25.	Ladegaard 1999 RCT Denmark	Laboratory: serological evidence Effectiveness: influenza-like illness (described as fever, history of fever or feeling feverish in the past week, myalgia, arthralgia, sore throat, cough, sneezing, runny nose, nasal congestion, headache). However, a positive laboratory finding for influenza converts the ILI definition into one of influenza.
26.	Larson 2010 cluster-RCT USA	Study goals: rates of symptoms and secondary transmission of URIs, incidence of virologically confirmed influenza, knowledge of prevention and treatment strategies for influenza and URIs, and rates of influenza vaccination. 1. Laboratory-confirmed influenza: nasal swabs to test for influenza types A and B as well as other common respiratory viruses by rapid culture (R-Mix, Diagnostic Hybrids, Inc., Athens, OH, USA). PCR and subtyping of the samples was done during the second half of the second year of the study. 2. Influenza-like illness: CDC definition of ILI from the Sentinel Physicians' Network was used to determine when masks should be worn: "temperature of ≥37.8°C and cough and/or sore throat in the absence of a known cause other than influenza".

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Table 9. Trial authors' outcome definitions *(Continued)*

		3. Episodes of URI = upper respiratory infection: not clear, no explicitly stated definition, reported that the most commonly reported URI symptoms are cough or rhinorrhoea.
27.	Little 2015 RCT England	Respiratory tract infections defined as 2 symptoms of an RTI for at least 1 day or 1 symptom for 2 consecutive days. For reported ILI, study authors did not use WHO or CDC definitions because these definitions require measured temperature, and thus were not appropriate (participants were not included after a clinical examination), and they did not use the European Centre for Disease Prevention and Control definition (1 systemic and 1 respiratory symptom) because, according to the international influenza collaboration, this definition does not necessarily differentiate ILI from a common cold. Influenzanet suggests making high temperature a separate element. Their pragmatic definition of ILI therefore required a high temperature (feeling very hot or very cold; or measured temperature > 37.5 °C), a respiratory symptom (sore throat, cough, or runny nose), and a systemic symptom (headache, severe fatigue, severe muscle aches, or severe malaise).
28.	Luby 2005 RCT Pakistan	Defined pneumonia in children according to the WHO clinical case definition: cough or difficulty breathing with a raised respiratory rate (> 60 per minute in individuals younger than 60 days old, > 50 per minute for those aged 60 to 364 days, and > 40 per minute for those aged 1 to 5 years)
29.	Millar 2016 cluster-RCT USA	Medically attended, outpatient cases of acute respiratory infection in the study population. The case definition was any occurrence of the following International Classification of Disease, 9 Revision, Clinical Modification (ICD-9) symptom or disease-specific codes: 460-466, 480-488, and specifically 465.9, 482.9, 486, and 487.1. **Acute respiratory infections (460 to 466)** 460 Acute nasopharyngitis (common cold) 461 Acute sinusitis 462 Acute pharyngitis 463 Acute tonsillitis 464 Acute laryngitis and tracheitis 465 Acute upper respiratory infections of multiple or unspecified sites 466 Acute bronchitis and bronchiolitis **Pneumonia and influenza (480 to 488)** 480 Viral pneumonia 481 Pneumococcal pneumonia (*Streptococcus pneumoniae* pneumonia) 482 Other bacterial pneumonia 483 Pneumonia due to other specified organism 484 Pneumonia in infectious diseases classified elsewhere 485 Bronchopneumonia, organism unspecified 486 Pneumonia, organism unspecified 487 Influenza 488 Influenza due to identified avian influenza virus 465.9 Acute upper respiratory infections of unspecified site

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Table 9. Trial authors' outcome definitions *(Continued)*

		482.9 Bacterial pneumonia NOS 487.1 Diagnosis of influenza with other respiratory manifestations
30.	Morton 2004 cluster-RCT Cross-over study USA	Respiratory illnesses defined by symptoms of upper respiratory infections such as nasal congestion, cough, or sore throat, in any combination, with or without fever
31.	Nicholson 2014 cluster-RCT India	Acute respiratory infections Operational definitions for all the illnesses were taken from Black's Medical Dictionary. ARIs defined as "Pneumonia, cough, fever, chest pain and shortness of breath, cold, inflammation of any or all of the airways, that is, nose, sinuses, throat, larynx, trachea and bronchi".
32.	Pandejpong 2012 cluster-RCT Thailand	Influenza-like illness defined if 2 or more symptoms of stuffy nose, cough, fever or chills, sore throat, headache, diarrhoea, presence of hand, foot, or mouth ulcers.
33.	Priest 2014 cluster-RCT New Zealand	Respiratory illness was defined as an episode of illness that included at least 2 of the following caregiver-reported symptoms for 1 day, or 1 of these symptoms for 2 days (but not fever alone): runny nose, stuffy or blocked nose or noisy breathing, cough, fever, sore throat, or sneezing.
34.	Ram 2015 RCT Bangladesh	Influenza-like illness Age-specific definitions of ILI. For individuals ≥ 5 years old, ILI was defined as history of fever with cough or sore throat. For children < 5 years old, ILI was defined as fever; study authors used this relatively liberal case definition in order to include influenza cases with atypical presentations in children. Laboratory-confirmed influenza infection Oropharyngeal swabs from index case patients for laboratory testing for influenza. All swabs were tested by PCR for influenza A and B, with further subtyping of influenza A isolates.
35.	Roberts 2000 cluster-RCT Australia	The symptoms of acute upper respiratory illness elicited from parents were: a runny nose, a blocked nose, and cough. Study authors used a definition of colds based on a community intervention trial of virucidal impregnated tissues. A cold was defined as either 2 symptoms for 1 day or 1 of the respiratory symptoms for at least 2 consecutive days, but not including 2 consecutive days of cough alone. Study authors defined a new episode of a cold as the occurrence of respiratory symptoms after a period of 3 symptom-free days.
36.	Sandora 2005 cluster-RCT USA	The overall rates of secondary respiratory and GI illness. Respiratory illness was defined as 2 of the following symptoms for 1 day or 1 of the symptoms for 2 consecutive days: (1) runny nose; (2) stuffy or blocked nose or noisy breathing; (3) cough; (4) fever, feels hot, or has chills; (5) sore throat; and (6) sneezing. An illness was considered new or separate when a period of at least 2 symptom-free days had elapsed since the previous illness. An illness was defined as a secondary case when it began 2 to 7 days after the onset of the same illness type (respiratory or GI) in another household member.

Table 9. Trial authors' outcome definitions *(Continued)*

37.	Savolainen-Kopra 2012 cluster-RCT Finland	Nasal and pharyngeal stick samples from participants with respiratory symptoms
38.	Simmerman 2011 cluster-RCT Thailand	Influenza-like illness defined by WHO as fever plus cough or sore throat, based on self-reported symptoms. Laboratory-confirmed secondary influenza virus infections amongst household members described as the secondary attack rate. The secondary influenza virus infection was defined as a positive rRT-PCR result on days 3 or 7 or a four-fold rise in influenza HI antibody titres with the virus type and subtype matching the index case.
39.	Stebbins 2011 cluster-RCT USA	The primary outcome was an absence episode associated with an influenza-like illness that was subsequently laboratory confirmed as influenza A or B. The following CDC definition for ILI was used: fever ≥ 38 °C with sore throat or cough.
40.	Talaat 2011 cluster-RCT Egypt	Nasal swab for QuickVue test for influenza A and B viruses. Influenza-like illness (defined as fever > 38 °C and either cough or sore throat).
41.	Temime 2018 cluster-RCT France	ARIs were defined as the combination of at least 1 respiratory symptom and 1 symptom of systemic infection.
42.	Turner 2004b RCT Canada	Virologic assays
43.	Turner 2012 RCT USA	Laboratory-confirmed rhinovirus infection by PCR assay. Common cold illness was defined as the presence of any of the symptoms of nasal obstruction, rhinorrhoea, sore throat, or cough on at least 3 consecutive days. Illnesses separated by at least 3 symptom-free days were considered as separate illnesses.
44.	Yeung 2011 cluster-RCT Hong Kong	Pneumonia
45.	Zomer 2015 cluster-RCT Netherlands	Incidence of gastrointestinal and respiratory infections in children monitored by parents. The common cold was defined as a blocked or runny nose with at least 1 of the following symptoms: coughing, sneezing, fever, sore throat, or earache.
Hand hygiene and masks (n = 6)		
46.	Aelami 2015 (conference abstract)	Influenza-like illness was defined as the presence of at least 2 of the following during their stay: fever, cough, and sore throat.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Table 9. Trial authors' outcome definitions *(Continued)*

	RCT Saudi Arabia	Safety: no outcomes on harms planned or reported.
47.	Aiello 2010 cluster-RCT USA	Influenza-like illness case definition (presence of cough and at least 1 constitutional symptom (fever/feverishness, chills, or body aches). Safety: no outcomes on harms planned or reported.
48.	Cowling 2009 cluster-RCT Hong Kong	2 clinical definitions of influenza. First definition was at least 2 of the following signs and symptoms: temperature 37.8 °C or greater, cough, headache, sore throat, and myalgia. The second was temperature 37.8 °C or greater plus cough or sore throat. Safety: no outcomes on harms planned or reported.
49.	Larson 2010 cluster-RCT USA	Study goals: rates of symptoms and secondary transmission of URIs, incidence of virologically confirmed influenza, knowledge of prevention and treatment strategies for influenza and URIs, and rates of influenza vaccination. 1. Laboratory-confirmed influenza: nasal swabs to test for influenza types A and B as well as other common respiratory viruses by rapid culture (R-Mix, Diagnostic Hybrids, Inc., Athens, OH, USA). PCR and subtyping of the samples was done during the second half of the second year of the study. 2. Influenza-like illness: CDC definition of ILI from the Sentinel Physicians' Network was used to determine when masks should be worn: "temperature of ≥37.8°C and cough and/or sore throat in the absence of a known cause other than influenza". 3. Episodes of URI = upper respiratory infection: not clear, no explicitly stated definition, reported that the most commonly reported URI symptoms are cough or rhinorrhoea. Safety: no outcomes on harms planned or reported.
50.	Simmerman 2011 cluster-RCT Thailand	Laboratory-confirmed secondary influenza virus infections amongst household members described as the secondary attack rate. The secondary influenza virus infection was defined as a positive rRT-PCR result on days 3 or 7 or a four-fold rise in influenza HI antibody titres with the virus type and subtype matching the index case. Influenza-like illness defined by WHO as fever plus cough or sore throat, based on self-reported symptoms. Safety: no outcomes on harms planned or reported.
51.	Suess 2012 cluster-RCT Germany	Quantitative RT-PCR for samples of nasal wash. Influenza virus infection as a laboratory-confirmed influenza infection in a household member who developed fever (> 38.0 °C), cough, or sore throat during the observation period. Also secondary outcome measure of the occurrence of ILI as defined by WHO as fever plus cough or sore throat. Safety: the study reported that the majority of participants (107/172, 62%) did not report any problems with mask wearing. This proportion was significantly higher in the group of adults (71/100, 71%) compared to the group of children (36/72, 50%) (P = 0.005). The main problem stated by participants (adults and children) was "heat/humidity" (18/34, 53% of children; 10/29, 35% of adults) (P = 0.1), followed by "pain" and "shortness of breath" when wearing a face mask.
Surface/object disinfection (with or without hand hygiene)(n = 8)

Table 9. Trial authors' outcome definitions *(Continued)*

52.	Ban 2015 cluster-RCT China	Acute respiratory illness classified as the appearance of 2 or more of the following symptoms: fever, cough and expectoration, runny nose and nasal congestion.
53.	Carabin 1999 cluster-RCT Canada	The presence of nasal discharge (runny nose) accompanied by 1 or several of the following symptoms: fever, sneezing, cough, sore throat, ear pain, malaise, irritability. A URTI was defined as a cold for 2 consecutive days.
54.	Chard 2019 cluster-RCT Laos	Pupils were considered to have symptoms of respiratory infection if they reported cough, runny nose, stuffy nose, or sore throat.
55.	Ibfelt 2015 cluster-RCT Denmark	Laboratory confirmation of 16 respiratory viruses: influenza A; influenza B; coronavirus NL63229E, OC43 and HKU1; parainfluenza virus 1, 2, 3, and 4; rhinovirus; RSV A/B; adenovirus; enterovirus; parechovirus; and bocavirus using quantitative PCR
56.	Kotch 1994 RCT USA	Respiratory symptoms include coughing, runny nose, wheezing or rattling in the chest, sore throat, or earache.
57.	McConeghy 2017 RCT USA	Classified infections as lower respiratory tract infections (i.e. pneumonia, bronchitis, or chronic obstructive pulmonary disease exacerbation) or other.
58.	Sandora 2008 cluster-RCT USA	RI was defined as an acute illness that included > 1 of the following symptoms: runny nose, stuffy or blocked nose, cough, fever or chills, sore throat, or sneezing.
59.	White 2001 DB-RCT USA	RI was defined as: cough, sneezing, sinus trouble, bronchitis, fever alone, pink-eye, headache, mononucleosis, and acute exacerbation of asthma.
Other (miscellaneous) interventions (n = 4)		
60.	Hartinger 2016 cluster-RCT Peru	ARI was defined as a child presenting cough or difficulty breathing, or both. ALRI was defined as a child presenting cough or difficulty breathing, with a raised respiratory rate > 50 per minute in children aged 6 to 11 months and > 40 per minute in children aged > 12 months on 2 consecutive measurements. An episode was defined as beginning on the first day of cough or difficulty breathing and ending with the last day of the same combination, followed by at least 7 days without those symptoms.
61.	Huda 2012 cluster-RCT Bangladesh	Study authors classified acute respiratory illness as having cough and fever or difficulty breathing and fever within 48 h prior to interview.

Table 9. Trial authors' outcome definitions *(Continued)*

62.	Najnin 2019 cluster-RCT Bangladesh	Classified participants as having respiratory illness if they reported having fever plus either cough or nasal congestion or fever plus breathing difficult.
63.	Satomura 2005 RCT Japan	Upper respiratory tract infection defined as all of the following conditions: 1. both nasal and pharyngeal symptoms; 2. severity of at least 1 symptom increased by 2 grades or more; and 3. worsening of a symptom of 1 increment or more for > 3 days. Because of the difference in the mode of transmission, study authors excluded influenza-like diseases featured by moderate or severe fever; anti-influenza vaccination in the preseason and arthralgia, and treated them separately. The incidence was determined by 1 study physician who was blinded to group assignment.
Virucidal tissues (n = 2)		
64.	Farr 1988a cluster-RCT USA trial 1 and trial 2	RI defined as: occurrence of at least 2 respiratory symptoms on the same day or the occurrence of a single respiratory symptom on 2 consecutive days (except for sneezing). The respiratory symptoms were as follows: sneezing, nasal congestion, nasal discharge, sore throat, scratchy throat, hoarseness, coughing, malaise, headache, feverishness, chilliness and myalgia.
65.	Longini 1988 DB-PC RCT USA	Respiratory illness defined as 1 or more of the following symptoms occurring during the course of acute episode: coryza, sore throat or hoarseness, earache, cough, pain on respiration, wheezy breathing or phlegm from the chest.

ALRI: acute lower respiratory infection
ARIs: acute respiratory infections
CDC: Centers for Disease Control and Prevention
CI: confidence interval
cluster-RCT: cluster-randomised controlled trial
CRI: clinical respiratory illness
DB-PC: double-blind, placebo-controlled
DB-RCT: double-blind randomised controlled trial
GI: gastrointestinal
HCW: healthcare workers
HI: haemagglutinin
hMPV: human metapneumo virus
ICD-9: International Classification of Disease, 9th Revision, Clinical Modification
ICD-10: International Classification of Disease, 10th Revision, Clinical Modification
ILI: influenza-like illness
NAT: nucleic acid testing
NOS: not otherwise specified
NTS: nasal and throat swab
PCR: polymerase chain reaction
PIV: parainfluenza virus
POCT: point-of-care testing
RCT: randomised controlled trial
RI: respiratory infection
RR: risk ratio
rRT-PCR: real-time reverse transcriptase polymerase chain reaction
RSV: respiratory syncytial virus
RTI: respiratory tract infection
RT-PCR: reverse transcriptase polymerase chain reaction
SAR: secondary attack ratios

Appendix 5. Previous search strategies (pre-2010)

Details of the 2010 update and the search strategy used in the original review and the 2009 search strategy updates for MEDLINE, CENTRAL, EMBASE and CINAHL

In the 2010 update we searched, as we have done previously, the Cochrane Central Register of Controlled Trials (CENTRAL) 2010, Issue 3, which includes the Acute Respiratory Infections Group's Specialised Register, MEDLINE (April 2009 to October week 2, 2010), EMBASE (April 2009 to October 2010) and CINAHL (January 2009 to October 2010). Details of previous searches are in Appendix 1. In addition, to include more of the literature of low-income countries in this update, we ran searches in LILACS (2008 to October 2010), Indian MEDLARS (2008 to October 2010) and IMSEAR (2008 to October 2010).

We used the following search strategy (updated to include new and emerging respiratory viruses) to search MEDLINE and CENTRAL. We combined the MEDLINE search strategy with the Cochrane Highly Sensitive Search Strategy for identifying randomised trials in MEDLINE: sensitivity- and precision-maximising version (2008 revision) (Ovid format) (Lefebvre 2011). We also included an additional search strategy based on the work of Fraser, Murray and Burr (Fraser 2006) to identify observational studies.

IMSEAR (Index Medicus for the South East Asia Region) search strategy
(influenza or flu or common cold or rhinovirus or coronavirus or adenovirus or severe acute respiratory syndrome or sars or respiratory syncytial virus or rsv or parainfluenza or enterovirus or bocavirus or metapneumovirus or parvovirus or parechovirus) and (handwashing or hand washing or hand hygiene or sanitizer or sanitiser or cleanser or disinfectant or gloves or masks or mask or protective clothing or protective devices or patient isolation or barrier or curtain or partition or cross infection or disease control or infection control or school or schools or bans or banning or banned or ban or distancing or quarantine or isolation or spatial separation or cohorting or cohort isolation)

In the first publication of this review we searched the Cochrane Central Register of Controlled Trials (CENTRAL) (The Cochrane Library 2006, issue 4); MEDLINE (1966 to November 2006); OLDMEDLINE (1950 to 1965); EMBASE (1990 to November 2006) and CINAHL (1982 to November 2006). The MEDLINE search terms were modified for OLDMEDLINE, EMBASE and CINAHL.

In this 2009 update we searched the Cochrane Central Register of Controlled Trials (CENTRAL) (The Cochrane Library 2009, issue 2); Ovid MEDLINE (2006 to May Week 1 2009); OLDMEDLINE (1950 to 1965); Ovid EMBASE (2006 to Week 18, 2009) and Ovid CINAHL (2006 to May Week 1 2009).

WHAT'S NEW

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Date	Event	Description
1 April 2020	New citation required and conclusions have changed	There is now sufficient randomised controlled trial (RCT) evidence to show that hand hygiene is likely to provide a modest- benefit. Uncertainty remains for the other interventions. Further RCT evidence is needed.
1 April 2020	New search has been performed	Searches updated. In this 2020 update we only searched for RCTs and cluster-RCTs. We included 44 new trials (Aelami 2015; Aiello 2012; Alzaher 2018; Arbogast 2016; Azor-Martinez 2016; Azor-Martinez 2018; Ban 2015; Barasheed 2014; Biswas 2019; Canini 2010; Chard 2019; Correa 2012; DiVita 2011; Feldman 2016; Goodall 2014; Hartinger 2016; Hubner 2010; Huda 2012; Ibfelt 2015; Ide 2014; Ide 2016; Little 2015; MacIntyre 2011; MacIntyre 2013; MacIntyre 2015; MacIntyre 2016; McConeghy 2017; Millar 2016; Miyaki 2011; Najnin 2019; Nicholson 2014; Pandejpong 2012; Priest 2014; Radonovich 2019; Ram 2015; Savolainen-Kopra 2012; Simmerman 2011; Stebbins 2011; Suess 2012; Talaat 2011; Temime 2018; Turner 2012; Yeung 2011; Zomer 2015). We excluded 12 new trials (Azor-Martinez 2014; Bowen 2007; Chami 2012; Denbak 2018; Lennell 2008; Nandrup-Bus 2009; Patel 2012; Rosen 2006; Slayton 2016; Stedman-Smith 2015; Uhari 1999; Vessey 2007). We identified 5 new ongoing trials (NCT03454009; NCT04267952; NCT04296643; NCT04337541; Wang 2015) one of which – NCT04337541 - published as this review was going to press. We focused on RCTs and cluster-RCTs only and removed observational studies from this update.

HISTORY

Protocol first published: Issue 4, 2006
Review first published: Issue 4, 2007

Date	Event	Description
22 October 2010	New search has been performed	Searches conducted. We included 7 new trials: 4 randomised controlled trials and 3 non-randomised comparative studies. We excluded 36 new trials.
22 October 2010	New citation required but conclusions have not changed	We updated the review again at the behest of the World Health Organization (WHO). External sources of support amended. External support from the WHO. The WHO interim guidelines document on 'Infection Prevention and Control of Epidemic and Pandemic Prone Acute Respiratory Diseases in Health Care' was published in 2007 to provide infection control guidance to help prevent the transmission of acute respiratory diseases in health care. The update of these guidelines will be evidence-based, and an update of this review was requested to assist in informing the evidence base for the revision of the WHO guidelines. Dr John Conly, Dr Mark Jones, and Sarah Thorning joined the review team.
7 May 2009	New search has been performed	For the 2009 update, we included 3 cluster-randomised controlled trials, Cowling 2009; MacIntyre 2009; Sandora 2008, and 1

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Date	Event	Description
		individual randomised controlled trial (Satomura 2005, with its linked publication Kitamura 2007). We also included 1 retrospective cohort study (Foo 2006), 1 case-control study (Yu 2007), and 2 prospective cohort studies (Wang 2007; Broderick 2008). The content and conclusions of the 2007 review changed little, but the additional 8 studies add more information and certainty. Our meta-analysis remains unchanged as there were no new studies for pooling.
30 April 2009	New citation required but conclusions have not changed	New author joined the review team.
8 July 2008	Amended	Converted to new review format.
20 August 2007	Amended	Review first published Issue 4, 2007.

CONTRIBUTIONS OF AUTHORS

Tom Jefferson (TOJ), Chris Del Mar (CDM), and Liz Dooley (LD) were responsible for drafting the protocol.
TOJ, Eliana Ferroni (EF), Bill Hewak (BH), and Adi Prabhala (AP) extracted study data, and Sree Nair (SN) performed the analyses in the original review.

TOJ, EF, Lubna A Al-Ansary (LA), Ghada A Bawazeer (GB), and CDM adjudicated in data extraction in the 2009 update. Mieke van Driel (MvD) assisted in writing the review, updating with the most recent studies, and additional tables (apart from TiDIER). MvD constructed the summary of results table which was removed in the 2020 review update.

TOJ and John Conly (JMC) extracted data, and CDM checked extractions and arbitrated in the 2010 update. All three review authors checked the search strategy terms. Sarah Thorning (ST) designed and carried out the searches. All 2010 review authors contributed to the final report.

For the 2020 update:
Updated searches: ST
Co-ordinated the update: LD
Updated Background section: CDM
Designed Excel forms for extracting study characteristics and tested their usefulness/applicability: MJ
Screened titles and abstracts, excluded irrelevant citations: MJ
Excluded irrelevant citations based on title and text in the trial registry entry: ST
Excluded irrelevant citations based on titles/abstracts and the full-text articles: GB
Selection of studies: MvD, MJ, GB, JC
Data extraction and management: MJ, EF, LA, GB, TOJ, TH, EB
Assessment of risk of bias in the included studies: TOJ, EB, LA, GB, MJ, EF
Adjudicated data extraction: MJ
Data analysis: MJ, EB
Wrote the update: MJ, TOJ, LD, LA, JMC, EB, MVD, GB, TH, CDM, PG

DECLARATIONS OF INTEREST

Tom Jefferson: Tom Jefferson's full disclosure is available at restoringtrials.org/competing-interests-tom-jefferson/.
Chris B Del Mar: a grant from WHO paid to Bond University and a grant from UK National Institute for Health Research (NIHR) to be paid to Bond University on publication of the review in the Cochrane Library. Funding from National Health and Medical Research Council (NHMRC) for research on antibiotic resistance.
Liz Dooley: a grant from the World Health Organization (WHO) paid to Bond University and a grant from UK NIHR to be paid to Bond University on publication of the review in the Cochrane Library.
Eliana Ferroni: none known.
Lubna A Al-Ansary: none known.

  Provided financial support for the 2020 update of this review. Reference number 2020/1011941

DIFFERENCES BETWEEN PROTOCOL AND REVIEW

We changed the title of the review in 2010 (see Published notes below).

For this 2020 update, we added one additional outcome: adverse events related to the intervention, and we split the outcomes into primary and secondary outcomes. We also focused only on RCTs and cluster-RCTs and removed observational studies.

NOTES

In Issue 1, 2010, the title of the review was changed from 'Interventions for the interruption or reduction of the spread of respiratory viruses' to 'Physical interventions to interrupt or reduce the spread of respiratory viruses'.

The original review was subsequently published as Jefferson T, Foxlee R, Del Mar C, Dooley L, Ferroni E, Hewak B, Prabhala A, Nair S, Rivetti A. Physical interventions to interrupt or reduce the spread of respiratory viruses: systematic review. BMJ 2008;336:77-80 and Jefferson T, Del Mar C, Dooley L, Ferroni E, Al-Ansary LA, Bawazeer GA, van Driel ML, Foxlee R, Rivetti A. Physical interventions to interrupt or reduce the spread of respiratory viruses: systematic review. BMJ 2009;339:b3675. DOI: 10.1136/bmj.b3675.

CANADA COVID-19 WEEKLY EPIDEMIOLOGY REPORT

28 MARCH TO 03 APRIL 2021 (WEEK 13)

Published: 09 April 2021

39 639 (↑28%) New cases reported in the last 7 days[a]	**195 (↓8%)** New deaths reported in the last 7 days[a]
5 663 (↑28%) Average number of cases reported daily in the last 7 days[a]	**28 (↓8%)** Average number of deaths reported daily in the last 7 days[a]
115 653 (↑6%) Average number of tests performed daily in the last 7 days[b]	**5.1% (↑0.8)** Percentage of positive tests in the last 7 days[b]

[a]Source: Provincial and Territorial Ministry of Health (MOH) websites as of 03 April 2021

[b]Source: National Microbiology Laboratory (NML) data for laboratory analyses as of 03 April 2021

Note: The percentages are calculated based on the difference in the total number of cases, deaths, or tests in the past 7 days compared to the prior 7 days, divided by the number of cases, deaths, or tests in the prior 7 days. The change in the percentage of positive tests is based on the difference in percentage points compared to the previous week.

KEY MESSAGES

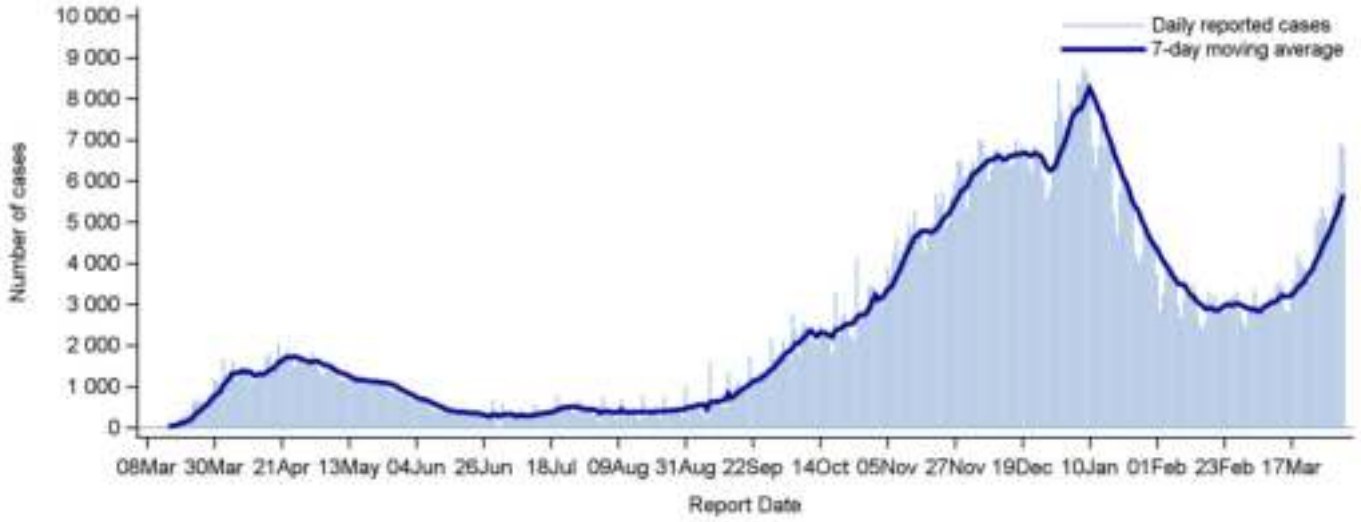
- In Canada, there was an average of **5 663 new cases reported daily** during the week of 28 March to 03 April (week 13), representing a **28% increase** compared to the previous week (week 12: 21 March to 27 March).
- British Columbia, Alberta, Saskatchewan, Ontario, Québec and Newfoundland and Labrador reported **increases in weekly numbers**, compared to the previous week.
- **Daily rates of cases per 100 000 population have increased among most age groups during the past week**. Among both males and females, case rates remain highest among individuals in the 20 to 39 year age group and lowest among individuals in the 80 years and older age group.
- **Long-term care facilities and retirement residences** continue to be the most commonly reported outbreak setting in Canada, and account for the greatest proportion of outbreak related cases and deaths.
- During week 13, **an average of 115 653 tests were performed daily** for COVID-19 across Canada. The weekly percentage of tests positive was **5.1%**, an increase from the previous week.
- There was an average of **28 new deaths reported daily** during week 13, representing an **8% decrease** compared to the previous week.
- **The number of hospitalizations and ICU admissions increased during week 13**. On 03 April 2021, there were 2 250 cases hospitalized and 801 cases in ICU, representing a 5% increase in the seven-day moving average of hospitalized cases and a 16% increase in the seven-day moving average of ICU admissions compared to one week prior.
- The overall cumulative hospitalization rate (including ICU admissions) is 139 cases per 100 000 population, with **the highest rates observed among those aged 80 years and older** (1 013 cases per 100 000 population).
- According to forecasting, between **1 093 510 to 1 150 910 cumulative reported cases** and **23 290 to 23 710 cumulative reported deaths** are expected by 18 April 2021.

NATIONAL DEMOGRAPHICS AND TRENDS

NATIONAL TRENDS IN CASES

- During week 13, a total of 39 639 cases of COVID-19 were reported in Canada, an average of 5 663 cases per day.
- The number of new cases represents a 28% increase compared to week 12.
- Since early March 2021, the number of new cases reported has consistently increased, with 6 822 new cases reported on 03 April 2021 (Figure 1).

Figure 1. Daily number of reported COVID-19 cases in Canada (and 7-day moving average), as of 03 April 2021 (N= 1 001 658)



Source: Provincial and Territorial MOH websites as of 03 April 2021

Note: The 7-day moving average is a trend indicator that captures the arithmetic mean of the daily reported cases over the previous seven days. The moving average helps smooth out day-to-day variability in reporting, filtering out the "noise" of short-term fluctuations. Fluctuations can be attributed to retrospective data, non-reporting on the weekends or provinces or territories reporting cases at a reduced frequency. Spikes in cases may be due to regular reporting variations (e.g. lower reporting on weekends or holidays), or periodic reporting of previous cases by provinces and territories.

Most provinces and territories, with the exception of Northwest Territories and Nunavut, reported new cases during week 13 (Table 1):

- The weekly number of new cases decreased in Manitoba, New Brunswick, Nova Scotia and Prince Edward Island, compared to the previous week. No change was observed in Yukon.
- The weekly number of new cases increased in British Columbia, Alberta, Saskatchewan, Ontario, Québec and Newfoundland and Labrador, compared to the previous week.
- Cases increased by 31% in Ontario and 33% in Québec, compared to the previous week. Together, these provinces accounted for about 64% of the cases reported during week 13.
- Cumulatively, Ontario reported the highest number of cases (n=358 558), while Québec has the highest incidence rate at 3 673.2 cases per 100 000 population.

Table 1. Trends of new cases in Canada and by province or territory, as of 03 April 2021

Province/Territory	Total number of cases (as of 03 April)[a]	Average number of cases reported daily (week 13)	Weekly number of cases reported		Percent change (%)[b]	Crude rate per 100 000 population (as of 03 April)
			21 March to 27 March (week 12)	28 March to 03 April (week 13)		
British Columbia	103 031	917	5 271	6 418	22%	2 001.5
Alberta	151 359	809	4 317	5 663	31%	3 423.0
Saskatchewan	34 323	220	1 324	1 540	16%	2 912.0
Manitoba	34 352	69	604	485	-20%	2 490.6
Ontario	358 558	2 552	13 609	17 866	31%	2 433.5
Québec	314 958	1 081	5 703	7 564	33%	3 673.2
Newfoundland and Labrador	1 020	1	1	5	400%	195.4
New Brunswick	1 641	10	82	70	-15%	210.0
Nova Scotia	1 732	3	27	23	-15%	176.9
Prince Edward Island	160	1	8	4	-50%	100.2
Yukon	74	0	1	1	0%	176.0
Northwest Territories	42	0	0	0	N/A	93.0
Nunavut	395	0	0	0	N/A	1 003.7
Canada[c]	**1 001 658**	**5 663**	**30 947**	**39 639**	**28%**	**2 635.5**

Source: Provincial and Territorial MOH websites as of 03 April 2021

[a] The number of cases includes the total confirmed and probable cases.

[b] The percentage is calculated based on the difference in the total number of cases in the past 7 days compared to the prior 7 days divided by the number of cases in the prior 7 days. Note that for provinces/territories with low case counts, an increase or decrease of only a few cases leads to a large percentage change. If the denominator is zero, the percent change cannot be calculated.

[c] Includes 13 cases identified in repatriated travelers (Grand Princess Cruise ship travelers) who were under quarantine in Trenton in March 2020.

Age-standardized rates take into account the differences in population size and age structure between provinces and territories to allow for more valid comparisons of COVID-19 spread in Canada.

Table 2 presents the age-standardized incidence rate by province or territory during week 13.

- Saskatchewan reported the highest age-standardized incidence rate (127.4 cases per 100 000 population).
- The second and third-highest age-standardized incidence rates were reported by Ontario (126.3 cases per 100 000 population) and British Columbia (125.2 cases per 100 000 population).

Table 2. Age-standardized incidence rates by province or territory for week 13

Province/Territory	Age-standardized incidence rate per 100 000 for week 13
British Columbia	125.2
Alberta	64.8
Saskatchewan	127.4
Manitoba	25.6
Ontario	126.3
Québec	75.1
Newfoundland and Labrador	N/A*
New Brunswick	N/A*
Nova Scotia	2.5
Prince Edward Island	3.8
Yukon	4.5
Northwest Territories	0.0
Nunavut	0.0
Canada	95.7**

Source: Detailed case information received by PHAC from provinces and territories, standardized to the July 1 2020 post-census population estimate.
*Age-standardized incidence could not be calculated as data was either not reported or partially reported to PHAC during week 13.
**The age-standardized incidence rate for Canada only includes provinces and territories for which data was available for week 13.
Note: Data are analyzed based on PHAC report date.

Table 3 outlines the total number of new cases, resolved cases, and deaths reported during week 13.

- Of the provinces and territories that reported new cases during week 13, all reported more new cases than new resolved cases.

Table 3. Summary of new COVID-19 cases, resolved cases, and deaths reported in Canada, and by province or territory, during week 13

Province/Territory	New cases	New resolved cases	New deaths
British Columbia	6 418	3 866	11
Alberta	5 663	2 210	14
Saskatchewan	1 540	1 208	6
Manitoba	485	418	5
Ontario	17 866	12 075	120
Québec	7 564	5 428	39
Newfoundland and Labrador	5	2	0

DEMOGRAPHIC DISTRIBUTION[a]

[a] Detailed case information received by PHAC from provinces and territories
Note: Data are analyzed based on PHAC report date.

- Cases for which PHAC received detailed individual case-level information during week 13 (n=34 754) ranged in age from less than one year to 102 years of age. The median age was 34 years, no change from what was observed during week 12.
- Table 4 presents a summary of the age and gender distribution of COVID-19 cases reported to PHAC during week 13:
    - Fifty-nine percent (59%) were individuals under 40 years of age.
    - The highest proportions of cases by age group were observed among those aged 0-19 years (22%) and 20-29 years (20%).
    - The highest age specific incidence rates were observed among those 20-29 and 30-39 years of age.

Table 4. Age, gender distribution, and rate of COVID-19 cases reported to PHAC, during week 13

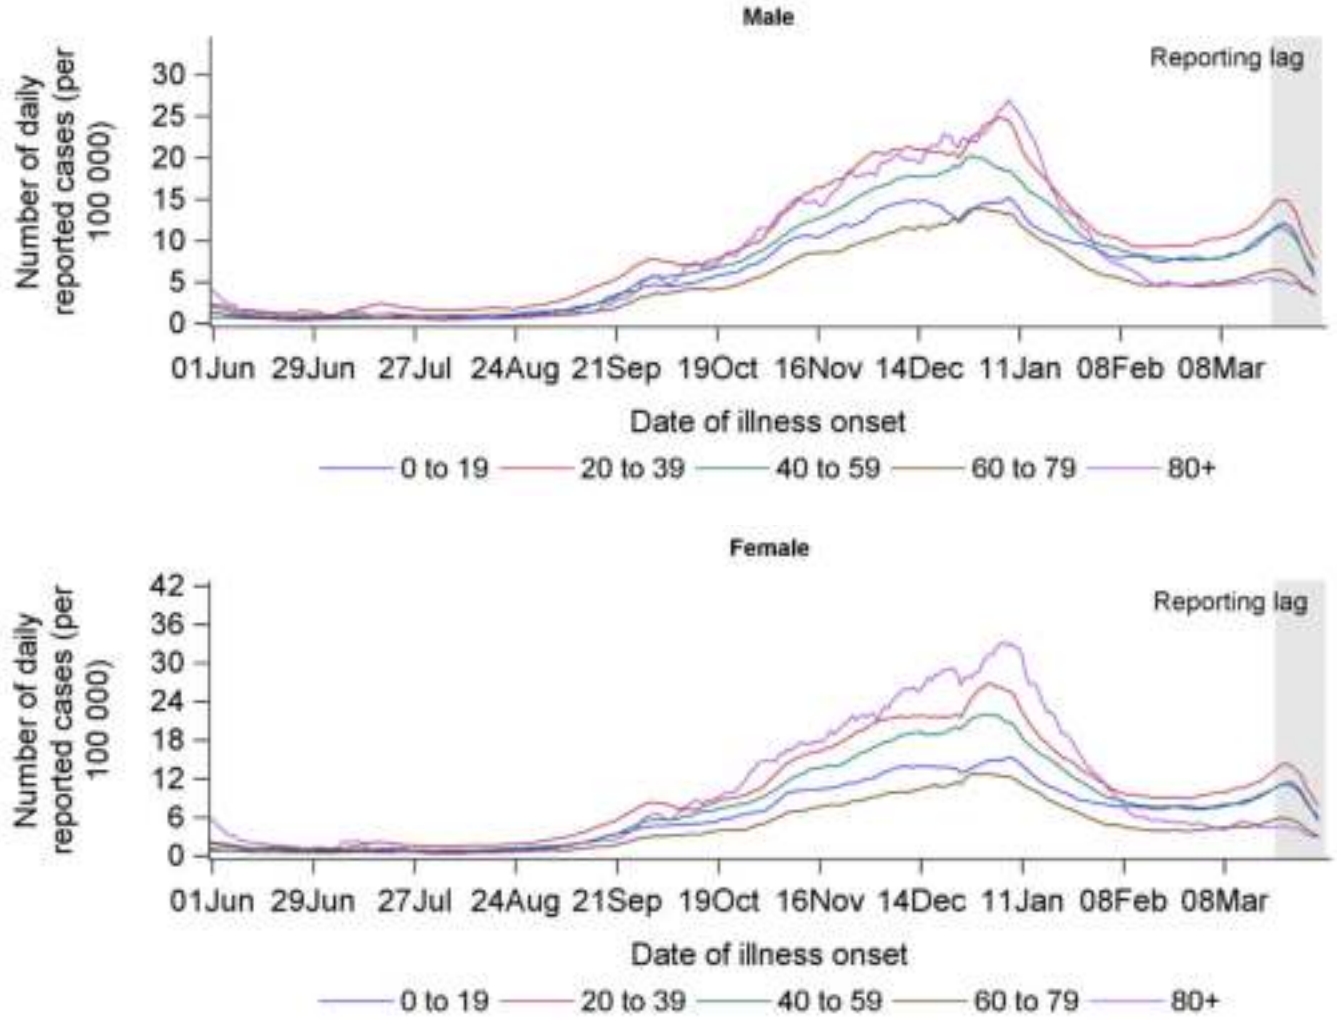
Age groups	Female			Male			Total[a]		
	n	%	Rate	n	%	Rate	n	%	Rate
≤ 19	3 945	22%	99.2	4 100	22%	98.5	8 045	22%	98.8
20-29	3 418	19%	138.6	3 644	20%	136.9	7 062	20%	137.7
30-39	2 893	16%	110.2	3 099	17%	116.2	5 992	17%	113.2
40-49	2 662	15%	108.7	2 659	14%	110.6	5 321	15%	109.6
50-59	2 289	13%	87.6	2 421	13%	93.7	4 710	13%	90.7
60-69	1 374	8%	56.9	1 538	8%	66.6	2 912	8%	61.6
70-79	679	4%	42.9	630	3%	44.2	1 309	4%	43.6
80+	396	2%	40.0	320	2%	47.5	716	2%	43.0
Total	17 656	100%	92.3	18 411	100%	97.5	36 067	100%	94.9

Source: Detailed case information received by PHAC from provinces and territories during week 13. Rates are presented per 100 000 individuals in the given age group based on the 1 July 2020 post-census population estimate.
[a] Cases not identified as male or female were removed from the total due to small numbers.
Note: Data are analyzed based on date reported to PHAC. Note that there is a period of time (lag time) where it is expected that cases have occurred but have not yet been reported nationally. Therefore, COVID-19 cases reported to PHAC during week 13 may include cases that occurred (based on date of illness onset, or lab related dates) in previous weeks.
Note: Cases with missing gender or age were excluded. Where available, gender data was used; when gender data was unavailable, sex data was used. Reliable data on gender diverse respondents are unavailable due to small counts.

Figure 2 presents cases by date of illness onset, stratified by gender and adjusted for population at the national level.

- Daily rates of cases have increased for most age groups in recent weeks; this follows the large decline observed since early January 2021.
- Daily rates of cases continue to remain highest among individuals in the 20 to 39 year age group for males and females. This age group has consistently been the highest since 20 January 2021 for males and 03 February 2021 for females.
- Daily rates of cases are lowest among individuals in the 80 years and older age group for both genders. The incidence rates for this age group are 1.9 times lower for males and 2.2 times lower for females compared to the 20 to 39 year age group.

Figure 2. Daily rate of cases per 100 000 population, by age and gender, from 1 June 2020 to 03 April 2021



Source: Detailed case information received by PHAC from provinces and territories. Rates are calculated based on the 1 July 2020 post-census population estimate.

Note: The shaded area represents a period of time (lag time) where it is expected that cases have occurred but have not yet been reported nationally. The earliest of the following dates were used as an estimate: Onset date, Specimen Collection Date, Laboratory Testing Date, Date Reported to Province or Territory, or Date Reported to PHAC.

Note: Where available, gender data was used; when gender data was unavailable, sex data was used. Reliable data on gender diverse respondents are unavailable due to small counts.

SYNDROMIC SURVEILLANCE

FLUWATCHERS

FluWatchers is an online health surveillance system that relies on volunteer reports to track the spread of Influenza-like illness (ILI) and symptoms compatible with COVID-19 across Canada. Some of the more commonly reported symptoms of COVID-19 include a new or worsening cough, fever or feeling feverish; therefore, reports of a minimum of cough or fever are being used to track COVID-19 within the FluWatchers system.

During week 13, 12 081 participants reported into the FluWatchers system. A total of 194 participants (1.6%) reported symptoms of cough or fever.

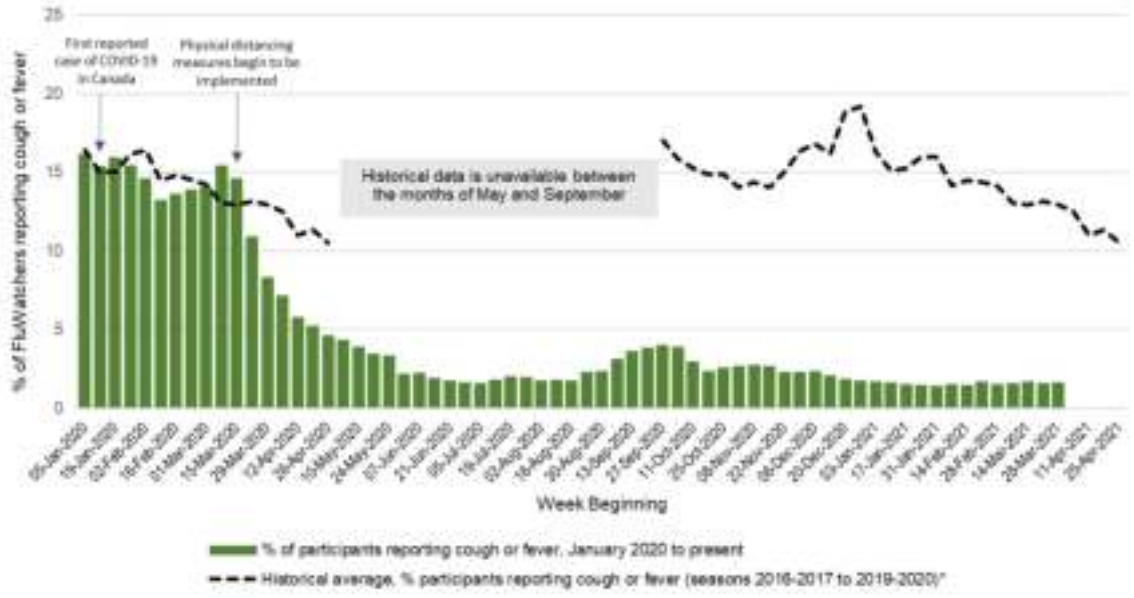
From mid-December 2020 to late-January 2021, FluWatchers activity was on a slow decline, despite increasing COVID-19 activity at the time. In recent weeks, activity due to seasonal respiratory viruses has been low and stable, COVID-19 activity has begun to increase and FluWatchers activity has slightly increased as well. Symptoms reports by FluWatchers participants remain below seasonal norms for this time of year.

Among the 194 participants reporting cough or fever:

- 88 (45%) sought medical attention;
- 76 (39%) were tested - 4 tests were positive for COVID-19 (8 tests had unknown results at the time of reporting)

Syndromic data captured by FluWatchers is sensitive to all circulating respiratory viruses, including COVID-19. The FluWatchers program is measuring total respiratory virus activity in the community. FluWatchers participants are a self-selected subset of the Canadian population that may not be representative of the Canadian population; thus, under representing the true measure of COVID activity in the population.

Figure 3. Percentage of FluWatchers Participants Reporting Cough or Fever (N=12 081 during week 13)



*Historical data is unavailable between the months of May and September. From January 2020 to May 2020, the historical epidemiological curve contains data from seasons 2016-2017 to 2018-2019. From October 2020 onwards, the historical epidemiological curve contains data from seasons 2016-2017 to 2019-2020; however, data from March 8, 2020 to May 2, 2020 are excluded from the historical epidemiological curve.

TRANSMISSION

TEMPORAL DISTRIBUTION BY EXPOSURE CATEGORY[a]

[a] Detailed case information received by PHAC from provinces and territories

During week 13, exposure and date of illness onset information was available for 20 329 cases. Of these:

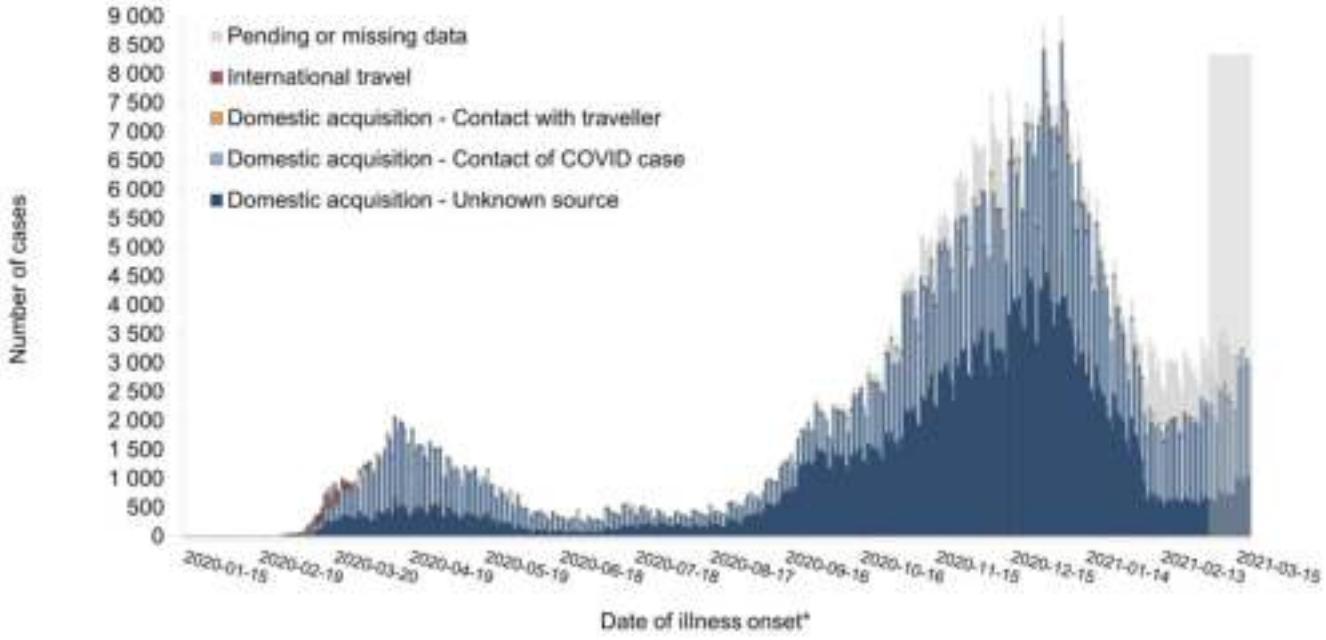
- 13 398 cases (66%) reported exposure in Canada to a known COVID-19 case;
- 6 820 cases (34%) reported exposure in Canada to an unknown source;
- 43 cases (<0.5%) reported exposure to a traveller; and
- 68 cases (<0.5%) reported having travelled outside of Canada during the exposure period.

Jurisdictions update exposure status on an ongoing basis as case investigations are completed and may result in changes to the percent distributions by exposure type for previous weeks (Figure 4).

Of the 883 392 cases submitted as of 03 April 2021 with information on the source of exposure and date of illness onset:

- 418 343 cases (47%) reported exposure in Canada to a known COVID-19 case;
- 449 898 cases (51%) reported exposure in Canada to an unknown source;
- 6 771 cases (1%) reported exposure to someone who had travelled; and
- 8 380 cases (1%) reported having travelled outside of Canada during the exposure period.

Figure 4. Number of reported COVID-19 cases in Canada, by date of illness onset and exposure category as of 03 April 2021 (n=991 533)



Source: Detailed case information received by PHAC from provinces and territories

* The earliest of the following dates were used as an estimate: Onset date, Specimen Collection Date, Laboratory Testing Date, Date Reported to Province or Territory, or Date Reported to PHAC.

Note: The shaded area represents a period of time (lag time) where it is expected that cases have occurred but have not yet been reported nationally. There is missing information for exposure variables from several provinces and territories.

INTERNATIONAL TRAVEL EXPOSURES[a]

[a] Detailed case information received by PHAC from provinces and territories

In Canada, the first cases of COVID-19 were attributed to international travel exposures. On 14 March 2020, the Government of Canada published a global Travel Health Notice advising Canadians against non-essential travel and advised Canadians abroad to return to Canada. By 21 March 2020, the Government of Canada prohibited all non-essential travel into Canada by foreign nationals. Since that time, the proportion of COVID-19 cases associated with international travel decreased from 22.3% (n=3 883) of all cases in March 2020 to 0.4% (n=127) in May 2020, and increased slightly over the summer months but has remained low since the fall (Table 5 and Figure 5). Since the spring of 2020, there have been significant efforts to enact border restrictions to reduce COVID-19 import to Canada.

As of 03 April 2021, 0.9% of cases with known exposure (n=8 380) have been associated with international travel. Since 01 July 2020, the United States, Mexico, and India are the top countries identified by cases that reported international travel during their exposure period.

Table 5. Number and percentage of COVID-19 cases associated with international travel by month of illness onset[a], as of 03 April 2021

Month	Number of COVID-19 cases associated with international travel	Percentage of COVID-19 cases associated with international travel[b]
January 2020	7	18.9%
February 2020	71	37.2%
March 2020	3 883	22.3%
April 2020	510	1.1%
May 2020	127	0.4%
June 2020	218	1.9%
July 2020	351	2.7%
August 2020	257	1.9%
September 2020	213	0.5%
October 2020	314	0.4%
November 2020	443	0.3%
December 2020	607	0.3%
January 2021	836	0.5%
February 2021	252	0.4%
March 2021	291	0.4%
Total	**8 380**	**0.9%**

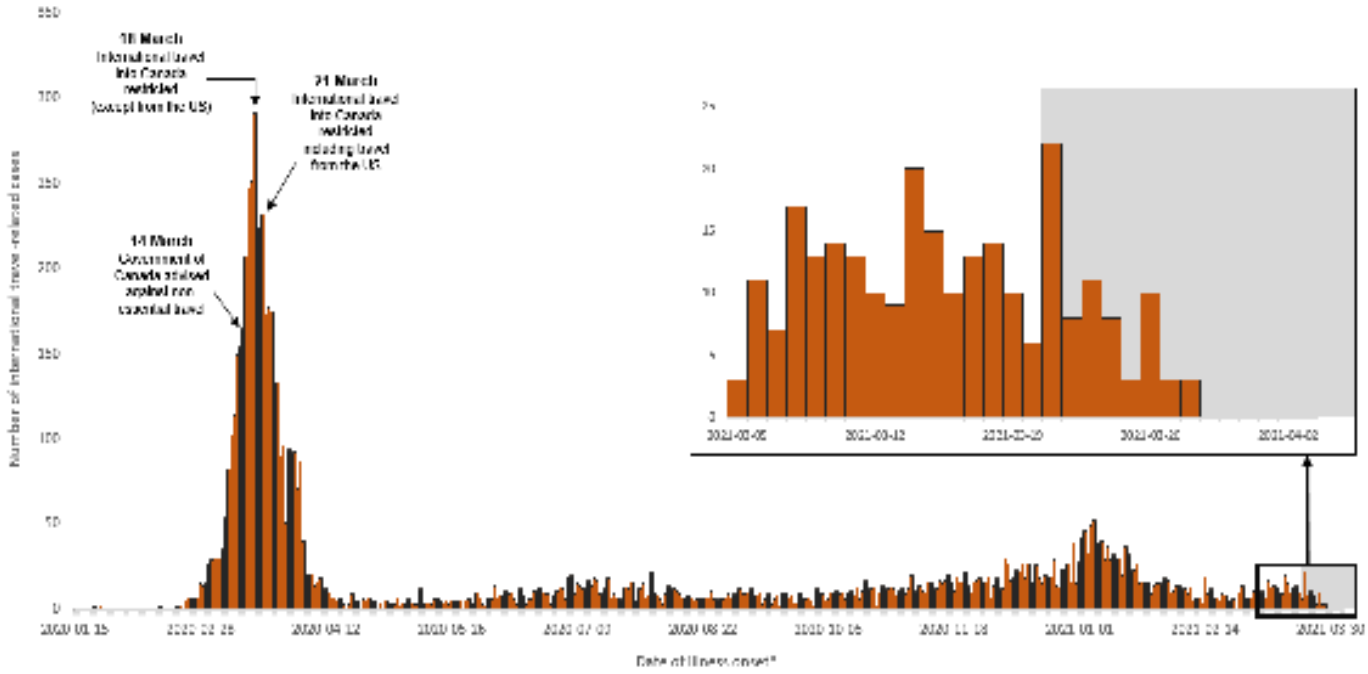
Source: Detailed case information received by PHAC from provinces and territories

Note: This is an underestimate of the total number of cases among returning travelers as exposure history are not available for all cases and not all jurisdictions have consistently reported exposure history to PHAC throughout the COVID-19 pandemic.

[a]The earliest of the following dates were used as an estimate: Onset Date, Specimen Collection Date, Laboratory Testing Date, Date Reported to Province or Territory, or Date Reported to PHAC.

[b]Only includes cases that have information on exposure.

Figure 5. Number of international travel-related COVID-19 cases in Canada, by date of illness onset[a] (n= 8 380) as of 03 April 2021



Source: Detailed case information received by PHAC from provinces and territories

* The earliest of the following dates were used as an estimate: Onset date, Specimen Collection Date, Laboratory Testing Date, Date Reported to Province or Territory, or Date Reported to PHAC.

Note: The shaded area represents a period of time (lag time) where it is expected that cases have occurred but have not yet been reported nationally.

Note: This is an underestimate of the total number of cases among returning travellers as exposure history are not available for all cases and not all jurisdictions have consistently reported exposure history to PHAC throughout the COVID-19 pandemic.

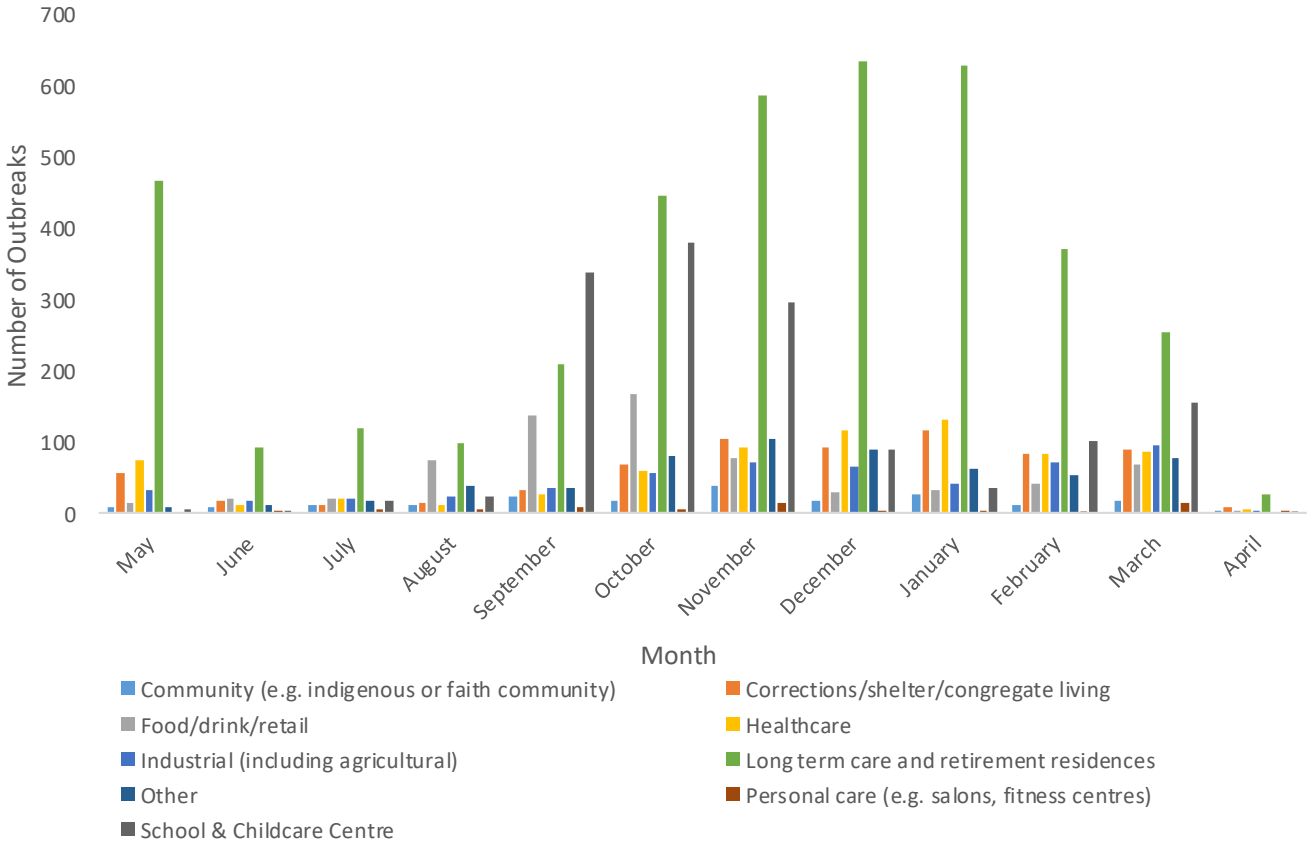
OUTBREAKS

Outbreaks have been a significant source of the spread of COVID-19 in Canada, and point to vulnerabilities in closed and crowded settings.

- Outbreaks have been detected in congregate living, workplace, and agricultural work settings, and namely in long-term care settings, meat processing plants, hospitals, small communities, and among farmworkers.
- Outbreaks continue to be observed in high-risk settings involving closed spaces, crowded places and close contact situations.
- Long-term care facilities and retirement residences continue to be the most commonly reported outbreak setting in Canada, and continue to account for the greatest proportion of outbreak related cases and deaths. This has been a consistent monthly trend with the exception of September, where reports of outbreaks in schools and childcare centres exceeded those in long-term care facilities and retirement residences.

Figure 6 and Table 6 identify common locations of outbreaks, as well as the number of cases and deaths associated with each.

Figure 6. Number of new outbreaks by setting as of 03 April 2021



Source: Publicly reported outbreak data, including Provincial and Territorial websites, as of 03 April 2021
Note: Schools with only one case, or those for which information on number of cases is unknown, have been excluded

Table 6. Total number of COVID-19 outbreaks, cases, and deaths by outbreak setting in Canada as of 03 April 2021[a]

Outbreak setting	Total number of outbreaks reported	Total number of cases reported	Total number of reported deaths	Outbreaks Reported in past 7 days
Community[b]	203	10 391	89	5
Corrections/shelter/congregate living	735	12 933	226	15
Food/drink/retail	685	2 489	3	20
Healthcare	765	10 648	812	18
Industrial (including agricultural)[c]	539	11 938	24	17
Long term care and retirement residences	4 430	66 863	12 473	61
Personal Care[d]	60	610	0	7
School & Childcare Centre[e]	1 438	8 199	1	31
Other[f]	585	5 331	6	17

Source: Publicly reported outbreak data, including Provincial and Territorial websites, as of 03 April 2021

[a]This is not an all-inclusive list and is subject to change based on current and active outbreak locations reported.

[b]Community includes population centres, Indigenous communities, Mennonite, Reserves, and small city outbreaks.

[c]The number of outbreaks in Windsor-Essex have been grouped into one cluster; industrial settings include: automotive manufacturing, distribution/processing facilities, worker camps, waste management/recycling, warehouse, etc.

[d]Personal care refers to personal care services, such as hair salons, nail salons, etc.

[e]Child and youth care include daycare centres and day camps; excludes any facilities that report only one case. Schools with only one case, or those for which information on number of cases is unknown, have been excluded

[f]Other groups together outbreaks in settings not listed in the categories above, for example social gatherings, office workplaces, recreational facilities, etc.

Note: These categories include both current and retrospective outbreak data.

LABORATORY-CONFIRMED COVID-19 DETECTION

During week 13, a total of 809 571 tests were performed, with an average of 115 653 tests performed daily for COVID-19 across Canada. The weekly percentage of tests positive during week 13 was 5.1%, an increase of 0.8% from the previous week (Table 7).

Table 7. Summary of COVID-19 tests performed in Canada, by province or territory, for week 13

Province/Territory	Cumulative number of tests performed as of 03 April 2021	Week 13 (28 March to 03 April, 2021)			
		Weekly number of tests performed	Average number of tests performed daily	Average # of tests performed daily per 1 000 population	Weekly percentage of tests positive[1]
British Columbia	2 222 958	61 093	8 728	1.7	10.4%
Alberta	3 746 782	80 346	11 478	2.6	7.5%
Saskatchewan	679 507	24 319	3 474	2.95	6.6%
Manitoba	598 266	12 269	1 753	1.27	4.7%
Ontario	12 630 159	353 513	50 502	3.43	5.3%
Québec	7 308 657	242 176	34 597	4.03	3.3%
Newfoundland and Labrador	223 240	3 977	568	1.09	0.2%
New Brunswick	269 376	7 763	1 109	1.42	1%
Nova Scotia	437 783	20 312	2 902	2.96	0.1%
Prince Edward Island	127 300	3 296	471	2.95	0.1%
Yukon	8 616	87	12	0.29	0%
Northwest Territories	16 195	308	44	0.97	0.6%
Nunavut	9 921	112	16	0.41	0%
Canada	**28 278 760**	**809 571**	**115 653**	**3.04**	**5.1%**

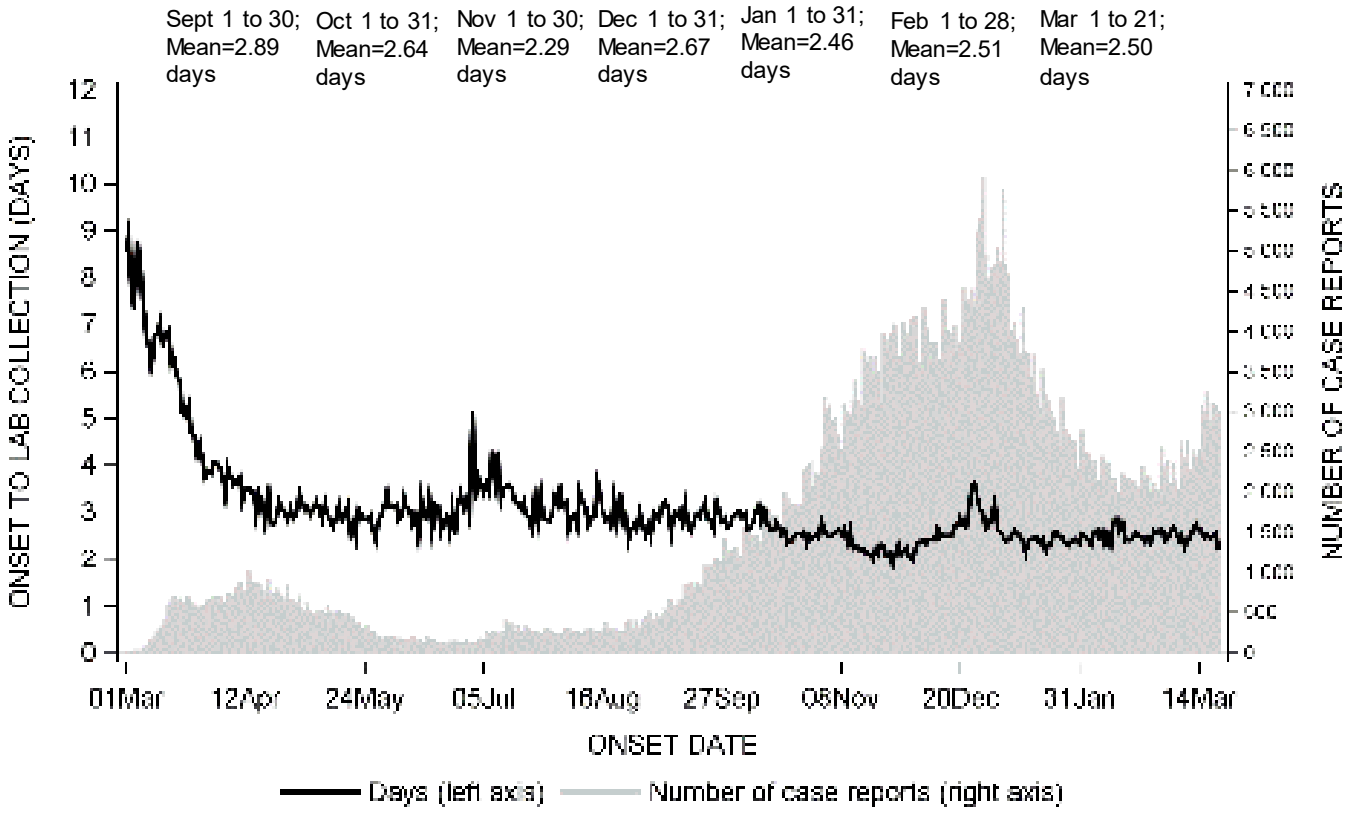
Source: NML Data for laboratory analyses as of 03 April 2021

[1] Weekly percentage of tests positive is calculated by dividing the total positive tests in the past 7 days by the total tests performed in the past 7 days

Note: Laboratory testing numbers may be an underestimate due to reporting delays and may not include additional sentinel surveillance or other testing conducted in the province or territory.

The mean time from symptom onset to lab specimen collection was 2.50 days in March 2021. This is similar to the mean of 2.51 days in February 2021 (Figure 7).

Figure 7. Onset date to laboratory collection date for cases reported to PHAC as of 03 April 2021



Source: Detailed case information received by PHAC from provinces and territories
Note: Date of symptom onset to date of specimen collection intervals of >15 days are deemed outliers, and not included in this figure.

SEVERITY INDICATORS

HOSPITALIZATIONS, INTENSIVE CARE, AND DEATHS

During week 13, detailed case information on hospitalization status was available for 18 578 cases. Among these cases:

- **700 (4%)** were hospitalized (including ICU admission), of whom:
  - **87 (12%)** were admitted to ICU.

Among the total number of hospitalizations reported during week 13 for which age information was available, 24% (n=166/695) were 40 to 59 years of age, 41% (n=287/695) were 60 to 79 years of age, and 21% (n=143/695) were 80 years and older (Table 8).

As of 03 April 2021, case information on hospitalization status was available for 694 621 cases, where:

- **52 835 (8%)** were hospitalized (including ICU admission), of whom:
  - **9 337 (18%)** were admitted to ICU.

Since the beginning of the pandemic, the 60 to 79 year age group has accounted for the highest proportion of cases hospitalized and admitted to ICU, followed closely by the 80 years and older age group (see table A5 in annex for cumulative counts).

Table 8. Number of COVID-19 cases hospitalized, and admitted to ICU, overall and by gender and age group, reported to PHAC during week 13[a]

Age groups	Hospitalized – non-ICU			Hospitalized – ICU		
	Female	Male	Total	Female	Male	Total
≤ 19	11	10	21	0	1	1
20-39	30	39	69	2	6	8
40-59	66	82	148	8	10	18
60-79	107	136	243	16	28	44
80+	61	66	127	9	7	16
Total	275	333	608	35	52	87

Source: Detailed case information received by PHAC from provinces and territories

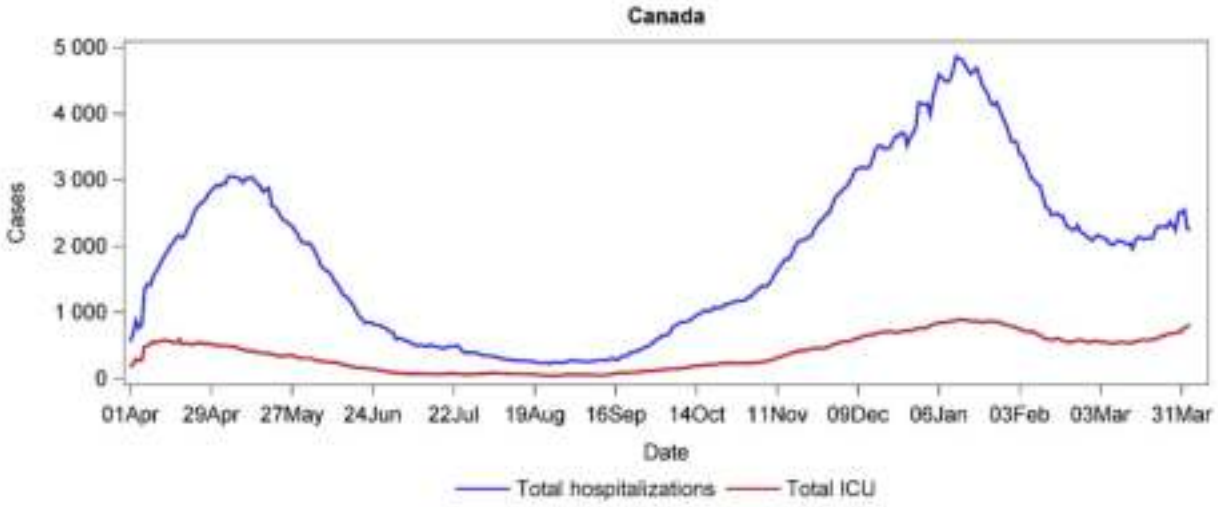
[a] Data are analyzed based on date reported to PHAC. Note that there is a period of time (lag time) where it is expected that cases have occurred but have not yet been reported nationally. Therefore, COVID-19 cases reported to PHAC during week 13 may include cases that occurred (based on date of illness onset, or lab related dates) in previous weeks.

Note: Non-ICU hospitalizations and ICU counts are mutually exclusive. Cases with missing gender, sex or age were excluded. Where available, gender data were used; when gender data were unavailable, sex data were used. Reliable data on gender diverse respondents are unavailable due to small counts.

Following a sharp decline in hospitalizations, and stabilized numbers of ICU admissions since early January 2021, the number of hospitalizations and ICU admissions have begun to increase (Figure 8). On 03 April 2021, there were 2 250 cases hospitalized and 801 cases in ICU, representing a 5% increase in the seven-day moving average of hospitalized cases and a 16% increase in the seven-day moving average of ICU admissions compared to one week prior.

Based on detailed case information received by PHAC from provinces and territories, the overall cumulative hospitalization rate (including ICU admissions) is 139 cases per 100 000 population, with the highest rates observed among those aged 80 years and older (1 013 cases per 100 000 population).

Figure 8. Number of COVID-19 cases in hospital and ICU daily in Canada, as of 03 April 2021



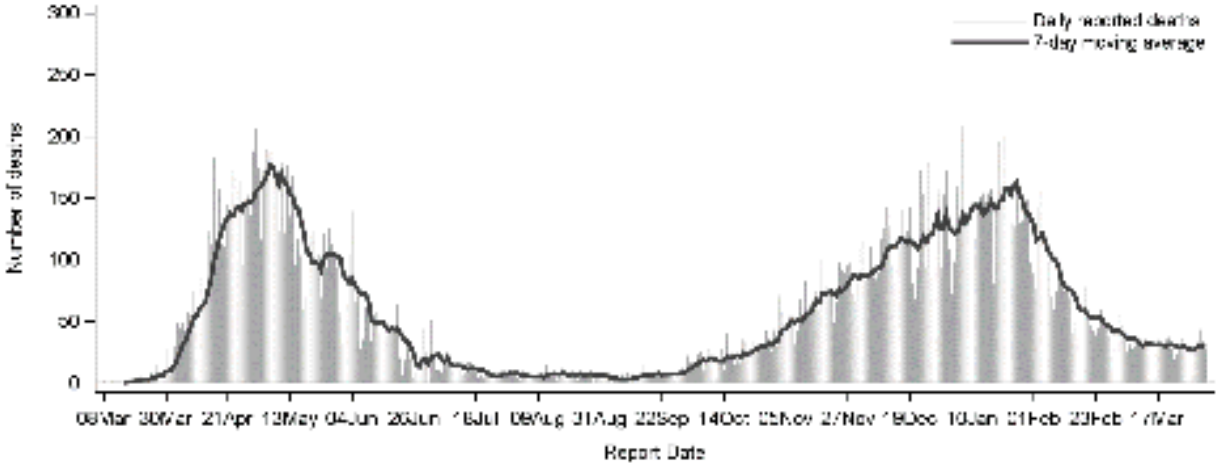
Source: Provincial and Territorial MOH websites as of 03 April 2021

During week 13, there were 195 COVID-19 related deaths reported in Canada.

- This represents an 8% decrease compared to the previous week.
- This amounts to an average of 28 deaths reported per day, compared to an average of 30 deaths per day during the previous week.
- There has been an overall decreasing trend in the number of deaths observed since late January 2021 (Figure 9).

Of the deaths reported during week 13, jurisdictions submitted case-level information to PHAC for 27 deaths, of which 18 (67%) were male and 96% were aged 60 years and older. To date, deaths are highest among those aged 80 years and older (Table A4 in the annex, cumulative counts).

Figure 9. Daily number of COVID-19 related deaths reported in Canada (and 7-day moving average), as of 03 April 2021 (N=23 050)



Source: Provincial and Territorial MOH websites as of 03 April 2021

Note: The 7-day moving average is a trend indicator that captures the arithmetic mean of the daily reported deaths over the previous seven days. The moving average helps smooth out day-to-day variability in reporting, filtering out the "noise" of short-term fluctuations. Fluctuations can be attributed to retrospective data or provinces or territories reporting cases at a reduced frequency.

CANADIAN ACUTE CARE HOSPITALS

Laboratory-confirmed COVID-19-associated hospitalizations in Canada are monitored through two sentinel hospital-based systems:

1. Canadian Nosocomial Infection Surveillance Program (CNISP) *
2. Serious Outcomes Surveillance Network of the Canadian Immunization Research Network (CIRN-SOS) **

NOTE: * denotes data from CNISP and ** data from CIRN-SOS

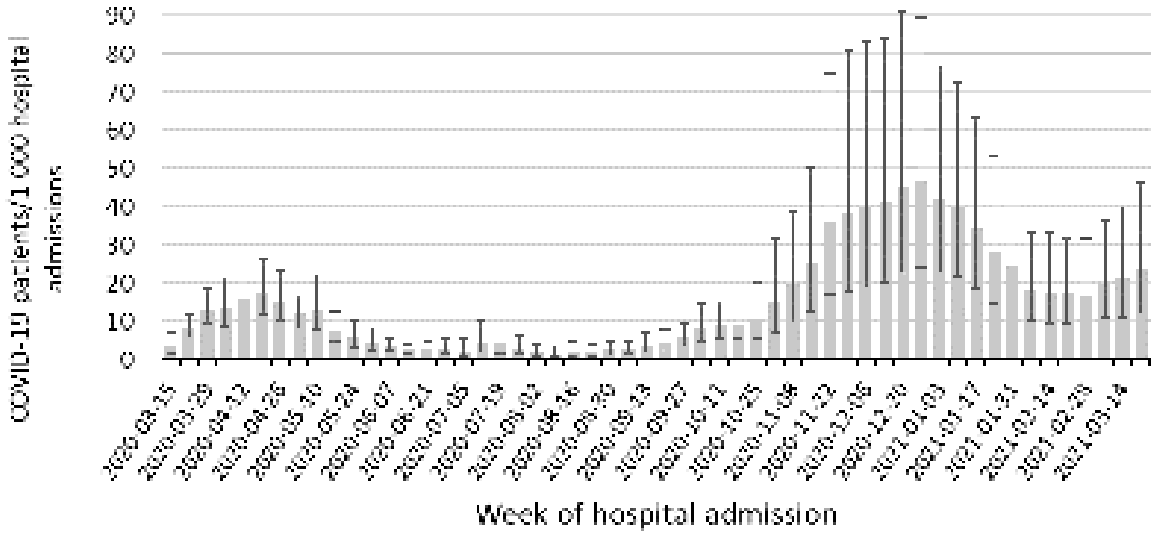
Key Findings*

- Among all patients hospitalized with COVID-19 since March 2020:
  - 20% have been admitted to the ICU (3 082/15 731)
  - 12% required mechanical ventilation (1 931/15 731)
  - <1% received extracorporeal membrane oxygenation (ECMO) (141/15 731)
  - 15% have died (all-cause mortality) (2 356/15 731)
- The median age of patients hospitalized with COVID-19 was 68 years (range 0-104 and 4% are pediatric (<18 years) (554/15 731)
- Males accounted for 54% of hospitalized patients (2 185/4 063)

Hospitalization Rates

- The weekly rate of new laboratory-confirmed COVID-19 patients per 1 000 hospital admissions was 23.8 for the most recent week of 21 March 2021 (Figure 10). The weekly incidence rate of hospitalizations has increased each week since the week of 28 February 2021 (Figure 10).

Figure 10. National rates of laboratory-confirmed COVID-19 patients per 1 000 admissions with 95% confidence intervals (n=15 731)*



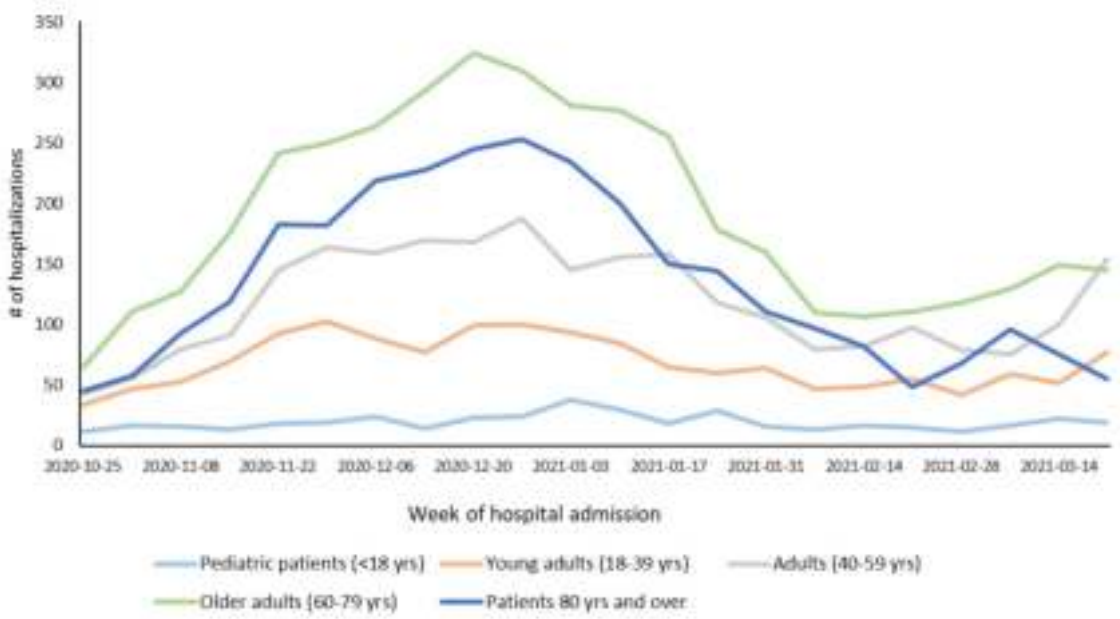
[a] Includes data from the 151 hospitals that have participated in all weeks of aggregate data collection. Denominator data are estimated using 2020 annual patient admissions.*

Hospitalization Trends

AGE *

- There was an increase observed in the number of hospitalizations among young adults (18-39 years) and adults (40-59 years) in the most recent week of 21 March 2021, with adults (40-59 years) accounting for the greatest number of hospitalizations for that week (Figure 11).
- Hospitalizations among patients 80 years and over have continued to decrease since the week of 07 March 2021 (Figure 11).
- Hospitalizations among pediatric patients (<18 years) have fluctuated, but consistently remained low (Figure 11).

Figure 11. Weekly number of new laboratory-confirmed COVID-19 patients by age group (n=11 728)*



CLINICAL PROGRESSION **

Time from symptom onset to hospital admission:

- Median length of time from symptom onset to hospital admission was shortest at 3 days among patients aged 80+ years (n=745), compared to 4 days among patients aged 16-39 years (n=162), 5 days among patients aged 60-79 years (n=852) and 6 days among patients aged 40-59 years (n=417).

Length of hospital stay:

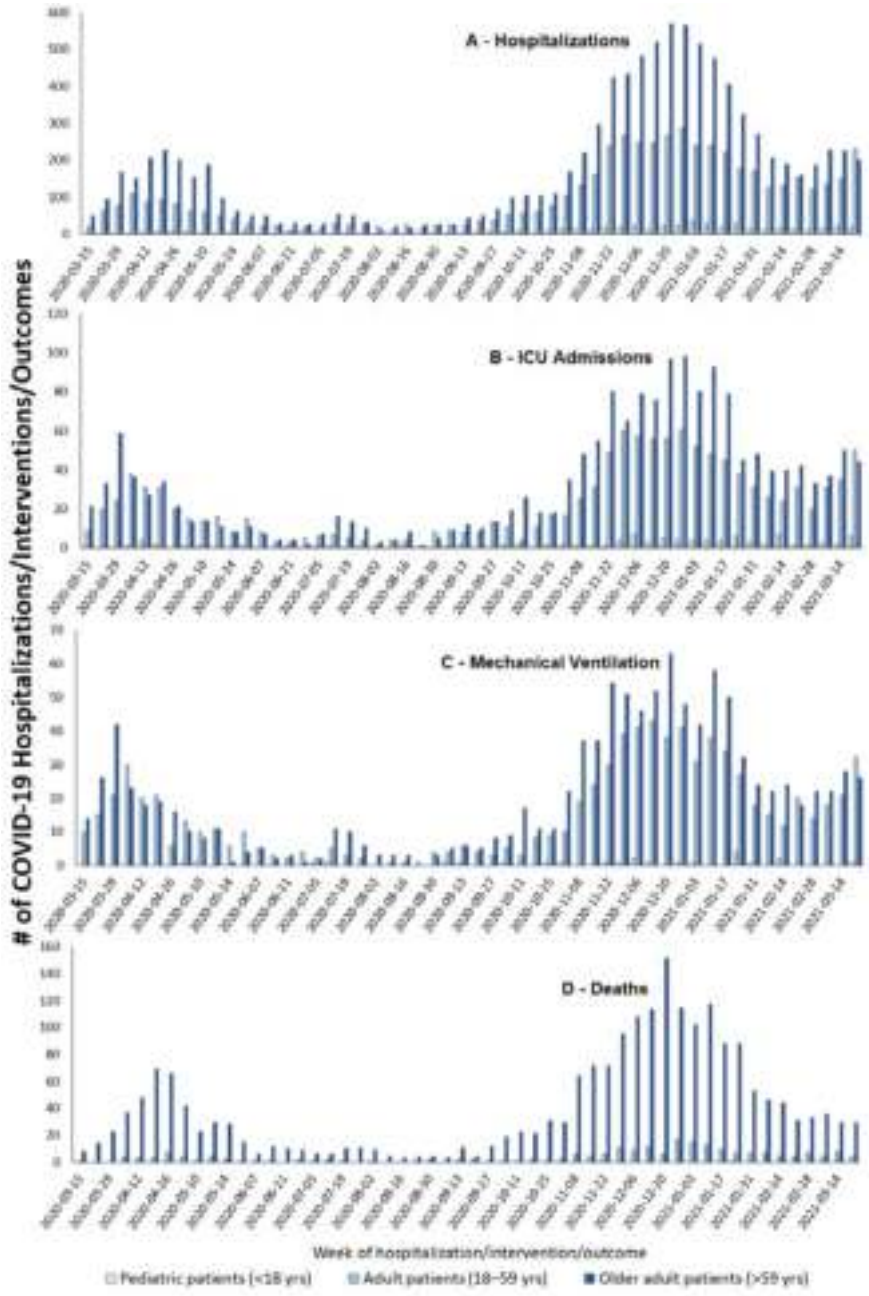
- Median length of hospital stay was longest among patients aged 80+ years (median=12 days, n=658) and patients aged 60-79 years (median=11 days, n=738). Values were comparatively lower for patients aged 40-59 years (median=6 days, n=352) and 16-39 years (median=4 days, n=134).

Note: Patients hospitalized before symptom onset were excluded from 'time from symptom onset to hospital admission' calculations. Length of stay is calculated as the time (in days) between date of hospital admission and date of outcome (including discharge, transfer, status change to alternate level of care, and death).

INTERVENTIONS/OUTCOMES *

- The number of new weekly hospitalizations, ICU admissions, and patients receiving mechanical ventilation have each increased since the week of 28 February 2021. Note that the increase observed in the most recent week of 21 March 2021 was largely driven by adult patients (18-59 years), as these measures all decreased among older adult patients (>59 years) (Figure 12).
- The number of deaths have remained relatively stable in recent weeks (Figure 12).

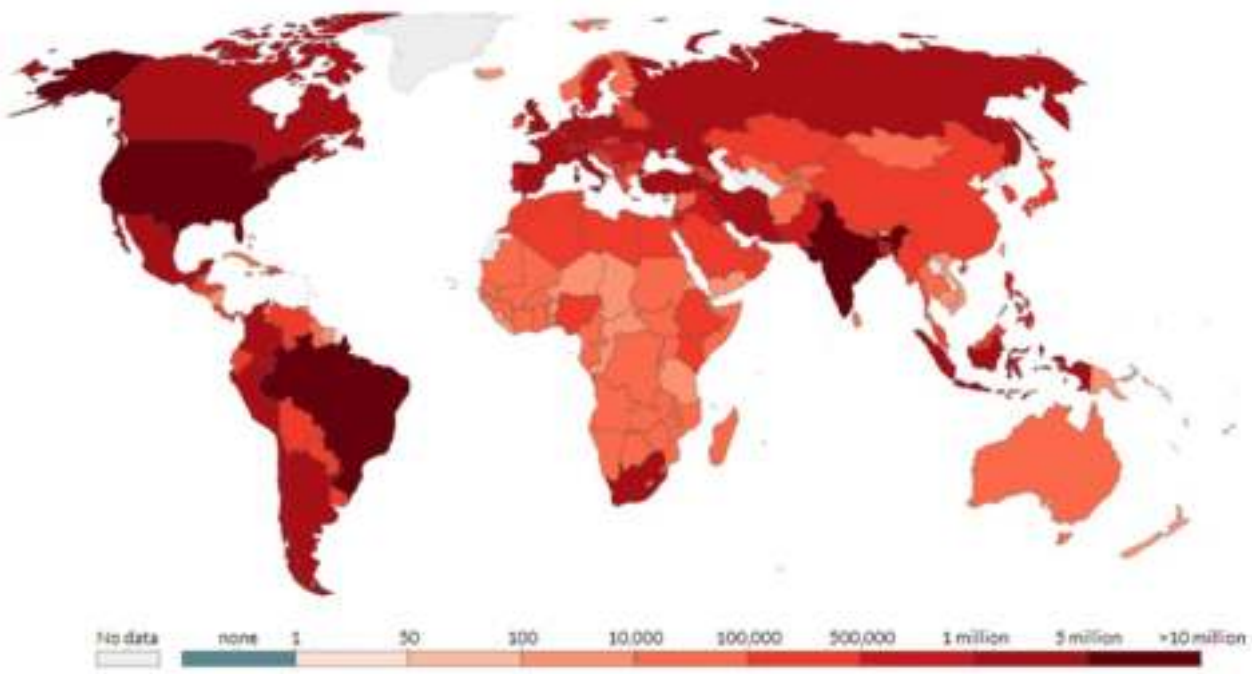
Figure 12. Weekly number of new laboratory-confirmed COVID-19 patients that were admitted to hospital (A; n=15 731), ICU (B; n=3 082), required mechanical ventilation (C; n=1 931), and deceased (D; n=2 356), by age group*



INTERNATIONAL

- As of 03 April 2021, there are over 129 million global cases of COVID-19 with over 2.8 million reported deaths (Figure 13).
- The region of Europe accounts for the highest number of cases reported.
- The following five countries account for the largest proportion of cases reported globally in the past 14 days:
    - Brazil (n=1 003 138)
    - India (n=886 379)
    - United States (n=885 934)
    - France (n=490 035)
    - Turkey (n=452 358)
- Canada's cases account for approximately 0.8% of all cases reported globally since the beginning of the pandemic.

Figure 13. International map of COVID-19 cases as of 03 April 2021 (n=129 943 007)

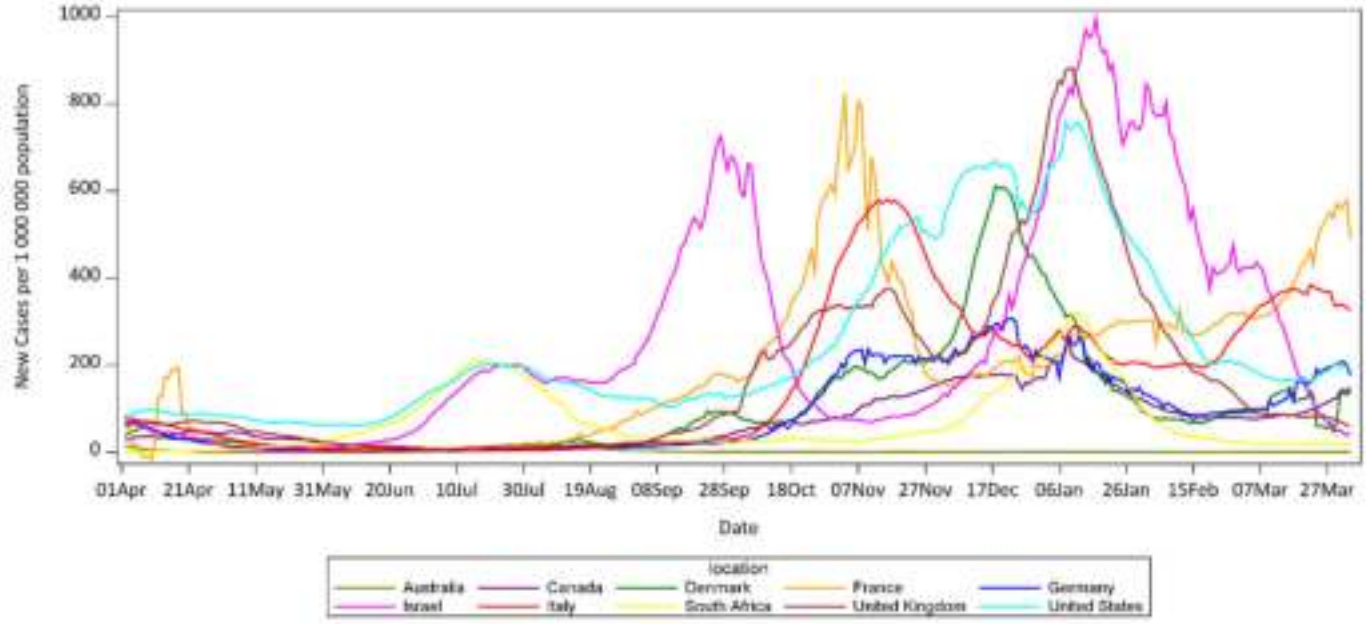


Source: Our World in Data – Coronavirus Pandemic (COVID-19) - https://ourworldindata.org/coronavirus

France continues to experience the highest rates of new cases compared to other countries, with 489.2 new cases per 100 000 population on 03 April 2021. Italy and the United States are second and third highest, with 325.6 and 195.2 new cases per 100 000 population, respectively.

Daily rates of cases in Canada are steadily increasing with 149.2 cases per 100 000 population on 03 April 2021. The rates of new cases in Canada are 3.3 times lower than France, 2.2 times lower than Italy, and 1.2 times lower than the United States.

Figure 14. Weekly new cases of COVID-19 in Canada compared to other countries as of 03 April 2021 (7-day moving average, population-adjusted)



Source: OurWorldInData, as of 03 April 2021

Up-to-date country-specific risk levels are found on travel health notices. For more information on COVID-19 internationally, please refer to the World Health Organization's COVID-19 Situation Report.

MODELLING

Estimates of transmission rates in Canada: Effective reproductive rate (*Rt*)

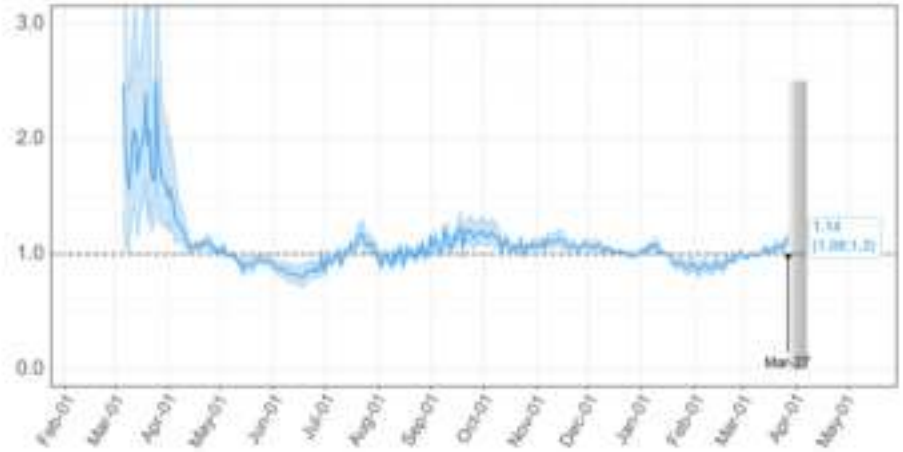
Rt is the time variable reproduction rate, representing the average number of newly infected people for each infected person. If Rt is less than 1 at a particular time (t), than the average number of people infected by one infected person is less than one, so the epidemic is being brought under control. If Rt is greater than 1, the average number of people infected by one infected person is greater than one, and the epidemic is growing. A value of Rt above 1 indicates that there is active community transmission, meaning that the disease will continue to spread in the population. The higher the Rt value, the faster the disease is spreading, which leads to an increase in the incidence of new cases.

However, there are some limitations to consider. As the epidemic continues, the Rt may not capture the current state of the epidemic with low case burden and the value must be interpreted based on the current landscape. The Rt can easily fluctuate when case numbers are low. It is also an average Rt for a population and does not point to local outbreaks driving case counts. Since the method used to calculate Rt is highly sensitive to the reported number of new cases, community outbreaks within specific provinces and territories will cause the estimated Rt value in that respective region to be higher, which may not always accurately depict overall transmission in the province or territory as a whole.

Figure 15 shows the Rt over time.

- In 2020, the reproductive rate was hovering under 1 in May and early June, followed by fluctuations in July. In early August, the Rt increased until the end of September when it decreased to just above 1. Between October 2020 and January 2021, the Rt fluctuated just above 1 with a slight increase in early November and early January. Starting in mid-January 2021, the Rt decreased to below 1, indicating that the epidemic was reducing nationally.
- Since early February 2021, the Rt has begun to slowly increase. The national Rt was 1.14 on 27 March 2021, an increase from 1.07 during the previous week.

Figure 15. Reproductive rate in Canada based on date of case report



Source: Calculated from detailed case information received by PHAC from provinces and territories
Note: Fluctuations are attributed to provincial and territorial reporting delays and non-reporting on the weekends

FORECASTING

Canada's approach to modelling:

Models cannot predict the course of the COVID-19 pandemic, but can help us understand all possible scenarios, support decisions on public health measures and help the health care sector plan for these scenarios.

Forecasting models use data to estimate how many new cases can be expected in the coming weeks. Figure 16 below shows the projected number of cases and deaths in Canada, with a 95% prediction interval calculated to 18 April 2021, using available data as of 03 April 2021.

- According to forecasting, between 1 093 510 to 1 150 910 cumulative reported cases and 23 290 to 23 710 cumulative reported deaths are expected by 18 April 2021.
- The black dots represent actual data (cumulative cases and cumulative deaths) prior to 03 April 2021 and the dashed lines show the predicted trajectories after that date.
- It is important to communicate uncertainties in the predictions. The red and green lines represent the upper and lower limits with 95% confidence, respectively.
- If the added data points since 03 April 2021 stay between the red and green lines, it means both (i) the prediction model is performing as expected; (ii) data generated by the epidemic and reporting mechanisms are as expected.
- If the added data points since 03 April 2021 fall outside these limits, especially above the red line, the model detects unexpected signals that require further epidemiologic investigation.

Figure 16. Projected numbers to 18 April 2021 and 95% prediction intervals based on data reported as of 03 April 2021

TECHNICAL NOTES

The data in the report are based on information from various sources described below. The information presented for case-based analyses, trend analyses and laboratory analyses are available as of **03 April 2021 at 4 p.m. EDT.**

DATA SOURCES AND DATA CAVEATS

Epidemiological data received by PHAC

Some of the epidemiological data for this report are based on detailed case information received by PHAC from provinces/territories (P/Ts). This information is housed in the PHAC COVID-19 database. Case counts and level of detail in case information submitted to PHAC varies by P/T due to:

- Possible reporting delay between time of case notification to the P/T public health authority and when detailed information is sent/received by PHAC.
- Preliminary data may be limited and data are not complete for all variables.
- Data on cases are updated on an ongoing basis after being received by PHAC and are subject to change.
- Variation in approaches to testing and testing criteria over time within and between P/Ts.
- The lag time from illness onset to PHAC report date is approximately two weeks and data within this period is subject to change.

Note: Missing data for hospitalizations, ICU admissions, and deceased were not included in calculations. Unless calculations were broken down by age and gender, cases with missing values for age and gender were included. P/Ts may define gender differently and some may be referring to biological sex. Case severity is likely underestimated due to underreporting of related variables, as well as events th at may have occurred after the completion of public health reporting, and therefore is not captured in the case report forms. Transmission data should be interpreted with caution as information on exposure are missing from several provinces and territories.

Provincial and territorial case counts

P/T information on case counts, resolved cases, and deaths associated with COVID-19 are collected from publicly available P/T websites, generally from the P/T ministry of health. Case definitions may vary by P/T.

- National COVID-19 case definitions are provided by PHAC for the purpose of standardized case classification and reporting. PHAC's national case definitions can be found here: https://www.canada.ca/en/public-health/services/diseases/2019-novel-coronavirus-infection/health-professionals/national-case-definition.html
- Only cases and deaths meeting P/T's definition for case classification are reported. For details on case definitions, please consult each P/T ministry of health website.

Laboratory information

Data on the number of tests conducted in each P/T are received from the National Microbiology Laboratory.

- Laboratory testing numbers may be an underestimate due to reporting delays and may not include additional sentinel surveillance or other testing performed. They are subject to changes as updates are received.

Outbreak data

Reporting delays and gaps in information that are available at the federal level present difficulties in reporting on local outbreaks. To ensure timely information is available, PHAC utilizes web-scraping techniques to gather outbreak data from media and P/T public health agency websites. There are several important limitations to these data:

- A nationally standardized outbreak definition does not yet exist. Cluster definitions vary according to P/T. The methods for defining an outbreak are currently in development and may change over time.
- The data do not represent all outbreaks that have occurred in Canada over the course of the pandemic, but they do provide a summary of clusters reported via non-traditional data sources. Data collection on outbreaks began 12 March 2020.
- Case-level data are generally not available for outbreaks detected via non-traditional data sources. Information presented is at the aggregate level only.

Population data

- Canadian population data from Statistics Canada Population estimates on 1 July 2020 are used for age-standardized and age-specific rate calculations.

International data

International data are retrieved from the European Centre for Disease Prevention and Control (ECDC) Situation update and Our World in Data.

- Given that the pandemic is rapidly evolving and the reporting cycles from government sources are different, the case numbers may not necessarily match what is being reported publicly. Rather, this reflects what is publicly available from the sources listed above.
- International comparisons should be interpreted with caution. Number of tests conducted, indications for testing, and diagnostic capacity by country have a large influence on total number of reported cases. Therefore, the data displayed may not represent the true incidence of disease within each country.

Canadian Acute-Care Hospitalization Data

Canadian Nosocomial Infection Surveillance Program (CNISP) collects information on hospitalized patients across all age groups (pediatric and adult).

- As of 27 March 2021, CNISP has collected weekly aggregate data on 15 731 adult and pediatric patients hospitalized with COVID-19 from 151 hospitals across all 10 provinces and 1 territory.
- CNISP has conducted surveillance among 56 hospitals across 10 provinces and 1 territory and as of 12 March 2021 has collected case-level data on 4 063 adult and pediatric patients hospitalized with COVID-19

Serious Outcomes Surveillance Network of the Canadian Immunization Research Network (CIRN-SOS) collects information on hospitalized adult patients aged 16 years or older.

- As of 1 April 2021, CIRN-SOS has collected case-level data on 2 950 adult patients (≥16 years) hospitalized with COVID-19 across 9 hospital sites in Alberta, Ontario, Québec, and Nova Scotia.
- Denominators may be lower depending on variable completeness.

*** denotes data from CNISP and ** data from CIRN-SOS**

ANNEX

Table A1. Cumulative number of COVID-19 cases, resolved cases, and deaths reported in Canada by province or territory, as of 03 April 2021

Province/Territory	Total cases	Total resolved cases	Total deaths
British Columbia	103 031	91 732	1 463
Alberta	151 359	138 560	1 994

Clustering and superspreading potential of SARS-CoV-2 infections in Hong Kong

Dillon C. Adam[1,2], Peng Wu[1]✉, Jessica Y. Wong[1], Eric H. Y. Lau[1], Tim K. Tsang[1], Simon Cauchemez[3], Gabriel M. Leung[1,4] and Benjamin J. Cowling[1,4]

Superspreading events (SSEs) have characterized previous epidemics of severe acute respiratory syndrome coronavirus (SARS-CoV) and Middle East respiratory syndrome coronavirus (MERS-CoV) infections[1–6]. For SARS-CoV-2, the degree to which SSEs are involved in transmission remains unclear, but there is growing evidence that SSEs might be a typical feature of COVID-19[7,8]. Using contact tracing data from 1,038 SARS-CoV-2 cases confirmed between 23 January and 28 April 2020 in Hong Kong, we identified and characterized all local clusters of infection. We identified 4–7 SSEs across 51 clusters ($n = 309$ cases) and estimated that 19% (95% confidence interval, 15–24%) of cases seeded 80% of all local transmission. Transmission in social settings was associated with more secondary cases than households when controlling for age ($P = 0.002$). Decreasing the delay between symptom onset and case confirmation did not result in fewer secondary cases ($P = 0.98$), although the odds that an individual being quarantined as a contact interrupted transmission was 14.4 (95% CI, 1.9–107.2). Public health authorities should focus on rapidly tracing and quarantining contacts, along with implementing restrictions targeting social settings to reduce the risk of SSEs and suppress SARS-CoV-2 transmission.

As of 25 August 2020 there were a total of 4,711 laboratory-confirmed cases of SARS-CoV-2 infection in Hong Kong. Since the first case was detected on 23 January, few were confirmed in Hong Kong up to 1 March, after which a substantial increase in international importations of COVID-19 cases (Fig. 1) resulted in a total ban on non-resident entry, mandatory 14-day monitored home quarantine for all resident arrivals and the implementation of various physical distancing measures[9]. After the number of cases began to subside, distancing measures were progressively relaxed from 8 May onward until a local resurgence of cases from 5 July brought their subsequent reintroduction (and maintenance at the time of writing).

For this study we collected information on 1,038 cases identified in Hong Kong up to 28 April. The majority (51.3%, 533/1,038) of SARS-CoV-2 infections confirmed during the study period (23 January–28 April) were associated with at least 1 of 137 clusters. Cases were linked to clusters (≥2 confirmed cases) based on the reported contact histories between cases (Methods). The median cluster size was 2 and the largest involved 106 cases (Extended Data Fig. 1). Of the cluster cases, 220 (41.3%, 220/533) belonged to 22 (22/137,16.0%) clusters initiated by another local case, compared to 89 (89/533, 16.7%) cases that belonged to 29 local clusters initiated by an imported case (29/137, 21.0%). However, most clusters were characterized as solely overseas-acquired (63.0%, 86/137) clusters and involved 224 cluster cases (42.0%, 224/533) where no onward local transmission could be identified but infection and contact between them (as family, friends or co-workers) was established overseas. Among the 505 sporadic cases not linked to any other case, 90.9% were acquired overseas (459/505), while the remaining 46 (9.1%) were sporadic cases infected locally based on recent travel histories. Overall, 31.4% (326/1,038) of all SARS-CoV-2 infections confirmed in Hong Kong during the study period were acquired within Hong Kong either within clusters or as untraceable sporadic local cases occurring through limited community transmission. Complete cluster composition is detailed in Supplementary Table 1. Of all cases confirmed in Hong Kong, 195 (18.8%, 195/1,038) were asymptomatic at confirmation (Supplementary Table 2) and, of these, most (83.1%, 162/195) were PCR-confirmed from 27 March onward (Extended Data Fig. 2).

The largest cluster comprised 106 cases and was traced back to a collection of four bars across Hong Kong (Fig. 2a), but the original source could not be determined. The first cases associated with this 'bar and band' cluster were reported for two customers who reported exposure to a bar in Lan Kwai Fong on 7 March (onset 11 March) before two staff members from the same bar fell ill on 10 and 11 March (confirmed on 24 and 25 March, Extended Data Fig. 3). Transmission to the other three bars is suspected to have occurred via a number of musicians who performed at the four venues. The earliest onset among the musicians was on 17 March, with most subsequently infected bar cases reporting exposures between 17 and 20 March; this constitutes at least one or more probable SSE (SSE #1). Of the 73 primary bar cases, 39 customers, 20 staff and 14 musicians were infected; the remaining 33 infections were secondary, tertiary or quaternary family, work or social contacts traced to the primary cases. This single outbreak accounted for 10.2% (106/1,038) of all cases in Hong Kong during the study period, regardless of source, and 32.5% of all locally acquired SARS-CoV2 infections (106/326).

The second-largest cluster comprised a total of 22 cases and was linked to two SSEs at a wedding and a preceding social event (Fig. 2b). Ten cases (SSE #2) resulted directly (and two indirectly) from the preceding social exposure (in total 13 cases including the source case); four of these subsequently attended the wedding. Transmission between wedding attendees could not be determined, but at least seven additional infections were confirmed among other guests (SSE #3). Two additional cases were identified among family members of an infected wedding guest. The third-largest cluster

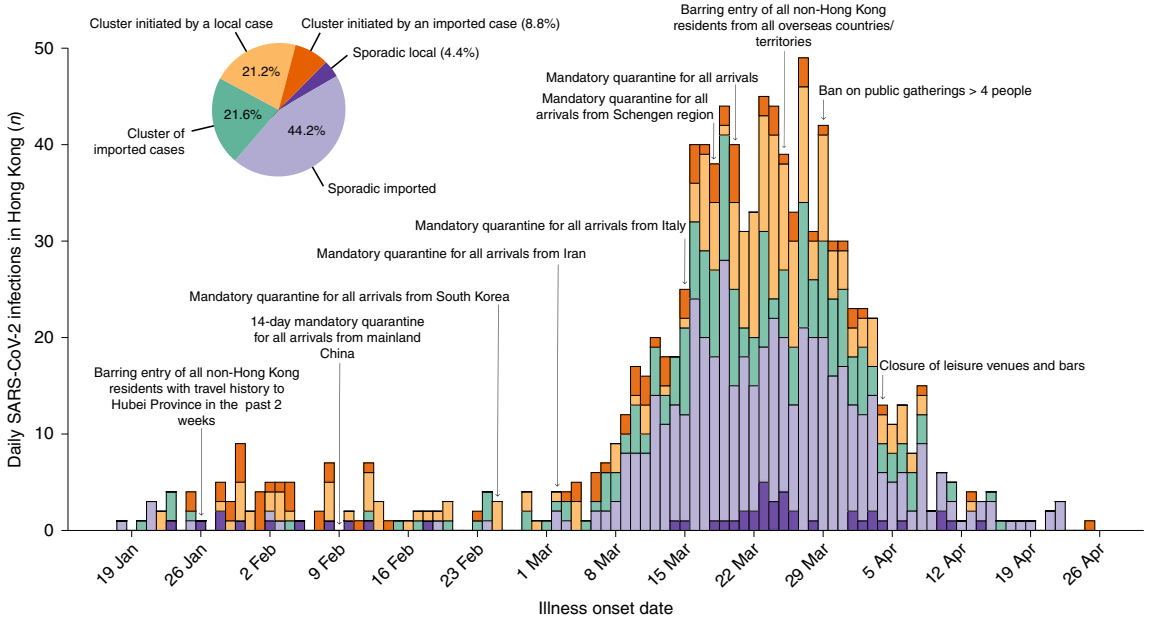

Fig. 1 | Epidemic curve of daily cases of laboratory-confirmed SARS-CoV-2 infection in Hong Kong by symptom onset date and colored by cluster category ($n=1,038$). The dates of major travel and community health interventions are indicated with arrows. Asymptomatic cases are included here by date of confirmation.

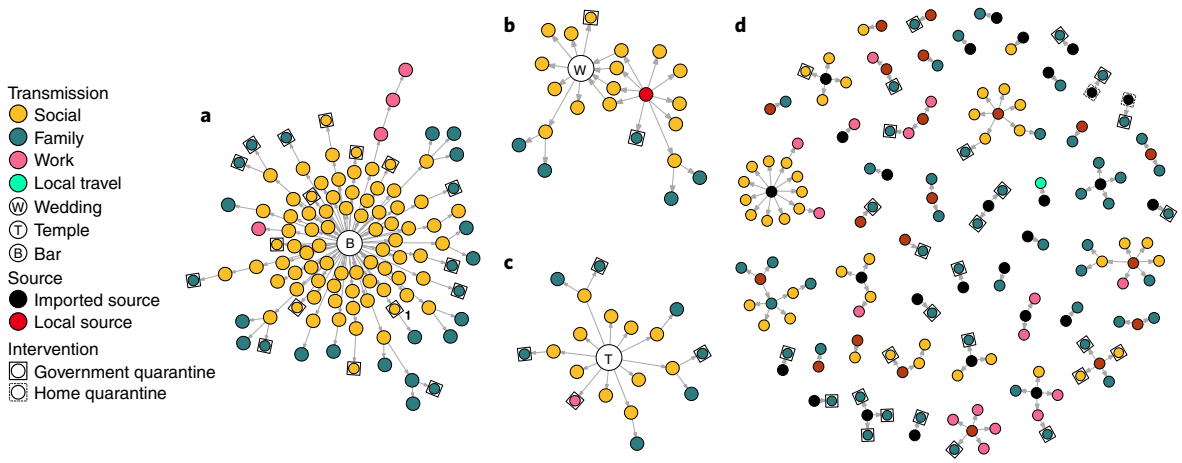

Fig. 2 | Chains of SARS-CoV-2 transmission in Hong Kong initiated by local or imported cases. a, Transmission network of the 'bar and band' cluster of undetermined source ($n=106$). **b**, Transmission network associated with a wedding without clear infector–infectee pairs but linked back to a preceding social gathering and local source ($n=22$). **c**, Transmission network associated with a temple cluster of undetermined source ($n=19$). **d**, All other clusters of SARS-CoV-2 infections where the source and transmission chain could be determined.

totaled 19 cases and was associated with attendance at a local temple, with 12 cases directly linked (SSE #4) to exposure at the temple (Fig. 2c). The seven remaining cases ($n=7/19$) were linked via secondary family exposures. The most recent case confirmed in this cluster was a monk who worked at the temple and reported no symptoms before confirmation. It is probable, but not definitive, that given the other 11 primary cases reported attending the temple over multiple days, the monk was the source of some or all of the other 11 temple cases[10]. All remaining local and imported SARS-CoV-2 clusters in Hong Kong, including three additional SSEs (SSE #5–7), are shown in Fig. 2d. In total we directly observed two to four SSEs (given a superspreading threshold of 6–8 secondary cases; Methods) where the sources were identified, or four to seven SSEs if including SSEs without a determined source.

Among the 533 cluster cases, all 224 solely overseas-acquired cluster cases were excluded from subsequent paired analyses due to uncertainties concerning the chain of transmission while overseas. For the remaining 309 cases within clusters initiated by a local or imported infection, 244 (244/309, 79.0%) were identified into 169 unique infector–infectee transmission pairs, with 91 unique infectors. The median serial interval (time between reported onset dates of all symptomatic infector–infectee pairs, $n=142$) was 4 days (interquartile range (IQR), 3–9 days), and the mean of the fitted normal distribution was 5.8 days (Fig. 3a, Supplementary Table 3 and Extended Data Fig. 4a). Seven instances of likely pre-symptomatic transmission were observed where onset of the infectee preceded that of the infector or occurred on the same day. The ages (two-sided t-test, $P=0.18$) and sex ($\chi^2=0.17$ $P=0.68$) of

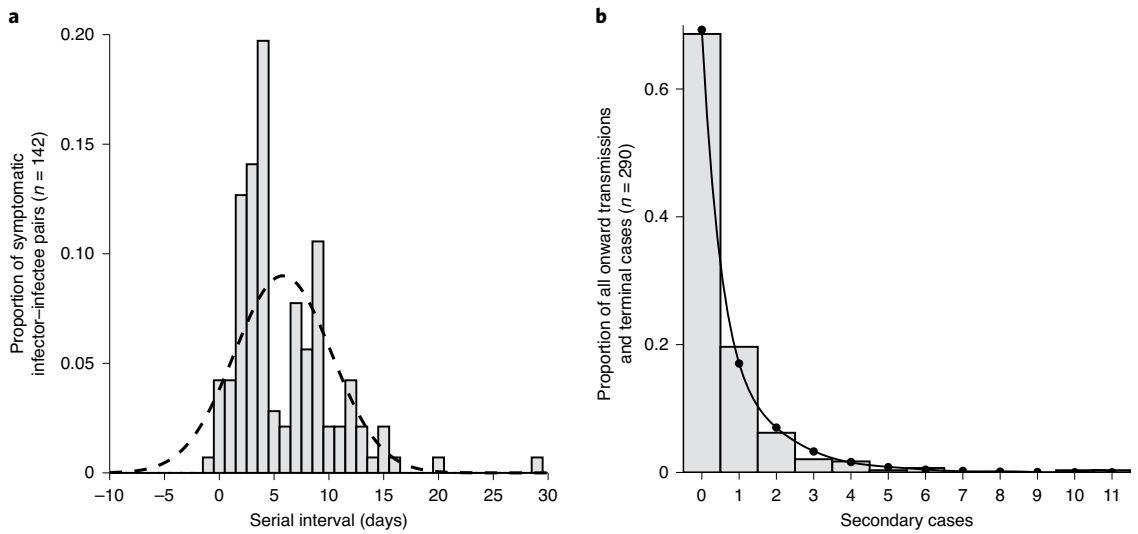

Fig. 3 | Characteristics of SARS-CoV-2 transmission in Hong Kong. a, Serial interval distribution of SARS-CoV-2 infections in Hong Kong among $n=142$ symptomatic infector–infectee pairs and the fitted normal distribution. This excludes 27 asymptomatic pairs (either as infector or infectee) due to a lack of symptom onset dates. **b**, Observed offspring distribution of $n=91$ SARS-CoV-2 infectors, $n=153$ terminal infectees and $n=46$ sporadic local cases in Hong Kong and corresponding fitted negative binomial distribution with parameters $R=0.58$ and $k=0.43$.

the infectors and infectees were not significantly different; however, a significantly higher risk of transmission was observed between cases of similar age ($P<0.001$, Extended Data Fig. 5).

From the observed offspring distribution and negative binomial distribution, we estimated an overall reproductive number, R, of 0.58 (95% confidence interval (CI), 0.45–0.72) and dispersion parameter, k, of 0.43 (95% CI, 0.29–0.67) during the study period (Fig. 3b, Supplementary Table 4 and Extended Data Fig. 4b). Because not all cases could be clearly linked into infector–infectee pairs using epidemiological data alone (35/309, 11.0%), a likelihood model based on the final size of all local clusters (cluster size model) was implemented to account for any potential bias. This increased the estimate of R to 0.74 (95% CI, 0.58–0.97) and decreased k to 0.33 (95% CI, 0.14–0.98). From these estimates we inferred that 17–19% (cluster size model and observed offspring distribution, respectively) of SARS-CoV-2 infections were responsible for 80% of all transmission events in Hong Kong, while 69% of cases did not infect anyone (Supplementary Table 5).

Additional sensitivity analyses slightly increased ($R=0.62$, 95% CI, 0.49–0.80) and decreased ($k=0.35$, 95% CI, 0.25–0.56) the estimates of R and k, respectively (relative to the observed offspring distribution) following the addition of likely but unconfirmed infector–infectee pairs from the wedding and temple clusters to the observed offspring distribution. Here, we assumed a single wedding guest infected seven other wedding guests and the temple monk infected all 11 other primary cases (Fig. 2b,c). These scenario estimates differed again ($R=0.72$, 95% CI, 0.53–0.94; $k=0.19$, 95% CI, 0.13–0.26) when assuming a single musician was the source of 67 unresolved bar and band cluster cases, excluding the earlier cases preceding the musician. Given these scenarios, the expected proportion of cases responsible for 80% of all SARS-CoV-2 transmission in Hong Kong was 18% (14–23%) in the first scenario and 13% (10–17%) in the second (Supplementary Table 5).

These results, however, should be interpreted in the context of constrained community transmission given the moderate levels of physical distancing practiced in Hong Kong, including school closures, some adults working at home, cancellation of mass gatherings, as well as improved hygiene and universal mask wearing, which exceeded 98% compliance from February onward[11,12]. In the absence of such policies it is possible that even greater levels of superspreading could be expected. For example, findings from Shenzhen (China)[13] estimated roughly comparable levels of SARS-CoV-2 overdispersion using contact tracing data ($k=0.58$, 95% CI, 0.35–1.18), but a study from Singapore[14] reported $k=0.11$ (95% CI, 0.05–0.25). Other studies utilizing global cluster size datasets have estimated similarly high potential for SARS-CoV-2 superspreading ($k=0.10$, 95% CI, 0.05–0.20), which together suggest that as few as 10% of cases could account for 80% of all SARS-CoV-2 transmission[15]. However, such extreme degrees of overdispersion can be advantageous to disease control efforts if interventions can effectively target the core high-risk groups or settings responsible for the majority of transmission[16,17].

We observed transmission within family households most frequently (92/169, 54.4%), followed by social (56/169, 33.1%) and work (20/169, 11.8%) settings. Social settings, however, were associated with both younger cases ($P=0.026$, Wilcoxon test) and more secondary cases compared to households with ($P<0.001$, negative binomial regression) and without ($P=0.002$) controlling for the age of individual infectors, although this was not the case for households versus work settings (Wilcoxon test, $P=0.64$; regression, $P=0.92$). Social venues such as bars, weddings, religious sites and restaurants, which have also been linked to an increased risk of SSE elsewhere[18], therefore appear at increased risk for large outbreaks and likely constitute the core behavioral risk factor for SARS-CoV-2 SSEs. This is certainly due to the greater numbers of contacts expected in such settings; however, owing to a lack of reported numbers on confirmed contacts who tested negative, we were unable to control for this in our study. We also cannot account for any potential selection bias in our results where small family clusters are more readily traceable than smaller social clusters, which might go unrecognized, thus biasing estimates of their frequency and size. Regardless, the potential for increased transmission or SSEs within social settings is apparent, and suppression measures should therefore focus on eliminating the risk of superspreading by reducing the numbers of contacts within such settings. This could be achieved either via venue closures, reduced capacity measures/physical distancing policies and mask usage[11].

Previous modeling has suggested that reduced delays between symptom onset and confirmation are important indicators in the control of SARS-CoV-2 outbreaks[16]. In our analysis, decreasing

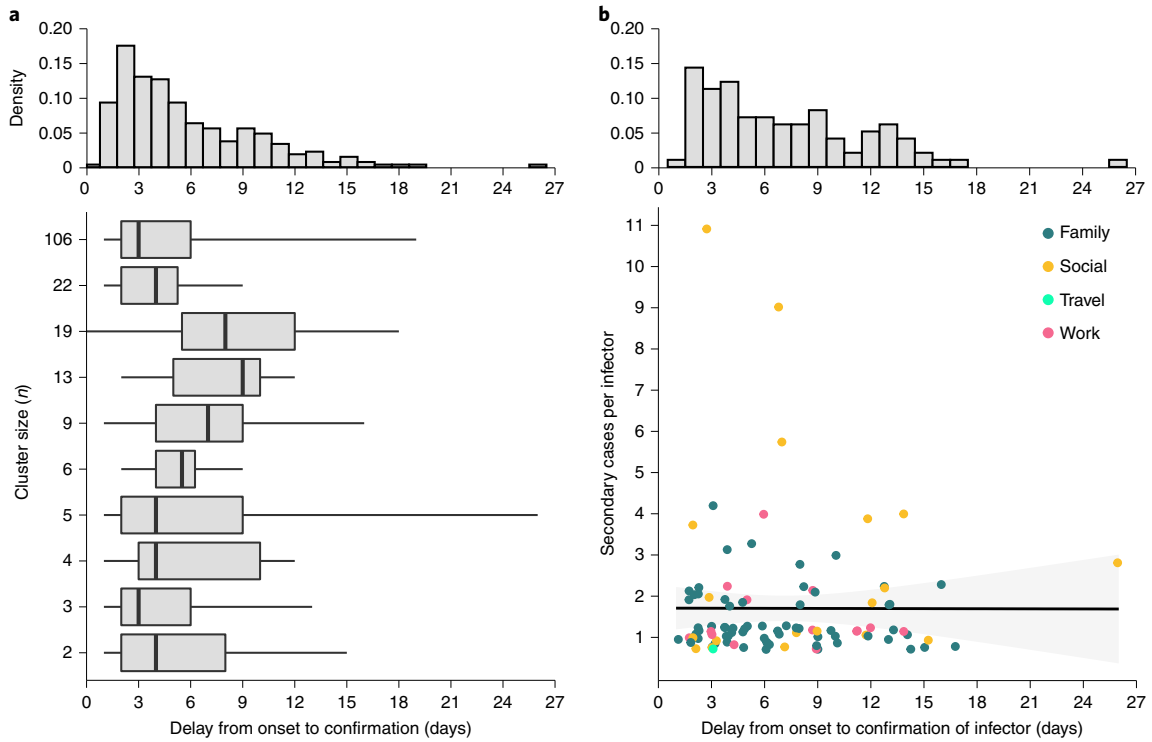

Fig. 4 | Delay from onset of symptoms to confirmation of SARS-CoV-2 infection in Hong Kong. a, Distribution and marginal density of delay in days from symptom onset to confirmation of $n=269$ local cluster cases by cluster size (excludes 40 asymptomatic cluster cases without reported onset dates). Whiskers identify the minima and maxima of the delays, bounds of boxes the 75th and 25th percentiles, and the center line the median. **b**, Delay from symptom onset to confirmation of $n=98$ symptomatic infectors (excludes two asymptomatic infectors) by the number of secondary infections and setting of contact. There is no linear relationship between an infector's delay to confirmation and the number of secondary infections (linear regression, $F<0.001$, d.f. $=96$, $R^2=-0.01$, two-sided $P=0.98$ without adjustment for multiple comparison). The center line of the regression indicates the conditional mean of the model and the shaded area the 95% CI. Note that both the number of secondary cases per infector and days from onset to confirmation are discrete integers (not continuous), but have been plotted here with a slight jitter to aid visualization.

delays from symptom onset to confirmation did not appear to correlate with smaller local cluster sizes (Fig. 4a) unless excluding the two largest clusters ($N<20$) (linear regression, $F=21.09$, d.f. $=6$, $R^2=-0.74$, two-sided $P=0.004$). However, among recognized transmission pairs, there was no linear relationship between increasing delay to confirmation of infectors and more secondary cases (Fig. 4b). By contrast, for SARS-CoV in 2003, delays in individual case confirmation had an adverse effect on disease control due to increased viral shedding during the late symptomatic period, which was highest approximately seven days after symptom onset[19–21]. For COVID-19, confirmation and isolation of cases will therefore have a limited effect on reducing transmission unless done very quickly, also noting the growing body of evidence of transmission during the pre- and early symptomatic periods[22–24]. In Hong Kong, the median time from symptom onset to confirmation was four days for local cluster cases and six days for infectors and, by this time, any onward transmission may have already occurred, although this does not take into account possible self-isolation prior to confirmation.

Sequestering confirmed contacts of cases to mandatory government quarantine was very effective at terminating chains of transmission. In total, 51 local cluster cases were placed in quarantine after identification as a close contact of a confirmed case but prior to their own confirmation. This total excludes two imported cases under travel-related home quarantine. Of the 189 cases terminal to the observable chain of transmission, 45 were first placed in government quarantine as contacts (23.8%, $n=45/189$). Only one quarantined contact, later confirmed as an asymptomatic case, was found to have passed on infection before sequestration (Fig. 2a,1). The odds, therefore, that a case was placed in government quarantine as a contact and terminated the chain of transmission (terminal case) was 14.4 (95% CI, 1.9–107.2, Supplementary Table 6). The most important public health measures are therefore likely to be early case identification followed by rapid and parallel (before contacts are confirmed as cases) contact tracing and quarantine (though we did not have data on the timing of contract tracing in relation to case confirmation, nor the timing of subsequent testing). Beyond such active suppression measures, intermittent physical distancing in high-risk social environments (together with mask wearing) may also be required to reduce transmission from unidentified infections and pre-symptomatic transmission, but must necessarily be balanced with the social, economic and educational costs associated with such policies. Notably, among infections acquired in Hong Kong, 14.1% (46/326) were sporadic local cases (that is, cases with neither traceable contact with another case/cluster nor a history of recent travel). This untraceable fraction could be interpreted as an upper bound on the proportion of transmission arising from anonymous interactions, fomites and/or aerosols. However, this finding may have to be restricted to the context of places similar to Hong Kong, where there is a widespread adoption of suppression measures[12].

Our study has some limitations. Primarily, because this study relies on contact tracing data, any degree of incompleteness in case and/or contact ascertainment could bias our results. Given that the source of 46 sporadic local cases could not be determined, as noted above, nor the source of 22 local index cluster cases, a degree of incompleteness and therefore bias is expected. In

Table 1 | Policy summary

Background	
Superspreading is a common feature of past betacoronavirus epidemics of SARS-CoV and MERS-CoV. We used contact tracing data to characterize SARS-CoV-2 clusters in Hong Kong and estimate the potential for superspreading while quantifying associated risks.	
Main findings and limitations	
Our findings indicate that there is substantial potential for SARS-CoV-2 superspreading. SARS-CoV-2 exhibits a high degree of individual transmission heterogeneity, and we estimate that 19% of SARS-CoV-2 infections in Hong Kong were responsible for 80% of all transmissions, while 69% of cases did not transmit to anyone. Gatherings in social settings such as bars, restaurants, weddings and religious sites appear to be at increased risk of superspreading events. Transmission in social settings was significantly associated with an increased number of secondary cases compared to transmission observed in family households. These findings take advantage of the quality of case ascertainment and contact tracing data in Hong Kong, although some incompleteness in links between cases could potentially bias our estimates of transmission heterogeneity.	
Policy implications	
These results suggest that reducing the occurrence of superspreading events by limiting gatherings in social settings can have a disproportionate effect on reducing SARS-CoV-2 transmission, which has important policy implications concerning the approach to COVID-19 suppression measures around the world.	

fact, the expected difference between R (biased downward) and k (biased upward) from our observed estimates and our cluster size model (Supplementary Table 5) indicates the presence of such bias. However, the inference of R and k in our cluster size model can also be affected by bias, where R may be underestimated due to imperfect case ascertainment or overestimated when larger clusters are more readily observed than smaller clusters[25]. In either case, however, k is more likely to be overestimated, as imperfect observation, regardless of the cause, tends to bias estimates toward greater transmission homogeneity[25]. This means that the potential for SARS-CoV-2 superspreading, as already suggested, and shown elsewhere[15], could be greater than our results suggest.

It is also possible that some cases may have been incorrectly attributed to clusters where the true source infection was elsewhere, such as an undetected or asymptomatic case, despite evidence of close contact. However, because there appears to be little evidence of widespread community transmission in Hong Kong during the study period (only 31.4% (326/1,038) of all confirmed cases acquired SARS-CoV-2 in Hong Kong), the risk of such an occurrence is low, albeit not zero. Interestingly, our dataset did not contain any instances of nosocomial transmission, which has been observed for SARS-CoV-2[26,27]. It should be noted, however, that hospital infection control in Hong Kong substantially strengthened following the 2002–2003 SARS epidemic. Seroprevalence studies among frontline healthcare workers in Hong Kong will be able to confirm the effectiveness of infection control and whether any unrecognized nosocomial transmission has occurred. Future studies could also incorporate SARS-CoV-2 genetic sequence data to assist in uncovering hidden chains of transmission within the city (including within hospitals) and to discretize clusters more accurately.

Overall, there is substantial heterogeneity in the transmissibility of SARS-CoV-2 infection and therefore potential for superspreading with COVID-19. SSEs pose considerable challenges for local SARS-CoV-2 control as they can quickly overwhelm contact tracing capacity, although most infected persons will generate few or no secondary infections but a small fraction can generate many. Indeed, we observed that 19% (15–24%) of cases were responsible for 80% of all SARS-CoV-2 transmission in Hong Kong (Supplementary Table 5), while 69% (65–71%) of cases did not transmit to anyone. Assuming that local elimination is not possible, disease control efforts should focus on the rapid tracing and quarantine of confirmed contacts, along with the implementation of physical distancing policies including either closures or reduced capacity measures targeting high-risk social settings such as bars, weddings, religious sites and restaurants to prevent the occurrence of SSEs; this would have considerable effect in reducing the overall reproductive number. In lieu of an effective and widely available vaccine, these results have important implications for the control of COVID-19 and the implementation and continuation of public health measures such as physical distancing policies and lockdowns around the world (Table 1).

Methods

Characterization of clusters and chains of SARS-CoV-2 transmission. Using case line lists and contact tracing data collected in Microsoft Excel by the Centre for Health Protection (CHP) of the Department of Health in Hong Kong, we characterized clusters of SARS-CoV-2 infections and chains of transmission within clusters up to 7 May 2020. All cases of SARS-CoV-2 infection were laboratory-confirmed via nasopharyngeal swab and PCR with reverse transcription (RT-PCR). In Hong Kong, all contacts of a confirmed case are traced and sent to mandatory government quarantine facilities for 14 days if negative at identification, or admitted to hospital if testing positive, regardless of symptom presentation. A close contact was defined as someone with prolonged face-to-face interaction with a confirmed case (with or without prior symptoms) in excess of 2 h if both persons were wearing a mask or 15 min without mask usage. However, data on mask usage among cases and contacts was not provided. Quarantined contacts who test positive in quarantine are transferred and isolated in hospital, while those who test negative at the end of the quarantine period are released back into the community. For imported cases, self-isolation at home (home quarantine) was mandatory (for all returning residents) if arriving after 20 March 2020.

We defined clusters as two or more confirmed infections with reported close contact. Local clusters were characterized by the travel history of the index case as either initiated by an imported case (that is, index acquired SARS-CoV-2 infection overseas based on reported onset dates and a recent history of overseas travel given a maximum 14-day incubation period) or initiated by a local case. Clusters of solely imported cases were characterized as overseas-acquired clusters if all cases were determined to have acquired SARS-CoV-2 infection overseas as before. Cases not linked to any cluster were categorized as sporadic local cases or sporadic imported cases if infection was acquired locally or overseas, respectively.

For cases within local and imported clusters (excludes overseas clusters), probable infector–infectee transmission pairs and chains of transmission within clusters were determined from reported contact histories data provided by the CHP. Within clusters, the case with the earliest onset date was considered the source of subsequent cases where contact was confirmed within the primary cluster setting. Subsequent transmission generations and clusters settings (secondary, tertiary, quaternary and so on) were traced back to the primary cluster case based on the reported contact histories only and did not rely on symptom onset dates, meaning that instances of asymptomatic or pre-symptomatic transmission were possible from cases intermediate to the chain of transmission. In such cases, asymptomatic transmission was characterized among infector–infectee pairs where close contact was confirmed and the infector reported no symptoms before confirmation, while pre-symptomatic transmission was characterized when the difference in days between the reported symptom onset of infector–infectee pairs was a non-positive integer. Symptom presentation was screened only at detection/confirmation by a healthcare professional including retrospective self-report of onset dates. Cases within the largest clusters where the source and chain of transmission were highly uncertain were excluded from the paired analysis; however, subsequent generations of transmission where the source case could be linked to the primary setting were not excluded (for example results see Fig. 2a–c). The effect of quarantining contacts on eliminating onward transmission was determined by odds ratios given the terminal or intermediate position of the contact (later confirmed as a case) in the chain of transmission. Each transmission pair was characterized by the reported setting of contact as either family, social, work or local travel (such as on public transport).

Statistical analyses. The age and sex of unique infectors ($n=91$) versus infectees ($n=169$) were compared using a two-sided t-test and χ^2 test, respectively. The age relationship between paired infector and infectee was assessed by linear regression ($n=169$). We modeled the relationship between the number of secondary cases per infector by transmission setting using negative binomial regression with and without controlling for infector age. We used 'family' as the reference category while excluding 'travel' due to the small sample size ($n=99$ unique infectors with seven infectors included more than once because they were associated with onward transmission across two or more settings but excluding one pair with transmission related to travel). Differences in the age of infectors ($n=99$) by setting and all cases by setting (infectors $n=99$ and infectees $n=168$, excluding one infectee via travel) were assessed using non-parametric Kruskal–Wallis and Wilcoxon rank-sum tests, without adjustment for multiple comparisons. We modeled the relationship between the delay in days from symptom onset to confirmation and the number of secondary cases per infector by linear regression as a proxy for individual duration of potential infectiousness in the community ($n=98$ infectors, including one travel-related infector but excluding two asymptomatic infectors whose delay could not be calculated). The mean delay from symptom onset to confirmation of 269 symptomatic cases within local clusters was also assessed by linear regression by cluster size with (10 discrete cluster sizes) and without (eight discrete cluster sizes) excluding the largest two clusters.

Serial interval and observed offspring distribution. We calculated serial intervals as the difference between the symptom onset dates of each infector–infectee pair, excluding asymptomatic cases, and fitted normal, lognormal, gamma and Weibull distributions using the R package 'fitdistrplus' by maximum-likelihood, excluding seven non-positive intervals for the latter three distributions. We generated the observed offspring distribution by calculating the number of secondary cases and similarly fit negative binomial, geometric and Poisson distributions as before. Cases terminal to the inferred chain of transmission and sporadic local cases were considered to have zero secondary cases. We compared each fit distribution using Akaike information criterion (AIC) scores and calculated confidence intervals for parameters from 1,000 bootstrapped replicates.

Superspreading and individual variance of SARS-CoV-2 transmission. Following the approach described by Lloyd Smith et al., estimates of the effective reproductive number (R) were determined from the mean of the negative binomial distribution fit to the observed offspring distribution, and the degree of transmission heterogeneity from the corresponding dispersion parameter k (ref. [28]). This was performed for all resolved pairs within clusters, including later generation pairs where prior transmission chains could not be determined from epidemiological data alone, which were excluded from the primary analysis. Owing to potential biases affecting the observed offspring distributions resulting from these exclusions, we performed a sensitivity analysis by generated two additional offspring distributions based on presumed but unconfirmed transmission scenarios (described in the results) where evidence was indicative but insufficient to fully resolve all pairs within clusters in the primary analysis. Furthermore, we implemented a likelihood-based branching process model to jointly infer R and k based on the final size of all local clusters, where sporadic local cases were considered clusters of size one as per Kucharski and Althaus[29]. For a given range of values for R (0.10–3.00) and k (0.01–55), the probability that an index case generates n_j clusters of size j is given by[25,30]

$$r_j = \frac{\Gamma(kj+j-1)}{\Gamma(kj)\Gamma(j+1)} \frac{\left(\frac{R_0}{k}\right)^{j-1}}{\left(1+\frac{R_0}{k}\right)^{kj+j-1}}$$

and the likelihood, assuming that the branching chains are self-limited, is

$$L = \prod_{j=1}^{\infty} r_j^{n_j}$$

We repeated the above analyses after sub-setting the data into epochs (epoch one, January–February 2020; epoch two, March–May 2020) by illness onset date of the infector (observed offspring distribution) or the onset date of each cluster's index case (cluster size model). Following from ref. [15], given parameters R and k, the expected proportion of cases responsible for 80% of transmission in Hong Kong is given by

$$1 - P80\% = \int_0^X \mathrm{NB}\left(\lfloor x \rfloor; k, \frac{k}{R_0+k}\right) \mathrm{d}x$$

where X satisfies

$$1 - 0.8 = \frac{1}{R_0} \int_0^X \lfloor x \rfloor \mathrm{NB}\left(\lfloor x \rfloor; k, \frac{k}{R_0+k}\right) \mathrm{d}x$$

and

$$\frac{1}{R_0} \int_0^X \lfloor x \rfloor \mathrm{NB}\left(\lfloor x \rfloor; k, \frac{k}{R_0+k}\right) \mathrm{d}x = \int_0^{X-1} \mathrm{NB}\left(\lfloor x \rfloor; k+1, \frac{k}{R_0+k}\right) \mathrm{d}x$$

The proportion of cases responsible for 0% of transmission (that is, did not spread to anyone) was calculated from the negative binomial distributions given all calculated parameters R and k where the number of secondary cases was input as zero ($x=0$). Finally, when given R_0, the superspreading threshold can be calculated as the 99th percentile of the Poisson(R_0) distribution[28] where $\Pr\left(Z \leq Z^{(99)} | Z \sim \mathrm{Poisson}(R_0)\right) = 0.01$. Therefore, with the global consensus of R_0 in the range 2–3 (refs. [31,32]), we defined the superspreading threshold for SARS-CoV-2 here as 6 to 8 secondary cases. All statistical analyses were performed in R version 3.6.1 (R Foundation for Statistical Computing). Ethics approval for this study was obtained from the Institutional Review Board of the University of Hong Kong. Data collection and analysis were part of a continuing public health outbreak investigation. Accordingly, informed consent to be included in this study was not required.

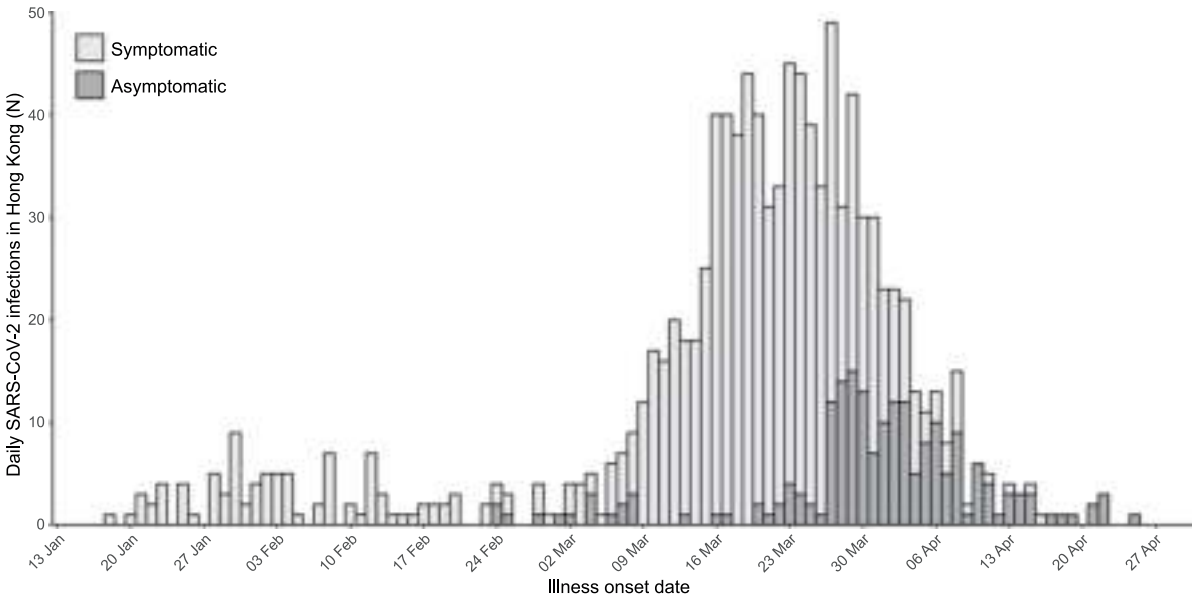
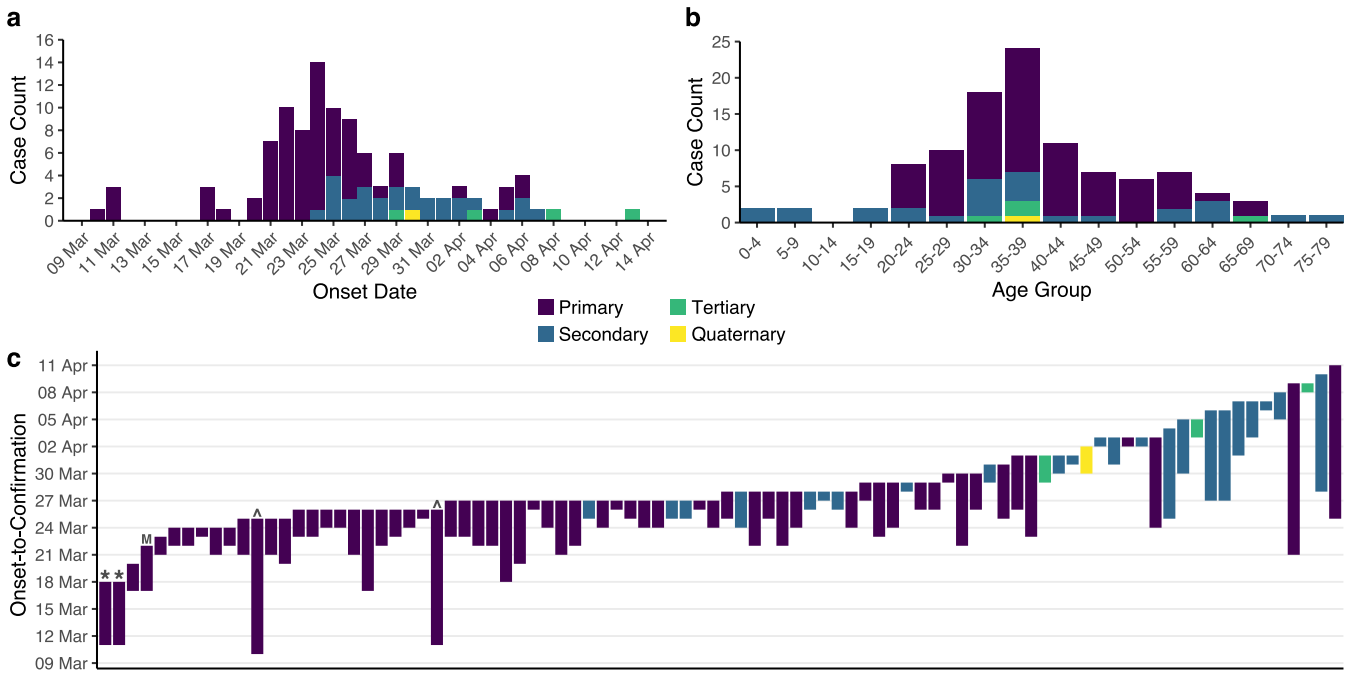
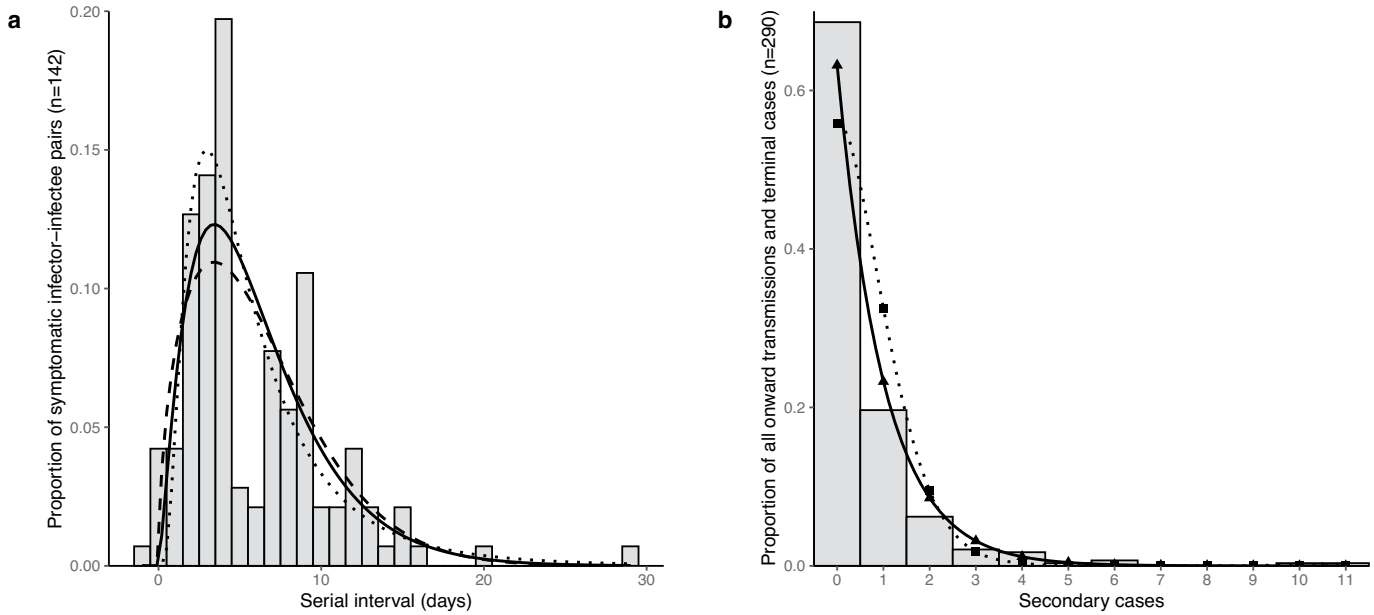
Extended Data Fig. 1 | SARS-CoV-2 cluster size in Hong Kong by onset date of the index case. SARS-CoV-2 cluster size in Hong Kong by onset date of the index case. Arrow indicates the earliest onset position (2020-03-10) of the largest local SARS-CoV-2 cluster (N = 106 cases) which is excluded here for visualization purposes only. The decreasing trend in clusters size was not significant (linear regression, F = 1.25, df = 135, R^2 = 0.001, p-value = 0.27). Shaded area indicates the 95% confidence interval of the regression. Final cluster sizes are plotted as integers however a slight vertical jitter is applied here also for visualization purposes.



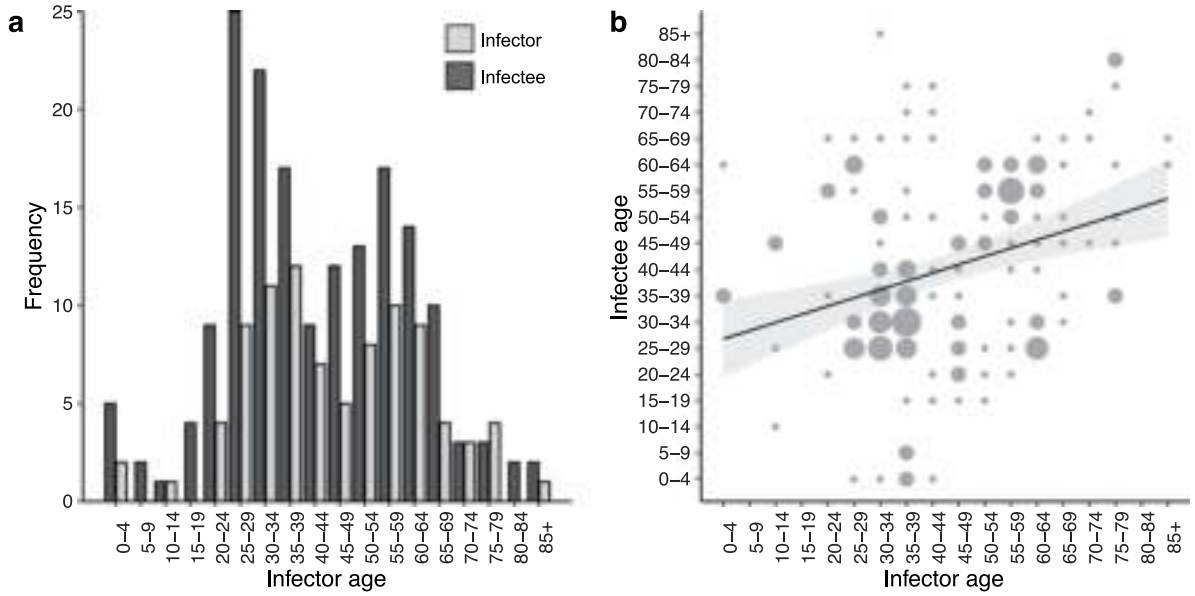
Extended Data Fig. 2 | Epidemic curve of daily SARS-CoV-2 infection in Hong Kong by symptom presentation. Epidemic curve of daily SARS-CoV-2 infection in Hong Kong by symptom presentation. Asymptomatic cases are indexed here by detection/confirmation date otherwise illness onset date is used. (Total = 1,038; Symptomatic = 843 [81.2%]; Asymptomatic = 195 [18.8%]).



Extended Data Fig. 3 | Characteristics of 106 'bar and band' SARS-CoV-2 cluster cases in Hong Kong. a, Epidemic curve of cases by onset date and transmission generation. Asymptomatic cases are included by date of confirmation. **b**, Age distribution of cases by generation. **c**, Period of symptom onset-to-confirmation and isolation of cases Asymptomatic cases are excluded due to a lack of reported onset date. *Two of the first customers described in the results with the earliest exposure dates linked to the cluster. ^Two staff at the first bar with the earliest onset and extended periods from onset to isolation. MThe first musician case who traveled between the other bars and is a potential but unconfirmed source of the remaining primary cases many of which reported exposure to the bar between the infectious period of the musician.



Extended Data Fig. 4 | Characteristics of SARS-CoV-2 transmission in Hong Kong with additional fitted distributions. a, Serial interval distribution among symptomatic SARS-CoV-2 infector-infectee pairs (n = 142) with fitted gamma (solid line), Weibull (dashed line) and lognormal (dotted) distributions. All distributions were fitted excluding observations ≤0. **b**, Empirical offspring distribution of n = 91 SARS-CoV-2 infectors, n = 153 terminal infectees and n = 46 sporadic local cases in Hong Kong with fitted geometric (solid – triangle) and Poisson distributions (dotted – square). Distribution parameters for a and b are shown in Supplementary Tables 3, 4.



Extended Data Fig. 5 | Age comparison among and between 169 SARS-CoV-2 transmission pairs. a, Age group distribution of infectors and infectees. The mean age difference between infectors (μ = 42.5) and infectees (μ = 46.1) was not significantly different (Two-sided t-test, t = −1.33 [−7.57, 1.49], df = 193.88, p-value = 0.18 without adjustment. Pairs were dependent only on the intermediate position in the transmission chain, so cases could be both an infector and infectee. **b**, Contact patterns among pairs by age group. The size of each point indicates the relative number of pairs in each combination. A significant positive trend by age group is shown (linear regression, F = 15.24, df = 156, R2 = 0.08, two=sided p-value = 0.000141 without adjustment). Shaded area indicates the 95% confidence interval of the regression. Age was missing for one case confirmed outside of Hong Kong and is excluded here.

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see our Editorial Policies and the Editorial Policy Checklist.

Statistics

For all statistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.

n/a	Confirmed	
☐	☒	The exact sample size (*n*) for each experimental group/condition, given as a discrete number and unit of measurement
☒	☐	A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
☐	☒	The statistical test(s) used AND whether they are one- or two-sided *Only common tests should be described solely by name; describe more complex techniques in the Methods section.*
☒	☐	A description of all covariates tested
☒	☐	A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
☐	☒	A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
☐	☒	For null hypothesis testing, the test statistic (e.g. *F*, *t*, *r*) with confidence intervals, effect sizes, degrees of freedom and *P* value noted *Give P values as exact values whenever suitable.*
☒	☐	For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
☒	☐	For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
☐	☒	Estimates of effect sizes (e.g. Cohen's *d*, Pearson's *r*), indicating how they were calculated

Our web collection on statistics for biologists contains articles on many of the points above.

Software and code

Policy information about availability of computer code

Data collection	Data was collected in MS Excel 365
Data analysis	All analyses were conducted with R version 3.6.1 (R Development Core Team, Vienna, Austria) and the 'fitdisterplus' package v1.0-14. Code for all analyses and figure production is available from https://github.com/dcadam/covid-19-sse

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors and reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research guidelines for submitting code & software for further information.

Data

Policy information about availability of data

All manuscripts must include a data availability statement. This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A list of figures that have associated raw data
- A description of any restrictions on data availability

All anonymized data collected and used for analysis are publicly available at https://github.com/dcadam/covid-19-sse

Field-specific reporting

Please select the one below that is the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

☒ Life sciences ☐ Behavioural & social sciences ☐ Ecological, evolutionary & environmental sciences

For a reference copy of the document with all sections, see nature.com/documents/nr-reporting-summary-flat.pdf

Life sciences study design

All studies must disclose on these points even when the disclosure is negative.

Sample size	Analysis was based on all available data on 1,038 COVID-19 cases in Hong Kong as of 28 April 2020
Data exclusions	No exclusions
Replication	This was an observational study collecting all available data without experimental conditions so no replication was necessary
Randomization	This was an observational study collecting all available data without experimental conditions so no randomization was necessary
Blinding	This was an observational study collecting all available data without experimental conditions so no blinding was necessary

Reporting for specific materials, systems and methods

We require information from authors about some types of materials, experimental systems and methods used in many studies. Here, indicate whether each material, system or method listed is relevant to your study. If you are not sure if a list item applies to your research, read the appropriate section before selecting a response.

☒	☐ MRI-based neuroimaging

Human research participants

Policy information about studies involving human research participants

Population characteristics	All COVID-19 patients in Hong Kong reported by the Centre for Health Protection of Hong Kong Special Administrative Region. Data collected included age, sex (M/F), symptom presentation (Y/N), date of symptom onset (if symptomatic), date of confirmation, contact setting with another confirmed case, quarantined as a contact of another case (Y/N) and travel-history.
Recruitment	No recruitment was necessary.
Ethics oversight	Ethics approval for this study was obtained from the Institutional Review Board of the University of Hong Kong. Data collection and analysis were part of a continuing public health outbreak investigation. Informed consent was not required.

Note that full information on the approval of the study protocol must also be provided in the manuscript.

Enhanced Epidemiologic Summary

COVID-19 Outbreaks and Cases in Ontario, by Setting: February 16, 2020 to December 26, 2020

This report includes the most current information available from the Ontario Ministry of Health (MOH) Case and Contact Management Solution (CCM) and other case management systems (CCM plus) as of **January 11, 2021.**

Please visit the interactive Ontario COVID-19 Data Tool to explore recent COVID-19 data by public health unit, age group, sex, and trends over time.[1] A Daily Epidemiological Summary, a Weekly Epidemiological Summary, as well as additional Enhanced Epidemiological Reports are available on the Public Health Ontario website.[2,3]

Purpose

This report provides an epidemiologic summary of cumulative confirmed COVID-19 outbreaks and outbreak-associated cases in Ontario by setting, with a focus on outbreaks and cases reported from other settings (i.e., outbreaks and associated cases outside of congregate care, congregate living and education settings). This report includes all COVID-19 cases linked to an outbreak.

Highlights

- In Ontario, from February 16, 2020 to December 26, 2020, there were 39,774 confirmed COVID-19 cases associated with 4,151 outbreaks reported across all settings. In comparison, there were 136,496 non-outbreak associated cases of COVID-19 reported in Ontario during the same period.
- Of the 4,151 outbreaks, 38.8% were in congregate care settings, 11.3% in congregate living settings, 17.7% in education settings, and 32.2% in other settings (Table 1).
    - Overall, long-term care homes (within congregate care settings) accounted for the largest proportion of all outbreaks (905/4,151, 21.8%).
    - Within other settings, workplaces accounted for the majority of outbreaks (872/1,335, 65.3%).
- Of the 39,774 outbreak-associated cases, 63.2% were in congregate care settings, 7.1% in congregate living settings, 6.2% in education settings, and 23.5% in other settings (Table 2).
    - Overall, long-term care homes accounted for the largest proportion of all reported outbreak-associated cases (18,475/39,774, 46.4%).

    - Within other settings, workplaces accounted for the majority of outbreak-associated cases (6,991/9,344, 74.8%).

    - Overall, across all setting types, a median of 2 cases (interquartile range [IQR]: 1-6) per outbreak was reported, with the highest median associated with farm workplace outbreaks (median of 14 cases per outbreak, maximum of 240 cases).

- Deaths were reported in 9.3% of all outbreak associated cases (Table 3).

    - Overall, long-term care homes accounted for the largest proportion of all outbreak-associated deaths (2,911/3,681, 79.1%).

- Compared to non-outbreak cases, a higher proportion of females and individuals 80 years and older were associated with outbreaks (Table 4).

- During the first wave of the pandemic, outbreaks were most commonly reported in congregate care settings. While fewer total outbreaks were reported during the first wave, these outbreaks were generally associated with more cases, peaking at 2,929 cases during week 16 (April 12, 2020 to April 18, 2020).

- In wave two, from August 30, 2020 (week 36) onward, the total number of outbreaks reported weekly increased. The number of outbreaks in congregate care continued to be significant, and outbreaks reported within congregate living, education, and other settings increased. Outbreak-associated cases have been steadily rising from week 36 onward.

Limitations

- The findings presented in this report include all cases and settings where local public health units declared an outbreak in a given setting. The outbreaks included in this report do not present the complete picture of settings where COVID-19 is being transmitted in Ontario, and may under-represent outbreaks in settings where contact tracing is more difficult.

- Outbreak-associated cases in this report do not include secondary cases acquired from outbreak-associated cases. As such, this report likely under-represents the true magnitude of cases impacted by a COVID-19 outbreak.

- Outbreak-associated cases in this report include all cases directly linked to an outbreak as determined by the local public health unit, but may not reflect where the case acquired the infection. Cases could represent employees, residents or members of the public.

- Definitions of outbreaks, including the number of cases, vary across settings. In addition, due to variations in data entry processes across public health units, some outbreaks included in this report may not have met the criteria included in an outbreak definition (i.e. size or duration of outbreak). Further there is no provincial outbreak definition for several setting types classified within the other settings category; as such, there may be variation in declaring outbreaks by public health unit.

- Trends in outbreaks reported across settings and within settings over time should be interpreted with caution, as provincial restrictions resulted in closures of several settings (e.g., school settings were subject to closure during wave one, and were permitted to open approximately

around week 36). The results in this report therefore do not represent a comprehensive assessment of risk in different settings.

Outbreak Characteristics

Table 1. Cumulative summary of confirmed COVID-19 outbreaks reported between February 16, 2020 and December 26, 2020, by setting type: Ontario

Setting Type	Number of outbreaks	Median number of cases per outbreak (IQR)	Maximum number of cases per outbreak	Median duration of closed outbreaks in days [1] (IQR)
Congregate care	**1,612**	**2 (1 - 9)**	**316**	**9 (0 - 21)**
Long-term care homes	905	2 (1 - 8)	316	9 (0 - 22)
Retirement homes	475	2 (1 - 7)	128	6 (0 - 18)
Hospitals	232	6 (3 - 12)	103	13 (6 - 21)
Congregate living	**470**	**2 (1 - 6)**	**215**	**6 (0 - 13)**
Correctional facility	16	2 (1 - 18)	114	3 (0 - 20)
Shelter	86	2 (1 - 5)	215	3 (0 - 13)
Group home/supportive housing	309	2 (1 - 6)	84	6 (0 - 13)
Short-term accommodations	7	1 (1 - 3)	5	4 (2 - 4)
Congregate other	52	4 (1 - 8)	75	7 (1 - 14)
Education	**734**	**2 (1 - 4)**	**50**	**6 (2 - 11)**
Child care	238	1 (1 - 2)	28	3 (0 - 9)
School – Elementary[2]	348	3 (2 - 4)	50	7 (4 - 12)
School – Elementary/secondary[2]	24	4 (2 - 6)	46	6 (2 - 14)
School – Secondary[2]	111	2 (2 - 5)	40	9 (5 - 16)
School – Post-secondary[2]	13	2 (2 - 3)	9	5 (5 - 6)

Setting Type	Number of outbreaks	Median number of cases per outbreak (IQR)	Maximum number of cases per outbreak	Median duration of closed outbreaks in days [1] (IQR)
Other settings[3]	**1,335**	**3 (1 - 6)**	**240**	**9 (5 - 16)**
Bar/restaurant/nightclub	122	3 (2 - 5)	40	7 (4 - 11)

Setting Type	Number of outbreaks	Median number of cases per outbreak (IQR)	Maximum number of cases per outbreak	Median duration of closed outbreaks in days [1] (IQR)
Manufacturing	298	3 (1 - 7)	57	12 (7 - 19)
Other[8]	228	3 (1 - 5)	56	7 (4 - 11)
Unknown	10	2 (0 - 15)	42	3 (0 - 22)
Total	**4,151**	**2 (1 - 6)**	**316**	**8 (2 - 16)**

Notes: Due to reporting delays and potential variations in data entry processes across public health units, there may be additional COVID-19 cases that have not yet been entered in CCM plus, or have not been entered as linked to an outbreak. As such, some outbreaks may have zero linked cases. This includes 121 outbreaks in congregate care, 46 outbreaks in congregate living, 61 outbreaks in education, and 204 outbreaks in other settings. Ongoing re-classification of settings for reported outbreaks can result in outbreak counts that may differ from counts previously reported in other reports. See Appendix A for full descriptions of outbreak categories.

[1]The median duration of outbreaks was only measured for outbreaks with a "Closed" Outbreak Classification status. Outbreak length was calculated using the 'Outbreak Date' as the start date and the 'Outbreak Date End' as the end date. The "Outbreak Date" is a calculated field used to determine the outbreak declared date using the following hierarchy of date fields (Onset date of the first case > Reported Date > Created Date). The "Outbreak Date End" is a calculated field used to determine the end date of the outbreak using the following hierarchy of date fields (Onset date of the last case > Date the outbreak was declared over). Due to variations in data entry practices and variability in case definitions, this can result in outbreaks having a duration length of 0 days (i.e. if only a single case is linked to an outbreak, the symptom onset date for the first and last case will be the same).

[2]Cumulative counts include COVID-19 school outbreaks reported starting week 36 (August 30 to September 5, 2020).

[3]Not all settings were open during the reporting period due to provincial public health measures.

[4]Captures outbreaks classified as having taken place in other medical/health-service related settings, including community health centres, home care services and wellness clinics.

[5]Captures outbreaks classified as having taken place in recreational settings including athletic facilities, recreational/community centres, golf courses, tennis courts and indoor playgrounds.

[6]Captures outbreaks classified as having taken place in auto dealerships and standalone retailers, as well as big box stores, among other retail settings.

[7]Captures outbreaks classified as having taken place in theatres, banquet halls (not including weddings), private transportation, private residences, and other community settings.

[8]Captures outbreaks classified as having taken place in locations such as: offices, banks, municipal services (e.g., fire station, police station), and veterinary clinics.

Other[7]	377	61.5	35 (24 - 51)
Culture and other recreation	620	51.8	33 (21 - 53)
Places of worship	221	52.9	40 (27 - 57)
Private events	193	54.9	30 (23 - 49)
Other[8]	206	47.6	28 (18 - 48)
Workplace	6,991	72.6	39 (29 - 51)
Construction	202	90.1	40 (28 - 51)
Logistics	1,211	58.8	36 (26 - 49)
Farm	1,779	86.6	35 (28 - 43)
Food processing	1,253	66.4	41 (30 - 52)
Manufacturing	1,681	75.1	47 (34 - 56)
Other[9]	865	63.1	41 (29 - 54)
Unknown	86	58.1	30 (21 - 47)
Total	**39,774**	**39.8**	**54 (34 - 81)**

Notes: See Appendix A for full descriptions of outbreak categories.
[1]Not all cases have a gender reported. The denominator for calculating male case percentages includes all cases.

[2]Includes all cases linked to an outbreak regardless of attendance/residence within the outbreak setting. Therefore, the range of ages of cases associated with an outbreak may not align with expected ages within that setting.
[3]Cumulative counts include COVID-19 school outbreaks reported starting week 36 (August 30 to September 5, 2020).
[4]Not all settings were open during the reporting period due to provincial public health measures.
[5]Captures outbreaks classified as having taken place in other medical/health-service related settings, including community health centres, home care services and wellness clinics.
[6]Captures outbreaks classified as having taken place in recreational settings including athletic facilities, recreational/community centres, golf courses, tennis courts and indoor playgrounds.
[7]Captures outbreaks classified as having taken place in auto dealerships and standalone retailers, including big box stores, among other retail settings.
[8]Captures outbreaks classified as having taken place in theatres, banquet halls (not including weddings), public and private transportation, private residences and other community settings.
[9]Captures outbreaks classified as having taken place in offices, banks, municipal services (e.g. fire station, police station), and veterinary clinics, among others.

Other[8]	13 (1.5%)	2 (0.2%)	0.4%	0.1%
Unknown	7 (8.1%)	0 (0.0%)	0.2%	0.0%
Total	**3,460 (8.7%)**	**3,681 (9.3%)**	100.0%	100.0%

Notes: See Appendix A for full descriptions of outbreak categories.
[1]Hospitalized cases associated with outbreaks classified within a hospital can include patients, staff or other hospital visitors. The number of hospitalized cases in hospital outbreak settings is lower than the total number of cases reported in hospital outbreak settings (Table 2), as the total number of cases includes healthcare workers in the facility who may not have been hospitalized.
[2]Includes COVID-19 school outbreaks reported starting week 36 (August 30 to September 5, 2020).
[3]Not all settings were opened during the reporting period due to provincial public health measures.
[4]Captures outbreaks classified as having taken place in other medical/health-service related settings, including community health centres, home care services and wellness clinics.
[5]Captures outbreaks classified as having taken place in recreational settings including athletic facilities, recreational/community centres, golf courses, tennis courts and indoor playgrounds.
[6]Captures outbreaks classified as having taken place in auto dealerships and standalone retailers, including big box stores, among other retail settings.
[7]Captures outbreaks classified as having taken place in theatres, banquet halls (not including weddings), public and private transportation, private residences and other community settings.
[8]Captures outbreaks classified as having taken place in offices, banks, municipal services (e.g. fire station, police station), and veterinary clinics, among others.
Data Source: CCM plus

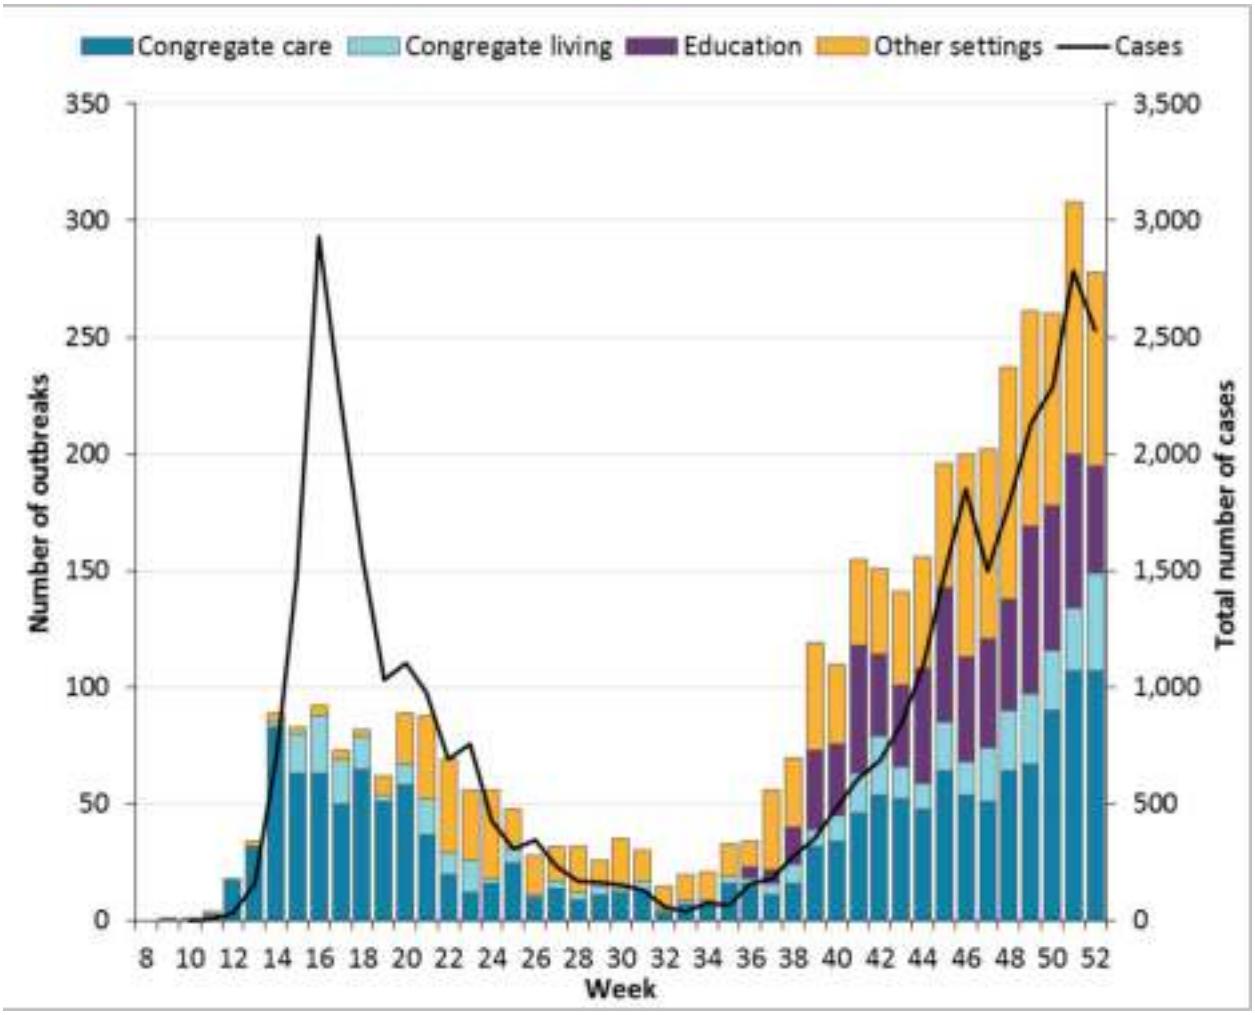
Table 4. Demographic characteristics of non-outbreak and outbreak-associated cases reported between February 16, 2020 and December 26, 2020

	Non-outbreak cases	Outbreak cases
Total number of cases	**136,496**	**39,774**
Gender: Female	65,801 (48.2%)	23,567 (59.3%)
Gender: Male	70,030 (51.3%)	15,840 (39.8%)
Age: 19 and under	19,856 (14.5%)	2,512 (6.3%)
Age: 20-39	54,023 (39.6%)	9,796 (24.6%)
Age: 40-59	40,039 (29.3%)	10,425 (26.2%)
Age: 60-79	19,086 (14.0%)	6,466 (16.3%)
Age: 80 and over	3,473 (2.5%)	10,565 (26.6%)

Note: Not all cases have an age or gender reported. The denominator for calculating percentages includes all cases.
Data Source: CCM plus

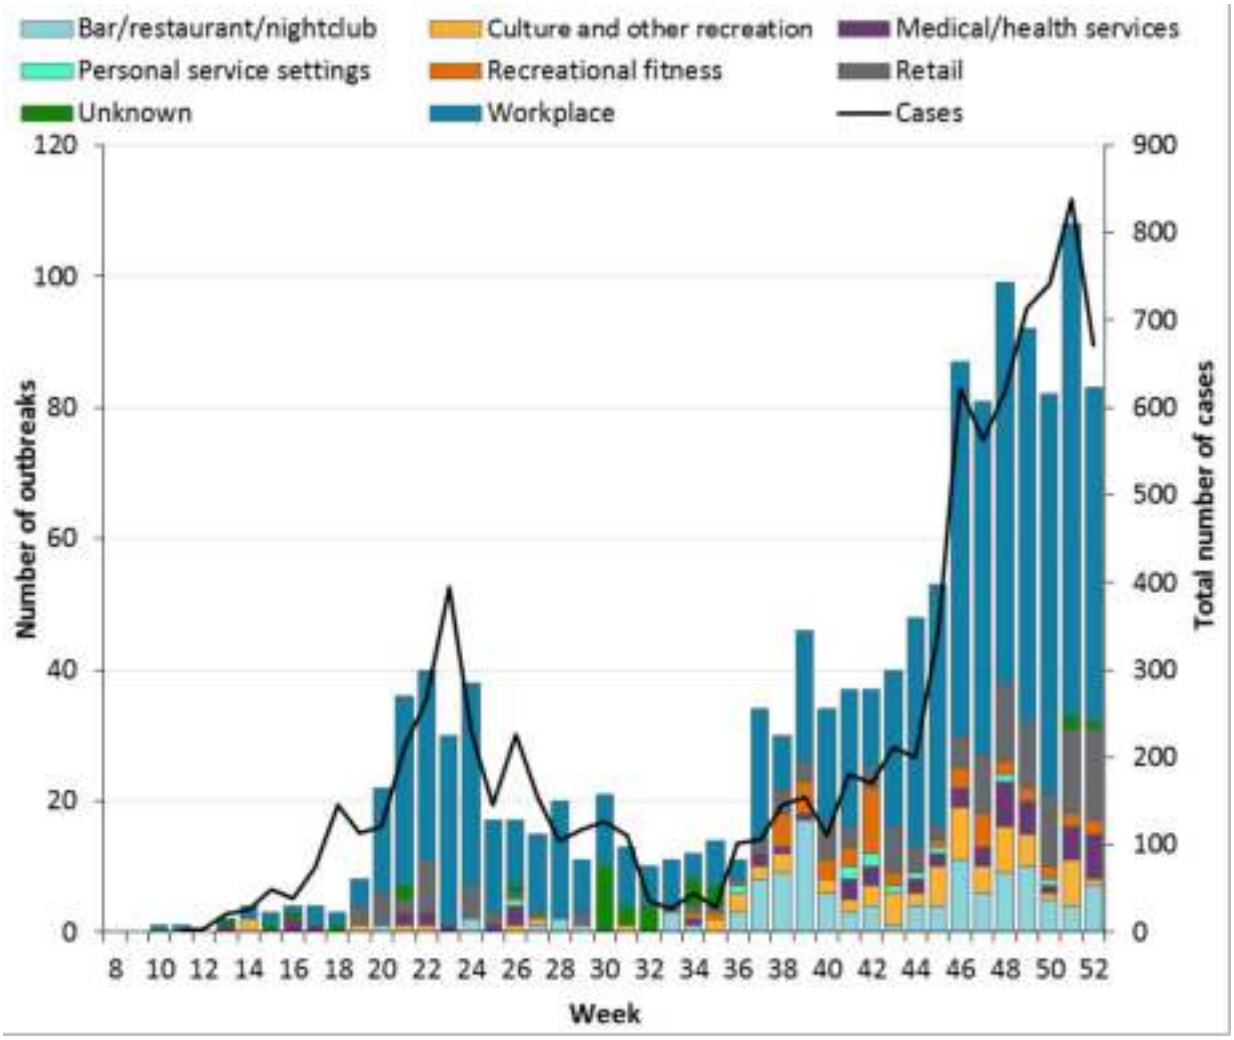
Time Trends

Figure 1a. Total number of public health unit declared COVID-19 outbreaks, and number of confirmed outbreak-associated cases, by setting type and week, reported between week 8 (February 16, 2020) and week 52 (December 26, 2020): Ontario



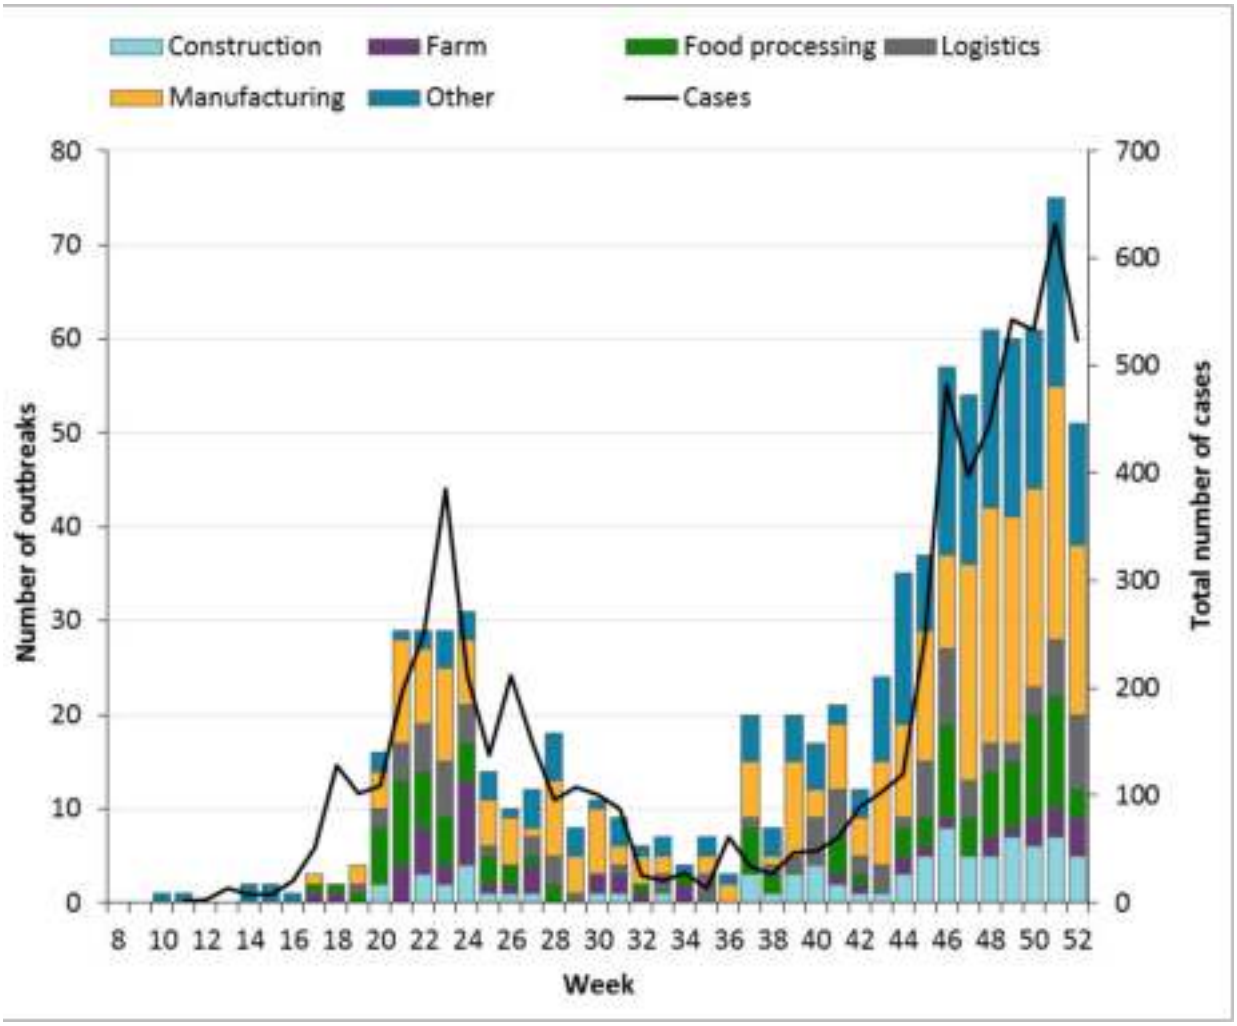
Notes: Number of outbreaks is based on week the outbreak was declared, while total number of cases is based on case reported week. Since many outbreaks are still ongoing, there were 3,261 cases with case reported dates that occurred outside of the week ranges of focus and were therefore not included in the figure. Includes outbreaks that are ongoing and outbreaks that are no longer active. Not all settings were open during the reporting period due to provincial public health measures. See Appendix A for full descriptions of outbreak categories.
Data Source: CCM plus

Figure 1b. Number of public health unit declared COVID-19 outbreaks in other settings, and number of confirmed other setting outbreak-associated cases, by setting type and week, reported between week 8 (February 16, 2020) and week 52 (December 26, 2020): Ontario



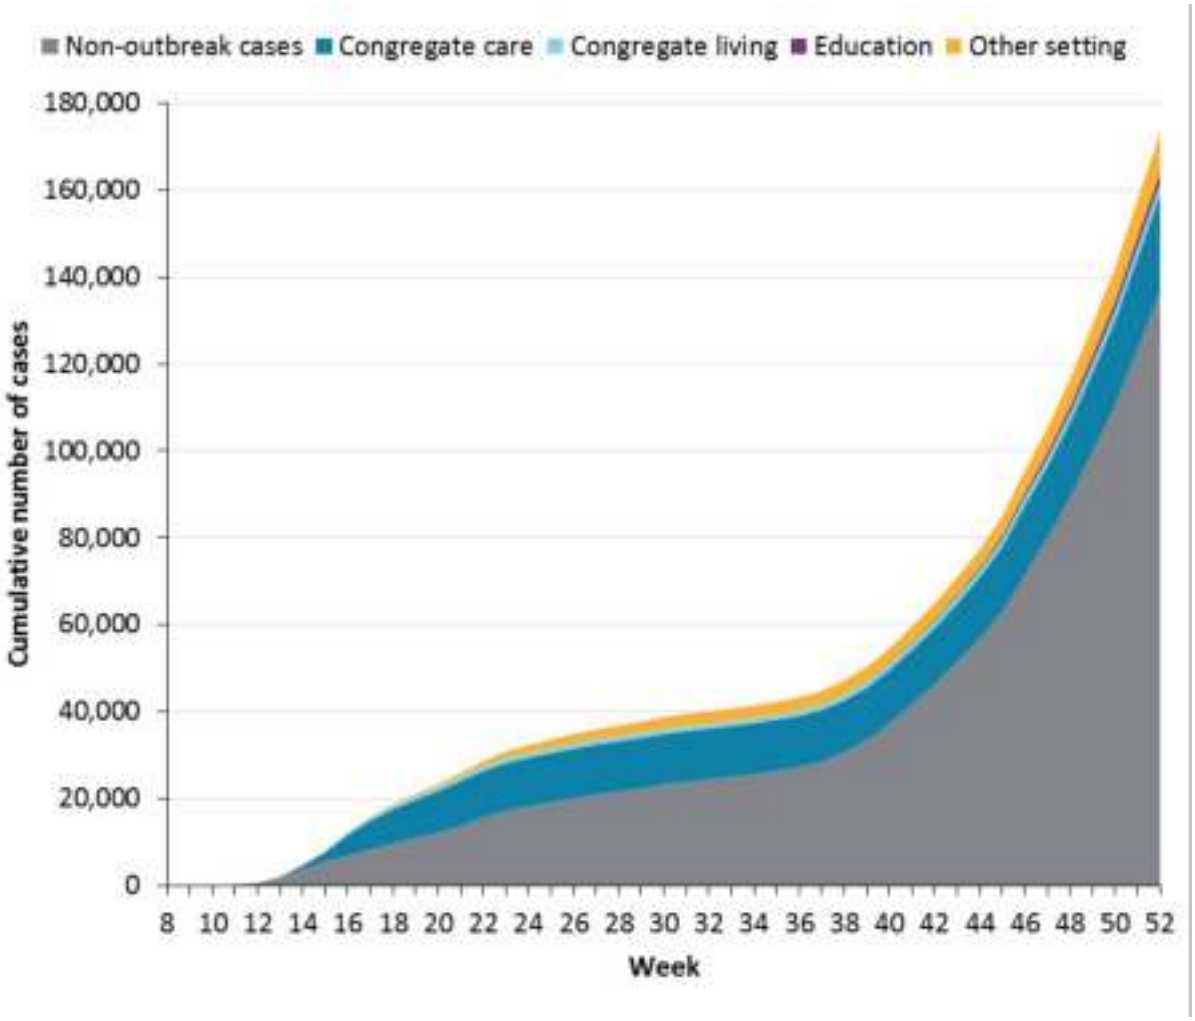
Notes: Number of outbreaks is based on week the outbreak was declared, while total number of cases is based on case reported week. Since many outbreaks are still ongoing, there were 399 cases with case reported dates that occurred outside of the week ranges of focus and were therefore not included in the figure. Includes outbreaks that are ongoing and outbreaks that are no longer active. Not all settings were open during the reporting period due to provincial public health measures. See Appendix A for full descriptions of outbreak categories.
Data Source: CCM plus

Figure 1c. Number of confirmed public health unit declared COVID-19 workplace[1] outbreaks, and number of confirmed workplace outbreak-associated cases, by setting type and week, reported between week 8 (February 16, 2020) and week 52 (December 26, 2020): Ontario



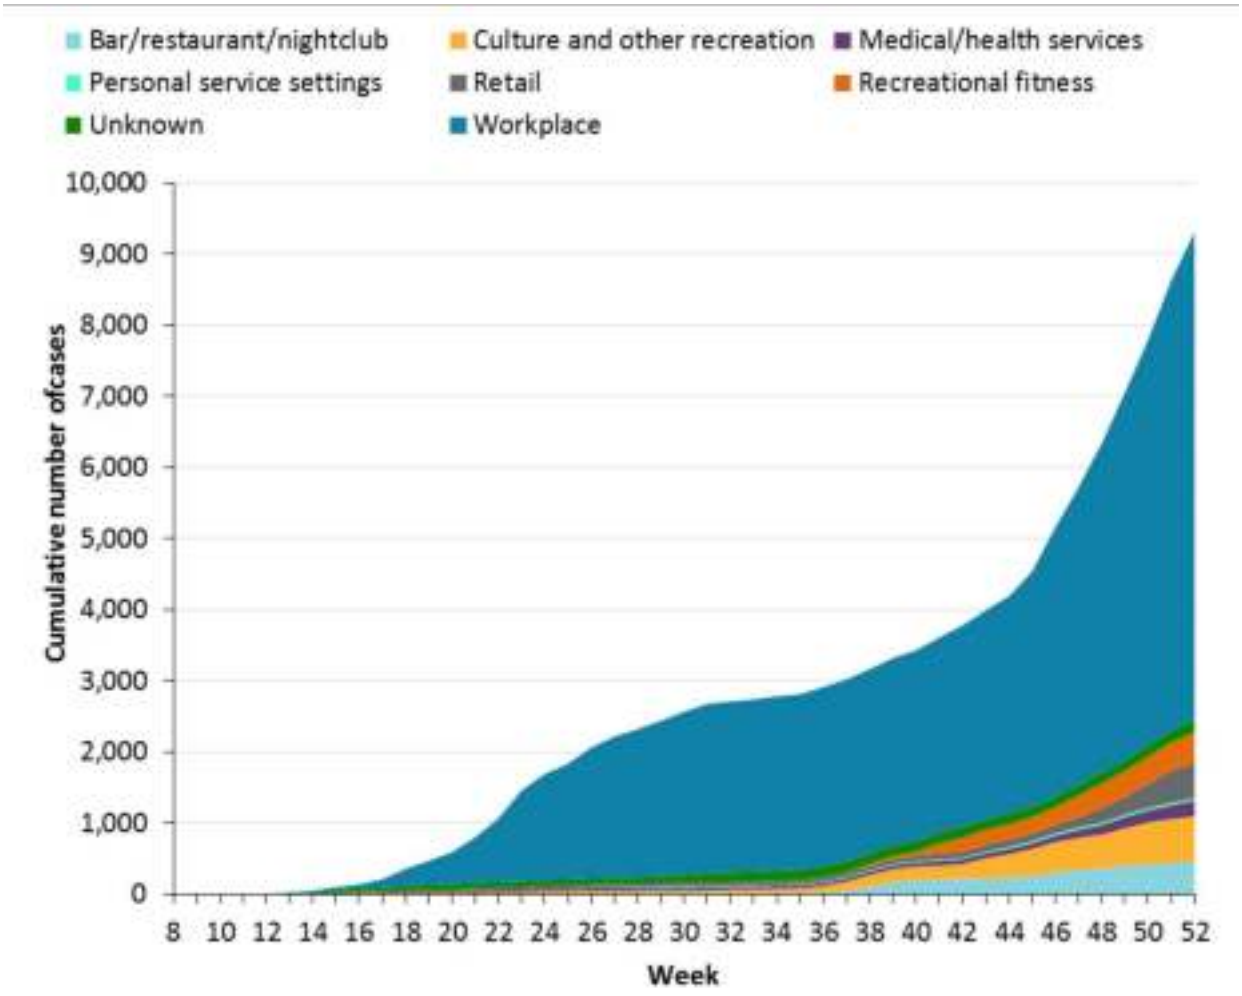
Notes: Number of outbreaks is based on week the outbreak was declared, while total number of cases is based on case reported week. Since many outbreaks are still ongoing, there were 347 cases with case reported dates that occurred outside of the week ranges of focus and were therefore not included in the figure. Includes outbreaks that are ongoing and outbreaks that are no longer active. Not all settings were open during the reporting period due to provincial public health measures. See Appendix A for full descriptions of outbreak categories.
[1]Workplaces do not include publically-accessible settings where people may also work (i.e., restaurants, gyms).
Data Source: CCM plus

Figure 2a. Cumulative number of outbreak and non-outbreak cases, by setting type and week, reported between week 8 (February 16, 2020) and week 52 (December 26, 2020): Ontario



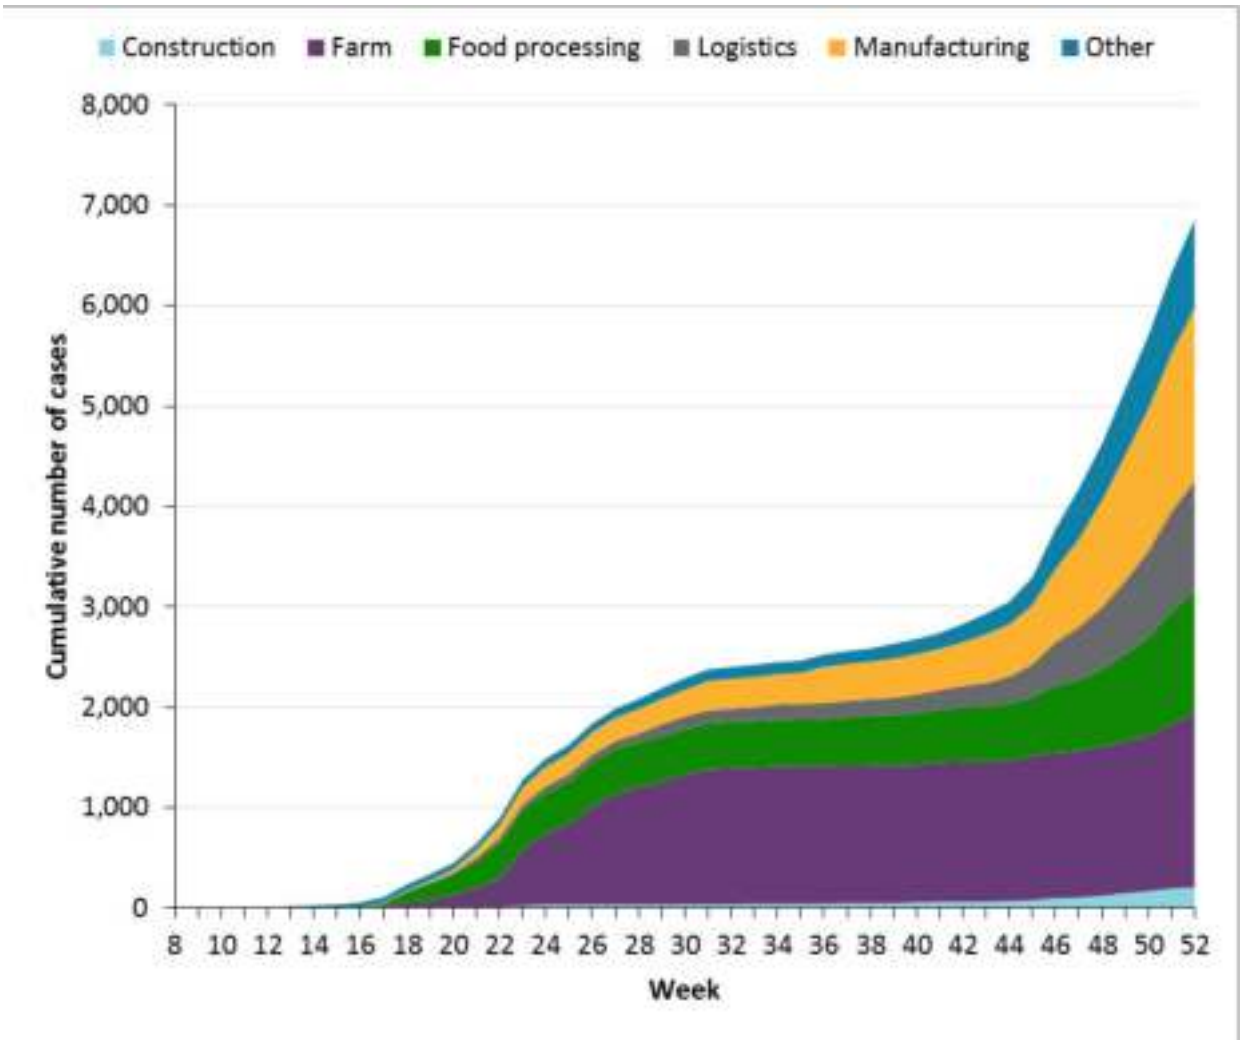
Notes: Based on case reported week. Non-outbreak cases refers to all COVID-19 cases not linked to a declared outbreak reported between weeks 8 and 52. Since many outbreaks are still ongoing, there were 3,267 outbreak-linked cases with case reported dates that occurred outside of the week ranges of focus and were therefore not included in the figure. Includes outbreaks that are ongoing and outbreaks that are no longer active. Not all settings were open during the reporting period due to provincial public health measures. See Appendix A for full descriptions of outbreak categories.
Data Source: CCM plus

Figure 2b. Cumulative number of confirmed cases from other setting outbreaks, by setting type and week, reported between week 8 (February 16, 2020) and week 52 (December 26, 2020): Ontario



Notes: Based on case reported week. Since many outbreaks are still ongoing, there were 399 cases with case reported dates that occurred outside of the week ranges of focus and were therefore not included in the figure. Includes outbreaks that are ongoing and outbreaks that are no longer active. Not all settings were open during the reporting period due to provincial public health measures. See Appendix A for full descriptions of outbreak categories.
Data Source: CCM plus

Figure 2c. Cumulative number of confirmed cases from workplace[1] outbreaks, by setting type and week, reported between week 8 (February 16, 2020) and week 52 (December 26, 2020): Ontario



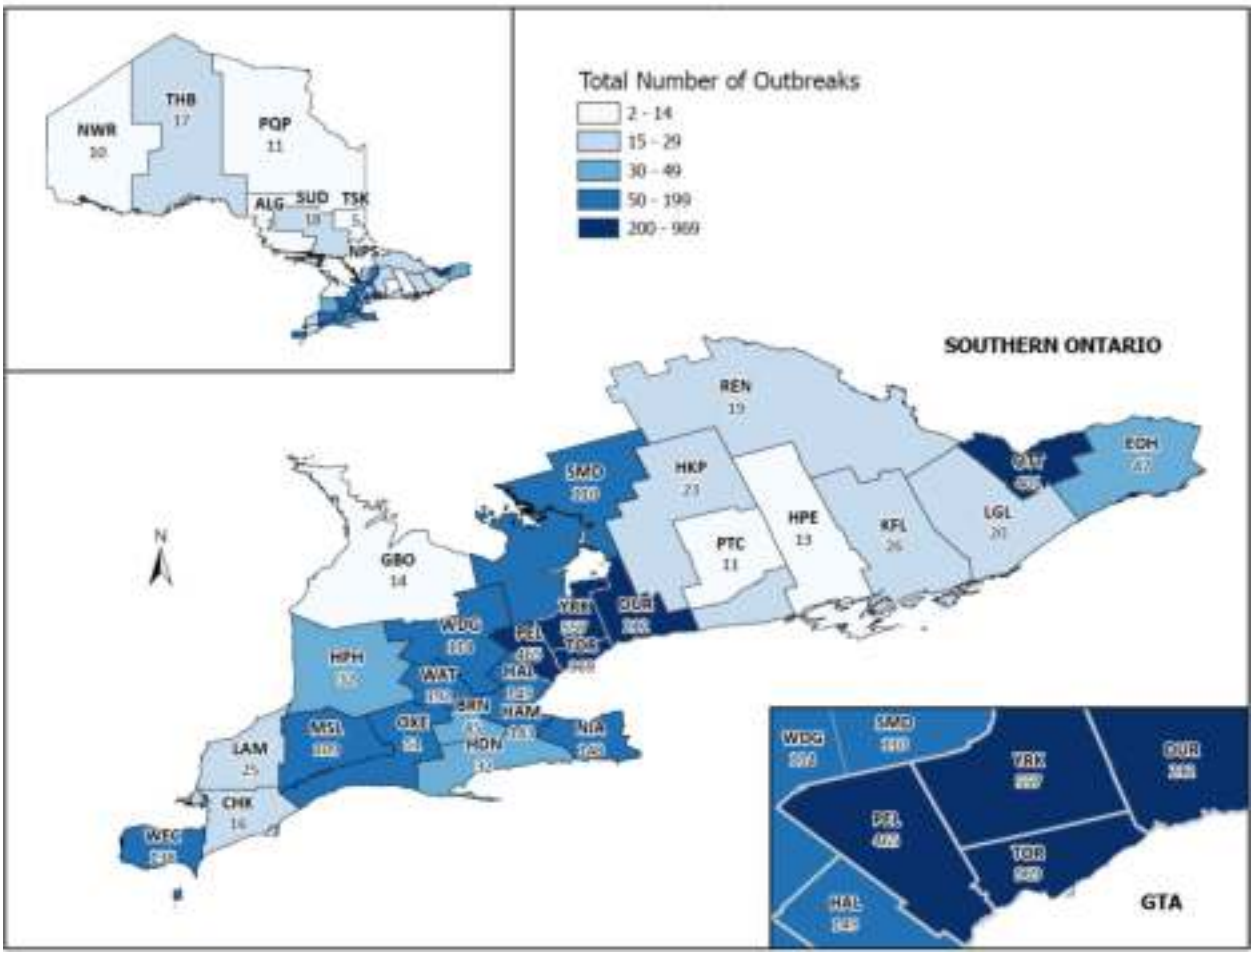
Notes: Based on case reported week. Since many outbreaks are still ongoing, there were 347 cases with case reported dates that occurred outside of the week ranges of focus and were therefore not included in the figure. Includes outbreaks that are ongoing and outbreaks that are no longer active. Not all settings were open during the reporting period due to provincial public health measures. See Appendix A for full descriptions of outbreak categories.

[1]Workplaces do not include publically-accessible settings where people may also work (i.e., restaurants, gyms).

Data Source: CCM plus

Geography

Figure 3. Number of confirmed COVID-19 outbreaks reported between February 16, 2020 and December 26, 2020 by public health unit: Ontario



Note: Includes outbreaks that are ongoing and outbreaks that are no longer active. Cut-offs for map categories were determined by natural breaks and adjusted for round numbers. Geography is based on public health unit where the outbreak was declared. Not all settings were open during the reporting period due to provincial public health measures. There was one outbreak that involved cases from Ontario and outside of Ontario and was not assigned to a public health unit. The data in this map are also available in Appendix B.
Data Source: CCM plus

Technical Notes

Data Sources

- The data for this report were based on:
    - Information extracted from the Ontario Ministry of Health (Ministry) integrated Public Health Information System (iPHIS) database for Toronto Public Health as of **January 11, 2021 at 1 p.m.**
    - Information successfully uploaded to the Ministry from Local Systems: Toronto Public Health (Coronavirus Rapid Entry System) CORES as of **January 11, 2021 at 2 p.m.**
    - Information successfully extracted from the Public Health Case and Contact Management Solution (CCM) for all other PHUs by PHO as of **January 11, 2021 at 1 p.m.**
- CCM and CCM plus (which includes CCM, iPHIS and CORES) are dynamic disease reporting systems, which allow ongoing updates to data previously entered. As a result, data extracted from CCM and the Local Systems represent a snapshot at the time of extraction and may differ from previous or subsequent reports. This applies to both case and outbreak data.

Data Caveats:

- The data included are for outbreaks reported in Ontario from February 16, 2020 to December 26, 2020 and cases linked to those outbreaks up until January 11th, 2021.
- Only confirmed outbreaks are included in this report.
- The outbreak data for these settings are restricted to those in which an outbreak was declared by the public health unit. The data also do not include cases linked to these settings as an exposure. Outbreaks are declared by the local medical officer of health or their designate in accordance to the Health Protection and Promotion Act and criteria outlined in Ministry guidance documents.[4]
- For outbreaks declared in certain settings such as long-term care, hospitals, educational settings, and workplaces, there are provincial outbreak definitions.[5-7] These definitions may have single case thresholds, and may also include changes in the case thresholds for declaring an outbreak over time (i.e.,., the threshold for declaring an outbreak in a child care setting increased from one to two cases as of November 9, 2020).[8] However, there is no provincial case definition for several other setting types reported as other settings. As such, a standard approach to declaring an outbreak across these settings may differ by public health unit.
    - All other setting outbreaks were manually classified based on the name, address, and additional relevant information available in CCM for the outbreak, as entered by the PHU. other setting outbreaks consisted of outbreaks outside of congregate care settings (i.e., hospitals, long-term care, retirement home), congregate living settings (i.e., correctional facilities, shelters, group homes, other congregate), and education settings (i.e., childcare settings and schools). All outbreak classifications are mutually exclusive. However, an outbreak declared in a restaurant may have been a workplace outbreak if cases were

identified among staff only. For the purposes of this report, a setting-based hierarchy was used.

    - Outbreaks reported in the workplace – arm category may include cases related to shared living amongst farm staff. As such, some of these outbreaks may be more similar to outbreaks in congregate living settings.

- For additional information regarding outbreak setting type classification definitions, please refer to Table 1 in the Appendix. Some outbreaks may be misclassified due to lack of information to assist with the manual classification process.

- All outbreaks reported as confirmed in CCM plus were included in these analyses regardless of whether the case data in CCM plus supported the outbreaks' classification.

- Due to reporting delays and potential variations in data entry processes across public health units, there may be additional COVID-19 cases that have not yet been entered in CCM plus, or have not been entered as linked to an outbreak. As such, some outbreaks may have zero linked cases as of the data extraction date. Results should be interpreted with caution due to potential under-detection of outbreak associated cases.

- The data only represent cases reported to public health units and recorded in CCM plus. As a result, all counts will be subject to varying degrees of underreporting due to a variety of factors, such as disease awareness and medical care seeking behaviours, which may depend on severity of illness, clinical practice, changes in laboratory testing, and reporting behaviours.

- Lags in CCM plus data entry due to weekend staffing may result in lower case counts than would otherwise be recorded.

- Outbreak-associated cases do not include secondary cases acquired from outbreak-associated cases.

- The data for these settings are restricted to those in which an outbreak was declared by the public health unit. They do not include cases linked to these settings as an exposure.

- Cases with unknown or missing ages were excluded from age-specific analyses.

- Only cases meeting the confirmed case classification as listed in the MOH COVID-19 case definition are included in the report counts from CCM plus.[4] This includes persons with a positive detection of serum/plasma immunoglobulin G (IgG) antibodies to SARS-CoV-2, which was added to the confirmed case definition on August 6, 2020.

- Cases of confirmed reinfection, i.e., where genome sequencing indicates the two episodes are caused by different viral lineages, added to the confirmed case definition on November 20, 2020, are counted as unique investigations.

- Case reported week uses the date the case was reported to the public health unit.

    - Outbreak reported week uses the date the public health unit reported the outbreak. If this date is unavailable, the date the public health unit created the outbreak is used.

    - Reported weeks were created to align with the Public Health Agency of Canada (PHAC) influenza surveillance weeks.

- ‘Cases associated with school outbreaks’ include cases that are linked to an outbreak, by school classification type (Elementary, Elementary/Secondary, Secondary, Post-Secondary), that met the definition of a school outbreak.

- School classification types are defined by the Ministry of Education. Some schools classified as secondary may also have an intermediate school in the same location that start in Grade 7.

    - Elementary/Secondary schools include public or private schools educating children in a combination of elementary and secondary grades (e.g., Kindergarten to Grade 8, Grades 9 to 12, and Kindergarten to Grade 12).

- School outbreaks include outbreaks declared on or after week 36 (August 30 to September 5, 2020).

- Hospitalization includes all cases for which a hospital admission date was reported at the time of data extraction. It includes cases that have been discharged from hospital as well as cases that are currently hospitalized. Emergency room visits are not included in the number of reported hospitalizations.

- Deaths are determined by using the outcome field in CCM. Any case marked ‘Fatal’ is included in the deaths data. The CCM field Type of Death is not used to further categorize the data.

- Ongoing outbreaks are those that are reported in CCM plus as ‘Open’ and without a ‘Declared Over Date’ recorded. Closed outbreaks are ‘Closed’ or have a ‘Declared Over Date’ recorded in CCM plus or where the outbreak start date (determined by the onset date of first case, or if missing the reported date, or if missing the created date) is more than 5 months from the current date, even for outbreaks where the outbreak status value selected in CCM/iPHIS is 'OPEN'.

- Orientation of case counts by geography is based on the diagnosing health unit (DHU). DHU refers to the case's public health unit of residence at the time of illness onset and not necessarily the location of exposure. Cases for which the DHU was reported as MOH (to signify a case that is not a resident of Ontario) have been excluded from the analyses.

- COVID-19 cases from CCM plus for which the Classification and/or Disposition was reported as ENTERED IN ERROR, DOES NOT MEET DEFINITION, IGNORE, DUPLICATE, or any variation on these values have been excluded. The provincial case count for COVID-19 includes cases that are counted once across all systems from which the case data are obtained. Duplicate records may exist if these records were not identified and resolved prior to data upload to the Ministry.

Appendix A: Definitions of outbreak settings

Table A1. Definitions for various setting types including congregate care, congregate living, education, and other settings.

Setting type	Definitions
Congregate care	
Long-term care homes	A facility that provides care and services for people who no longer are able to live independently or who require onsite nursing care, 24-hour supervision or personal support. LTC Homes are governed under the Long Term Care Homes Act (LTCHA) and Ontario Regulation 79/10.
Retirement homes	A residential complex or the part of a residential complex, that is occupied primarily by persons who are 65 years of age or older, that is occupied or intended to be occupied by at least the prescribed number of persons who are not related to the operator of the home, and where the operator of the home makes at least two care services available, directly or indirectly, to the residents. Retirement homes are governed under the Retirement Homes Act, 2010, S.O. 2010, c. 11.
Hospitals	Any institution, building or other premises or place that is established for the purposes of the treatment of patients and that is approved under the Public Hospitals Act, R.S.O. 1990, c. P.40.
Congregate living	
Correctional facility	An institution established or continued under section 14, whether it is operated or maintained by the Ministry or by a contractor, but does not include a place of open custody, a place of secure custody, a place of temporary detention or a lock-up established under section 16.1 of the *Police Services Act*; ("établissement correctional"). Ministry of Correctional Services Act, R.S.O. 1990, c. M.22.
Shelter	A facility set up to provide for the needs of homeless people; often including temporary residence, food, sanitation and other forms of support.
Group Home/Supportive Housing	A home providing staff-supported residential accommodation in a group setting for special populations that need a supervised living environment. Common examples include children and youth in care, individuals with developmental or physical disabilities, individuals recovering from substance abuse, teenaged mothers, or victims of domestic violence.

Setting type	Definitions
Short-term accommodations	A short-term rental is all or part of a dwelling unit that is offered for accommodations for less than 28 consecutive days with or without payment. This includes but is not limited to bed and breakfasts (B&Bs), hotels and motels.
Congregate other	Other setting in which persons live in a group setting with shared amenities.
Education	
Child care	Facility that provides temporary care for or supervision of children and is operated under the Child Care and Early Years Act, 2014, S.O. 2014, c. 11.
School – Elementary	Elementary schools include a public or private school educating children in elementary (Kindergarten to Grade 8) grades
School - Elementary/Secondary	Elementary/ Secondary schools include a public or private school educating children in a combination of elementary (Kindergarten to Grade 8) and secondary (Grade 9 to 12) grades (e.g., K-12 combined).
School – Secondary	Secondary schools include a public or private school educating children in secondary (Grade 9 to 12) grades
School - Post-secondary	Educational facility offering the highest level of educational attainment including apprenticeships or trades certificate or diploma; general or vocational college, or other non-university certificate or diploma; university certificate or diploma below bachelor level; or a university degree.
Other settings	
Bar/restaurant/nightclub	A facility for socialization/entertainment where food and/or drinks may be served.

Setting type	Definitions
Medical/Health Service	A facility or business that provides health or medical services in a community or non-institutional setting. This includes but is not limited to doctors offices or clinics, wellness clinics, dental offices, and at home care.
Personal service settings	A facility that provides personal services including invasive services that is operated under the O. Reg. 136/18. (e.g. tattoo parlours, hair salons, tanning studios).
Recreational fitness	A facility that provides activities where the primary purpose of the activity is participation, with the related goals of improved physical fitness, fun, and social involvement.
Retail	A setting in which goods and/or services are sold to individual consumers for their personal use. This includes but is not limited to grocery stores, pharmacies, and shopping malls.
Culture and other recreation	A setting in which social gatherings take place, including places of worship, indoor and outdoor private events (including weddings and funerals), and other community gathering spaces.
Workplace – Construction	A workplace comprised of employees working on developing, maintaining or repairing residential and non-residential buildings, or parts within. Outbreaks and cases captured in this setting include outbreaks associated with construction worksites and may include offices related to the construction industry.
Workplace – Logistics	A workplace comprised of employees working in warehouses, transportation, shipping or postal services.
Workplace – Farm	A workplace comprised of an area of land and its buildings used for growing crops and/or rearing animals, including greenhouses.
Workplace - Food Processing	A food service establishment that is a commercial operation that processes food for human consumption, and provides processed food for sale and distribution to other business entities such as restaurants and grocery stores.
Workplace – Manufacturing	A workplace comprised of employees working at a production line, where labour and machinery are used to produce goods from raw materials and smaller components.

Setting type	Definitions
Workplace – other	Other places of employment including offices, banks, municipal services (e.g. fire station), and veterinary clinics, among others.
Unknown	Setting that cannot be classified due to missing or inadequate data.

Appendix B: Outbreaks across public health units

Table A2. Number of confirmed COVID-19 outbreaks reported between February 16, 2020 and December 26, 2020 by public health unit: Ontario

Public Health Unit Name	Abbreviation	Number of outbreaks
Algoma Public Health	ALG	2
Brant County Health Unit	BRN	45
Chatham-Kent Public Health Services	CHK	16
City of Hamilton Public Health Services	HAM	143
Durham Region Health Department	DUR	212
Eastern Ontario Health Unit	EOH	47
Grey Bruce Health Unit	GBO	14
Haldimand-Norfolk Health Unit	HDN	32
Haliburton, Kawartha, Pine Ridge District Health Unit	HKP	23
Halton Region Public Health	HAL	149
Hastings & Prince Edward Public Health	HPE	13
Huron Perth Public Health	HPH	32
Kingston, Frontenac, Lennox & Addington Public Health	KPL	26
Lambton County Public Health	LAM	25
Leeds, Grenville and Lanark District Health Unit	LGL	20
Middlesex-London Health Unit	MSL	109
Niagara Region Public Health	NIA	148
North Bay Parry Sound District Health Unit	MPS	6
Northwestern Health Unit	NWR	10
Ottawa Public Health	OTT	401

Public Health Unit Name	Abbreviation	Number of outbreaks
Peel Public Health	PEL	465
Peterborough Public Health	PTC	11
Porcupine Health Unit	PQP	11
Public Health Sudbury & District	SUD	18
Region of Waterloo Public Health and Emergency Services	WAT	192
Renfrew County and District Health Unit	REN	19
Simcoe Muskoka District Health Unit	SMD	110
Southwestern Public Health	OXE	51
Thunder Bay District Health Unit	THB	17
Timiskaming Health Unit	TSK	5
Toronto Public Health	TOR	969
Wellington-Dufferin-Guelph Public Health	WDG	114
Windsor-Essex County Health Unit	WEC	138
York Region Public Health	YRK	557

Note: Includes outbreaks that are ongoing and outbreaks that are no longer active. Geography is based on public health unit where the outbreak was declared. Not all settings were open during the reporting period due to provincial public health measures. There was one outbreak that involved cases from Ontario and outside of Ontario and was not assigned to a public health unit.
Data Source: CCM plus

Mask use in the context of COVID-19

Interim guidance

1 December 2020

World Health Organization

This document, which is an update of the guidance published on 5 June 2020, includes new scientific evidence relevant to the use of masks for reducing the spread of SARS-CoV-2, the virus that causes COVID-19, and practical considerations. It contains updated evidence and guidance on the following:

- mask management;
- SARS-CoV-2 transmission;
- masking in health facilities in areas with community, cluster and sporadic transmission;
- mask use by the public in areas with community and cluster transmission;
- alternatives to non-medical masks for the public;
- exhalation valves on respirators and non-medical masks;
- mask use during vigorous intensity physical activity;
- essential parameters to be considered when manufacturing non-medical masks (Annex).

Key points

- The World Health Organization (WHO) advises the use of masks as part of a comprehensive package of prevention and control measures to limit the spread of SARS-CoV-2, the virus that causes COVID-19. A mask alone, even when it is used correctly, is insufficient to provide adequate protection or source control. Other infection prevention and control (IPC) measures include hand hygiene, physical distancing of at least 1 metre, avoidance of touching one's face, respiratory etiquette, adequate ventilation in indoor settings, testing, contact tracing, quarantine and isolation. Together these measures are critical to prevent human-to-human transmission of SARS-CoV-2.
- Depending on the type, masks can be used either for protection of healthy persons or to prevent onward transmission (source control).
- WHO continues to advise that anyone suspected or confirmed of having COVID-19 or awaiting viral laboratory test results should wear a medical mask when in the presence of others (this does not apply to those awaiting a test prior to travel).
- For any mask type, appropriate use, storage and cleaning or disposal are essential to ensure that they are as effective as possible and to avoid an increased transmission risk.

<u>Mask use in health care settings</u>

- WHO continues to recommend that health workers (1) providing care to suspected or confirmed COVID-19 patients wear the following types of mask/respirator in addition to other personal protective equipment that are part of standard, droplet and contact precautions:
  - medical mask in the absence of aerosol generating procedures (AGPs)
  - respirator, N95 or FFP2 or FFP3 standards, or equivalent in care settings for COVID-19 patients where AGPs are performed; these may be used by health workers when providing care to COVID-19 patients in other settings if they are widely available and if costs is not an issue.
- In areas of known or suspected community or cluster SARS-CoV-2 transmission WHO advises the following:
  - universal masking for all persons (staff, patients, visitors, service providers and others) within the health facility (including primary, secondary and tertiary care levels; outpatient care; and long-term care facilities)
  - wearing of masks by inpatients when physical distancing of at least 1 metre cannot be maintained or when patients are outside of their care areas.
- In areas of known or suspected sporadic SARS-CoV-2 transmission, health workers working in clinical areas where patients are present should continuously wear a medical mask. This is known as targeted continuous medical masking for health workers in clinical areas;
- Exhalation valves on respirators are discouraged as they bypass the filtration function for exhaled air by the wearer.

<u>Mask use in community settings</u>

- Decision makers should apply a risk-based approach when considering the use of masks for the general public.
- In areas of known or suspected community or cluster SARS-CoV-2 transmission:
  - WHO advises that the general public should wear a non-medical mask in indoor (e.g. shops, shared workplaces, schools - see Table 2 for details) or outdoor settings where physical distancing of at least 1 metre cannot be maintained.
  - If indoors, unless ventilation has been be assessed to be adequate[1], WHO advises that the general public should wear a non-medical mask, regardless of whether physical distancing of at least 1 metre can be maintained.

[1] For adequate ventilation refer to regional or national institutions or heating, refrigerating and air-conditioning societies enacting ventilation requirements. If not available or applicable, a recommended ventilation rate of 10 l/s/person should be met (except healthcare facilities which have specific requirements). For more information consult "Coronavirus (COVID-19) response

- Individuals/people with higher risk of severe complications from COVID-19 (individuals ≥ 60 years old and those with underlying conditions such as cardiovascular disease or diabetes mellitus, chronic lung disease, cancer, cerebrovascular disease or immunosuppression) should wear medical masks when physical distancing of at least 1 metre cannot be maintained.

- In any transmission scenarios:
  - Caregivers or those sharing living space with people with suspected or confirmed COVID-19, regardless of symptoms, should wear a medical mask when in the same room.

Mask use in children (2)

- Children aged up to five years should not wear masks for source control.
- For children between six and 11 years of age, a risk-based approach should be applied to the decision to use a mask; factors to be considered in the risk-based approach include intensity of SARS-CoV-2 transmission, child's capacity to comply with the appropriate use of masks and availability of appropriate adult supervision, local social and cultural environment, and specific settings such as households with elderly relatives, or schools.
- Mask use in children and adolescents 12 years or older should follow the same principles as for adults.
- Special considerations are required for immunocompromised children or for paediatric patients with cystic fibrosis or certain other diseases (e.g., cancer), as well as for children of any age with developmental disorders, disabilities or other specific health conditions that might interfere with mask wearing.

Manufacturing of non-medical (fabric) masks (Annex)

- Homemade fabric masks of three-layer structure (based on the fabric used) are advised, with each layer providing a function: 1) an innermost layer of a hydrophilic material 2) an outermost layer made of hydrophobic material 3) a middle hydrophobic layer which has been shown to enhance filtration or retain droplets.
- Factory-made fabric masks should meet the minimum thresholds related to three essential parameters: filtration, breathability and fit.
- Exhalation valves are discouraged because they bypass the filtration function of the fabric mask rendering it unserviceable for source control.

Methodology for developing the guidance

Guidance and recommendations included in this document are based on published WHO guidelines (in particular the WHO Guidelines on infection prevention and control of epidemic- and pandemic-prone acute respiratory infections in health care) (2) and ongoing evaluations of all available scientific evidence by the WHO ad hoc COVID-19 Infection Prevention and Control Guidance Development Group (COVID-19 IPC GDG) (see acknowledgement section for list of GDG members). During emergencies WHO publishes interim guidance, the development of which follows a transparent and robust process of evaluation of the available evidence on benefits and harms. This evidence is evaluated through expedited systematic reviews and expert consensus-building through weekly GDG consultations, facilitated by a methodologist and, when necessary, followed up by surveys. This process also considers, as much as possible, potential resource implications, values and preferences, feasibility, equity, and ethics. Draft guidance documents are reviewed by an external review panel of experts prior to publication.

Purpose of the guidance

This document provides guidance for decision makers, public health and IPC professionals, health care managers and health workers in health care settings (including long-term care and residential), for the public and for manufactures of non-medical masks (Annex). It will be revised as new evidence emerges.

WHO has also developed comprehensive guidance on IPC strategies for health care settings (3), long-term care facilities (LTCF) (4), and home care (5).

Background

The use of masks is part of a comprehensive package of prevention and control measures that can limit the spread of certain respiratory viral diseases, including COVID-19. Masks can be used for protection of healthy persons (worn to protect oneself when in contact with an infected individual) or for source control (worn by an infected individual to prevent onward transmission) or both.

However, the use of a mask alone, even when correctly used (see below), is insufficient to provide an adequate level of protection for an uninfected individual or prevent onward transmission from an infected individual (source control). Hand hygiene, physical distancing of at least 1 metre, respiratory etiquette, adequate ventilation in indoor settings, testing, contact tracing, quarantine, isolation and other infection prevention and control (IPC) measures are critical to prevent human-to-human transmission of SARS-CoV-2, whether or not masks are used (6).

Mask management

For any type of mask, appropriate use, storage and cleaning, or disposal are essential to ensure that they are as effective as possible and to avoid any increased risk of transmission. Adherence to correct mask management practices varies, reinforcing the need for appropriate messaging (7).

WHO provides the following guidance on the correct use of masks:

- Perform hand hygiene before putting on the mask.
- Inspect the mask for tears or holes, and do not use a damaged mask.
- Place the mask carefully, ensuring it covers the mouth and nose, adjust to the nose bridge and tie it securely to minimize any gaps between the face and the mask. If using ear loops, ensure these do not cross over as this widens the gap between the face and the mask.

resources from ASHRAE and others''
https://www.ashrae.org/technical-resources/resources

- Avoid touching the mask while wearing it. If the mask is accidently touched, perform hand hygiene.
- Remove the mask using the appropriate technique. Do not touch the front of the mask, but rather untie it from behind.
- Replace the mask as soon as it becomes damp with a new clean, dry mask.
- Either discard the mask or place it in a clean plastic resealable bag where it is kept until it can be washed and cleaned. Do not store the mask around the arm or wrist or pull it down to rest around the chin or neck.
- Perform hand hygiene immediately afterward discarding a mask.
- Do not re-use single-use mask.
- Discard single-use masks after each use and properly dispose of them immediately upon removal.
- Do not remove the mask to speak.
- Do not share your mask with others.
- Wash fabric masks in soap or detergent and preferably hot water (at least 60° Centigrade/140° Fahrenheit) at least once a day. If it is not possible to wash the masks in hot water, then wash the mask in soap/detergent and room temperature water, followed by boiling the mask for 1 minute.

Scientific evidence

Transmission of the SARS-CoV-2 virus

Knowledge about transmission of the SARS-CoV-2 virus is evolving continuously as new evidence accumulates. COVID-19 is primarily a respiratory disease, and the clinical spectrum can range from no symptoms to severe acute respiratory illness, sepsis with organ dysfunction and death.

According to available evidence, SARS-CoV-2 mainly spreads between people when an infected person is in close contact with another person. Transmissibility of the virus depends on the amount of viable virus being shed and expelled by a person, the type of contact they have with others, the setting and what IPC measures are in place. The virus can spread from an infected person's mouth or nose in small liquid particles when the person coughs, sneezes, sings, breathes heavily or talks. These liquid particles are different sizes, ranging from larger 'respiratory droplets' to smaller 'aerosols.' Close-range contact (typically within 1 metre) can result in inhalation of, or inoculation with, the virus through the mouth, nose or eyes (8-13).

There is limited evidence of transmission through fomites (objects or materials that may be contaminated with viable virus, such as utensils and furniture or in health care settings a stethoscope or thermometer) in the immediate environment around the infected person (14-17). Nonetheless, fomite transmission is considered a possible mode of transmission for SARS-CoV-2, given consistent finding of environmental contamination in the vicinity of people infected with SARS-CoV-2 and the fact that other coronaviruses and respiratory viruses can be transmitted this way (12).

Aerosol transmission can occur in specific situations in which procedures that generate aerosols are performed. The scientific community has been actively researching whether the SARS-CoV-2 virus might also spread through aerosol transmission in the absence of aerosol generating procedures (AGPs) (18, 19). Some studies that performed air sampling in clinical settings where AGPs were not performed found virus RNA, but others did not. The presence of viral RNA is not the same as replication- and infection-competent (viable) virus that could be transmissible and capable of sufficient inoculum to initiate invasive infection. A limited number of studies have isolated viable SARS-CoV-2 from air samples in the vicinity of COVID-19 patients (20, 21).

Outside of medical facilities, in addition to droplet and fomite transmission, aerosol transmission can occur in specific settings and circumstances, particularly in indoor, crowded and inadequately ventilated spaces, where infected persons spend long periods of time with others. Studies have suggested these can include restaurants, choir practices, fitness classes, nightclubs, offices and places of worship (12).

High quality research is required to address the knowledge gaps related to modes of transmission, infectious dose and settings in which transmission can be amplified. Currently, studies are underway to better understand the conditions in which aerosol transmission or superspreading events may occur.

Current evidence suggests that people infected with SARS-CoV-2 can transmit the virus whether they have symptoms or not. However, data from viral shedding studies suggest that infected individuals have highest viral loads just before or around the time they develop symptoms and during the first 5-7 days of illness (12). Among symptomatic patients, the duration of infectious virus shedding has been estimated at 8 days from the onset of symptoms (22-24) for patients with mild disease, and longer for severely ill patients (12). The period of infectiousness is shorter than the duration of detectable RNA shedding, which can last many weeks (17).

The incubation period for COVID-19, which is the time between exposure to the virus and symptom onset, is on average 5-6 days, but can be as long as 14 days (25, 26).

Pre-symptomatic transmission – from people who are infected and shedding virus but have not yet developed symptoms – can occur. Available data suggest that some people who have been exposed to the virus can test positive for SARS-CoV-2 via polymerase chain reaction (PCR) testing 1-3 days before they develop symptoms (27). People who develop symptoms appear to have high viral loads on or just prior to the day of symptom onset, relative to later on in their infection (28).

Asymptomatic transmission – transmission from people infected with SARS-CoV-2 who never develop symptoms – can occur. One systematic review of 79 studies found that 20% (17–25%) of people remained asymptomatic throughout the course of infection. (28). Another systematic review, which included 13 studies considered to be at low risk of bias, estimated that 17% of cases remain asymptomatic (14%–20%) (30). Viable virus has been isolated from specimens of pre-symptomatic and asymptomatic individuals, suggesting that people who do not have symptoms may be able to transmit the virus to others. (25, 29-37)

Studies suggest that asymptomatically infected individuals are less likely to transmit the virus than those who develop symptoms (29). A systematic review concluded that individuals who are asymptomatic are responsible for transmitting fewer infections than symptomatic and pre-symptomatic cases (38). One meta-analysis estimated that there is a 42% lower relative risk of asymptomatic transmission compared to symptomatic transmission (30).

Guidance on mask use in health care settings

Masks for use in health care settings

Medical masks are defined as surgical or procedure masks that are flat or pleated. They are affixed to the head with straps that go around the ears or head or both. Their performance characteristics are tested according to a set of standardized test methods (ASTM F2100, EN 14683, or equivalent) that aim to balance high filtration, adequate breathability and optionally, fluid penetration resistance (39, 40).

Filtering facepiece respirators (FFR), or respirators, offer a balance of filtration and breathability. However, whereas medical masks filter 3 micrometre droplets, respirators must filter more challenging 0.075 micrometre solid particles. European FFRs, according to standard EN 149, at FFP2 performance there is filtration of at least 94% solid NaCl particles and oil droplets. US N95 FFRs, according to NIOSH 42 CFR Part 84, filter at least 95% NaCl particles. Certified FFRs must also ensure unhindered breathing with maximum resistance during inhalation and exhalation. Another important difference between FFRs and other masks is the way filtration is tested. Medical mask filtration tests are performed on a cross-section of the masks, whereas FFRs are tested for filtration across the entire surface. Therefore, the layers of the filtration material and the FFR shape, which ensure the outer edges of the FFR seal around wearer's face, result in guaranteed filtration as claimed. Medical masks, by contrast, have an open shape and potentially leaking structure. Other FFR performance requirements include being within specified parameters for maximum CO_2 build up, total inward leakage and tensile strength of straps (41, 42).

A. Guidance on the use of medical masks and respirators to provide care to suspected or confirmed COVID-19 cases

Evidence on the use of mask in health care settings

Systematic reviews have reported that the use of N95/P2 respirators compared with the use of medical masks (see mask definitions, above) is not associated with statistically significant differences for the outcomes of health workers acquiring clinical respiratory illness, influenza-like illness (risk ratio 0.83, 95%CI 0.63-1.08) or laboratory-confirmed influenza (risk ratio 1.02, 95%CI 0.73-1.43); harms were poorly reported and limited to discomfort associated with lower compliance (43, 44). In many settings, preserving the supply of N95 respirators for high-risk, aerosol-generating procedures is an important consideration (45).

A systematic review of observational studies on the betacoronaviruses that cause severe acute respiratory syndrome (SARS), Middle East respiratory syndrome (MERS) and COVID-19 found that the use of face protection (including respirators and medical masks) is associated with reduced risk of infection among health workers. These studies suggested that N95 or similar respirators might be associated with greater reduction in risk than medical or 12–16-layer cotton masks. However, these studies had important limitations (recall bias, limited information about the situations when respirators were used and limited ability to measure exposures), and very few studies included in the review evaluated the transmission risk of COVID-19 (46). Most of the studies were conducted in settings in which AGPs were performed or other high-risk settings (e.g., intensive care units or where there was exposure to infected patients and health workers were not wearing adequate PPE).

WHO continues to evaluate the evidence on the effectiveness of the use of different masks and their potential harms, risks and disadvantages, as well as their combination with hand hygiene, physical distancing of at least 1 metre and other IPC measures.

Guidance

WHO's guidance on the type of respiratory protection to be worn by health workers providing care to COVID-19 patients is based on 1) WHO recommendations on IPC for epidemic- and pandemic-prone acute respiratory infections in health care (47); 2) updated systematic reviews of randomized controlled trials on the effectiveness of medical masks compared to that of respirators for reducing the risk of clinical respiratory illness, influenza-like illness (ILI) and laboratory-confirmed influenza or viral infections. WHO guidance in this area is aligned with guidelines of other professional organizations, including the European Society of Intensive Care Medicine and the Society of Critical Care Medicine, and the Infectious Diseases Society of America (48, 49).

The WHO COVID-19 IPC GDG considered all available evidence on the modes of transmission of SARS-CoV-2 and on the effectiveness of medical mask versus respirator use to protect health workers from infection and the potential for harms such as skin conditions or breathing difficulties.

Other considerations included availability of medical masks versus respirators, cost and procurement implications and equity of access by health workers across different settings.

The majority (71%) of the GDG members confirmed their support for previous recommendations issued by WHO on 5 June 2020:

1. In the absence of aerosol generating procedures (AGPs)[2], WHO recommends that health workers providing care to patients with suspected or confirmed COVID-19 should wear a medical mask (in addition to other PPE that are part of droplet and contact precautions).
2. In care settings for COVID-19 patients where AGPs are performed, WHO recommends that health workers should wear a respirator (N95 or FFP2 or FFP3 standard, or equivalent) in addition to other PPE that are part of airborne and contact precautions.

In general, health workers have strong preferences about having the highest perceived protection possible to prevent COVID-19 infection and therefore may place high value on the potential benefits of respirators in settings without AGPs. WHO recommends respirators primarily for settings where AGPs are performed; however, if health workers prefer them and they are sufficiently available and cost is not an issue, they could also be used during care for COVID-19 patients in other settings. For additional guidance on PPE, including PPE

[2] The WHO list of AGPs includes tracheal intubation, non-invasive ventilation, tracheotomy, cardiopulmonary resuscitation, manual ventilation before intubation, bronchoscopy, sputum induction using nebulized hypertonic saline, and dentistry and autopsy procedures.

beyond mask use by health workers, see WHO IPC guidance during health care when COVID-19 infection is suspected (3) and also WHO guidance on the rational use of PPE (45).

Exhalation valves on respirators are discouraged as they bypass the filtration function for exhaled air.

B. Guidance on the use of mask by health workers, caregivers and others based on transmission scenario

Definitions

Universal masking in health facilities is defined as the requirement for all persons (staff, patients, visitors, service providers and others) to wear a mask at all times except for when eating or drinking.

Targeted continuous medical mask use is defined as the practice of wearing a medical mask by all health workers and caregivers working in clinical areas during all routine activities throughout the entire shift.

Health workers are all people primarily engaged in actions with the primary intent of enhancing health. Examples are: nursing and midwifery professionals, doctors, cleaners, other staff who work in health facilities, social workers, and community health workers.

Evidence on universal masking in health care settings

In areas where there is community transmission or large-scale outbreaks of COVID-19, universal masking has been adopted in many hospitals to reduce the potential of transmission by health workers to patients, to other staff and anyone else entering the facility (50).

Two studies found that implementation of a universal masking policy in hospital systems was associated with decreased risk of healthcare-acquired SARS-CoV-2 infection. However, these studies had serious limitations: both were before-after studies describing a single example of a phenomenon before and after an event of interest, with no concurrent control group, and other infection control measures were not controlled for (51, 52). In addition, observed decreases in health worker infections occurred too quickly to be attributable to the universal masking policy.

Guidance

Although more research on universal masking in heath settings is needed, it is the expert opinion of the majority (79%) of WHO COVID-19 IPC GDG members that universal masking is advisable in geographic settings where there is known or suspected community or cluster transmission of the SARS-CoV-2 virus.

1. In areas of known or suspected community or cluster SARS-CoV-2 transmission, universal masking should be advised in all health facilities (see Table 1).

- All health workers, including community health workers and caregivers, should wear a medical mask at all times, for any activity (care of COVID-19 or non-COVID-19 patients) and in any common area (e.g., cafeteria, staff rooms).
- Other staff, visitors, outpatients and service providers should also wear a mask (medical or non-medical) at all times
- Inpatients are not required to wear a mask (medical or non-medical) unless physical distancing of at least 1 metre cannot be maintained (e.g., when being examined or visited at the bedside) or when outside of their care area (e.g., when being transported).
- Masks should be changed when they become soiled, wet or damaged or if the health worker/caregiver removes the mask (e.g., for eating or drinking or caring for a patient who requires droplet/contact precautions for reasons other than COVID-19).

2. In the context of known or suspected sporadic SARS-CoV-2 virus transmission, WHO provides the following guidance:

- Health workers, including community health workers and caregivers who work in clinical areas, should continuously wear a medical mask during routine activities throughout the entire shift, apart from when eating and drinking and changing their medical masks after caring for a patient who requires droplet/contact precautions for other reasons. In all cases, medical masks must be changed when wet, soiled, or damaged; used medical masks should be properly disposed of at the end of the shift; and new clean ones should be used for the next shift or when medical masks are changed.
- It is particularly important to adopt the continuous use of masks in potentially high transmission risk settings including triage, family physician/general practitioner offices; outpatient departments; emergency rooms; COVID-19 designated units; haematology, oncology and transplant units; and long-term health and residential facilities.
- Staff who do not work in clinical areas (e.g., administrative staff) do not need to wear a medical mask during routine activities if they have no exposure to patients.

Whether using masks for universal masking within health facilities or targeted continuous medical mask use throughout the entire shift, health workers should ensure the following:

- Medical mask use should be combined with other measures including frequent hand hygiene and physical distancing among health workers in shared and crowded places such as cafeterias, break rooms, and dressing rooms.
- The medical mask should be changed when wet, soiled, or damaged.
- The medical mask should not be touched to adjust it or if displaced from the face for any reason. If this happens, the mask should be safely removed and replaced, and hand hygiene performed.
- The medical mask (as well as other personal protective equipment) should be discarded and changed after caring for any patient who requires contact/droplet precautions for other pathogens, followed by hand hygiene.
- Under no circumstances should medical masks be shared between health workers or between others wearing them. Masks should be appropriately disposed of whenever removed and not reused.

- A particulate respirator at least as protective as a United States of America (US) National Institute for Occupational Safety and Health-certified N95, N99, US Food and Drug Administration surgical N95, European Union standard FFP2 or FFP3, or equivalent, should be worn in settings for COVID-19 patients where AGPs are performed (see WHO recommendations below). In these settings, this includes continuous use by health workers throughout the entire shift, when this policy is implemented.

Note: Decision makers may consider the transmission intensity in the catchment area of the health facility or community setting and the feasibility of implementing a universal masking policy compared to a policy based on assessed or presumed exposure risk. Decisions need to take into account procurement, sustainability and costs of the policy. When planning masks for all health workers, long-term availability of adequate medical masks (and when applicable, respirators) for all workers should be ensured, in particular for those providing care for patients with confirmed or suspected COVID-19. Proper use and adequate waste management should be ensured.

The potential harms and risks of mask and respirator use in the health facility setting include:

- contamination of the mask due to its manipulation by contaminated hands (53, 54);
- potential self-contamination that can occur if medical masks are not changed when wet, soiled or damaged; or by frequent touching/adjusting when worn for prolonged periods (55);
- possible development of facial skin lesions, irritant dermatitis or worsening acne, when used frequently for long hours (56-58);
- discomfort, facial temperature changes and headaches from mask wearing (44, 59, 60);
- false sense of security leading potentially to reduced adherence to well recognized preventive measures such as physical distancing and hand hygiene; and risk-taking behaviours (61-64);
- difficulty wearing a mask in hot and humid environments
- possible risk of stock depletion due to widespread use in the context of universal masking and targeted continuous mask use and consequent scarcity or unavailability for health workers caring for COVID 19 patients and during health care interactions with non-COVID-19 patients where medical masks or respirators might be required.

Alternatives to medical masks in health care settings

The WHO's disease commodity package (DCP) for COVID-19 recommends medical masks for health workers to be type II or higher (65). Type II medical masks provide a physical barrier to fluids and particulate materials and have bacterial filtration efficiency of ≥98% compared to Type I mask, which has bacterial filtration efficiency of ≥95% and lower fluid resistance (66) In case of stock outs of type II or higher medical masks, health workers should use a type I medical mask as an alternative. Other alternatives such as face shields or fabric masks should be carefully evaluated.

Face shields are designed to provide protection from splashes of biological fluid (particularly respiratory secretions), chemical agents and debris (67, 68) into the eyes. In the context of protection from SARS-CoV-2 transmission through respiratory droplets, face shields are used by health workers as personal protective equipment (PPE) for eye protection in combination with a medical mask or a respirator (69, 70) While a face shield may confer partial protection of the facial area against respiratory droplets, these and smaller droplets may come into contact with mucous membranes or with the eyes from the open gaps between the visor and the face (71,67).

Fabric masks are not regulated as protective masks or part of the PPE directive. They vary in quality and are not subject to mandatory testing or common standards and as such are not considered an appropriate alternative to medical masks for protection of health workers. One study that evaluated the use of cloth masks in a health care facility found that health care workers using 2 ply cotton cloth masks (a type of fabric mask) were at increased risk of influenza-like illness compared with those who wore medical masks (72).

In the context of severe medical mask shortage, face shields alone or in combination with fabric mask may be considered as a last resort (73). Ensure proper design of face shields to cover the sides of the face and below the chin.

As for other PPE items, if production of fabric masks for use in health care settings is proposed locally in situations of shortage or stock out, a local authority should assess the product according to specific minimum performance standards and required technical specifications (see Annex).

Additional considerations for community care settings

Like other health workers, community health workers should apply standard precautions for all patients at all times, with particular emphasis regarding hand and respiratory hygiene, surface and environmental cleaning and disinfection and the appropriate use of PPE. When a patient is suspected or confirmed of having COVID-19, community health workers should always apply contact and droplet precautions. These include the use of a medical mask, gown, gloves and eye protection (74).

IPC measures that are needed will depend on the local COVID-19 transmission dynamics and the type of contact required by the health care activity (see Table 1). The community health workforce should ensure that patients and workforce members apply precautionary measures such as respiratory hygiene and physical distancing of at least 1 metre (3.3 feet). They also may support set-up and maintenance of hand hygiene stations and community education (74). In the context of known or suspected community or cluster transmission, community health workers should wear a medical mask when providing essential routine services (see Table 1).

Table 1. Mask use in health care settings depending on transmission scenario, target population, setting, activity and type*

Transmission scenario	Target population (who)	Setting (where)	Activity (what)	Mask type (which one) *
Known or suspected community or cluster transmission of SARS-CoV-2	Health workers and caregivers	Health facility (including primary, secondary, tertiary care levels, outpatient care, and long-term care facilities)	For any activity in patient-care areas (COVID-19 or non-COVID-19 patients) or in any common areas (e.g., cafeteria, staff rooms)	Medical mask (or respirator if aerosol generating procedures performed)
	Other staff, patients, visitors, service suppliers		For any activity or in any common area	Medical or fabric mask
	Inpatients	In single or multiple-bed rooms	When physical distance of at least 1 metre cannot be maintained	
	Health workers and caregivers	Home visit (for example, for antenatal or postnatal care, or for a chronic condition)	When in direct contact with a patient or when a distance of at least 1 metre cannot be maintained.	Medical mask
		Community	Community outreach programmes/essential routine services	
Known or suspected sporadic transmission of SARS-CoV-2 cases	Health workers and caregivers	Health facility (including primary, secondary, tertiary care levels, outpatient care, and long-term care facilities)	In patient care area- irrespective of whether patients have suspected/confirmed COVID-19	Medical mask
	Other staff, patients, visitors, service suppliers and all others		No routine activities in patient areas	Medical mask not required. Medical mask should be worn if in contact or within 1 metre of patients, or according to local risk assessment
	Health workers and caregivers	Home visit (for example, for antenatal or postnatal care, or for a chronic condition)	When in direct contact or when a distance of at least 1metre cannot be maintained.	Medical mask
		Community	Community outreach programs (e.g., bed net distribution)	
No documented SARS-CoV-2 transmission	Health workers and caregivers	Health facility (including primary, secondary, tertiary care levels, outpatient care, and long-term care facilities)	Providing any patient care	Medical mask use according to standard and transmission-based precautions
		Community	Community outreach programs	
Any transmission scenario	Health workers	Health care facility (including primary, secondary, tertiary care levels, outpatient care, and long-term care facilities), in settings where aerosol generating procedures (AGP) are performed	Performing an AGP on a suspected or confirmed COVID-19 patient or providing care in a setting where AGPs are in place for COVID-19 patients	Respirator (N95 or N99 or FFP2 or FFP3)

**This table refers only to the use of medical masks and respirators. The use of medical masks and respirators may need to be combined with other personal protective equipment and other measures as appropriate, and always with hand hygiene.*

Guidance on mask use in community settings

Evidence on the protective effect of mask use in community settings

At present there is only limited and inconsistent scientific evidence to support the effectiveness of masking of healthy people in the community to prevent infection with respiratory viruses, including SARS-CoV-2 (75). A large randomized community-based trial in which 4862 healthy participants were divided into a group wearing medical/surgical masks and a control group found no difference in infection with SARS-CoV-2 (76). A recent systematic review found nine trials (of which eight were cluster-randomized controlled trials in which clusters of people, versus individuals, were randomized) comparing medical/surgical masks versus no masks to prevent the spread of viral respiratory illness. Two trials were with healthcare workers and seven in the community. The review concluded that wearing a mask may make little or no difference to the prevention of influenza-like illness (ILI) (RR 0.99, 95%CI 0.82 to 1.18) or laboratory confirmed illness (LCI) (RR 0.91, 95%CI 0.66-1.26) (44); the certainty of the evidence was low for ILI, moderate for LCI.

By contrast, a small retrospective cohort study from Beijing found that mask use by entire families before the first family member developed COVID-19 symptoms was 79% effective in reducing transmission (OR 0.21, 0.06-0.79) (77). A case-control study from Thailand found that wearing a medical or non-medical mask all the time during contact with a COVID-19 patient was associated with a 77% lower risk of infection (aOR 0.23; 95% CI 0.09–0.60) (78). Several small observational studies with epidemiological data have reported an association between mask use by an infected person and prevention of onward transmission of SARS-CoV-2 infection in public settings. (8, 79-81).

A number of studies, some peer reviewed (82-86) but most published as pre-prints (87-104), reported a decline in the COVID-19 cases associated with face mask usage by the public, using country- or region-level data. One study reported an association between community mask wearing policy adoption and increased movement (less time at home, increased visits to commercial locations) (105). These studies differed in setting, data sources and statistical methods and have important limitations to consider (106), notably the lack of information about actual exposure risk among individuals, adherence to mask wearing and the enforcement of other preventive measures (107, 108).

Studies of influenza, influenza-like illness and human coronaviruses (not including COVID-19) provide evidence that the use of a medical mask can prevent the spread of infectious droplets from a symptomatic infected person to someone else and potential contamination of the environment by these droplets (75). There is limited evidence that wearing a medical mask may be beneficial for preventing transmission between healthy individuals sharing households with a sick person or among attendees of mass gatherings (44, 109-114).

A meta-analysis of observational studies on infections due to betacoronaviruses, with the intrinsic biases of observational data, showed that the use of either disposable medical masks or reusable 12–16-layer cotton masks was associated with protection of healthy individuals within households and among contacts of cases (46). This could be considered to be indirect evidence for the use of masks (medical or other) by healthy individuals in the wider community; however, these studies suggest that such individuals would need to be in close proximity to an infected person in a household or at a mass gathering where physical distancing cannot be achieved to become infected with the virus. Results from cluster randomized controlled trials on the use of masks among young adults living in university residences in the United States of America indicate that face masks may reduce the rate of influenza-like illness but showed no impact on risk of laboratory-confirmed influenza (115, 116).

Guidance

The WHO COVID-19 IPC GDG considered all available evidence on the use of masks by the general public including effectiveness, level of certainty and other potential benefits and harms, with respect to transmission scenarios, indoor versus outdoor settings, physical distancing and ventilation. Despite the limited evidence of protective efficacy of mask wearing in community settings, in addition to all other recommended preventive measures, the GDG advised mask wearing in the following settings:

1. In areas with known or suspected community or cluster transmission of SARS-CoV-2, WHO advises mask use by the public in the following situations (see Table 2):

   Indoor settings:

- in public indoor settings where ventilation is known to be poor regardless of physical distancing: limited or no opening of windows and doors for natural ventilation; ventilation system is not properly functioning or maintained; or cannot be assessed;
- in public indoor settings that have adequate[3] ventilation if physical distancing of at least 1 metre cannot be maintained;
- in household indoor settings: when there is a visitor who is not a household member and ventilation is known to be poor, with limited opening of windows and doors for natural ventilation, or the ventilation system cannot be assessed or is not properly functioning, regardless of whether physical distancing of at least 1 metre can be maintained;
- in household indoor settings that have adequate ventilation if physical distancing of at least 1 metre cannot be maintained.

[3] For adequate ventilation refer to regional or national institutions or heating, refrigerating and air-conditioning societies enacting ventilation requirements. If not available or applicable, a recommended ventilation rate of 10 l/s/person should be met (except healthcare facilities which have specific requirements). For more information consult "Coronavirus (COVID-19) response resources from ASHRAE and others'' https://www.ashrae.org/technical-resources/resources

Table 2. Mask use in community settings depending on transmission scenario, setting, target population, purpose and type*

Transmission scenario	Situations/settings (where)	Target Population (who)	Purpose of mask use (why)	Mask type (which one)
Known or suspected community or cluster transmission of SARS-CoV-2	Indoor settings, where ventilation is known to be poor or cannot be assessed or the ventilation system is not properly maintained, regardless of whether physical distancing of at least 1 meter can be maintained	General population in public* settings such as shops, shared workplaces, schools, churches, restaurants, gyms, etc. or in enclosed settings such as public transportation. For households, in indoor settings, when there is a visitor who is not a member of the household	Potential benefit for source control	Fabric mask
	Indoor settings that have adequate [4] ventilation if physical distancing of at least 1 metre cannot be maintained			
	Outdoor settings where physical distancing cannot be maintained	General population in settings such as crowded open-air markets, lining up outside a building, during demonstrations, etc.		
	Settings where physical distancing cannot be maintained, and the individual is at increased risk of infection and/or negative outcomes	Individuals/people with higher risk of severe complications from COVID-19: • People aged ≥60 years • People with underlying comorbidities, such as cardiovascular disease or diabetes mellitus, chronic lung disease, cancer, cerebrovascular disease, immunosuppression, obesity, asthma	Protection	Medical mask
Known or suspected sporadic transmission, or no documented SARS-CoV-2 transmission	Risk-based approach	General population	Potential benefit for source control and/or protection	Depends on purpose (see details in the guidance content)
Any transmission scenario	Any setting in the community	Anyone suspected or confirmed of having COVID-19, regardless of whether they have symptoms or not, or anyone awaiting viral test results, when in the presence of others	Source control	Medical mask

**Public indoor setting includes any indoor setting outside of the household*

[4] For adequate ventilation refer to regional or national institutions or heating, refrigerating and air-conditioning societies enacting ventilation requirements. If not available or applicable, a recommended ventilation rate of 10l/s/person should be met (except healthcare facilities which have specific requirements).). For more information consult "Coronavirus (COVID-19) response resources from ASHRAE and others'' https://www.ashrae.org/technical-resources/resources

In outdoor settings:

- where physical distancing of at least 1 metre cannot be maintained;
- individuals/people with higher risk of severe complications from COVID-19 (individuals ≥ 60 years old and those with underlying conditions such as cardiovascular disease or diabetes mellitus, chronic lung disease, cancer, cerebrovascular disease or immunosuppression) should wear medical masks in any setting where physical distance cannot be maintained.

2. In areas with known or suspected sporadic transmission or no documented transmission, as in all transmission scenarios, WHO continues to advise that decision makers should apply a risk-based approach focusing on the following criteria when considering the use of masks for the public:

- **Purpose of mask use**. Is the intention source control (preventing an infected person from transmitting the virus to others) or protection (preventing a healthy wearer from the infection)?
- **Risk of exposure to SARS-CoV-2**. Based on the epidemiology and intensity of transmission in the population, is there transmission and limited or no capacity to implement other containment measures such as contact tracing, ability to carry out testing and isolate and care for suspected and confirmed cases? Is there risk to individuals working in close contact with the public (e.g., social workers, personal support workers, teachers, cashiers)?
- **Vulnerability of the mask wearer/population**. Is the mask wearer at risk of severe complications from COVID-19? Medical masks should be used by older people (≥ 60 years old), immunocompromised patients and people with comorbidities, such as cardiovascular disease or diabetes mellitus, chronic lung disease, cancer and cerebrovascular disease (117).
- **Setting in which the population lives**. Is there high population density (such as in refugee camps, camp-like settings, and among people living in cramped conditions) and settings where individuals are unable to keep a physical distance of at least 1 metre (for example, on public transportation)?
- **Feasibility**. Are masks available at an affordable cost? Do people have access to clean water to wash fabric masks, and can the targeted population tolerate possible adverse effects of wearing a mask?
- **Type of mask**. Does the use of medical masks in the community divert this critical resource from the health workers and others who need them the most? In settings where medical masks are in short supply, **stocks should be prioritized for health workers and at-risk individuals.**

The decision of governments and local jurisdictions whether to recommend or make mandatory the use of masks should be based on the above assessment as well as the local context, culture, availability of masks and resources required.

3. In any transmission scenario:

- Persons with any symptoms suggestive of COVID-19 should wear a medical mask and (5) additionally:
  - self-isolate and seek medical advice as soon as they start to feel unwell with potential symptoms of COVID-19, even if symptoms are mild);
  - follow instructions on how to put on, take off, and dispose of medical masks and perform hand hygiene (118);
  - follow all additional measures, in particular respiratory hygiene, frequent hand hygiene and maintaining physical distance of at least 1 metre from other persons (46). If a medical mask is not available for individuals with suspected or confirmed COVID-19, a fabric mask meeting the specifications in the Annex of this document should be worn by patients as a source control measure, pending access to a medical mask. The use of a non-medical mask can minimize the projection of respiratory droplets from the user (119, 120).
  - Asymptomatic persons who test positive for SARS-CoV-2, should wear a medical mask when with others for a period of 10 days after testing positive.

Potential benefits/harms

The potential advantages of mask use by healthy people in the general public include:

- reduced spread of respiratory droplets containing infectious viral particles, including from infected persons before they develop symptoms (121);
- reduced potential for stigmatization and greater of acceptance of mask wearing, whether to prevent infecting others or by people caring for COVID-19 patients in non-clinical settings (122);
- making people feel they can play a role in contributing to stopping spread of the virus;
- encouraging concurrent transmission prevention behaviours such as hand hygiene and not touching the eyes, nose and mouth (123-125);
- preventing transmission of other respiratory illnesses like tuberculosis and influenza and reducing the burden of those diseases during the pandemic (126).

The potential disadvantages of mask use by healthy people in the general public include:

- headache and/or breathing difficulties, depending on type of mask used (55);
- development of facial skin lesions, irritant dermatitis or worsening acne, when used frequently for long hours (58, 59, 127);
- difficulty with communicating clearly, especially for persons who are deaf or have poor hearing or use lip reading (128, 129);
- discomfort (44, 55, 59)
- a false sense of security leading to potentially lower adherence to other critical preventive measures such as physical distancing and hand hygiene (105);
- poor compliance with mask wearing, in particular by young children (111, 130-132);
- waste management issues; improper mask disposal leading to increased litter in public places and environmental hazards (133);
- disadvantages for or difficulty wearing masks, especially for children, developmentally challenged persons, those with mental illness, persons with cognitive impairment, those with asthma or chronic respiratory or breathing problems, those who have had facial trauma or recent oral maxillofacial surgery and those living in hot and humid environments (55, 130).

Considerations for implementation

When implementing mask policies for the public, decision-makers should:

- clearly communicate the purpose of wearing a mask, including when, where, how and what type of mask should be worn; explain what wearing a mask may achieve and what it will not achieve; and communicate clearly that this is one part of a package of measures along with hand hygiene, physical distancing, respiratory etiquette, adequate ventilation in indoor settings and other measures that are all necessary and all reinforce each other;
- inform/train people on when and how to use masks appropriately and safely (see mask management and maintenance sections);
- consider the feasibility of use, supply/access issues (cleaning, storage), waste management, sustainability, social and psychological acceptance (of both wearing and not wearing different types of masks in different contexts);
- continue gathering scientific data and evidence on the effectiveness of mask use (including different types of masks) in non-health care settings;
- evaluate the impact (positive, neutral or negative) of using masks in the general population (including behavioural and social sciences) through good quality research.

Mask use during physical activity

Evidence

There are limited studies on the benefits and harms of wearing medical masks, respirators and non-medical masks while exercising. Several studies have demonstrated statistically significant deleterious effects on various cardiopulmonary physiologic parameters during mild to moderate exercise in healthy subjects and in those with underlying respiratory diseases (134-140). The most significant impacts have been consistently associated with the use of respirators and in persons with underlying obstructive airway pulmonary diseases such as asthma and chronic obstructive pulmonary disease (COPD), especially when the condition is moderate to severe (136). Facial microclimate changes with increased temperature, humidity and perceptions of dyspnoea were also reported in some studies on the use of masks during exercise (134, 141). A recent review found negligeable evidence of negative effects of mask use during exercise but noted concern for individuals with severe cardiopulmonary disease (142).

Guidance

WHO advises that people should not wear masks during vigorous intensity physical activity (143) because masks may reduce the ability to breathe comfortably. The most important preventive measure is to maintain physical distancing of at least 1 meter and ensure good ventilation when exercising.

If the activity takes place indoors, adequate ventilation should be ensured at all times through natural ventilation or a properly functioning or maintained ventilation system (144). Particular attention should be paid to cleaning and disinfection of the environment, especially high-touch surfaces. If all the above measures cannot be ensured, consider temporary closure of public indoor exercise facilities (e.g., gyms).

Face shields for the general public

At present, face shields are considered to provide a level of eye protection only and should not be considered as an equivalent to masks with respect to respiratory droplet protection and/or source control. Current laboratory testing standards only assess face shields for their ability to provide eye protection from chemical splashes (145).

In the context of non-availability or difficulties wearing a non-medical mask (in persons with cognitive, respiratory or hearing impairments, for example), face shields may be considered as an alternative, noting that they are inferior to masks with respect to droplet transmission and prevention. If face shields are to be used, ensure proper design to cover the sides of the face and below the chin.

Medical masks for the care of COVID-19 patients at home

WHO provides guidance on how to care for patients with confirmed and suspected COVID-19 at home when care in a health facility or other residential setting is not possible (5).

- Persons with suspected COVID-19 or mild COVID-19 symptoms should wear a medical mask as much as possible, especially when there is no alternative to being in the same room with other people. The mask should be changed at least once daily. Persons who cannot tolerate a medical mask should rigorously apply respiratory hygiene (i.e., cover mouth and nose with a disposable paper tissue when coughing or sneezing and dispose of it immediately after use or use a bent elbow procedure and then perform hand hygiene).
- Caregivers of or those sharing living space with people with suspected COVID-19 or with mild COVID-19 symptoms should wear a medical mask when in the same room as the affected person.

Annex: Updated guidance on non-medical (fabric) masks

Background

A non-medical mask, also called fabric mask, community mask or face covering, is neither a medical device nor personal protective equipment. Non-medical masks are aimed at the general population, primarily for protecting others from exhaled virus-containing droplets emitted by the mask wearer. They are not regulated by local health authorities or occupational health associations, nor is it required for manufacturers to comply with guidelines established by standards organizations. Non-medical masks may be homemade or manufactured. The essential performance parameters include good breathability, filtration of droplets originating from the wearer, and a snug fit covering the nose and mouth. Exhalation valves on masks are discouraged as they bypass the filtration function of the mask.

Non-medical masks are made from a variety of woven and non-woven fabrics, such as woven cotton, cotton/synthetic blends, polyesters and breathable spunbond polypropylene, for example. They may be made of different combinations of fabrics, layering sequences and available in diverse shapes. Currently, more is known about common household fabrics and combinations to make non-medical masks with target filtration efficiency and breathability (119, 146-150). Few of these fabrics and combinations have been systematically evaluated and there is no single design, choice of material, layering or shape among available non-medical masks that are considered optimal. While studies have focussed on single fabrics and combinations, few have looked at the shape and universal fit to the wearer. The unlimited combination of available fabrics and materials results in variable filtration and breathability.

In the context of the global shortage of medical masks and PPE, encouraging the public to create their own fabric masks may promote individual enterprise and community integration. Moreover, the production of non-medical masks may offer a source of income for those able to manufacture masks within their communities. Fabric masks can also be a form of cultural expression, encouraging public acceptance of protection measures in general. The safe re-use of fabric masks will also reduce costs and waste and contribute to sustainability (151-156).

This Annex is destined intended for two types of readers: homemade mask makers and factory-made masks manufacturers. Decision makers and managers (national/sub-national level) advising on a type of non-medical mask are also the focus of this guidance and should take into consideration the following features of non-medical masks: breathability, filtration efficiency (FE), or filtration, number and combination of fabric layers material used, shape, coating and maintenance.

Evidence on the effectiveness of non-medical (fabric) masks

A number of reviews have been identified on the effectiveness of non-medical masks (151-156). One systematic review (155) identified 12 studies and evaluated study quality. Ten were laboratory studies (157-166), and two reports were from a single randomized trial (72, 167). The majority of studies were conducted before COVID-19 emerged or used laboratory generated particles to assess filtration efficacy. Overall, the reviews concluded that cloth face masks have limited efficacy in combating viral infection transmission.

Homemade non-medical masks

Homemade non-medical masks made of household fabrics (e.g., cotton, cotton blends and polyesters) should ideally have a three-layer structure, with each layer providing a function (see Figure 1) (168). It should include:

1. an innermost layer (that will be in contact with the face) of a hydrophilic material (e.g., cotton or cotton blends of terry cloth towel, quilting cotton and flannel) that is non-irritating against the skin and can contain droplets (148)
2. a middle hydrophobic layer of synthetic breathable non-woven material (spunbond polypropylene, polyester and polyaramid), which may enhance filtration, prevent permeation of droplets or retain droplets (148, 150)
3. an outermost layer made of hydrophobic material (e.g. spunbond polypropylene, polyester or their blends), which may limit external contamination from penetrating through the layers to the wearer's nose and mouth and maintains and prevents water accumulation from blocking the pores of the fabric (148).

Although a minimum of three layers is recommended for non-medical masks for the most common fabric used, single, double or other layer combinations of advanced materials may be used if they meet performance requirements. It is important to note that with more tightly woven materials, breathability may be reduced as the number of layers increases. A quick check may be performed by attempting to breathe, through the mouth, through the multiple layers.

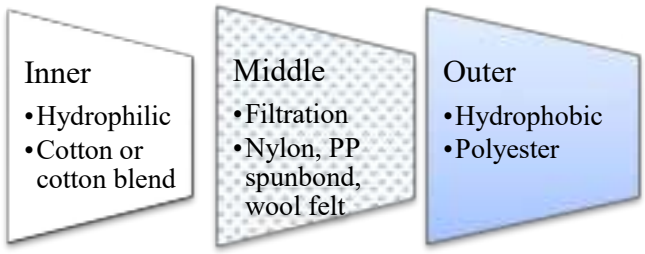

Figure 1. Non-medical mask construction using breathable fabrics such as cotton, cotton blends, polyesters, nylon and polypropylene spunbond that are breathable may impart adequate filtration performance when layered. Single- or double-layer combinations of advanced materials may be used if they meet performance requirements (72).

Assumptions regarding homemade masks are that individual makers only have access to common household fabrics and do not have access to test equipment to confirm target performance (filtration and breathability). Figure 1 illustrates a multi-layer mask construction with examples of fabric options. Very porous materials, such as gauze, even with multiple layers, may provide very low filtration efficiency (147). Higher thread count fabrics offer improved filtration performance (169). Coffee filters, vacuum bags and materials not meant for clothing should be avoided as they may contain injurious content when breathed in. Microporous films such as Gore-Tex are not recommended (170).

Factory-made non-medical masks: general considerations for manufacturers

The non-medical mask, including all components and packaging, must be non-hazardous, non-toxic and child-friendly (no exposed sharp edges, protruding hardware or rough materials). Factory-made non-medical masks must be made using a process that is certified to a quality management system (e.g., ISO 9001). Social accountability standards (e.g., SAI SA8000) for multiple aspects of fair labour practices, health and safety of the work force and adherence to UNICEF's Children's Rights and Business Principles are strongly encouraged.

Standards organizations' performance criteria

Manufacturers producing masks with consistent standardized performance can adhere to published, freely available guidance from several organizations including those from: the French Standardization Association (AFNOR Group), The European Committee for Standardization (CEN), Swiss National COVID-19 Task Force, the American Association of Textile Chemists and Colorists (AATCC), the South Korean Ministry of Food and Drug Safety (MFDS), the Italian Standardization Body (UNI) and the Government of Bangladesh.

Essential parameters

The essential parameters presented in this section are the synthesis of the abovementioned regional and national guidance. They include filtration, breathability and fit. Good performance is achieved when the three essential parameters are optimized at the preferred threshold (Figure 2).

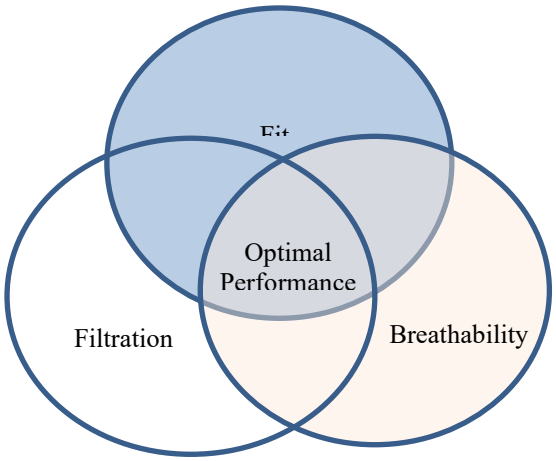

Figure 2. Illustration of the three essential parameters of filtration, breathability and fit.

The summary of the three essential parameters can be found in Table 1 and the additional performance considerations in Table 2. The minimum threshold is the minimum acceptable parameter, while the preferred threshold is the optimum.

Filtration and breathability

Filtration depends on the filtration efficiency (in %), the type of challenge particle (oils, solids, droplets containing bacteria) and the particle size (see Table 1). Depending on the fabrics used, filtration and breathability can complement or work against one another. The selection of material for droplet filtration (barrier) is as important as breathability. Filtration is dependent on the tightness of the weave, fibre or thread diameter. Non-woven materials used for disposable masks are manufactured using processes to create polymer fibres that are thinner than natural fibres such as cotton and that are held together by partial melting.

Breathability is the difference in pressure across the mask and is typically reported in millibars (mbar) or Pascals (Pa) or, normalized to the cm^2 in $mbar/cm^2$ or Pa/cm^2. Acceptable breathability of a medical mask should be below 49 Pa/cm^2. For non-medical masks, an acceptable pressure difference, over the whole mask, should be below 60 Pa/cm^2, with lower values indicating better breathability.

Non-medical fabric masks consisting of two layers of polypropylene spunbond and two layers of cotton have been shown to meet the minimum requirements for droplet filtration and breathability of the CEN CWA 17553 guidance. It is preferable not to select elastic material to make masks as the mask material may be stretched over the face, resulting in increased pore size and lower filtration through multiple usage. Additionally, elastic fabrics are sensitive to washing at high temperatures thus may degrade over time.

Coating the fabric with compounds like wax may increase the barrier and render the mask fluid resistant; however, such coatings may inadvertently completely block the pores and make the mask difficult to breathe through. In addition to decreased breathability unfiltered air may more likely escape the sides of the mask on exhalation. Coating is therefore not recommended.

Valves that let unfiltered air escape the mask are discouraged and are an inappropriate feature for masks used for the purpose of preventing transmission.

Table 1. Essential parameters (minimum and preferred thresholds) for manufactured non-medical mask

Essential Parameters	Minimum threshold	Preferred threshold
1. Filtration*		
1.1. filtration efficiency	70% @ 3 micron	> 70%, without compromising breathability
1.2. Challenge particle	Solid: sodium chloride (NaCl), Talcum powder, Holi powder, dolomite, Polystyrene Latex spheres Liquid: DEHS Di-Ethyl-Hexyl-Sebacat, paraffin oil	Based on availability
1.3. Particle size	Choose either sizes: 3 µm, 1 µm, or smaller	Range of particle sizes
2. Breathability		
2.1. Breathing resistance**	≤60 Pa/cm^2	Adult: ≤ 40 Pa/cm^2 Paediatric: ≤ 20 Pa/cm^2
2.2 Exhalation valves	Not recommended	N/A
3. Fit		
3.1. Coverage	Full coverage of nose and mouth, consistent, snug perimeter fit at the nose bridge, cheeks, chin and lateral sides of the face; adequate surface area to minimize breathing resistance and minimize side leakage	Same as current requirements
3.2 Face seal	Not currently required	Seal as good as FFR (respirator): Fit factor of 100 for N95 Maximum Total Inward Leakage of 25% (FFP1 requirement)
3.2. Sizing	Adult and child	Should cover from the bridge of the nose to below the chin and cheeks on either side of the mouth Sizing for adults and children (3-5, 6-9, 10-12, >12)
3.3Strap strength		> 44.5 N

* Smaller particle may result in lower filtration.
** High resistance can cause bypass of the mask. Unfiltered air will leak out the sides or around the nose if that is the easier path.

Fit: shape and sizing

Fit is the third essential parameter, and takes into consideration coverage, seal, sizing, and strap strength. Fit of masks currently is not defined by any standard except for the anthropometric considerations of facial dimensions (ISO/TS 16976-2) or simplified to height mask (South Korean standard for KF-AD). It is important to ensure that the mask can be held in place comfortably with as little adjustment of the elastic bands or ties as possible.

Mask shapes typically include flat-fold or duckbill and are designed to fit closely over the nose, cheeks and chin of the wearer. Snug fitting designs are suggested as they limit leaks of unfiltered air escaping from the mask (148). Ideally the mask should not have contact with the lips, unless hydrophobic fabrics are used in at least one layer of the mask (148). Leaks where unfiltered air moves in and out of the mask may be attributed to the size and shape of the mask (171).

Additional considerations

Optional parameters to consider in addition to the essential performance parameters include if reusable, biodegradability for disposal masks, antimicrobial performance where applicable and chemical safety (see Table 2).

Non-medical masks intended to be reusable should include instructions for washing and must be washed a minimum of five cycles, implying initial performance is maintained after each wash cycle.

Advanced fabrics may be biodegradable or compostable at the end of service life, according to a recognized standard process (e.g., UNI EN 13432, UNI EN 14995 and UNI / PdR 79).

Manufacturers sometimes claim their NM masks have antimicrobial performance. Antimicrobial performance may be due to coatings or additives to the fabric fibres. Treated fabrics must not come into direct contact with mucous membranes; the innermost fabric should not be treated with antimicrobial additives, only the outermost layer. In addition, antimicrobial fabric standards (e.g., ISO 18184, ISO 20743, AATCC TM100, AATCC 100) are generally slow acting. The inhibition on microbial growth may take full effect after 2- or 24-hour contact time depending on the standard. The standards have generally been used for athletic apparel and substantiate claims of odour control performance. These standards are not appropriate for non-medical cloth masks and may provide a false sense of protection from infectious agents. If claims are maid, manufacturers should specify which standard supports antimicrobial performance, the challenge organism and the contact time.

Volatile additives are discouraged as these may pose a health risk when inhaled repeatedly during wear. Certification according to organizations including OEKO-TEX (Europe) or SEK (Japan), and additives complying with REACH (Europe) or the Environmental Protection Agency (EPA, United States of America) indicate that textile additives are safe and added at safe levels.

Table 2. Additional parameters for manufactured non-medical masks

Additional parameters	Minimum thresholds
If reusable, number of wash cycles	5 cycles
Disposal	Reusable If biodegradable (CFC-BIO), according to UNI EN 13432, UNI EN 14995
Antimicrobial (bacteria, virus, fungus) performance	ISO 18184 (virus) ISO 20743 (bacteria) ISO 13629 (fungus) AATCC TM100 (bacteria)
Chemical safety	Comply with REACH regulation, including inhalation safety

Effectiveness of Adding a Mask Recommendation to Other Public Health Measures to Prevent SARS-CoV-2 Infection in Danish Mask Wearers

A Randomized Controlled Trial

Henning Bundgaard, DMSc; Johan Skov Bundgaard, BSc; Daniel Emil Tadeusz Raaschou-Pedersen, BSc; Christian von Buchwald, DMSc; Tobias Todsen, MD; Jakob Boesgaard Norsk, MD; Mia M. Pries-Heje, MD; Christoffer Rasmus Vissing, MD; Pernille B. Nielsen, MD; Ulrik C. Winsløw, MD; Kamille Fogh, MD; Rasmus Hasselbalch, MD; Jonas H. Kristensen, MD; Anna Ringgaard, PhD; Mikkel Porsborg Andersen, PhD; Nicole Bakkegård Goecke, PhD; Ramona Trebbien, PhD; Kerstin Skovgaard, PhD; Thomas Benfield, DMSc; Henrik Ullum, PhD; Christian Torp-Pedersen, DMSc; and Kasper Iversen, DMSc

Background: Observational evidence suggests that mask wearing mitigates transmission of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). It is uncertain if this observed association arises through protection of uninfected wearers (protective effect), via reduced transmission from infected mask wearers (source control), or both.

Objective: To assess whether recommending surgical mask use outside the home reduces wearers' risk for SARS-CoV-2 infection in a setting where masks were uncommon and not among recommended public health measures.

Design: Randomized controlled trial (DANMASK-19 [Danish Study to Assess Face Masks for the Protection Against COVID-19 Infection]). (ClinicalTrials.gov: NCT04337541)

Setting: Denmark, April and May 2020.

Participants: Adults spending more than 3 hours per day outside the home without occupational mask use.

Intervention: Encouragement to follow social distancing measures for coronavirus disease 2019, plus either no mask recommendation or a recommendation to wear a mask when outside the home among other persons together with a supply of 50 surgical masks and instructions for proper use.

Measurements: The primary outcome was SARS-CoV-2 infection in the mask wearer at 1 month by antibody testing, polymerase chain reaction (PCR), or hospital diagnosis. The secondary outcome was PCR positivity for other respiratory viruses.

Results: A total of 3030 participants were randomly assigned to the recommendation to wear masks, and 2994 were assigned to control; 4862 completed the study. Infection with SARS-CoV-2 occurred in 42 participants recommended masks (1.8%) and 53 control participants (2.1%). The between-group difference was −0.3 percentage point (95% CI, −1.2 to 0.4 percentage point; $P = 0.38$) (odds ratio, 0.82 [CI, 0.54 to 1.23]; $P = 0.33$). Multiple imputation accounting for loss to follow-up yielded similar results. Although the difference observed was not statistically significant, the 95% CIs are compatible with a 46% reduction to a 23% increase in infection.

Limitation: Inconclusive results, missing data, variable adherence, patient-reported findings on home tests, no blinding, and no assessment of whether masks could decrease disease transmission from mask wearers to others.

Conclusion: The recommendation to wear surgical masks to supplement other public health measures did not reduce the SARS-CoV-2 infection rate among wearers by more than 50% in a community with modest infection rates, some degree of social distancing, and uncommon general mask use. The data were compatible with lesser degrees of self-protection.

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the cause of coronavirus disease 2019 (COVID-19), has infected more than 54 million persons (1,2). Measures to impede transmission in health care and community settings are essential (3). The virus is transmitted person-to-person, primarily through the mouth, nose, or eyes via respiratory droplets, aerosols, or fomites (4,5). It can survive on surfaces for up to 72 hours (6), and touching a contaminated surface followed by face touching is another possible route of transmission (7). Face masks are a plausible means to reduce transmission of respiratory viruses by minimizing the risk that respiratory droplets will reach wearers' nasal or oral mucosa. Face masks are also hypothesized to reduce face touching (8,9), but frequent face and mask touching has been reported among health care personnel (10). Observational evidence supports the efficacy of face masks in health care settings (11,12) and as source control in patients infected with SARS-CoV-2 or other coronaviruses (13).

An increasing number of localities recommend masks in community settings on the basis of this observational evidence, but recommendations vary and controversy

exists (14). The World Health Organization (WHO) and the U.S. Centers for Disease Control and Prevention (15) strongly recommend that persons with symptoms or known infection wear masks to prevent transmission of SARS-CoV-2 to others (source control) (16). However, WHO acknowledges that we lack evidence that wearing a mask protects healthy persons from SARS-CoV-2 (prevention) (17). A systematic review of observational studies reported that mask use reduced risk for SARS, Middle East respiratory syndrome, and COVID-19 by 66% overall, 70% in health care workers, and 44% in the community (12). However, surgical and cloth masks were grouped in preventive studies, and none of the 3 included non–health care studies related directly to COVID-19. Another systematic review (18) and American College of Physicians recommendations (19) concluded that evidence on mask effectiveness for respiratory infection prevention is stronger in health care than community settings.

Observational evidence suggests that mask wearing mitigates SARS-CoV-2 transmission, but whether this observed association arises because masks protect uninfected wearers (protective effect) or because transmission is reduced from infected mask wearers (source control) is uncertain. Here, we report a randomized controlled trial (20) that assessed whether a recommendation to wear a surgical mask when outside the home among others reduced wearers' risk for SARS-CoV-2 infection in a setting where public health measures were in effect but community mask wearing was uncommon and not recommended.

METHODS

Trial Design and Oversight

DANMASK-19 (Danish Study to Assess Face Masks for the Protection Against COVID-19 Infection) was an investigator-initiated, nationwide, unblinded, randomized controlled trial (ClinicalTrials.gov: NCT04337541). The trial protocol was registered with the Danish Data Protection Agency (P-2020-311) (Part 10 of the **Supplement**, available at Annals.org) and published (21). The researchers presented the protocol to the independent regional scientific ethics committee of the Capital Region of Denmark, which did not require ethics approval (H-20023709) in accordance with Danish legislation (Parts 11 and 12 of the **Supplement**). The trial was done in accordance with the principles of the Declaration of Helsinki.

Participants and Study Period

During the study period (3 April to 2 June 2020), Danish authorities did not recommend use of masks in the community and mask use was uncommon (<5%) outside hospitals (22). Recommended public health measures included quarantining persons with SARS-CoV-2 infection, social distancing (including in shops and public transportation, which remained open), limiting the number of persons seen, frequent hand hygiene and cleaning, and limiting visitors to hospitals and nursing homes (23,24). Cafés and restaurants were closed during the study until 18 May 2020.

Eligible persons were community-dwelling adults aged 18 years or older without current or prior symptoms or diagnosis of COVID-19 who reported being outside the home among others for at least 3 hours per day and who did not wear masks during their daily work. Recruitment involved media advertisements and contacting private companies and public organizations. Interested citizens had internet access to detailed study information and to research staff for questions (Part 3 of the **Supplement**). At baseline, participants completed a demographic survey and provided consent for researchers to access their national registry data (Parts 4 and 5 of the **Supplement**). Recruitment occurred from 3 through 24 April 2020. Half of participants were randomly assigned to a group on 12 April and half on 24 April.

Intervention

Participants were enrolled and data registered using Research Electronic Data Capture (REDCap) software (25). Eligible participants were randomly assigned 1:1 to the mask or control group using a computer algorithm and were stratified by the 5 regions of Denmark (**Supplement Table 1**, available at Annals.org). Participants were notified of allocation by e-mail, and study packages were sent by courier (Part 7 of the **Supplement**). Participants in the mask group were instructed to wear a mask when outside the home during the next month. They received 50 three-layer, disposable, surgical face masks with ear loops (TYPE II EN 14683 [Abena]; filtration rate, 98%; made in China). Participants in both groups received materials and instructions for antibody testing on receipt and at 1 month. They also received materials and instructions for collecting an oropharyngeal/nasal swab sample for polymerase chain reaction (PCR) testing at 1 month and whenever symptoms compatible with COVID-19 occurred during follow-up. If symptomatic, participants were strongly encouraged to seek medical care. They registered symptoms and results of the antibody test in the online REDCap system. Participants returned the test material by prepaid express courier.

Written instructions and instructional videos guided antibody testing, oropharyngeal/nasal swabbing, and proper use of masks (Part 8 of the **Supplement**), and a help line was available to participants. In accordance with WHO recommendations for health care settings at that time, participants were instructed to change the mask if outside the home for more than 8 hours. At baseline and in weekly follow-up e-mails, participants in both groups were encouraged to follow current COVID-19 recommendations from the Danish authorities.

Antibody and Viral PCR Testing

Participants tested for SARS-CoV-2 IgM and IgG antibodies in whole blood using a point-of-care test (Lateral Flow test [Zhuhai Livzon Diagnostics]) according to the manufacturer's recommendations and as previously described (26). After puncturing a fingertip with a lancet, they withdrew blood into a capillary tube and placed 1 drop of blood followed by 2 drops of saline in the test chamber in each of the 2 test plates (IgM and IgG). Participants reported IgM and IgG results separately as

Downloaded from https://annals.org by McMaster University on 01/19/2021.

"1 line present" (negative), "2 lines present" (positive), or "I am not sure, or I could not perform the test" (treated as a negative result). Participants were categorized as seropositive if they had developed IgM, IgG, or both. The manufacturer reported that sensitivity was 90.2% and specificity 99.2%. A previously reported internal validation using 651 samples from blood donors before November 2019 and 155 patients with PCR-confirmed SARS-CoV-2 infection estimated a sensitivity of 82.5% (95% CI, 75.3% to 88.4%) and specificity of 99.5% (CI, 98.7% to 99.9%) (26). We (27) and others (28) have reported that oropharyngeal/nasal swab sampling for SARS-CoV-2 by participants, as opposed to health care workers, is clinically useful. Descriptions of RNA extraction, primer and probe used, reverse transcription, preamplification, and microfluidic quantitative PCR are detailed in Part 6 of the **Supplement**.

Data Collection

Participants received 4 follow-up surveys (Parts 4 and 5 of the **Supplement**) by e-mail to collect information on antibody test results, adherence to recommendations on time spent outside the home among others, development of symptoms, COVID-19 diagnosis based on PCR testing done in public hospitals, and known COVID-19 exposures.

Outcomes

The primary outcome was SARS-CoV-2 infection, defined as a positive result on an oropharyngeal/nasal swab test for SARS-CoV-2, development of a positive SARS-CoV-2 antibody test result (IgM or IgG) during the study period, or a hospital-based diagnosis of SARS-CoV-2 infection or COVID-19. Secondary end points included PCR evidence of infection with other respiratory viruses (**Supplement Table 2**, available at Annals.org).

Sample Size Calculations

The sample size was determined to provide adequate power for assessment of the combined composite primary outcome in the intention-to-treat analysis. Authorities estimated an incidence of SARS-CoV-2 infection of at least 2% during the study period. Assuming that wearing a face mask halves risk for infection, we estimated that a sample of 4636 participants would provide the trial with 80% power at a significance level of 5% (2-sided a level). Anticipating 20% loss to follow-up in this community-based study, we aimed to assign at least 6000 participants.

Statistical Analysis

Participants with a positive result on an antibody test at baseline were excluded from the analyses. We calculated CIs of proportions assuming binomial distribution (Clopper–Pearson).

The primary composite outcome (intention-to-treat) was compared between groups using the χ^2 test. Odds ratios and confidence limits were calculated using logistic regression. We did a per protocol analysis that included only participants reporting complete or predominant use of face masks as instructed. A conservative sensitivity analysis assumed that participants with a positive result on an antibody test at the end of the study who had not provided antibody test results at study entrance had had a positive result at entrance. To further examine the uncertainty of loss to follow-up, we did (post hoc) 200 imputations using the R package smcfcs, version 1.4.1 (29), to impute missing values of outcome. We included sex, age, type of work, time out of home, and outcome in this calculation.

Prespecified subgroups were compared by logistic regression analysis. In a post hoc analysis, we explored whether there was a subgroup defined by a constellation of participant characteristics for which a recommendation to wear masks seemed to be effective. We included sex, age, type of work, time out of home, and outcome in this calculation.

Two-sided *P* values less than 0.05 were considered statistically significant. Analyses were done using R, version 3.6.1 (R Foundation).

Role of the Funding Source

An unrestricted grant from the Salling Foundations supported the study, and the BESTSELLER Foundation donated the Livzon tests. The funders did not influence study design, conduct, or reporting.

Results

Participants

A total of 17 258 Danish citizens responded to recruitment, and 6024 completed the baseline survey and fulfilled eligibility criteria. The first participants (group 1; $n = 2995$) were randomly assigned on 12 April 2020 and were followed from 14 to 16 April through 15 May 2020. Remaining participants (group 2; $n = 3029$) were randomly assigned on 24 April 2020 and were followed from 2 to 4 May through 2 June 2020. A total of 3030 participants were randomly assigned to the recommendation to wear face masks, and 2994 were assigned not to wear face masks (**Figure**); 4862 participants (80.7%) completed the study. **Table 1** shows baseline characteristics, which were well balanced between groups. Participants reported having spent a median of 4.5 hours per day outside the home.

Adherence

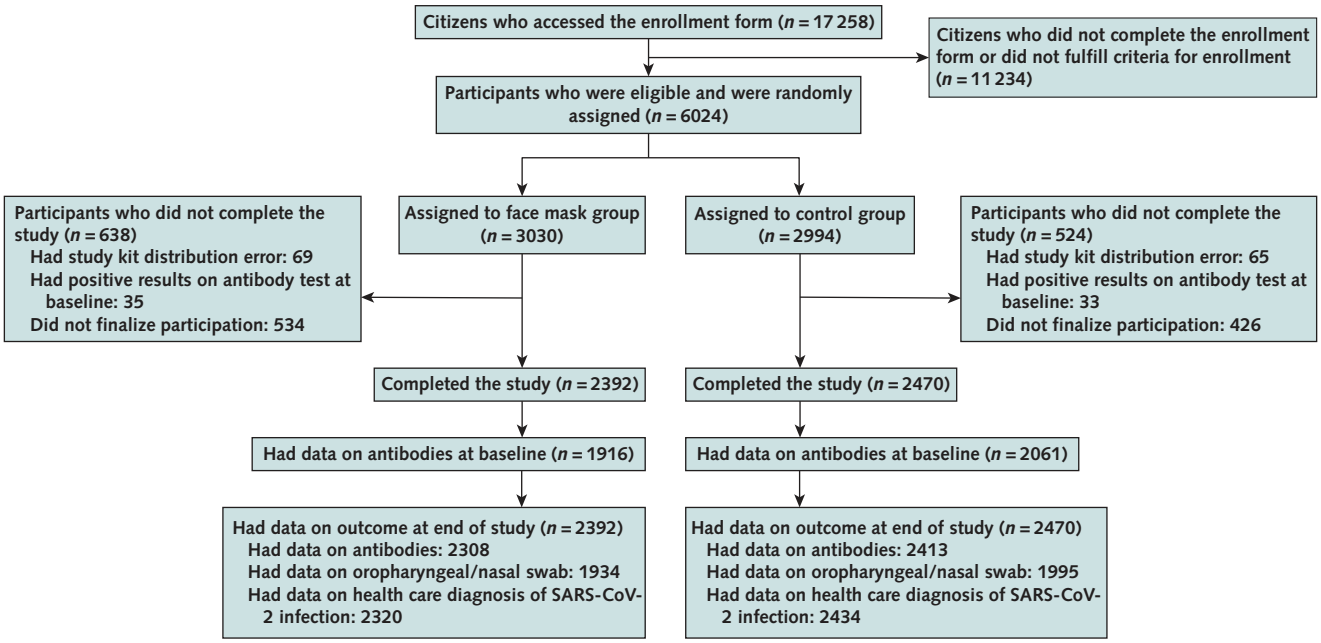
Based on the lowest adherence reported in the mask group during follow-up, 46% of participants wore the mask as recommended, 47% predominantly as recommended, and 7% not as recommended.

Primary Outcome

The primary outcome occurred in 42 participants (1.8%) in the mask group and 53 (2.1%) in the control group. In an intention-to-treat analysis, the between-group difference was −0.3 percentage point (CI, −1.2 to 0.4 percentage point; $P = 0.38$) (odds ratio [OR], 0.82 [CI, 0.54 to 1.23]; $P = 0.33$) in favor of the mask group (**Supplement Figure 1**, available at Annals.org). When this analysis was repeated with multiple imputation for missing data due to loss to follow-up, it yielded similar results (OR, 0.81 [CI, 0.53 to 1.23]; $P = 0.32$). **Table 2**

Downloaded from https://annals.org by McMaster University on 01/19/2021.

Figure 1. Study flow diagram.



Inclusion and exclusion criteria are described in the Methods section, and criteria for completion of the study are given in the Supplement (available at Annals.org). SARS-CoV-2 = severe acute respiratory syndrome coronavirus 2.

provides data on the components of the primary end point, which were similar between groups.

In a per protocol analysis that excluded participants in the mask group who reported nonadherence (7%), SARS-CoV-2 infection occurred in 40 participants (1.8%) in the mask group and 53 (2.1%) in the control group (between-group difference, −0.4 percentage point [CI, −1.2 to 0.5 percentage point]; $P = 0.40$) (OR, 0.84 [CI, 0.55 to 1.26]; $P = 0.40$). **Supplement Figure 2** (available at Annals.org) provides results of the prespecified subgroup analyses of the primary composite end point. No statistically significant interactions were identified.

In the preplanned psensitivity analysis, those who had a positive result on an antibody test at 1 month but had not provided antibody results at baseline were considered to have had positive results at baseline ($n = 18$)—that is, they were excluded from the analysis. In this analysis, the primary outcome occurred in 33 participants (1.4%) in the face mask group and 44 (1.8%) in the control group (between-group difference, −0.4 percentage point [CI, −1.1 to 0.4 percentage point]; $P = 0.22$) (OR, 0.77 [CI, 0.49 to 1.22]; $P = 0.26$).

Three post hoc (not preplanned) analyses were done. In the first, which included only participants reporting wearing face masks "exactly as instructed," infection (the primary outcome) occurred in 22 participants (2.0%) in the face mask group and 53 (2.1%) in the control group (between-group difference, −0.2 percentage point [CI, −1.3 to 0.9 percentage point]; $P = 0.82$) (OR, 0.93 [CI, 0.56 to 1.54]; $P = 0.78$). The second post hoc analysis excluded participants who did not provide antibody test results at baseline; infection occurred in 33 participants (1.7%) in the face mask group and 44 (2.1%) in the control group (between-group difference, −0.4 percentage point [CI, −1.4 to 0.4 percentage point]; $P = 0.33$) (OR, 0.80 [CI, 0.51 to 1.27]; $P = 0.35$). In the third post hoc analysis, which investigated constellations of patient characteristics, we did not find a subgroup where face masks were effective at conventional levels of statistical significance (data not shown).

A total of 52 participants in the mask group and 39 control participants reported COVID-19 in their household. Of these, 2 participants in the face mask group and 1 in the control group developed SARS-CoV-2 infection, suggesting that the source of most observed infections was outside the home. Reported symptoms did not differ between groups during the study period (**Supplement Table 3**, available at Annals.org).

Secondary Outcomes

In the mask group, 9 participants (0.5%) were positive for 1 or more of the 11 respiratory viruses other than SARS-CoV-2, compared with 11 participants (0.6%) in the control group (between-group difference, −0.1

Downloaded from https://annals.org by McMaster University on 01/19/2021.

percentage point [CI, −0.6 to 0.4 percentage point]; P = 0.87) (OR, 0.84 [CI, 0.35 to 2.04]; P = 0.71). Positivity for any virus, including SARS-CoV-2, occurred in 9 mask participants (0.5%) versus 16 control participants (0.8%) (between-group difference, −0.3 percentage point [CI, −0.9 to 0.2 percentage point]; P = 0.26) (OR, 0.58 [CI, 0.25 to 1.31]; P = 0.19).

Discussion

In this community-based, randomized controlled trial conducted in a setting where mask wearing was uncommon and was not among other recommended public health measures related to COVID-19, a recommendation to wear a surgical mask when outside the home among others did not reduce, at conventional levels of statistical significance, incident SARS-CoV-2 infection compared with no mask recommendation. We designed the study to detect a reduction in infection rate from 2% to 1%. Although no statistically significant difference in SARS-CoV-2 incidence was observed, the 95% CIs are compatible with a possible 46% reduction to 23% increase in infection among mask wearers. These findings do offer evidence about the degree of protection mask wearers can anticipate in a setting where others are not wearing masks and where other public health measures, including social distancing, are in effect. The findings, however, should not be used to conclude that a recommendation for everyone to wear masks in the community would not be effective in reducing SARS-CoV-2 infections, because the trial did not test the role of masks in source control of SARS-CoV-2 infection. During the study period, authorities did not recommend face mask use outside hospital settings and mask use was rare in community settings (22). This means that study participants' exposure was overwhelmingly to persons not wearing masks.

The observed infection rate was similar to that reported in other large Danish studies during the study period (26,30). Of note, the observed incidence of SARS-CoV-2 infection was higher than we had estimated when planning a sample size that would ensure more than 80% power to detect a 50% decrease in infection. The intervention lasted only 1 month and was carried out during a period when Danish authorities recommended quarantine of diagnosed patients, physical distancing, and hand hygiene as general protective means against SARS-CoV-2 transmission (23). Cafés and restaurants were closed through 18 May, but follow-up of the second randomized group continued through 2 June.

The first randomized group was followed while the Danish society was under lockdown. Reopening occurred (18 May 2020) during follow-up of the second group of participants, but it was not reflected in the outcome because infection rates were similar between groups (**Supplement Figure 2**). The relative infection rate between mask wearers and those not wearing masks would most likely be affected by changes in applied protective means or in the virulence of SARS-CoV-2, whereas the rate difference between the 2 groups would probably not be affected solely by a higher–or lower–number of infected citizens.

Although we saw no statistically significant difference in presence of other respiratory viruses, the study was not sufficiently powered to draw definite conclusions about the protective effect of masks for other viral infections. Likewise, the study had limited power for any of the subgroup analyses.

Table 1. Characteristics of Participants Completing the Study

Characteristic	Face Mask Group (n = 2392)	Control Group (n = 2470)
Mean age (SD), *y*	47.4 (14)	47.0 (13)
Female sex, *n (%)*	1545 (64.6)	1571 (63.6)
Smoker, *n (%)*	478 (20.0)	499 (20.2)
Wears eyeglasses daily, *n (%)*	956 (40.0)	929 (37.6)
Capital Region resident, *n (%)**	1220 (51.0)	1289 (52.2)
Provided antibody test results at baseline, *n (%)*	1916 (80.1)	2061 (83.4)
Occupation, *n (%)*		
Shop employee	108 (4.5)	85 (3.4)
Cashier	101 (4.2)	96 (3.9)
Craftsperson	110 (4.6)	103 (4.2)
Office employee	265 (11.1)	312 (12.6)
Manager	111 (4.6)	108 (4.4)
Transportation employee	617 (25.8)	625 (25.3)
Service employee	107 (4.5)	104 (4.2)
Home care/nursing home employee	197 (8.2)	229 (9.3)
Early childhood care staff	89 (3.7)	88 (3.6)
Salesperson	37 (1.5)	47 (1.9)
Other	650 (27.2)	673 (27.2)

* According to national authority data, the Capital Region had a higher frequency of coronavirus disease 2019 than other Danish regions; see subgroup analyses in **Supplement Figure 2** (available at Annals.org).

Table 2. Distribution of the Components of the Composite Primary Outcome

Outcome Component	Face Mask Group (*n* = 2392), *n (%)*	Control Group (*n* = 2470), *n (%)*	Odds Ratio (95% CI)*
Primary composite end point	42 (1.8)	53 (2.1)	0.82 (0.54–1.23)
Positive antibody test result†			
IgM	31 (1.3)	37 (1.5)	0.87 (0.54–1.41)
IgG	33 (1.4)	32 (1.3)	1.07 (0.66–1.75)
Positive SARS-CoV-2 RT-PCR	0 (0)	5 (0.2)	–
Health care–diagnosed SARS-CoV-2 or COVID-19	5 (0.2)	10 (0.4)	0.52 (0.18–1.53)

COVID-19 = coronavirus disease 2019; RT-PCR = reverse transcriptase polymerase chain reaction; SARS-CoV-2 = severe acute respiratory syndrome coronavirus 2.
* Calculated using logistic regression. The between-group differences in frequencies of positive SARS-CoV-2 RT-PCR were not statistically significant ($P = 0.079$).
† 124 participants in the mask group and 140 in the control group registered "not done" or unclear results of the antibody test–i.e., they were included in the analysis because they sent an oropharyngeal swab for PCR.

The primary outcome was mainly defined by antibodies against SARS-CoV-2. This definition was chosen because the viral load of infected patients may be only transiently detectable (31,32) and because approximately half of persons infected with SARS-CoV-2 are asymptomatic (33,26). Masks have been hypothesized to reduce inoculum size (34) and could increase the likelihood that infected mask users are asymptomatic, but this hypothesis has been challenged (35). For these reasons, we did not rely solely on identification of SARS-CoV-2 in oropharyngeal/nasal swab samples. As mentioned in the Methods section, an internal validation study estimated that the point-of-care test has 82.5% sensitivity and 99.5% specificity (26).

The observed rate of incident SARS-CoV-2 infection was similar to what was estimated during trial design. These rates were based on thorough screening of all participants using antibody measurements combined with PCR, whereas the observed official infection rates relied solely on PCR test–based estimates during the period. In addition, authorities tested only a small subset of primarily symptomatic citizens of the entire population, yielding low incidence rates. On this basis, the infection rates we report here are not comparable with the official SARS-CoV-2 infection rates in the Danish population. The eligibility requirement of at least 3 hours of exposure to other persons outside the home would add to this difference. Between 6 April and 9 May 2020, we found a similar seroprevalence of SARS-CoV-2 of 1.9% (CI, 0.8% to 2.3%) in Danish blood donors using the Livzon point-of-care test and assessed by laboratory technicians (36). Testing at the end of follow-up, however, may not have captured any infections contracted during the last part of the study period, but this would have been true in both the mask and control groups and was not expected to influence the overall findings.

The face masks provided to participants were high-quality surgical masks with a filtration rate of 98% (37). A published meta-analysis found no statistically significant difference in preventing influenza in health care workers between respirators (N95 [American standard] or FFP2 [European standard]) and surgical face masks (38). Adherence to mask use may be higher than observed in this study in settings where mask use is common. Some mask group participants (14%) reported adverse reactions from other citizens (**Supplement Table 4**, available at Annals.org). Although adherence may influence the protective effect of masks, sensitivity analyses had similar results across reported adherence.

How SARS-CoV-2 is transmitted–via respiratory droplets, aerosols, or (to a lesser extent) fomites–is not firmly established. Droplets are larger and rapidly fall to the ground, whereas aerosols are smaller ($\leq$5 μm) and may evaporate and remain in the air for hours (39). Transmission of SARS-CoV-2 may take place through multiple routes. It has been argued that for the primary route of SARS-CoV-2 spread–that is, via droplets–face masks would be considered effective, whereas masks would not be effective against spread via aerosols, which might penetrate or circumnavigate a face mask (37,39). Thus, spread of SARS-CoV-2 via aerosols would at least partially explain the present findings. Lack of eye protection may also have been of importance, and use of face shields also covering the eyes (rather than face masks only) has been advocated to halt the conjunctival route of transmission (40, 41). We observed no statistically significant interaction between wearers and nonwearers of eyeglasses (**Supplement Figure 2**). Recent reports indicate that transmission of SARS-CoV-2 via fomites is unusual (42), but masks may alter behavior and potentially affect fomite transmission.

The present findings are compatible with the findings of a review of randomized controlled trials of the efficacy of face masks for prevention (as personal protective equipment) against influenza virus (18). A recent meta-analysis that suggested a protective effect of face masks in the non–health care setting was based on 3 observational studies that included a total of 725 participants and focused on transmission of SARS-CoV-1 rather than SARS-CoV-2 (12). Of 725 participants, 138 (19%) were infected, so the transmission rate seems to be higher than for SARS-CoV-2. Further, these studies focused on prevention of infection in healthy mask wearers from patients with a known, diagnosed infection rather than prevention of transmission from persons in their surroundings in general. In addition, identified comparators (control participants) not wearing masks may also have missed other protective means. Recent observational studies that indicate a protective association between mandated mask use in the community and SARS-CoV-2 transmission are limited by study design

Downloaded from https://annals.org by McMaster University on 01/19/2021.

and simultaneous introduction of other public health interventions (14, 43).

Several challenges regarding wearing disposable face masks in the community exist. These include practical aspects, such as potential incorrect wearing, reduced adherence, reduced durability of the mask depending on type of mask and occupation, and weather. Such circumstances may necessitate the use of multiple face masks during the day. In our study, participants used a mean of 1.7 masks per weekday and 1.3 per weekend day (**Supplement Table 4**). Wearing a face mask may be physically unpleasant, and psychological barriers and other side effects have been described (44). "Face mask policing" between citizens might reinforce use of masks but may be challenging. In addition, the wearer of a face mask may change to a less cautious behavior because of a false sense of security, as pointed out by WHO (17); accordingly, our face mask group seemed less worried (**Supplement Table 4**), which may explain their increased willingness to wear face masks in the future (**Supplement Table 5**, available at Annals.org). These challenges, including costs and availability, may reduce the efficacy of face masks to prevent SARS-CoV-2 infection.

The potential benefits of a community-wide recommendation to wear masks include combined prevention and source control for symptomatic and asymptomatic persons, improved attention, and reduced potential stigmatization of persons wearing masks to prevent infection of others (17). Although masks may also have served as source control in SARS-CoV-2–infected participants, the study was not designed to determine the effectiveness of source control.

The most important limitation is that the findings are inconclusive, with CIs compatible with a 46% decrease to a 23% increase in infection. Other limitations include the following. Participants may have been more cautious and focused on hygiene than the general population; however, the observed infection rate was similar to findings of other studies in Denmark (26,30). Loss to follow-up was 19%, but results of multiple imputation accounting for missing data were similar to the main results. In addition, we relied on patient-reported findings on home antibody tests, and blinding to the intervention was not possible. Finally, a randomized controlled trial provides high-level evidence for treatment effects but can be prone to reduced external validity.

Our results suggest that the recommendation to wear a surgical mask when outside the home among others did not reduce, at conventional levels of statistical significance, the incidence of SARS-CoV-2 infection in mask wearers in a setting where social distancing and other public health measures were in effect, mask recommendations were not among those measures, and community use of masks was uncommon. Yet, the findings were inconclusive and cannot definitively exclude a 46% reduction to a 23% increase in infection of mask wearers in such a setting. It is important to emphasize that this trial did not address the effects of masks as source control or as protection in settings where social distancing and other public health measures are not in effect.

Reduction in release of virus from infected persons into the environment may be the mechanism for mitigation of transmission in communities where mask use is common or mandated, as noted in observational studies. Thus, these findings do not provide data on the effectiveness of widespread mask wearing in the community in reducing SARS-CoV-2 infections. They do, however, offer evidence about the degree of protection mask wearers can anticipate in a setting where others are not wearing masks and where other public health measures, including social distancing, are in effect. The findings also suggest that persons should not abandon other COVID-19 safety measures regardless of the use of masks. While we await additional data to inform mask recommendations, communities must balance the seriousness of COVID-19, uncertainty about the degree of source control and protective effect, and the absence of data suggesting serious adverse effects of masks (45).

ABSTRACT

Background

Viral epidemics or pandemics of acute respiratory infections (ARIs) pose a global threat. Examples are influenza (H1N1) caused by the H1N1pdm09 virus in 2009, severe acute respiratory syndrome (SARS) in 2003, and coronavirus disease 2019 (COVID-19) caused by SARS-CoV-2 in 2019. Antiviral drugs and vaccines may be insufficient to prevent their spread. This is an update of a Cochrane Review published in 2007, 2009, 2010, and 2011. The evidence summarised in this review does not include results from studies from the current COVID-19 pandemic.

Objectives

To assess the effectiveness of physical interventions to interrupt or reduce the spread of acute respiratory viruses.

Search methods

We searched CENTRAL, PubMed, Embase, CINAHL on 1 April 2020. We searched ClinicalTrials.gov, and the WHO ICTRP on 16 March 2020. We conducted a backwards and forwards citation analysis on the newly included studies.

Selection criteria

We included randomised controlled trials (RCTs) and cluster-RCTs of trials investigating physical interventions (screening at entry ports, isolation, quarantine, physical distancing, personal protection, hand hygiene, face masks, and gargling) to prevent respiratory virus transmission. In previous versions of this review we also included observational studies. However, for this update, there were sufficient RCTs to address our study aims.

Data collection and analysis

We used standard methodological procedures expected by Cochrane. We used GRADE to assess the certainty of the evidence. Three pairs of review authors independently extracted data using a standard template applied in previous versions of this review, but which was revised

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

to reflect our focus on RCTs and cluster-RCTs for this update. We did not contact trialists for missing data due to the urgency in completing the review. We extracted data on adverse events (harms) associated with the interventions.

Main results

We included 44 new RCTs and cluster-RCTs in this update, bringing the total number of randomised trials to 67. There were no included studies conducted during the COVID-19 pandemic. Six ongoing studies were identified, of which three evaluating masks are being conducted concurrent with the COVID pandemic, and one is completed.

Many studies were conducted during non-epidemic influenza periods, but several studies were conducted during the global H1N1 influenza pandemic in 2009, and others in epidemic influenza seasons up to 2016. Thus, studies were conducted in the context of lower respiratory viral circulation and transmission compared to COVID-19. The included studies were conducted in heterogeneous settings, ranging from suburban schools to hospital wards in high-income countries; crowded inner city settings in low-income countries; and an immigrant neighbourhood in a high-income country. Compliance with interventions was low in many studies.

The risk of bias for the RCTs and cluster-RCTs was mostly high or unclear.

Medical/surgical masks compared to no masks

We included nine trials (of which eight were cluster-RCTs) comparing medical/surgical masks versus no masks to prevent the spread of viral respiratory illness (two trials with healthcare workers and seven in the community). There is low certainty evidence from nine trials (3507 participants) that wearing a mask may make little or no difference to the outcome of influenza-like illness (ILI) compared to not wearing a mask (risk ratio (RR) 0.99, 95% confidence interval (CI) 0.82 to 1.18. There is moderate certainty evidence that wearing a mask probably makes little or no difference to the outcome of laboratory-confirmed influenza compared to not wearing a mask (RR 0.91, 95% CI 0.66 to 1.26; 6 trials; 3005 participants). Harms were rarely measured and poorly reported. Two studies during COVID-19 plan to recruit a total of 72,000 people. One evaluates medical/surgical masks (N = 6000) (published *Annals of Internal Medicine*, 18 Nov 2020), and one evaluates cloth masks (N = 66,000).

N95/P2 respirators compared to medical/surgical masks

We pooled trials comparing N95/P2 respirators with medical/surgical masks (four in healthcare settings and one in a household setting). There is uncertainty over the effects of N95/P2 respirators when compared with medical/surgical masks on the outcomes of clinical respiratory illness (RR 0.70, 95% CI 0.45 to 1.10; very low-certainty evidence; 3 trials; 7779 participants) and ILI (RR 0.82, 95% CI 0.66 to 1.03; low-certainty evidence; 5 trials; 8407 participants). The evidence is limited by imprecision and heterogeneity for these subjective outcomes. The use of a N95/P2 respirator compared to a medical/surgical mask probably makes little or no difference for the objective and more precise outcome of laboratory-confirmed influenza infection (RR 1.10, 95% CI 0.90 to 1.34; moderate-certainty evidence; 5 trials; 8407 participants). Restricting the pooling to healthcare workers made no difference to the overall findings. Harms were poorly measured and reported, but discomfort wearing medical/surgical masks or N95/P2 respirators was mentioned in several studies. One ongoing study recruiting 576 people compares N95/P2 respirators with medical surgical masks for healthcare workers during COVID-19.

Hand hygiene compared to control

Settings included schools, childcare centres, homes, and offices. In a comparison of hand hygiene interventions with control (no intervention), there was a 16% relative reduction in the number of people with ARIs in the hand hygiene group (RR 0.84, 95% CI 0.82 to 0.86; 7 trials; 44,129 participants; moderate-certainty evidence), suggesting a probable benefit. When considering the more strictly defined outcomes of ILI and laboratory-confirmed influenza, the estimates of effect for ILI (RR 0.98, 95% CI 0.85 to 1.13; 10 trials; 32,641 participants; low-certainty evidence) and laboratory-confirmed influenza (RR 0.91, 95% CI 0.63 to 1.30; 8 trials; 8332 participants; low-certainty evidence) suggest the intervention made little or no difference. We pooled all 16 trials (61,372 participants) for the composite outcome of ARI or ILI or influenza, with each study only contributing once and the most comprehensive outcome reported. The pooled data showed that hand hygiene may offer a benefit with an 11% relative reduction of respiratory illness (RR 0.89, 95% CI 0.84 to 0.95; low-certainty evidence), but with high heterogeneity. Few trials measured and reported harms.

There are two ongoing studies of handwashing interventions in 395 children outside of COVID-19.

We identified one RCT on quarantine/physical distancing. Company employees in Japan were asked to stay at home if household members had ILI symptoms. Overall fewer people in the intervention group contracted influenza compared with workers in the control group (2.75% versus 3.18%; hazard ratio 0.80, 95% CI 0.66 to 0.97). However, those who stayed at home with their infected family members were 2.17 times more likely to be infected.

We found no RCTs on eye protection, gowns and gloves, or screening at entry ports.

Authors' conclusions

The high risk of bias in the trials, variation in outcome measurement, and relatively low compliance with the interventions during the studies hamper drawing firm conclusions and generalising the findings to the current COVID-19 pandemic.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

There is uncertainty about the effects of face masks. The low-moderate certainty of the evidence means our confidence in the effect estimate is limited, and that the true effect may be different from the observed estimate of the effect. The pooled results of randomised trials did not show a clear reduction in respiratory viral infection with the use of medical/surgical masks during seasonal influenza. There were no clear differences between the use of medical/surgical masks compared with N95/P2 respirators in healthcare workers when used in routine care to reduce respiratory viral infection. Hand hygiene is likely to modestly reduce the burden of respiratory illness. Harms associated with physical interventions were under-investigated.

There is a need for large, well-designed RCTs addressing the effectiveness of many of these interventions in multiple settings and populations, especially in those most at risk of ARIs.

PLAIN LANGUAGE SUMMARY

Do physical measures such as hand-washing or wearing masks stop or slow down the spread of respiratory viruses?

What are respiratory viruses?

Respiratory viruses are viruses that infect the cells in your airways: nose, throat, and lungs. These infections can cause serious problems and affect normal breathing. They can cause flu (influenza), severe acute respiratory syndrome (SARS), and COVID-19.

How do respiratory viruses spread?

People infected with a respiratory virus spread virus particles into the air when they cough or sneeze. Other people become infected if they come into contact with these virus particles in the air or on surfaces on which they have landed. Respiratory viruses can spread quickly through a community, through populations and countries (causing epidemics), and around the world (causing pandemics).

How can we stop the spread of respiratory viruses?

Physical measures to try to stop respiratory viruses spreading between people include:

· washing hands often;

· not touching your eyes, nose, or mouth;

· sneezing or coughing into your elbow;

· wiping surfaces with disinfectant;

· wearing masks, eye protection, gloves, and protective gowns;

· avoiding contact with other people (isolation or quarantine);

· keeping a certain distance away from other people (distancing); and

· examining people entering a country for signs of infection (screening).

Why we did this Cochrane Review

We wanted to find out whether physical measures stop or slow the spread of respiratory viruses.

What did we do?

We searched for studies that looked at physical measures to stop people catching a respiratory virus infection.

We were interested in how many people in the studies caught a respiratory virus infection, and whether the physical measures had any unwanted effects.

Search date: This is an update of a review first published in 2007. We included evidence published up to 1 April 2020.

What we found

We identified 67 relevant studies. They took place in low-, middle-, and high-income countries worldwide: in hospitals, schools, homes, offices, childcare centres, and communities during non-epidemic influenza periods, the global H1N1 influenza pandemic in 2009, and epidemic influenza seasons up to 2016. No studies were conducted during the COVID-19 pandemic. We identified six ongoing, unpublished studies; three of them evaluate masks in COVID-19.

One study looked at quarantine, and none eye protection, gowns and gloves, or screening people when they entered a country.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

We assessed the effects of:

· medical or surgical masks;

· N95/P2 respirators (close-fitting masks that filter the air breathed in, more commonly used by healthcare workers than the general public); and

· hand hygiene (hand-washing and using hand sanitiser).

What are the results of the review?

Medical or surgical masks

Seven studies took place in the community, and two studies in healthcare workers. Compared with wearing no mask, wearing a mask may make little to no difference in how many people caught a flu-like illness (9 studies; 3507 people); and probably makes no difference in how many people have flu confirmed by a laboratory test (6 studies; 3005 people). Unwanted effects were rarely reported, but included discomfort.

N95/P2 respirators

Four studies were in healthcare workers, and one small study was in the community. Compared with wearing medical or surgical masks, wearing N95/P2 respirators probably makes little to no difference in how many people have confirmed flu (5 studies; 8407 people); and may make little to no difference in how many people catch a flu-like illness (5 studies; 8407 people) or respiratory illness (3 studies; 7799 people). Unwanted effects were not well reported; discomfort was mentioned.

Hand hygiene

Following a hand hygiene programme may reduce the number of people who catch a respiratory or flu-like illness, or have confirmed flu, compared with people not following such a programme (16 studies; 61,372 people). Few studies measured unwanted effects; skin irritation in people using hand sanitiser was mentioned.

How reliable are these results?

Our confidence in these results is generally low for the subjective outcomes related to respiratory illness, but moderate for the more precisely defined laboratory-confirmed respiratory virus infection, related to masks and N95/P2 respirators. The results might change when further evidence becomes available. Relatively low numbers of people followed the guidance about wearing masks or about hand hygiene, which may have affected the results of the studies.

Key messages

We are uncertain whether wearing masks or N95/P2 respirators helps to slow the spread of respiratory viruses.

Hand hygiene programmes may help to slow the spread of respiratory viruses.

Summary of findings 1. Medical/surgical masks compared to no masks for preventing the spread of viral respiratory illness

Randomised studies: medical/surgical masks compared to no masks for preventing the spread of viral respiratory illness

Patient or population: general population and healthcare workers
Setting: community and hospitals
Intervention: medical/surgical masks
Comparison: no masks

Outcomes	Anticipated absolute effects* (95% CI)		Relative effect (95% CI)	№ of participants (studies)	Certainty of the evidence (GRADE)	Comments
	Risk with no masks	Risk with randomised studies: masks				
Viral illness - influenza-like illness	Study population		RR 0.99 (0.82 to 1.18)	3507 (9 RCTs)	⊕⊕⊖⊖ LOW[a,b]	
	160 per 1000	158 per 1000 (131 to 189)				
Viral illness - laboratory-confirmed influenza	Study population		RR 0.91 (0.66 to 1.26)	3005 (6 RCTs)	⊕⊕⊕⊖ MODERATE[b]	
	40 per 1000	36 per 1000 (26 to 50)				
Influenza-like illness in healthcare workers	Study population		RR 0.37 (0.05 to 2.50)	1070 (2 RCTs)	⊕⊕⊖⊖ LOW[a,b]	Studies in healthcare workers only
	40 per 1000	15 per 1000 (2 to 100)				
Adverse events	-		-	(3 RCTs)	⊕⊖⊖⊖ VERY LOW[a,c]	Adverse events were not reported consistently and could not be meta-analysed. Adverse events reported for masks included warmth, discomfort, respiratory difficulties, humidity, pain, and shortness of breath, in up to 45% of participants.

*__The risk in the intervention group__ (and its 95% confidence interval) is based on the median observed risk in the comparison group of included studies and the **relative effect** of the intervention (and its 95% CI).

BACKGROUND

Description of the condition

Epidemic and pandemic viral infections pose a serious threat to people worldwide. Epidemics of note include severe acute respiratory syndrome (SARS) in 2003 and the Middle East respiratory syndrome (MERS), which began in 2012. Major pandemics include the H1N1 influenza caused by the H1N1pdm09 virus in 2009 and the coronavirus disease 2019 (COVID-19) caused by SARS-CoV-2.

Even non-epidemic acute respiratory infections (ARIs) place a huge burden on healthcare systems around the world, and are a prominent cause of morbidity (WHO 2017). Furthermore, ARIs are often antecedents to lower respiratory tract infections caused by bacterial pathogens (i.e. pneumonia), which cause millions of deaths worldwide, mostly in low-income countries (Schwartz 2018).

High viral load, high levels of transmissibility, susceptible populations, and symptomatic patients are considered to be the drivers of such epidemics and pandemics (Jefferson 2006a). Preventing the spread of respiratory viruses from person to person may be effective at reducing the spread of outbreaks. Physical interventions, such as the use of masks and physical distancing measures, might prevent the spread of respiratory viruses which are transmitted by large droplets from infected to susceptible people. This review assumes that physical interventions used to prevent transmission of respiratory viruses are similar for most viral ARIs.

Description of the intervention

Single measures of intervention (Demicheli 2018a; Demicheli 2018b; Jefferson 2014; Jefferson 2018; Thomas 2010), such as the use of vaccines or antivirals, may be insufficient to contain the spread of influenza, but combinations of interventions may reduce the reproduction number to below 1. For some respiratory viruses there are no licensed interventions, and a combination of social and physical interventions may be the only option to reduce the spread of outbreaks, particularly those that may be capable of becoming epidemic or pandemic in nature (Luby 2005). Such interventions were emphasised in the World Health Organization's latest Global Influenza Strategy 2019 to 2030, and have several possible advantages over other methods of suppressing ARI outbreaks since they may be instituted rapidly and may be independent of any specific type of infective agent, including novel viruses. In addition, the possible effectiveness of public health measures during the Spanish flu pandemic of 1918 to 1919 in US cities supports the impetus to investigate the existing evidence on the effectiveness of such interventions (Bootsma 2007), including quarantine (such as isolation, physical distancing) and the use of disinfectants. We also considered the major societal implications for any community adopting these measures (CDC 2005a; CDC 2005b; WHO 2006b; WHO 2020a; WHO 2020b).

How the intervention might work

Epidemics and pandemics are more likely during antigenic change (changes in the viral composition) in the virus or transmission from animals (domestic or wild) when there is no natural human immunity (Bonn 1997). High viral load, high levels of transmissibility, and symptomatic patients are considered to be the drivers of such epidemics and pandemics (Jefferson 2006b).

Physical interventions, such as the use of masks, physical distancing measures, school closures, and limitations of mass gatherings, might prevent the spread of the virus transmitted by large droplets or aerosols from infected to susceptible individuals. The use of hand hygiene, gloves, and protective gowns can also prevent the spread by limiting the transfer of viral particles onto and from fomites (inanimate objects such as flat surfaces, tabletops, utensils, porous surfaces, or nowadays cell phones, which can transmit the agent if contaminated). Such public health measures were widely adopted during the Spanish flu pandemic and have been the source of considerable debate (Bootsma 2007).

Why it is important to do this review

Although the benefits of physical interventions seem self-evident, given the global importance of interrupting viral transmission, having up-to-date estimates of their effectiveness is necessary to inform planning, decision-making, and policy. The outbreak of COVID-19 has prompted this update. Physical methods have several possible advantages over other methods of suppressing ARI outbreaks, including their rapid deployment and ability to be independent of the infective agent, including novel viruses.

The last update of this review in 2011, Jefferson 2011, identified 23 trials on physical interventions that might interrupt or reduce the spread of respiratory viruses. Because of poor reporting and heterogeneity, and the relatively small number of included trials, it was not possible to perform a meta-analysis. Case-control studies were sufficiently homogenous to permit meta-analysis, which provided evidence that hand-washing for a minimum of 11 times daily prevented cases of SARS during the 2003 epidemic (odds ratio 0.54, 95% confidence interval 0.44 to 0.67). Many randomised trials have been published in the past decade, prompting us to focus only on these for the current update.

This is the fourth update of a Cochrane Review first published in 2007 (Jefferson 2007; Jefferson 2009; Jefferson 2010; Jefferson 2011).

OBJECTIVES

To assess the effectiveness of physical interventions to interrupt or reduce the spread of acute respiratory viruses.

METHODS

Criteria for considering studies for this review

Types of studies

For this 2020 update we only considered individual-level RCTs, or cluster-RCTs, or quasi-RCTs for inclusion.

In previous versions of the review we also included observational studies (cohorts, case-controls, before-after, and time series studies). However, for this update there were sufficient randomised studies to address our study aims, so we excluded observational studies (which are known to be at a higher risk of bias).

Types of participants

People of all ages.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Types of interventions

We included randomised controlled trials (RCTs) and cluster-RCTs of trials investigating physical interventions (screening at entry ports, isolation, quarantine, physical distancing, personal protection, hand hygiene, face masks, and gargling) to prevent respiratory virus transmission compared with doing nothing or with another intervention.

Types of outcome measures

For this 2020 update we added one outcome: adverse events related to the intervention, and we split the outcomes into primary and secondary outcomes.

Primary outcomes

1. Numbers of cases of viral illness (including ARIs, influenza-like illness (ILI), and laboratory-confirmed influenza, or other viral pathogens).
2. Adverse events related to the intervention.

Secondary outcomes

1. Deaths.
2. Severity of viral illness as reported in the studies.
3. Absenteeism.
4. Hospital admissions.
5. Complications related to the illness, e.g. pneumonia.

Search methods for identification of studies

Electronic searches

For this 2020 update, we refined the original search strategy using a combination of previously included studies and automation tools (Clark 2020). We converted this search using the Polyglot Search Translator (Clark 2020), and ran the searches in the following databases:

1. the Cochrane Central Register of Controlled Trials (CENTRAL) (2020, Issue 3), which includes the Acute Respiratory Infections Group's Specialised Register (searched 1 April 2020) (Appendix 1);
2. PubMed (2010 to 1 April 2020) (Appendix 2);
3. Embase (2010 to 1 April 2020) (Appendix 3);
4. CINAHL (Cumulative Index to Nursing and Allied Health Literature) (2010 to 1 April 2020) (Appendix 4);
5. US National Institutes of Health Ongoing Trials Register ClinicalTrials.gov (January 2010 to 16 March 2020); and

We combined the database searches with the Cochrane Highly Sensitive Search Strategy for identifying randomised trials in MEDLINE: sensitivity- and precision-maximising version (2008 revision) (Lefebvre 2011). Details of previous searches are available in Appendix 5.

Searching other resources

We conducted a backwards-and-forwards citation analysis in Scopus on all newly included studies to identify other potentially relevant studies.

Data collection and analysis

Selection of studies

The search and citation analysis results were initially screened via the RobotSearch tool (Marshall 2018) to exclude all studies that were obviously not RCTs. We scanned the titles and abstracts of studies identified by the searches. We obtained the full-text articles of studies that either appeared to meet our eligibility criteria or for which there was insufficient information to exclude it. We then used a standardised form to assess the eligibility of each study based on the full article.

Data extraction and management

Three pairs of review authors (MJ/EF, LA/GB, EB/TOJ) independently applied the inclusion criteria to all identified and retrieved articles, and extracted data using a standard template that had been developed for and applied to previous versions of the review, but was revised to reflect our focus on RCTs and cluster-RCTs for this update. Any disagreements were resolved through discussion. We extracted and reported descriptions of interventions using the Template for Intervention Description and Replication (TIDieR) template (Table 1).

Assessment of risk of bias in included studies

Three pairs of review authors (TOJ/EB, LA/GB, MJ/EF) independently assessed risk of bias for the method of random sequence generation and allocation concealment (selection bias), blinding of participants and personnel (performance bias), blinding of outcome assessment (detection bias), outcome reporting (attrition bias), and selective reporting (reporting bias). We used the Cochrane 'Risk of bias' tool to assess risk of bias, classifying each 'Risk of bias' domain as 'low', 'high', or 'unclear'. The following were indications for low risk of bias:

1. method of random sequence generation: the method was well-described and is likely to produce balanced and truly random groups;
2. allocation concealment: the next treatment allocation was not known to participant/cluster or treating staff until after consent to join the study;
3. blinding of participants and personnel: the method is likely to maintain blinding throughout the study;
4. blinding of outcome assessors: all outcome assessors were unaware of treatment allocation;
5. outcome reporting: participant attrition throughout the study is reported, and reasons for loss are appropriately described; and
6. selective reporting: all likely planned and collected outcomes have been reported.

Measures of treatment effect

When possible, we performed meta-analysis and summarised effectiveness as risk ratio (RR) using 95% confidence intervals (CIs). For studies that could not be pooled, we used the effect measures reported by the trial authors (such as RR or incidence rate ratio (IRR) with 95% CI or, when these were not available, relevant P values).

Unit of analysis issues

Many of the included studies were cluster-RCTs. To avoid any unit of analysis issues, we only included treatment effect estimates that were based on methods that were appropriate for the analysis of

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

cluster trials, such as mixed models and generalised estimating equations. Given this restriction, we used the generalised inverse-variance method of meta-analysis. Some cluster-RCTs that did not report cluster-adjusted treatment effects provided sufficient data (number of events and participants by treatment group and intraclass correlations) for us to calculate appropriate treatment effect estimates and standard errors. For studies with multiple treatment groups but only one control group, where appropriate, we adjusted standard errors upwards to avoid unit of analysis errors in the meta-analyses.

Dealing with missing data

Given the urgency of this update, we did not contact authors of studies with significant missing data. Previously, whenever details of studies were unclear, or studies were only known to us by abstracts or communications at meetings, we corresponded with first or corresponding authors.

Assessment of heterogeneity

Aggregation of data was dependent on types of comparisons, sensitivity and homogeneity of definitions of exposure, populations and outcomes used. We calculated the I^2 statistic and Chi^2 test for each pooled estimate to assess the presence of statistical heterogeneity (Higgins 2002; Higgins 2003).

Assessment of reporting biases

Given the widely disparate nature of our evidence base, we limited our assessment of possible reporting biases to funnel plot visual inspection if we had > 10 included studies.

Data synthesis

If possible and appropriate, we combined studies in a meta-analysis. We used the generalised inverse-variance random-effects model. We chose the random-effects model because we expected clinical heterogeneity due to differences in pooled interventions and outcome definitions, and methodological heterogeneity due to pooling of RCTs and cluster-RCTs.

Subgroup analysis and investigation of heterogeneity

We conducted two post hoc subgroup analyses:

1. healthcare workers for the comparison of masks versus control; and
2. children for the comparison of hand hygiene versus control.

We did not conduct further investigation of heterogeneity due to insufficient numbers of studies included in the comparisons.

Sensitivity analysis

We conducted a sensitivity analysis for hand hygiene versus control where we included the most precise and unequivocal measure of viral illness reported for each included study.

Summary of findings and assessment of the certainty of the evidence

We created three 'Summary of findings' tables using the following outcomes: numbers of cases of viral illness (including ARIs, ILI, and laboratory-confirmed influenza) and adverse events related to the intervention (Summary of findings 1; Summary of findings 2; Summary of findings 3). We planned to include the secondary outcomes of deaths; severity of viral illness as reported in the studies; absenteeism; hospital admissions; and complications related to the illness (e.g. pneumonia). However, this data were poorly reported in the included studies. We used the five GRADE considerations (study limitations, consistency of effect, imprecision, indirectness, and publication bias) to assess the certainty of evidence as it related to the studies which contributed data to the meta-analyses for the prespecified outcomes (Atkins 2004). We used the methods and recommendations described in Section 8.5 and Chapter 12 of the *Cochrane Handbook for Systematic Reviews of Interventions* (Higgins 2011), employing GRADEpro GDT software (GRADEpro GDT 2015). We justified all decisions to down- or upgrade the certainty of the evidence in footnotes, and made comments to aid the reader's understanding of the review where necessary.

RESULTS

Description of studies

See Characteristics of included studies and Characteristics of excluded studies tables.

Results of the search

We identified a total of 3180 titles in this 2020 update. We excluded 3092 titles and retrieved the full papers of 88 studies, to include 44 new studies. See Figure 1.

Included studies

The 44 newly included studies were all RCTs (n = 11) or cluster-RCTs (n = 33) published between 2010 and 2019. We included 23 RCTs in the 2011 version of the review. For detailed descriptions of the interventions of the included studies, see Table 1.

Fifteen trials focused on using masks (Aiello 2010; Aiello 2012; Barasheed 2014; Canini 2010; Cowling 2008; Ide 2016; Jacobs 2009; Loeb 2009; MacIntyre 2009; MacIntyre 2011; MacIntyre 2013; MacIntyre 2015; MacIntyre 2016; Radonovich 2019; Suess 2012). Ten of the 15 trials compared medical/surgical masks to no mask (control) (Aiello 2010; Aiello 2012; Barasheed 2014; Canini 2010; Cowling 2008; Jacobs 2009; MacIntyre 2009; MacIntyre 2015; MacIntyre 2016; Suess 2012). One study compared catechin-treated masks to no mask (Ide 2016), and one study included cloth masks versus control (third arm in MacIntyre 2015). Three of the 15 trials were in healthcare workers (Ide 2016; Jacobs 2009; MacIntyre 2015), whilst the remaining trials were in non-healthcare workers (students, households, families, or pilgrims). Only one trial was conducted during H1N1 pandemic season (Suess 2012).

Five of the 15 trials compared N95 masks or P2 masks to medical/surgical masks (Loeb 2009; MacIntyre 2009; MacIntyre 2011; MacIntyre 2013; Radonovich 2019). All of these trials, except for one study that was conducted on household individuals (MacIntyre 2009), included healthcare workers either in a hospital setting, Loeb 2009; MacIntyre 2011; MacIntyre 2013, or an outpatient setting (MacIntyre 2009; Radonovich 2019).

One trial evaluated the effectiveness of quarantining workers of one of two sibling companies in Japan whose family members had developed an ILI during the 2009 to 2010 H1N1 influenza pandemic (Miyaki 2011).

Fifteen trials compared hand hygiene interventions with no hand hygiene (control) and provided data suitable for meta-analysis. The populations in these trials included adults, children, and families, in settings such as schools (Biswas 2019; Stebbins 2011), childcare centres (Azor-Martinez 2018; Correa 2012; Roberts 2000; Zomer 2015), homes/households (Cowling 2009; Larson 2010; Little 2015; Nicholson 2014; Ram 2015; Sandora 2005; Simmerman 2011), offices (Hubner 2010), and military trainees (Millar 2016). None of the trials was conducted during a pandemic, although some of the studies were conducted during peak influenza seasons.

A further 10 trials that compared a variety of hand hygiene modalities to control provided insufficient information to include in meta-analyses. Three trials were in children: one was conducted in daycare centres in Denmark examining a multimodal hygiene programme (Ladegaard 1999), and two trials compared a hand hygiene campaign or workshop in an elementary school environment in Saudi Arabia, Alzaher 2018, and Egypt, Talaat 2011. Three trials tested virucidal hand treatment in an experimental setting, Gwaltney 1980; Turner 2004a, and in a community, Turner 2012, in the USA. Feldman 2016 compared hand-washing with chlorhexidine gluconate amongst Israeli sailors. One trial compared hand sanitiser packaged in a multimodal hygiene programme amongst office employees in the USA (Arbogast 2016). Two trials were conducted in a long-term facility setting: one trial examined the effect of a bundle hand hygiene programme on infectious risk in nursing home residents in France (Temime 2018), and the other trial compared the effect of using hand sanitisers in healthcare workers on the rate of infections (including respiratory infections) in nursing home residents in Hong Kong (Yeung 2011).

Five trials compared different hand hygiene interventions in a variety of settings such as schools (Morton 2004 in kindergartens and elementary schools in the USA; Priest 2014 in primary schools in New Zealand; and Pandejpong 2012 in kindergartens in Thailand). One study was conducted in low-income neighbourhoods in Karachi, Pakistan (Luby 2005), and one was conducted in a workplace environment in Finland (Savolainen-Kopra 2012). A variety of interventions were used across these trials such as soap and water (Luby 2005; Savolainen-Kopra 2012), hand sanitiser (Morton 2004; Pandejpong 2012; Priest 2014; Savolainen-Kopra 2012), body wash (Luby 2005), and alcohol-based hand wipes (Morton 2004), with or without additional hygiene education. There was considerable variation in interventions, and the information in the trial reports was insufficient to permit meta-analysis.

Seven trials compared a combined intervention of hand hygiene and face masks with control. Four of these trials were carried out in households in Germany (Suess 2012), Thailand (Simmerman 2011), Hispanic immigrant communities in the USA (Larson 2010), and households in Hong Kong (Cowling 2009). Two trials were conducted amongst university student residences (Aiello 2010; Aiello 2012), and one trial in a group of pilgrims at the annual Hajj (Aelami 2015). Moreover, six trials evaluated the incremental benefit of combining surgical mask in addition to hand hygiene with soap, Simmerman 2011, hand sanitiser, Aiello 2010; Aiello 2012; Larson 2010; Suess 2012, or both, Cowling 2009, versus mask or hand hygiene alone on the outcomes of ILI and influenza. Aelami 2015 investigated a hygienic package (alcohol-based handrub (gel or spray), surgical masks, soap, and paper handkerchiefs) with a control group.

Seven trials compared a multimodal combination of hand hygiene and disinfection of surfaces, toys, linen, or other components of the environment with a control (Ban 2015; Carabin 1999; Ibfelt 2015; Kotch 1994; McConeghy 2017; Sandora 2008; White 2001). Variation in scope and type of interventions and insufficient data in trial reports precluded meta-analysis. All studies except for one were in children (McConeghy 2017 was in nursing population).

Three trials included in two papers investigated the role of virucidal tissues in interrupting transmission of naturally occurring respiratory infections in households (Farr 1988a; Farr 1988b; Longini 1988). Four cluster-RCTs implemented complex, multimodal sanitation, education, cooking, and hygiene interventions (Chard 2019; Hartinger 2016; Huda 2012; Najnin 2019). All four of these trials were conducted in low-income countries in settings with minimal to no access to basic sanitation.

Three trials assessed the effect of gargling on the incidence of upper respiratory tract infections (URTIs) or influenza: gargling with povidone-iodine (Satomura 2005), green tea (Ide 2014), and tap water (Goodall 2014).

Ongoing studies

We identified six ongoing studies. Two assess hand hygiene measures (NCT03454009; NCT04267952), and four assess face masks (NCT04471766; NCT04296643; NCT04337541; Wang 2015) one of which – NCT04337541 - published as this review update was going to press.

Excluded studies

We excluded a total of 160 studies. We identified 12 new studies for exclusion at the data extraction stage of this 2020 update, all of which appeared to be eligible at screening. Six of the 12 studies were ineligible due to only reporting composite outcomes that included other infections besides those caused by respiratory viruses (Azor-Martinez 2014; Bowen 2007; Chami 2012; Denbak 2018; Stedman-Smith 2015; Vessey 2007); two trials measured absenteeism due to non-specific infection (Lennell 2008; Rosen 2006); one trial only had two clusters (Nandrup-Bus 2009); one study was not an RCT (Patel 2012); one study evaluated a hand hygiene intervention that was antibacterial rather than antiviral (Slayton 2016); and one study had no respiratory illness data for extraction (Uhari 1999).

Risk of bias in included studies

The overall risk of bias is presented graphically in Figure 2 and summarised in Figure 3. Details on risk of bias for the included studies are provided below.

Allocation

For this 2020 review, information on sequence generation was overall poorly reported in most of the newly included studies. Twenty-one newly included studies provided adequate information on randomisation scheme and were judged as at low risk of bias (Aiello 2012; Azor-Martinez 2016; Azor-Martinez 2018; Biswas 2019; Canini 2010; Correa 2012; Goodall 2014; Ide 2014; MacIntyre 2015; MacIntyre 2016; Millar 2016; Najnin 2019; Priest 2014; Radonovich 2019; Ram 2015; Simmerman 2011; Stebbins 2011; Suess 2012; Talaat 2011; Turner 2012; Zomer 2015). Nine studies described the use of computerised sequence generation program/software (Aiello 2012; Azor-Martinez 2018; Biswas 2019; Canini 2010; Millar 2016; Najnin 2019; Radonovich 2019; Talaat 2011; Turner 2012). One study used random number tables for sequence generation (Azor-Martinez 2016). Three studies described using the random function in Microsoft Excel (Correa 2012; MacIntyre 2016; Suess 2012). Two studies used statistical software to generate a randomisation allocation (MacIntyre 2015; Priest 2014). Two studies reported using block randomisation: Ram 2015 used block randomisation, and an independent investigator generated the list of random assignments, whilst Simmerman 2011 performed block randomisation. Stebbins 2011 used constrained randomisation, and Zomer 2015 reported using stratified randomisation by means of computer generation with a 1:1 ratio in each of the strata.

Fourteen studies reported insufficient information to permit a judgement on the adequacy of the process to minimise selection bias (Aelami 2015; Alzaher 2018; Arbogast 2016; Barasheed 2014; Chard 2019; DiVita 2011; Feldman 2016; Hubner 2010; Ibfelt 2015; McConeghy 2017; Miyaki 2011; Pandejpong 2012; Savolainen-Kopra 2012; Yeung 2011). Six studies provided some description about sequence generation, but it was still unclear (Hartinger 2016; Huda 2012; Ide 2016; Little 2015; MacIntyre 2011; MacIntyre 2013). Huda 2012 mentioned random number tables, but it was unclear if this was for random selection or randomisation. Ide 2016 used computer-generated randomisation, but the method was not stated. Hartinger 2016 used covariate-constrained randomisation, but the method was not described. In Little 2015, participants were automatically randomly assigned by the intervention software, but the sequence generation was not described. Two studies used a secure computerised randomisation program (MacIntyre 2011; MacIntyre 2013), but the sequence generation was not described.

Three of the newly included studies were poorly randomised (Ban 2015; Nicholson 2014; Temime 2018). Ban 2015 included only two clusters, and the randomisation scheme was not reported. Nicholson 2014 used coin tossing, which can lead to a large imbalance. Temime 2018 used “simple randomisation” with no further description.

For the RCTs included in previous versions of the review, three were poorly reported with no description of randomisation sequence or concealment of allocation (Gwaltney 1980; Turner 2004a; Turner 2004b). The quality of the cluster-RCTs varied, with four studies not providing a description of the randomisation procedure (Carabin 1999; Kotch 1994; Morton 2004; White 2001). We rated seven studies as at low risk of bias for sequence generation (Cowling 2008; Cowling 2009; Luby 2005; Roberts 2000; Sandora 2005; Sandora 2008; Satomura 2005), and a further six studies as at unclear risk of bias (Farr 1988a; Farr 1988b; Ladegaard 1999; Loeb 2009; Longini 1988; MacIntyre 2009).

Many of the newly included cluster-RCTs did not report adequately on allocation concealment. Twenty-one of these studies reported adequate allocation and were judged as at low risk of bias (Aiello 2012; Alzaher 2018; Azor-Martinez 2016; Azor-Martinez 2018; Biswas 2019; Canini 2010; Chard 2019; Goodall 2014; Ide 2014; Ide 2016; Little 2015; MacIntyre 2011; MacIntyre 2015; Nicholson 2014; Priest 2014; Radonovich 2019; Ram 2015; Savolainen-Kopra 2012; Stebbins 2011; Suess 2012; Turner 2012). Aiello 2012 randomised all residence houses in each of the residence halls prior to the intervention implementation. Alzaher 2018 allocated schools prior to all schoolgirls attending selected schools being invited to participate. Azor-Martinez 2016 allocated schools/classes prior to children's recruitment. Azor-Martinez 2018 assigned clusters prior to recruitment. Biswas 2019 completed the allocation prior to individuals being recruited. Chard 2019 allocated schools prior to individuals being recruited. Goodall 2014 used opaque, sealed, serially numbered envelopes that were only accessed when two study personnel were present. Ide 2014 also reported using individual drawing of sealed, opaque envelopes to randomly assign participants to the study groups. MacIntyre 2011 randomised hospitals prior to inclusion of participants. In MacIntyre 2015, hospital wards were randomised prior to recruitment of individuals. Nicholson 2014 used coin tossing to assign communities to intervention or control arms. Radonovich 2019 used constrained randomisation to resolve any potential imbalance between covariates between the trial arms. Four studies reported the use of central randomisation: Canini 2010 used central randomisation employing an interactive voice response system; Ide 2016 used central randomisation services; in Little 2015 participants were automatically randomly assigned by the intervention software; and Ram 2015 described a central allocation through data collectors notifying the field research officer, who consulted the block randomisation list to make the assignment of the household compound to intervention or control. Savolainen-Kopra 2012 randomised clusters by matching prior to the onset of the interventions. Four studies reported that allocation was assigned by personnel (investigator, physician, or statistician) unaware of the randomisation sequence (Priest 2014; Stebbins 2011; Suess 2012; Turner 2012). Twenty-two studies reported insufficient information to permit a judgement on the adequacy of the process to minimise selection bias (Aelami 2015; Arbogast 2016; Ban 2015; Barasheed 2014; Correa 2012; DiVita 2011; Feldman 2016; Hartinger 2016; Hubner 2010; Huda 2012; Ibfelt 2015; MacIntyre 2013; McConeghy 2017; Millar 2016; Miyaki 2011; Najnin 2019; Pandejpong 2012; Simmerman 2011; Talaat 2011; Temime 2018; Yeung 2011; Zomer 2015). Two studies provided some information about allocation, but it was not enough to permit a judgement on risk of bias (Barasheed 2014; Simmerman 2011). Barasheed 2014 randomised pilgrim tents using an independent study co-ordinator who was not an investigator, but did not describe how this was done. Simmerman 2011 described using a study co-ordinator to assign households to study arm (after consent was obtained). Only one of the newly added studies was judged as at high risk of bias, where random assignment was allocated by doctors enrolling the participants (MacIntyre 2016). Of the previously included RCTs, 14 provided no or an insufficient description of concealment of allocation (Carabin 1999; Farr 1988a; Farr 1988b; Gwaltney 1980; Kotch 1994; Ladegaard 1999; Larson 2010; MacIntyre 2009; Morton 2004; Roberts 2000; Sandora 2008; Turner 2004a; Turner 2004b; White 2001). We assessed all of the remaining studies as at low risk of bias (Canini 2010; Cowling 2008; Cowling 2009; Loeb 2009; Longini 1988; Luby 2005; Sandora

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

2005; Satomura 2005). Aiello 2010 used the drawing of a uniform ticket with the name of each hall out of a container and was rated as at high risk of bias.

Blinding

Although blinding is less of a concern in cluster-RCTs, the risk of bias is substantial when the outcomes are subjective and the outcome assessor is not blinded. We judged 26 studies to have a high risk of bias (Aiello 2012; Alzaher 2018; Arbogast 2016; Azor-Martinez 2016; Azor-Martinez 2018; Ban 2015; Biswas 2019; Carabin 1999; Chard 2019; Correa 2012; Cowling 2008; Ide 2014; Kotch 1994; Ladegaard 1999; Little 2015; MacIntyre 2011; MacIntyre 2015; MacIntyre 2016; McConeghy 2017; Najnin 2019; Nicholson 2014; Ram 2015; Sandora 2008; Savolainen-Kopra 2012; Temime 2018; Zomer 2015). We assessed five cluster-RCTs as at low risk of bias. Farr 1988a and Farr 1988b were double-blinded studies and were judged as at low risk of bias. MacIntyre 2013 and Simmerman 2011 reported laboratory-confirmed influenza, and blinding would not have affected the result. In Miyaki 2011 the self-reported respiratory symptoms were confirmed by a physician. We judged three cluster-RCTs to have a low risk of detection bias because the outcome was laboratory-confirmed influenza, Barasheed 2014; Suess 2012, or physician-confirmed ILI, Pandejpong 2012. Two cluster-RCTs provided insufficient data to judge the effect of non-blinding. Talaat 2011 included outcomes that were both self-reported ILI and laboratory-confirmed influenza. In Yeung 2011 the detection of cases was based on record for hospitalisation related to infection (including pneumonia). Eleven cluster-RCTs were not blinded, but we judged the primary outcome to be unaffected by non-blinding. Seven trials reported laboratory-confirmed influenza (Aiello 2012; Cowling 2009; Larson 2010; Loeb 2009; MacIntyre 2009; Millar 2016; Stebbins 2011). Four studies reported self-reported outcome (Canini 2010; Priest 2014; Roberts 2000; Sandora 2008), but outcome assessors were not aware of the intervention assignment. Five RCTs were double-blinded and were judged as at low risk of bias (Goodall 2014; Ide 2016; Longini 1988; Luby 2005; White 2001), whilst two studies were single-blinded where investigators, Radonovich 2019, or laboratory personnel, Turner 2012, were blinded. Four RCTs were not blinded and were judged as at high risk of bias given the subjective nature of the outcome assessed (Hubner 2010; Ibfelt 2015; Jacobs 2009; Satomura 2005). Turner 2004a and Turner 2004b were double-blind studies, but insufficient information was provided to assess risk of bias.

Incomplete outcome data

In this 2020 review, we assessed 26 newly included trials as having a low risk of attrition bias, with sufficient evidence from the participant flow chart, and explanation of loss to follow-up (which was minimal) similar between groups (Aiello 2012; Alzaher 2018; Arbogast 2016; Azor-Martinez 2018; Barasheed 2014; Canini 2010; Chard 2019; Correa 2012; Goodall 2014; Hartinger 2016; Hubner 2010; Ide 2014; Ide 2016; MacIntyre 2011; MacIntyre 2013; MacIntyre 2015; MacIntyre 2016; Miyaki 2011; Pandejpong 2012; Radonovich 2019; Ram 2015; Simmerman 2011; Suess 2012; Turner 2012; Yeung 2011; Zomer 2015). Seven studies did not report sufficient information on incomplete data (attrition bias) (Aelami 2015; DiVita 2011; Feldman 2016; Hartinger 2016; Ibfelt 2015; McConeghy 2017; Priest 2014). Twelve studies had a high risk of attrition bias (Azor-Martinez 2016; Ban 2015; Biswas 2019; Huda 2012; Little 2015; Millar 2016; Najnin 2019; Nicholson 2014; Savolainen-Kopra 2012; Stebbins 2011; Talaat 2011; Temime 2018). In Azor-Martinez 2016, attrition levels were high and differed between the two groups. Ban 2015 did not report on reasons for loss to follow-up. Biswas 2019 did not provide information on missing participants (28 children in the control schools and two children in the intervention schools). Huda 2012 did not provide a flow diagram of study participants. Little 2015 had high attrition that differed between the two groups. Attrition in Millar 2016 differed amongst the three groups. In addition, ARI cases were captured utilising clinic-based medical records for those participants who sought hospital care only. In Najnin 2019, there was high migration movement during the study, which could have distorted the baseline characteristics even more. There was no description of how such migration and changes in the intervention group were dealt with. In Nicholson 2014, households were removed from the study if they provided no data for five consecutive weeks. Although attrition was reported in Savolainen-Kopra 2012, and 76% of volunteers who were recruited at the beginning of the reporting period completed the study, new recruits were added during the study to replace volunteers lost in most clusters. The total number of reporting participants at the end of the trial was 626 (91.7%) compared to the beginning, meaning that 15.7% of participants were replaced during the study. In Stebbins 2011 reasons for episodes of absence in 66% of the study participants were not reported. Talaat 2011 did not provide a flow chart of clusters flow during the study period and provided no information on withdrawal. Temime 2018 was greatly biased due to underreporting of outcomes in the control groups. Furthermore, no study flow chart was provided, and there was no reporting on any exclusions.

Selective reporting

In this 2020 review, 22 newly included studies reported all specified outcomes and were judged as at low risk of reporting bias (Aiello 2012; Barasheed 2014; Canini 2010; Chard 2019; Goodall 2014; Hartinger 2016; Ibfelt 2015; Ide 2016; Little 2015; MacIntyre 2011; MacIntyre 2013; MacIntyre 2015; MacIntyre 2016; Pandejpong 2012; Priest 2014; Radonovich 2019; Savolainen-Kopra 2012; Simmerman 2011; Suess 2012; Temime 2018; Turner 2012; Zomer 2015). For 18 studies, it is unlikely that other outcomes were measured and not reported, although no protocol was available to assess reporting bias (Aelami 2015; Alzaher 2018; Arbogast 2016; Azor-Martinez 2016; Azor-Martinez 2018; Ban 2015; Biswas 2019; Correa 2012; DiVita 2011; Feldman 2016; Hubner 2010; Huda 2012; Ide 2014; Miyaki 2011; Nicholson 2014; Stebbins 2011; Talaat 2011; Yeung 2011). Three studies were at high risk of reporting bias (McConeghy 2017; Millar 2016; Najnin 2019). In McConeghy 2017, URTI was mentioned in the methods (the intervention presumably would have targeted these), but only lower respiratory tract infection (LRTI) and overall infection were reported. Millar 2016 was originally conducted for another purpose; we could not find the respiratory outcomes reported in the study as part of the original study protocol. In Najnin 2019, the published study protocol did not include respiratory illness as an outcome.

Other potential sources of bias

An additional consideration for cluster-RCTs is identification/recruitment bias, where individuals are recruited in the trial after clusters are randomised. Such bias can introduce an imbalance amongst groups. Of the cluster-RCTs included in our 2020 review, we judged 13 to have a low risk of identification/recruitment bias (Arbogast 2016; Biswas 2019; Canini 2010; Cowling 2008; Longini

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

1988; Luby 2005; MacIntyre 2015; MacIntyre 2016; Roberts 2000; Sandora 2005; Suess 2012; Temime 2018; White 2001). In Arbogast 2016, all identified individuals (office workers) were included in the assigned cluster. Schools were identified and then randomised to the clusters; students were then randomly selected from each classroom and school. Nine studies described identification of participants, consenting/enrolling, and then randomising to the clusters (Canini 2010; Cowling 2008; Longini 1988; Luby 2005; MacIntyre 2015; MacIntyre 2016; Roberts 2000; Sandora 2005; White 2001). Suess 2012 identified and consented patients, then recruitment was performed by physicians unaware of cluster assignment. In Temime 2018, directors of the included nursing homes agreed to participate in the study before randomisation, and written consent was not required from the residents. We judged 11 cluster-RCTs as at high risk of identification/recruitment bias (Aiello 2010; Aiello 2012; Azor-Martinez 2018; Chard 2019; Correa 2012; Cowling 2009; Larson 2010; McConeghy 2017; Nicholson 2014; Priest 2014; Savolainen-Kopra 2012). In Aiello 2010 and Aiello 2012, recruitment continued for two weeks after start of the study, which could have introduced bias. Six trials identified and recruited participants after cluster randomisation (Azor-Martinez 2018; Chard 2019; Cowling 2009; Larson 2010; McConeghy 2017; Nicholson 2014). Three trials recruited new participants after the start of the study to replace those lost to follow-up (Correa 2012; Priest 2014; Savolainen-Kopra 2012). We judged five cluster-RCTs to have probable identification/recruitment bias (Alzaher 2018; Barasheed 2014; MacIntyre 2011; Najnin 2019; Radonovich 2019), whereas in 19 studies there were insufficient details to permit a judgement of risk of bias (Carabin 1999; DiVita 2011; Feldman 2016; Hartinger 2016; Huda 2012; Ibfelt 2015; Kotch 1994; Ladegaard 1999; MacIntyre 2009; MacIntyre 2013; Millar 2016; Miyaki 2011; Pandejpong 2012; Radonovich 2019; Sandora 2008; Stebbins 2011; Talaat 2011; Yeung 2011; Zomer 2015).

Twenty-six cluster-RCTs reported intracluster correlation coefficient (ICC) to adjust sample size, taking into consideration clustering effects, and described adjusting outcomes for clustering effect using different statistical methods, or provided justification for not performing adjusted analysis for clustering (Aiello 2010; Aiello 2012; Arbogast 2016; Canini 2010; Carabin 1999; Correa 2012; Cowling 2008; Cowling 2009; Hartinger 2016; Huda 2012; Little 2015; Luby 2005; MacIntyre 2009; MacIntyre 2011; MacIntyre 2013; MacIntyre 2015; MacIntyre 2016; McConeghy 2017; Priest 2014; Radonovich 2019; Ram 2015; Roberts 2000; Stebbins 2011; Suess 2012; Talaat 2011; Temime 2018). Five cluster-RCTs did not report the ICC but described adjusting outcomes for clustering effect using different statistical methods, or explained why adjusted analysis for clustering was not performed (Biswas 2019; Chard 2019; McConeghy 2017; Simmerman 2011; Zomer 2015). Thirteen cluster-RCTs provided insufficient details on ICC and/or did not perform adjusted analysis or justified the absence of it (Alzaher 2018; Azor-Martinez 2016; Azor-Martinez 2018; Barasheed 2014; Feldman 2016; Larson 2010; Millar 2016; Miyaki 2011; Najnin 2019; Nicholson 2014; Pandejpong 2012; Savolainen-Kopra 2012; Yeung 2011). Two cluster-RCTs reported the ICC but did not perform adjusted analysis or justified the absence of it (Sandora 2005; Sandora 2008).

Effects of interventions

See: **Summary of findings 1** Medical/surgical masks compared to no masks for preventing the spread of viral respiratory illness; **Summary of findings 2** N95 respirators compared to medical/surgical masks for preventing the spread of viral respiratory illness; **Summary of findings 3** Hand hygiene compared to control for preventing the spread of viral respiratory illness

Comparison 1: Medical/surgical masks compared to no masks

We included nine trials (eight of which were cluster-RCTs) comparing medical/surgical masks versus no masks (Aiello 2012; Barasheed 2014; Canini 2010; Cowling 2008; Jacobs 2009; MacIntyre 2009; MacIntyre 2015; MacIntyre 2016; Suess 2012). Two trials were conducted with healthcare workers (HCWs) (Jacobs 2009; MacIntyre 2015), whilst the other seven studies included people living in the community. All trials were conducted in non-pandemic settings.

Primary outcomes

1. Numbers of cases of viral illness (including ARIs, ILI, and laboratory-confirmed influenza)

Pooling of all nine trials found an estimate of effect for the outcomes of ILI cases (risk ratio (RR) 0.99, 95% confidence interval (CI) 0.82 to 1.18; low-certainty evidence; Analysis 1.1) suggesting that wearing a medical/surgical mask may make little or no difference for this outcome. Similarly, the estimate of effect for laboratory-confirmed influenza cases (RR 0.91, 95% CI 0.66 to 1.26; 6 trials; moderate-certainty evidence; Analysis 1.1) suggests that wearing a medical/surgical mask probably makes little or no difference compared to not wearing a mask for this outcome. We downgraded the certainty of the evidence two levels for ILI due to inconsistency of the effect across studies and wide CI of the pooled effect. Sixty-five per cent of the weight of the ILI analysis was carried by one study (Aiello 2012).

A separate analysis of the two trials in healthcare workers for the outcome ILI (RR 0.37, 95% CI 0.05 to 2.50; low-certainty evidence; Analysis 1.2) suggests that there is considerable uncertainty as to whether there is any benefit (Jacobs 2009; MacIntyre 2015). The effect estimate was downgraded due to very wide CI interval of the pooled effect.

The design of most trials assessed whether masks protected the wearer. Four trials were cluster-RCTs, with all participants in the intervention clusters required to wear masks, thus assessing both source control and personal protection. In two trials the clusters were households with a member with new influenza; neither of these studies found any protective effect (RR 1.03 in 105 households (Canini 2010); RR 1.21 in 145 households (MacIntyre 2009)). In two trials the clusters were college dormitories during the influenza season; neither study found any reduction (RR 1.10 in 37 dormitories (Aiello 2012); RR 0.90 in three dormitories (Aiello 2010)). We excluded Aiello 2010 from the meta-analysis since we did not consider 'randomisation' of three clusters to three arms to be a proper randomised trial.

2. Adverse events related to the intervention

Canini 2010 reported that 38 (75%) of participants in the intervention arm experienced discomfort with the mask use due to warmth (45%), respiratory difficulties (33%), and humidity (33%). Children reported feeling pain more frequently (3/12) than other participants wearing adult face masks (1/39; P = 0.04). In MacIntyre 2015, adverse events associated with face mask use were reported in 40.4% (227/562) of HCWs in the medical-mask arm. General discomfort (35.1%; 397/1130) and breathing problems (18.3%;

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

207/1130) were the most frequently reported adverse events. Suess 2012 reported that the majority of participants (107/172; 62%) did not report any problems with mask-wearing. More adults reported no problems (71%) compared to children (36/72; 50%; P = 0.005). The main issues when wearing a face mask for adults as well as for children were "heat/humidity" (18/34; 53% of children; 10/29; 35% of adults; P = 0.1), followed by "pain" and "shortness of breath". Cowling 2008 mentioned that no adverse events were reported. The other trials did not report measuring adverse outcomes.

Secondary outcomes

1. Deaths

Not reported.

2. Severity of viral illness as reported in the studies

Jacobs 2009 reported that participants in the mask group were significantly more likely to experience more days with headache and feeling bad. They found no significant differences between the two groups for symptom severity scores. None of the other trials reported this outcome.

3. Absenteeism

Not reported.

4. Hospital admissions

Not reported.

5. Complications related to the illness (e.g. pneumonia)

Not reported.

Comparison 2: N95/P2 respirators compared to medical/surgical masks

We included five trials comparing medical/surgical masks with N95/P2 respirators (Loeb 2009; MacIntyre 2009; MacIntyre 2011; MacIntyre 2013; Radonovich 2019). All of these trials except MacIntyre 2009 included HCWs. MacIntyre 2009 included carers and household members of children with a respiratory illness recruited from a paediatric outpatient department and a paediatric primary care practice in Sydney, Australia.

Primary outcomes

1. Numbers of cases of viral illness (including ARIs, ILI, and laboratory-confirmed influenza)

Pooling of three trials found an estimate of effect suggesting considerable uncertainty as to whether an N95/P2 respirator provides any benefit compared to medical/surgical masks for the outcome of clinical respiratory illness (RR 0.70, 95% CI 0.45 to 1.10; very low-certainty evidence; Analysis 2.1) (MacIntyre 2011; MacIntyre 2013 (2 arms); Radonovich 2019). Based on five trials conducted in four healthcare settings and one household (Loeb 2009; MacIntyre 2009; MacIntyre 2011; MacIntyre 2013; Radonovich 2019), the estimates of effect for the outcome of ILI (RR 0.82, 95% CI 0.66 to 1.03; low-certainty evidence; Analysis 2.1) suggest that N95/P2 respirators may make little or no difference for this outcome. The estimate of the effect for the outcome of laboratory-confirmed influenza infection (RR 1.10, 95% CI 0.90 to 1.34; moderate-certainty evidence; Analysis 2.1) suggests that the use of a N95/P2 respirator compared to a medical/surgical mask probably makes little or no difference for this more precise and objective outcome. The outcomes clinical respiratory illness and ILI were reported separately. Considering how these outcomes were defined, it is highly likely that there was considerable overlap between the two, therefore these outcomes were not combined into a single clinical outcome (Analysis 2.1). The laboratory-confirmed viral respiratory infection outcome included influenza primarily but multiple other common viral respiratory pathogens were also included in several studies. The laboratory-confirmed viral infection outcome was considered more precise and objective in comparison to the clinical outcomes, which were more subjective and considered to be less precise. The findings did not change when we restricted the evidence to HCWs (Analysis 2.2).

2. Adverse events related to the intervention

Harms were poorly reported, but generally discomfort wearing medical/surgical masks and N95/P32 respirators was mentioned in several studies. Radonovich 2019 mentioned that participants wearing the N95 respirator reported skin irritation and worsening of acne. MacIntyre 2011 reported that adverse events were more common with N95 respirators; in particular, discomfort was reported in 41.9% of N95 wearers versus 9.8% of medical-mask wearers (P < 0.01); headaches were more common with N95 (13.4% versus 3.9%; P < 0.01); difficulty breathing was reported more often in the N95 group (19.4% versus 12.5%; P = 0.01); and N95 caused more problems with pressure on the nose (52.2% versus 11.0%; P < 0.01). In MacIntyre 2013, fewer participants using the N95 respirator reported problems (38% (195/512) versus 48% (274/571) of participants in the medical-mask arm; P = 0.001). Loeb 2009 mentioned that no adverse events were reported.

The one trial conducted in the community mentioned that more than 50% of participants reported concerns with both types of masks, mainly that wearing them was uncomfortable, but there were no significant differences between the P2 (N95) and surgical-mask groups (MacIntyre 2009).

Secondary outcomes

1. Deaths

Not reported.

2. Severity of viral illness as reported in the studies

Not reported.

3. Absenteeism

Loeb 2009 reported that 42 participants (19.8%) in the surgical-mask group reported an episode of work-related absenteeism compared with 39 (18.6%) of participants in the N95 respiratory group (absolute risk difference −1.24%, 95% CI −8.75% to 6.27%; P = 0.75).

4. Hospital admissions

Not reported.

5. Complications related to the illness (e.g. pneumonia)

Loeb 2009 reported that there were no episodes of LRTIs.

Comparison 3: Hand hygiene compared to control

Sixteen trials compared hand hygiene interventions with control and provided sufficient data to include in meta-analyses (Azor-Martinez 2018; Biswas 2019; Correa 2012; Cowling 2008; Cowling

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

2009; Hubner 2010; Larson 2010; Little 2015; Millar 2016; Nicholson 2014; Ram 2015; Roberts 2000; Sandora 2005; Simmerman 2011; Stebbins 2011; Zomer 2015). The populations of these studies included adults, children, and families, in settings such as schools, childcare centres, homes, and offices. None of the studies was conducted during a pandemic, although a few studies were conducted during peak influenza seasons. A further 16 trials comparing hand hygiene to a control had other outcomes or insufficient information to include in meta-analyses (Alzaher 2018; Arbogast 2016; Azor-Martinez 2016; DiVita 2011; Feldman 2016; Gwaltney 1980; Ladegaard 1999; Luby 2005; Morton 2004; Priest 2014; Savolainen-Kopra 2012; Talaat 2011; Temime 2018; Turner 2012; White 2001; Yeung 2011). The results of these trials were consistent with the findings of our meta-analyses. The results for all outcomes from the 16 trials that were meta-analysed and the 16 trials that were not meta-analysed are shown in Table 2.

Primary outcomes

1. Numbers of cases of viral illness (including ARIs, ILI, and laboratory-confirmed influenza)

Pooling of seven trials for the broad outcome of ARI showed a 16% relative reduction in the numbers of participants with ARI (RR 0.84, 95% CI 0.82 to 0.86; moderate-certainty evidence; Analysis 3.1.1) in the hand hygiene group (Analysis 3.1), suggesting a probable benefit (Azor-Martinez 2018; Correa 2012; Larson 2010; Little 2015; Millar 2016; Nicholson 2014; Sandora 2005). When considering the more strictly defined outcomes of ILI, Biswas 2019; Cowling 2008; Cowling 2009; Hubner 2010; Larson 2010; Little 2015; Ram 2015; Roberts 2000; Simmerman 2011; Zomer 2015, and laboratory-confirmed influenza, Biswas 2019; Cowling 2008; Cowling 2009; Hubner 2010; Larson 2010; Ram 2015; Simmerman 2011; Stebbins 2011, the estimates of the effect were heterogeneous, suggesting that hand hygiene made little or no difference (RR 0.98, 95% CI 0.85 to 1.13 for ILI; low-certainty evidence; Analysis 3.1.2) (RR 0.91, 95% CI 0.63 to 1.30 for laboratory-confirmed influenza; low-certainty evidence; Analysis 3.1.3) (Analysis 3.1). All 16 trials could be pooled for analysis of the composite outcome 'ARI or ILI or influenza', with each study only contributing once with the most comprehensive outcome (in terms of number of events) reported showing an 11% relative reduction in participants with a respiratory illness, suggesting that hand hygiene may offer a benefit (RR 0.89, 95% CI 0.84 to 0.95; low-certainty evidence; Analysis 3.2), but with high heterogeneity. In a sensitivity analysis we used only the most precise and unequivocal (with laboratory confirmed considered the most precise and an undefined ARI considered the least precise) outcome reported in each of 11 studies identified by JMC, an infectious disease physician, and found an estimate of effect in favour of hand hygiene, but with wider CIs (RR 0.92, 95% CI 0.80 to 1.05; Analysis 3.3).

We considered that studies in children might have a different effect than studies in adults, so we conducted subgroup analysis by age group. We found no evidence of a difference in treatment effect by age group (P = 0.21; Analysis 3.4).

2. Adverse events related to the intervention

Correa 2012 reported that no adverse events were observed; in the study by Priest 2014, skin reaction was recorded for 10.4% of participants in the hand sanitiser group versus 10.3% in the control group (RR 1.01, 95% CI 0.78 to 1.30).

Secondary outcomes

1. Deaths

Not reported.

2. Severity of viral illness as reported in the studies

Not reported.

3. Absenteeism

Three trials measured absenteeism from school or work and demonstrated a 36% relative reduction in the numbers of participants with absence in the hand hygiene group (RR 0.64, 95% CI 0.58 to 0.71; Analysis 3.5) (Azor-Martinez 2016; Hubner 2010; Nicholson 2014).

4. Hospital admissions

Not reported.

5. Complications related to the illness (e.g. pneumonia)

Not reported.

Comparison 4: Hand hygiene + medical/surgical masks compared to control

Primary outcomes

1. Numbers of cases of viral illness (including ARIs, ILI, and laboratory-confirmed influenza)

Six trials (Aelami 2015; Aiello 2012; Cowling 2009; Larson 2010; Simmerman 2011; Suess 2012) were able to be pooled to compare the use of the combination of hand hygiene and medical/surgical masks with control. Four of these trials were in households, two in university student residences, and one at the annual Hajj pilgrimage. For both outcomes (ILI and influenza), pooling demonstrated an estimate of effect suggesting little or no difference between the hand hygiene and medical/surgical mask combination and control. The number of trials and events was lower than for comparisons of hand hygiene alone, or medical/surgical masks alone, and the confidence interval was wide. For ILI, the RR for intervention compared to control was 1.03 (95% CI 0.77 to 1.37; Analysis 4.1.1), and for influenza it was 0.97 (95% CI 0.69 to 1.36; Analysis 4.1.2) (Analysis 4.1). Full results of these trials are shown in Table 3

2. Adverse events related to the intervention

Adverse events related to mask wearing in the study by Suess 2012 are reported under Comparison 1 (medical/surgical masks). There was no mention of adverse events related to hand hygiene.

Secondary outcomes

1. Deaths

Not reported.

2. Severity of viral illness as reported in the studies

Not reported.

3. Absenteeism

Not reported.

4. Hospital admissions

Not reported.

5. Complications related to the illness, e.g. pneumonia

Not reported.

Comparison 5: Hand hygiene + medical/surgical masks compared to hand hygiene

Primary outcomes

1. Numbers of cases of viral illness (including ARIs, ILI and laboratory-confirmed influenza)

Three trials studied the addition of medical/surgical masks to hand hygiene (Cowling 2009; Larson 2010; Simmerman 2011). All three trials had three arms, and are also included in the comparison of hand hygiene plus medical/surgical mask versus control (Comparison 4). All three studies showed no difference between hand hygiene plus medical/surgical mask groups and hand hygiene alone, for all outcomes. The estimates of effect suggested little or no difference when adding masks to hand hygiene compared to hand hygiene alone: for the outcome ILI (RR 1.03, 95% CI 0.69 to 1.53; 3 trials) and the outcome laboratory-confirmed influenza (RR 0.99, 95% CI 0.69 to 1.44), the estimates of effect were not different and the CIs were relatively wide, suggesting little or no difference (Analysis 5.1). However, the CIs around the estimates were wide and do not rule out an important benefit.

2. Adverse events related to the intervention

Not reported.

Secondary outcomes

1. Deaths

Not reported.

2. Severity of viral illness as reported in the studies

Not reported.

3. Absenteeism

Not reported.

4. Hospital admissions

Not reported.

5. Complications related to the illness (e.g. pneumonia)

Not reported.

Comparison 6: Medical/surgical masks compared to other (non-N95) masks

One trial compared medical/surgical masks with cloth masks in hospital healthcare workers (MacIntyre 2015), and another trial compared catechin-treated masks versus control masks in healthcare workers and staff of hospitals, rehabilitation centres, and nursing homes in Japan (Ide 2016).

Primary outcomes

1. Numbers of cases of viral illness (including ARIs, ILI, and laboratory-confirmed influenza)

MacIntyre 2015 found that the rate of ILI was higher in the cloth mask arm compared to the medical/surgical masks arm (RR 13.25, 95% CI 1.74 to 100.97).

Ide 2016 did not find a benefit from the catechin-treated masks over untreated masks on influenza infection rates (adjusted odds ratio (OR) 2.35, 95% CI 0.40 to 13.72; P = 0.34).

2. Adverse events related to the intervention

In MacIntyre 2015 adverse events associated with face mask use were reported in 40.4% (227/562) of HCWs in the medical/surgical mask arm and 42.6% (242/568) in the cloth mask arm (P = 0.45). The most frequently reported adverse events were general discomfort (35.1%; 397/1130) and breathing problems (18.3%; 207/1130). Laboratory tests showed the penetration of particles through the cloth masks to be very high (97%) compared with medical/surgical masks (44%). Ide 2016 reported that there were no serious adverse events associated with the intervention.

Secondary outcomes

1. Deaths

Not reported.

2. Severity of viral illness as reported in the studies

Not reported.

3. Absenteeism

Not reported.

4. Hospital admissions

Not reported.

5. Complications related to the illness (e.g. pneumonia)

Not reported.

Comparison 7: Soap + water compared to sanitiser, and comparisons of different types of sanitiser

Two trials compared soap and water with sanitiser (Azor-Martinez 2018; Savolainen-Kopra 2012). Another trial compared different types of hand sanitiser in a virus challenge study (Turner 2004a; Turner 2004b), and one trial studied the frequency of use of hand sanitiser (Pandejpong 2012). The full results of these four trials are shown in Table 4.

Primary outcomes

1. Numbers of cases of viral illness (including ARIs, ILI, and laboratory-confirmed influenza)

In the trial by Azor-Martinez 2018, ARI incidence was significantly higher in the soap-and-water group compared with the hand sanitiser group (rate ratio 1.21, 95% CI 1.06 to 1.39). In contrast, there was no significant difference between interventions in Savolainen-Kopra 2012. In the rhinovirus challenge study (Turner 2004a; Turner 2004b), all hand sanitisers tested led to a significant lowering of infection rates, but no differences between sanitisers were observed. The study sample size was small.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

2. Adverse events related to the intervention

Two trials stated that no adverse events were observed (Pandejpong 2012; Savolainen-Kopra 2012).

Secondary outcomes

1. Deaths

Not reported.

2. Severity of viral illness as reported in the studies

Not reported.

3. Absenteeism

The authors of Azor-Martinez 2018 also observed a significant benefit for hand sanitiser in reduction in days absent, whereas there was no difference between intervention groups in the Savolainen-Kopra 2012 trial. The study on frequency of use of sanitiser found that use of sanitiser every hour significantly reduced days absent compared with use every two hours or with use only before the lunch break (Pandejpong 2012).

4. Hospital admissions

Not reported.

5. Complications related to the illness (e.g. pneumonia)

Not reported.

Comparison 8: Surface/object disinfection (with or without hand hygiene) compared to control

Primary outcomes

1. Numbers of cases of viral illness (including ARIs, ILI, and laboratory-confirmed influenza)

Six trials contributed data to this comparison (Ban 2015; Carabin 1999; Ibfelt 2015; Kotch 1994; McConeghy 2017; Sandora 2008). Full results of these trials are shown in Table 5. Five of the six trials combined disinfection with other interventions such as hand hygiene education, provision of hand hygiene products, and audits. Ban 2015 utilised a combination of provision of hand hygiene products, and cleaning and disinfection of surfaces, and demonstrated a significant reduction in ARI in the intervention group (OR 0.47, 95% CI 0.48 to 0.65). A similar result was seen in Carabin 1999, with a significant reduction in episodes of ARI. Two studies tested multicomponent interventions and observed no significant difference in ARI outcomes (Kotch 1994; McConeghy 2017).

One trial compared disinfection alone to usual care (Ibfelt 2015). This study demonstrated a significant reduction in some viruses detected on surfaces in the childcare centres (adenovirus, rhinovirus, respiratory syncytial virus (RSV), and metapneumovirus), but not in other viruses, including coronavirus.

2. Adverse events related to the intervention

Not reported.

Secondary outcomes

1. Deaths

Not reported.

2. Severity of viral illness as reported in the studies

Not reported.

3. Absenteeism

Only one study measured this outcome (Sandora 2008), observing no significant difference between groups for the outcome of absence due to respiratory illness (rate ratio for intervention to control 1.10, 95% CI 0.97 to 1.24).

4. Hospital admissions

Not reported.

5. Complications related to the illness (e.g. pneumonia)

Not reported.

Comparison 9: Complex interventions compared to control

Complex interventions are either multifaceted environmental programmes (such as those in low-income countries) or combined interventions including hygiene measures and gloves, gowns, and masks.

Four trials studied complex hygiene and sanitation interventions in low-income country settings (Chard 2019; Hartinger 2016; Huda 2012; Najnin 2019). Full results from these studies are given in Table 6.

Primary outcomes

1. Numbers of cases of viral illness (including ARIs, ILI, and laboratory-confirmed influenza)

All four trials of complex interventions observed no significant differences between groups in rates of viral respiratory illness.

2. Adverse events related to the intervention

Not reported

Secondary outcomes

1. Deaths

Not reported.

2. Severity of viral illness as reported in the studies

Not reported.

3. Absenteeism

Not reported.

4. Hospital admissions

Not reported.

5. Complications related to the illness (e.g. pneumonia)

Not reported.

Comparison 10: Physical distancing/quarantine compared to control

We found one quasi-cluster-RCT assessing the effectiveness of quarantining workers of one of two sibling companies in Japan whose family members developed an ILI during the 2009 to 2010 H1N1 influenza pandemic (Miyaki 2011). Workers in the intervention group were asked to stay home on full pay until

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

five days after the household member(s) showed resolution of symptoms or two days after alleviation of fever.

Primary outcomes

1. Numbers of cases of viral illness (including ARIs, ILI, and laboratory-confirmed influenza)

Compliance with the intervention was 100%. In the intervention group 2.75% of workers contracted influenza, compared with 3.18% in the control group (Cox hazard ratio 0.799, 95% CI 0.66 to 0.97; P = 0.02), indicating that the rate of infection was reduced by 20% in the intervention group. However, the risk of a worker being infected was 2.17-fold higher in the intervention group where workers stayed at home with their infected family members. The authors concluded that quarantining workers who have infected household members could be a useful additional measure to control the spread of respiratory viruses in an epidemic setting.

2. Adverse events related to the intervention

Not reported.

Secondary outcomes

1. Deaths

Not reported.

2. Severity of viral illness as reported in the studies

Not reported.

3. Absenteeism

Not reported.

4. Hospital admissions

Not reported.

5. Complications related to the illness (e.g. pneumonia)

Not reported.

Comparison 11: Eye protection compared to control

We did not find any randomised studies investigating the effect of eye protection compared to control.

Comparison 12: Gargling compared to control

Three trials investigated the effect of gargling. Satomura 2005 compared throat gargling with povidone-iodine versus tap water in healthy adults. Ide 2014 compared gargling with green tea versus tap water in high school students, and Goodall 2014 compared gargling with tap water with no gargling in university students.

Primary outcomes

1. Numbers of cases of viral illness (including ARIs, ILI, and laboratory-confirmed influenza)

Satomura 2005 reported that gargling with tap water reduced the incidence of URTIs compared to the control group (usual care) (hazard ratio (HR) 0.60, 95% CI 0.39 to 0.95). Gargling with povidone-iodine did not reduce the incidence of URTIs compared to the control group (HR 0.88, 95% CI 0.58 to 1.34).

Goodall 2014 found no difference in laboratory-confirmed URTIs between the gargling (tap water) and no-gargling groups (RR for gargling versus no gargling 0.82, 95% CI 0.53 to 1.26; P = 0.36).

In a meta-analysis of gargling versus control based on two trials (Goodall 2014; Satomura 2005), the pooled estimate of effect suggested little or no difference for the outcome of clinical URTI due to gargling (RR 0.91, 95% CI 0.63 to 1.31; Analysis 6.1).

There was no difference in the incidence of laboratory-confirmed influenza between high school students gargling with green tea compared with those using tap water (adjusted OR 0.69, 95% CI 0.37 to 1.28; P = 0.24) (Ide 2014). There was also no difference in the incidence of clinically defined influenza (adjusted OR 0.75, 95% CI 0.50 to 1.13; P = 0.17). However, the authors reported that adherence to the interventions amongst students was low.

2. Adverse events related to the intervention

Satomura 2005 reported no adverse events during the 60-day intervention period. Ide 2014 also did not observe any adverse events during the study. Goodall 2014 did not report on adverse effects.

Secondary outcomes

1. Deaths

Not reported.

2. Severity of viral illness as reported in the studies

Satomura 2005 reported that the mean peak score in bronchial symptoms was lower in the water gargling group (0.97) than in the povidone-iodine gargling group (1.41) and the control group (1.40), P = 0.055. Other symptoms were not significantly different between groups. Goodall 2014 reported that symptom severity was greater in the gargling group for clinical and laboratory-confirmed URTI, but this was not statistically significant (225.3 versus 191.8, and 210.5 versus 191.8, respectively). Ide 2014 did not report symptom or illness severity.

3. Absenteeism

Not reported.

4. Hospital admissions

Not reported.

5. Complications related to the illness (e.g. pneumonia)

Not reported.

Comparison 13: Virucidal tissues compared to control

Two reports (three trials) conducted in the USA studied the effect of virucidal tissues (Farr 1988a; Farr 1988b; Longini 1988). Full results from these studies are given in Table 7.

Primary outcomes

1. Numbers of cases of viral illness (including ARIs, ILI, and laboratory-confirmed influenza)

The three trials of virucidal tissues reported no differences in infection rates between tissues and placebo, and between tissues and no tissues (Farr 1988a; Farr 1988b; Longini 1988).

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

2. Adverse events related to the intervention

Farr 1988b reported cough in 4% of participants using virucidal tissues versus 57% in the placebo group, but 24% reported nasal burning in the virucidal tissue group versus 8% in the placebo group. Longini 1988 did not report on adverse effects.

Secondary outcomes

1. Deaths

Not reported.

2. Severity of viral illness as reported in the studies

Not reported.

3. Absenteeism

Not reported.

4. Hospital admissions

Not reported.

5. Complications related to the illness (e.g. pneumonia)

Not reported.

DISCUSSION

Summary of main results

See Table 8.

1. Medical/surgical masks compared to no masks

The pooled estimates of effect from RCTs and cluster-RCTs for wearing medical/surgical masks compared to no masks suggests little or no difference in interrupting the spread of ILI (RR 0.99, 95% CI 0.82 to 1.18; low-certainty evidence) or laboratory-confirmed influenza (RR 0.91, 95% CI 0.66 to 1.26; moderate-certainty evidence) in the combined analysis of all populations from the included trials. We found similar results for ILI in HCWs (RR 0.37, 95% CI 0.05 to 2.50; very low-certainty evidence). Four trials were cluster-RCTs, with all participants in the intervention clusters required to wear masks, thus assessing both source control and personal protection. In two trials the clusters were households with a member with new influenza; neither trial found any protective effect (RR 1.03 in 105 households (Canini 2010); RR 1.21 in 145 households (MacIntyre 2009)). In two trials the clusters were college dormitories during the influenza season; neither trial found any reduction (RR 1.10 in 37 dormitories (Aiello 2012); RR 0.90 in three dormitories (Aiello 2010)). We excluded Aiello 2010 from meta-analysis since we did not consider 'randomisation' of three clusters to three arms was a proper randomised trial.

Less than half of the trials comparing masks with no masks addressed harms of mask wearing (Canini 2010; Cowling 2008; MacIntyre 2015; Suess 2012). Warmth, respiratory difficulties, humidity, and general discomfort were the most frequently reported adverse events. More adults reported no harms compared to children.

In one trial (MacIntyre 2015), cloth masks were associated with a significantly higher risk of both ILI and laboratory-confirmed respiratory virus infection in HCWs. In addition, filtration capacity of the two-ply cotton cloth masks was found to be only 3% and markedly less than with surgical masks based on standardised particle testing. The authors suggested moisture retention, poor filtration, and penetration of the virus through the mask as plausible explanations for the increased risk of infection.

We did not find any randomised trials assessing the effectiveness of barrier interventions using a combination of masks, gloves, and gowns.

2. N95 respirators compared to medical/surgical masks

Comparisons between N95 respirators and surgical masks for the outcomes of clinical respiratory illness and the outcome of laboratory-confirmed influenza showed estimates of effect suggesting considerable uncertainty for any benefit for the former outcome and probably little or no difference for the latter outcome. Five trials (four in healthcare settings and one in a household setting) compared N95/P2 respirators with surgical masks. Pooling of three of these trials showed an estimate of effect suggesting considerable uncertainty as to whether there was any benefit comparing N95 respirators and medical/surgical face masks for the outcome of clinical respiratory illness (RR 0.70, 95% CI 0.45 to 1.10; very low-certainty evidence), and that N95 respirators may make little or no difference for the outcome ILI (RR 0.82, 95% CI 0.66 to 1.03; low-certainty evidence) and probably little or no difference for the outcome laboratory-confirmed influenza (RR 1.10, 95% CI 0.90 to 1.34; moderate-certainty evidence). The presence of imprecision (wide confidence intervals) and heterogeneity, particularly for the more subjective and less precise outcomes of clinical respiratory illness and ILI compared to laboratory-confirmed influenza infection, makes it difficult to assess whether there may be a benefit of either medical/surgical masks or N95/P2 respirators. Restricting the pooling to HCWs made no difference to the overall findings. The two trials with the largest event rates were quite consistent in their findings of no significant differences between N95 and surgical masks for the outcomes laboratory-confirmed influenza and all laboratory-confirmed viral infections (Loeb 2009; Radonovich 2019). Three of the trials contributing to this analysis were carried out by members of the same group (MacIntyre 2009; MacIntyre 2011; MacIntyre 2013).

In general, harms were poorly reported or not reported at all in trials comparing N95 respirators with surgical masks. General discomfort resulting in reduced wear compliance was the most frequently reported harm.

3. Hand hygiene compared to control

We found that the estimate of effect may offer a benefit for hand hygiene for the composite outcome 'ARI or ILI or influenza' (RR 0.89, 95% CI 0.84 to 0.95; low-certainty evidence), and probably offers a benefit for the outcomes ARI alone (RR 0.84, 95% CI 0.82 to 0.86; moderate-certainty evidence) and absenteeism (RR 0.64, 95% CI 0.58 to 0.71). An observed estimate of effect in favour of hand hygiene for laboratory-confirmed influenza but with wider CIs may be a consequence of smaller sample sizes in conjunction with a more rigorous outcome measure.

4. Hand hygiene + medical/surgical masks compared to control

The estimate of effect of combined hand hygiene and mask interventions compared to control in six (mostly small) trials suggested that the intervention may make little or no difference for the outcomes ILI (RR 1.03, 95% CI 0.77 to 1.37) and laboratory-confirmed influenza (four trials) (RR 0.97, 95% CI 0.69 to 1.36).

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

5. Hand hygiene + medical/surgical masks compared to hand hygiene

We also found an estimate of effect suggesting that adding masks to hand hygiene compared to hand hygiene alone may make little or no difference for the outcomes ILI (RR 1.03, 95% CI 0.69 to 1.53; 3 trials) and laboratory-confirmed influenza (RR 0.99, 95% CI 0.69 to 1.44).

6. Medical/surgical masks compared to other (non-N95) masks

One trial found that medical/surgical masks were more effective than cloth masks at reducing the rate of ILI (RR 13.25, 95% CI 1.74 to 100.97) (MacIntyre 2015), but the extremely wide CIs make this finding difficult to interpret. One trial did not find a benefit from catechin-treated masks over untreated masks on influenza infection rates (adjusted OR 2.35, 95% CI 0.40 to 13.72; P = 0.34) (Ide 2016).

Harms of wearing masks were reported in 40.4% of HCWs using medical/surgical masks, and in 42.6% of those wearing cloth masks (P = 0.45) (MacIntyre 2015). The penetration of particles was higher in cloth masks (97%) compared to medical/surgical masks (44%).

7. Soap + water compared to sanitiser, and comparisons of different types of sanitiser

There were too few trials comparing different types of hand hygiene interventions to be certain of any true differences between soap and water, alcohol-based hand sanitisers, or other types of interventions. Also, it is uncertain whether the incremental effect of adding virucidals or antiseptics to hand-washing actually decreased the respiratory disease burden outside the confines of the rather atypical studies. The extra benefit may have been, at least in part, accrued by confounding additional routines.

8. Surface/object disinfection (with or without hand hygiene) compared to control

We identified six trials on surface/object disinfection (with or without hand hygiene), and although they were heterogeneous (and therefore could not be pooled), three of them showed a clear benefit compared to controls (Ban 2015; Carabin 1999; Ibfelt 2015).

We found no RCTs with nose disinfection, or disinfection of living quarters as described in observational studies reported in Jefferson 2011.

9. Complex interventions compared to control

Four trials studied complex hygiene and sanitation interventions, all in low-income country settings (Chard 2019; Hartinger 2016; Huda 2012; Najnin 2019). These trials could not be pooled due to the heterogeneity of the interventions and settings. All four trials found no significant differences between groups in the rates of viral respiratory illness.

10. Physical distancing/quarantine compared to control

A disappointing finding was the lack of proper evaluation of global and highly resource-intensive measures such as screening at entry ports and physical distancing. We identified only one trial that evaluated the effect of quarantine (Miyaki 2011), and found a reduction in influenza transmission to co-workers when those with infected household members stayed home from work. However, staying home increased their risk of being infected two-fold.

11. Eye protection compared to control

We did not find any trials assessing the effectiveness and safety of eye protection.

12. Gargling compared to control

Three trials addressed the use of gargling in preventing respiratory infections (Goodall 2014; Ide 2014; Satomura 2005). Although the trials used a variety of liquids and different outcomes, pooling the results of the two trials that compared gargling with tap water versus control did not show a favourable effect in reducing URTIs (RR 0.91, 95% CI 0.63 to 1.31) (Goodall 2014; Satomura 2005).

13. Virucidal tissues compared to control

Two reports (three trials) identified in Jefferson 2011 studied the effect of virucidal tissues compared to placebo or no tissues (Farr 1988a; Farr 1988b; Longini 1988). These trials found no differences in infection rates and could not be pooled.

Overall completeness and applicability of evidence

Several features need consideration before making generalisations based on the included studies.

The settings of the included studies, which were conducted over four decades, were heterogeneous and ranged from suburban schools, Carabin 1999, to emergency departments, intensive care units, and paediatric wards, Loeb 2009, in high-income countries; slums in low-income countries (Luby 2005); and an upper Manhattan immigrant Latino neighbourhood (Larson 2010). Few attempts were made to obtain socio-economic diversity by (for example) involving more schools in the evaluations of the same programme. We identified only a few studies from low-income countries, where the vast majority of the burden of ARIs lies and where inexpensive interventions are so critical. Additionally, limited availability of over-the-counter medications and national universal comprehensive health insurance provided with consequent physician prescription of symptomatic treatment may further limit the generalisability of findings.

The included trials generally reported few events and were conducted mostly during non-epidemic periods. The large study by Radonovich 2019 is an exception as it crossed over two of the highest reporting years for influenza in the USA between 2010 and 2017 (Elflein 2019). None of the trials were conducted during a pandemic such as SARS-CoV-1, SARS-CoV-2, or Middle East respiratory syndrome (MERS).

Of the trials assessing the effect of masks, six were carried out in those at greater exposure (i.e. HCWs) (Jacobs 2009; Loeb 2009; MacIntyre 2011; MacIntyre 2013; MacIntyre 2015; Radonovich 2019). None of these studies included HCWs undertaking aerosol-generating procedures, for which the World Health Organization (WHO) currently recommends the N95 or equivalent mask. Three trials on hand hygiene interventions were carried out in nursing homes, and included HCWs (McConeghy 2017; Temime 2018; Yeung 2011). The scarcity of RCTs on HCWs limits the generalisability of such results.

The variable quality of the methods of some studies is striking. Incomplete or no reporting of randomisation (Turner 2004a), blinding (Farr 1988a; Farr 1988b), numerators and denominators (Carabin 1999; Kotch 1994), interventions, and cluster coefficients

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

in the relevant trials (Carabin 1999), led to a considerable loss of information. Potential biases were often not discussed.

Inappropriate placebos caused design problems. In some studies the placebo probably carried sufficient effect to dilute the intervention effects (Longini 1988). Two valiant attempts with virucidal tissues probably failed because placebo handkerchiefs were impregnated with a dummy compound that stung the users' nostrils (Farr 1988a; Farr 1988b).

Some studies used impractical interventions. Volunteers subjected to the intervention hand cleaner (organic acids) were not allowed to use their hands between cleaning and virus challenge, so the effect of normal use of the hands on the intervention remains unknown (Turner 2004a; Turner 2004b). Two per cent aqueous iodine painted on the hands, although a successful antiviral intervention, causes unacceptable cosmetic staining, which is impractical for all but those at the highest risk of epidemic contagion (Gwaltney 1980).

Compliance with interventions, especially educational programmes, was a problem for many studies despite the importance of many such low-cost interventions. Compliance with mask wearing varied; it was generally around 60% to 80%, but was reported to be as low as 40% (see Table 1). Overall, the logistics of carrying out trials that involve sustained behaviour change are demanding, particularly in challenging settings such as immigrant neighbourhoods or students' halls of residence.

The identified trials provided sparse and unsystematic data on adverse effects of the intervention, and few of the RCTs measured or reported compliance with the intervention, which is especially important for the use of medical/surgical masks or N95 respirators. No studies investigated how the level of adherence may have influenced the effect size.

We did not identify any studies assessing the effects of eye protection, and we identified only one study on physical distancing, during the 2009 H1N1 influenza pandemic. The dearth of evidence and predominant setting of seasonal viral circulation limits generalisability of our findings to other contexts such as the COVID-19 pandemic and any future epidemics due to other respiratory viruses.

Quality of the evidence

We found the available evidence base identified through our search processes to be of variable quality. Reporting of sequence generation and allocation concealment were poor in 30% to 50% of studies across the categories of intervention comparisons. Given the nature of the intervention comparison, blinding of treatment allocation after randomisation was rarely achieved. Although blinding of outcome assessment is highly feasible and desirable, most outcomes were assessed by self-reports. Outcomes in some studies were poorly defined, with a lack of clarity as to the possible aetiologic agents (bacterial versus viral). Some studies used laboratory-confirmed outcomes, both adding precision and lowering the risk of bias (see Table 9 for heterogeneity of trial outcome definitions). We found no evidence of selective reporting of outcomes within the included studies. We believe publication bias is unlikely, as the included studies demonstrated a range of effects, both positive and negative, over all study sizes. The variable quality of the studies hampers drawing any firm conclusions.

Potential biases in the review process

The non-drug (and often locally manufactured) nature of most of the interventions in this review, the lack of effective regulation in some settings, and the possible endless number of manufacturers make it difficult to gauge the existence of unpublished data. Non-drug interventions typically have no or very poor regulation.

In this 2020 update, we focused on RCTs and cluster-RCTs, providing a higher level of evidence compared with the previous version of the review, which also meta-analysed observational studies when appropriate (Jefferson 2011). However, many of the trials were small and hence underpowered, and at high or unclear risk of bias due to poor reporting of methods and lack of blinding. The populations, outcomes, comparators, and interventions tested were heterogeneous.

Due to the urgency of this update in the context of the COVID-19 pandemic, we did not contact trial authors to request missing data. This means that we have not considered studies that included other non-respiratory infections and did not provide stratified data by type of infection.

Agreements and disagreements with other studies or reviews

Several reviews of RCTs have found broadly similar results to this review for face masks. In a meta-analysis comparing surgical masks with N95 respirators, Smith 2016 pooled three trials (Loeb 2009; MacIntyre 2011; MacIntyre 2013), and found an estimate of effect suggesting no difference for laboratory-confirmed respiratory infections (OR 0.89, 95% CI 0.64 to 1.24) or ILI (OR 0.51, 95% CI 0.19 to 1.41). A similar meta-analysis, Offeddu 2017, based on two trials, MacIntyre 2011; MacIntyre 2015, concluded that masks (either N95/P2 respirators or medical/surgical masks) were effective against clinical respiratory infections (RR 0.59, 95% CI 0.46 to 0.77) and ILI (RR 0.34, 95% CI 0.14 to 0.82). Pooling of two studies, MacIntyre 2011; MacIntyre 2013, also found an estimate of effect that favoured N95 respirators to medical/surgical masks for clinical respiratory infections (RR 0.47, 95% CI 0.36 to 0.62), but not for ILI based on three studies, Loeb 2009: MacIntyre 2011; MacIntyre 2013 (RR 0.59, 95% CI 0.27 to 1.28) (Offeddu 2017). The outcome of clinical respiratory infection is considered to be the most subjective and least precise outcome.

A recent meta-analysis included five trials comparing N95/P2 respirators with medical/surgical masks and found no difference between groups for either influenza (RR 1.09, 95% CI 0.92 to 1.28) or respiratory viral infections (RR 0.89, 95% CI 0.70 to 1.11) (Long 2020). By excluding Loeb 2009 (an open, non-inferiority RCT that compared surgical masks with N95 respirators in protecting HCWs against influenza), the authors reported a significant protective effect against viral infections (RR 0.61, 95% CI 0.39 to 0.98). The authors do not report a rationale for the exclusion in the sensitivity analysis and do not report on exclusion of the studies with low weighting, which arguably would be more relevant in a sensitivity analysis. The two trials that make up 96% of the weighting, Loeb 2009; Radonovich 2019, demonstrated no significant differences in the outcome events. A recent meta-analysis of four RCTs (Bartoszko 2020), adjusting for clustering, which compared N95 respirators with the use of medical masks, found pooled estimates of effect that did not demonstrate any difference in any laboratory-confirmed viral respiratory infection

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

(OR 1.06, 95% CI 0.90 to 1.25), laboratory-confirmed influenza (OR 0.94, 95% CI 0.73 to 1.20), or clinical respiratory illness (OR 1.49, 95% CI 0.98 to 2.28), with the evidence profile suggesting that there was greater imprecision and inconsistency in the outcome of clinical respiratory illness. Moreover, in another recent systematic review that assessed the effectiveness of personal protective and environmental measures in non-healthcare settings (funded by the WHO), 10 RCTs reporting estimates of the effectiveness of face masks in reducing laboratory-confirmed influenza virus infections in the community were identified (Xiao 2020). The evidence from these RCTs suggested that the use of face masks either by infected persons or by uninfected persons does not have a substantial effect on influenza transmission.

The findings from several systematic reviews and meta-analyses over the last decade have not demonstrated any difference in the clinical effectiveness of N95 respirators or equivalent compared to the use of surgical masks when used by HCWs in multiple healthcare settings for the prevention of respiratory virus infections, including influenza.

Reviews based on observational studies have usually found a stronger protective effect for face masks, but have important biases. The review by Chu 2020 did not consider RCTs of influenza transmission, but only the observational studies examining impact on SARS, MERS, or SARS-CoV-2. For N95 masks versus no mask in HCWs, there was a large protective effective with an OR of 0.04 (95% CI 0.004 to 0.30); for surgical masks versus no masks, there was an OR of 0.33 (0.17 to 0.61) overall, but four of these studies were in healthcare settings. Chu 2020 has been criticised for several reasons: use of an outdated 'Risk of bias' tool; inaccuracy of distance measures; and not adequately addressing multiple sources of bias, including recall and classification bias and in particular confounding. Confounding is very likely, as preventive behaviours such as mask use, social distancing, and hand hygiene are correlated behaviours, and hence any effect estimates are likely to be overly optimistic.

Also based on observational studies, Jefferson 2011 found a protective effect of wearing surgical masks with hygienic measures compared to not wearing masks in the SARS 2003 outbreak (OR 0.32, 95% CI 0.26 to 0.39). However, the evidence was based on case-control studies carried out during the outbreak. There was some additional but very limited supportive evidence from the cohort studies in Jefferson 2011.

Although the use of eye protection and physical distancing measures are widely believed to be effective in reducing transmission of respiratory viruses and mitigating the impact of an influenza pandemic, we found only one trial investigating the role of self-quarantine in reducing the incidence of H1N1 influenza events in the workplace, and no trials examining the effect of eye protection. The evidence for these measures was derived largely from observational studies and simulation studies, and the overall quality of supporting evidence is relatively low. The finding of limited evidence evaluating these interventions was also consistent with a recent review funded by the WHO for the preparation of its guidelines on the use of non-pharmaceutical interventions for pandemic influenza in non-medical settings (Fong 2020).

There are several previous systematic reviews on hand hygiene and respiratory infections. Five of them reviewed the evidence in a community setting (Moncion 2019; Rabie 2006; Saunders-Hastings 2017; Warren-Gash 2013: Wong 2014), and three focused on children (Mbakaya 2017; Willmott 2016; Zivich 2018). The earliest review in 2006 included eight studies (Rabie 2006), three of which were RCTs. The pooled estimate of seven studies was described as “indicative” of the effect of hand hygiene, but the studies were of poor quality. The Warren-Gash 2013 review included 16 studies (10 of which were RCTs) and reported mixed and inconclusive results. A 2014 review identified 10 RCTs and reported that the combination of hand hygiene with face masks in high-income countries (five trials) significantly reduced the incidence of laboratory-confirmed influenza and ILI, whilst hand hygiene alone did not (Wong 2014). This significant reduction in laboratory-confirmed influenza and ILI for hand hygiene and face masks may have been based on the raw numbers without adjusting for any clustering effects in the included cluster trials, which produced inappropriately narrow CIs, and possibly biased treatment effect estimates. Moreover, trials from the low-income countries were not included in the review, and this significant effect was not demonstrated when all the trials identified in the review were combined. The Saunders-Hastings 2017 review of studies evaluating the effectiveness of personal protective measures in interrupting pandemic influenza transmission only identified two RCTs (Azor-Martinez 2014; Suess 2012), which reported a significant effect of hand hygiene. The Moncion 2019 review identified seven RCTs of hand hygiene compared to control, with mixed results for preventing the transmission of laboratory-confirmed or possible influenza. Systematic reviews of RCTs of hand hygiene interventions amongst children, Mbakaya 2017; Willmott 2016, or at a non-clinical workplace, Zivich 2018, identified heterogeneous trials with quality problems including small numbers of clusters and participants, inadequate randomisation, and self-reported outcomes. Evidence of impact on respiratory infections was equivocal.

AUTHORS' CONCLUSIONS

Implications for practice

The evidence summarised in this review on the use of masks is largely based on studies conducted during traditional peak respiratory virus infection seasons up until 2016. We will incorporate relevant published studies in COVID-19 when their results are available. The observed lack of effect of mask wearing in interrupting the spread of ILI or influenza in our review has many potential reasons, including: poor study design; insufficiently powered studies arising from low viral circulation in some studies; lower compliance with mask wearing, especially among children; quality of the masks used; self-contamination of the mask by hands; lack of protection from eye exposure from respiratory droplets (allowing a route of entry of respiratory viruses into the nose via the lacrimal duct); saturation of masks with saliva from extended use (promoting virus survival in proteinaceous material); and risk compensation behaviour leading to an exaggerated sense of security (Brosseau 2020; Canini 2010; Cassell 2006; MacIntyre 2015; Rengasamy 2010; Zamora 2006).

Our findings show that hand hygiene has a modest effect as a physical intervention to interrupt the spread of respiratory viruses, but several questions remain. First, the high heterogeneity between studies may suggest that there are differences in the effect of different interventions. The poor reporting limited our ability to extract the information needed to assess any 'dose response'

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

relationship, and there are few head-to-head trials comparing hand hygiene materials (such as alcohol-based sanitiser or soap and water). Second, the sustainability of hand hygiene is unclear where participants in some studies achieved 5 to 10 hand-washings per day, but compliance may have diminished with time as motivation decreased, or due to adverse effects from frequent hand-washing. Third, there is little evidence about the effectiveness of combinations of hand hygiene with other interventions, and how those are best introduced and sustained. Finally, some interventions were intensively implemented within small organisations, and involved education or training as a component, and the ability to scale these up to broader interventions is unclear.

Our findings with respect to hand hygiene should be considered generally relevant to all viral respiratory infections, given the diverse populations where transmission of viral respiratory infections occurs. The participants were adults, children and families, and multiple congregation settings including schools, childcare centres, homes, and offices. Most respiratory viruses, including the pandemic SARS-CoV-2, are considered to be predominantly spread via respiratory droplets or contact routes, or both (WHO 2020c). Data from studies of SARS-CoV-2 contamination of the environment based on the presence of viral ribonucleic acid (RNA) suggest significant fomite contamination from the virus (Ong 2020; Wu 2020). Hand hygiene would be expected to be beneficial in reducing the spread of SARS-CoV-2 similar to other beta coronaviruses (SARS-CoV-1, Middle East respiratory syndrome (MERS), and human coronaviruses), which are very susceptible to the concentrations of alcohol commonly found in most hand sanitiser preparations (Rabenau 2005; WHO 2020c). Support for this effect is the finding that poor hand hygiene, despite the use of full PPE, was independently associated with an increased risk of SARS-CoV-2 transmission to healthcare workers in a retrospective cohort study in Wuhan, China in both a high-risk and low-risk clinical unit for patients infected with COVID-19 (Ran 2020). The practice of hand hygiene appears to have a consistent effect in all settings, and should be an essential component of other interventions.

The highest-quality cluster-RCTs indicate that the most effect on preventing respiratory virus spread from hygienic measures occurs in younger children. This may be because younger children are least capable of hygienic behaviour themselves (Roberts 2000), and have longer-lived infections and greater social contact, thereby acting as portals of infection into the household (Monto 1969). Additional benefit from reduced transmission from them to other members of the household is broadly supported by the results of other study designs where the potential for confounding is greater.

Routine long-term implementation of some of the interventions covered in this review may be problematic, particularly maintaining strict hygiene and barrier routines for long periods of time. This would probably only be feasible in highly motivated environments, such as hospitals. Many of the trial authors commented on the major logistical burdens that barrier routines imposed at the community level. However, the threat of a looming epidemic may provide stimulus for their inception.

Implications for research

Public health measures and physical interventions can be highly effective to interrupt the spread of respiratory viral infections, especially when they are part of a structured and co-ordinated programme that includes instruction and education, and when they are delivered together. Our review has provided important insights into research gaps that need to be addressed with respect to these physical interventions and their implementation. The 2014 WHO document 'Infection prevention and control of epidemic- and pandemic-prone acute respiratory infections in health care' identified several research gaps as part of their GRADE assessment of their infection prevention and control recommendations, which remain very relevant (WHO 2014). Research gaps identified during the course of our review and the WHO 2014 document may be considered from the perspective of both general and specific themes.

A general theme identified was the need to provide outcomes with explicitly defined clinical criteria for acute respiratory infections (ARIs) and discrete laboratory-confirmed outcomes of viral ARIs using molecular diagnostic tools which are now widely available. Our review found large disparities between studies with respect to the clinical outcome events, which were imprecisely defined in several studies, and there were differences in the extent to which laboratory-confirmed viruses were included in the studies that assessed them. Another general theme identified was the lack of consideration of sociocultural factors that might affect compliance with the interventions, especially those employed in the community setting. In addition, the cost and resource implications of the physical interventions employed in different settings would have important relevance for low- to middle-income countries. Resources have been a major issue with the COVID-19 pandemic, with global shortages of several components of PPE. Several specific research gaps related to physical interventions were identified within the WHO 2014 document and are congruent with many of the findings of our current update, including the following: transmission dynamics of respiratory viruses from patients to healthcare workers during aerosol-generating procedures; a lack of precision with regards to defining aerosol-generating procedures; the safety of cohorting of patients with the same suspected but unconfirmed diagnosis in a common unit or ward with patients infected with the same known pathogen in healthcare settings; the optimal duration of the use of physical interruptions to prevent spread of ARI viruses; use of spatial separation or physical distancing (in healthcare and community settings, respectively) alone versus spatial separation or physical distancing with the use of other added physical interventions coupled with examining discrete distance parameters (e.g. 1 metre, 2 metres, or > 2 metres); the effectiveness of respiratory etiquette (i.e. coughing/sneezing into tissues or a sleeved bent elbow); the effectiveness of triage and early identification of infected individuals with an ARI in both hospital and community settings; use of frequent disinfection techniques appropriate to the setting (high-touch surfaces in the environment, gargling with oral disinfectants, and virucidal tissues or clothing) alone or in combination with facial masks and hand hygiene; the use of ultraviolet light germicidal irradiation for disinfection of air in healthcare and selected community settings; and the use of widespread compliance with effective vaccination strategies.

There is a clear requirement to conduct large, pragmatic trials to evaluate the best combinations in the community and in healthcare settings with multiple respiratory viruses and in different sociocultural settings. RCTs with a pragmatic design, similar to the Luby 2005 trial, should be conducted whenever possible. Alternately, large population-based cohort studies may

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

also be considered if individual RCTs prove to be too expensive or less practical, depending on the issue that is being addressed.

Several specific research gaps deserve expedited attention and may be highlighted within the context of the COVID-19 pandemic. The use of facial masks in the community setting represents one of the most pressing needs to address, given the polarised opinions around the world. Both broad-based ecological studies, adjusting for confounding and high-quality randomised trials, may be necessary to determine if there is an independent contribution to their use as a physical intervention, and how they may best be deployed to optimise their contribution. The type of fabric and weave used in the face mask is an equally pressing concern, given that surgical masks with their cotton-polypropylene fabric appear to be effective in the healthcare setting, but there are questions about the effectiveness of simple cotton masks. In addition, these masking intervention studies should focus on measuring not only benefits but also compliance, harms, and risk compensation if the latter may lead to a lower protective effect. In addition, although the use of surgical masks versus N95 respirators demonstrates no differences in clinical effectiveness to date, their use needs to be studied in the setting of a new pandemic such as COVID-19, and with concomitant measurement of harms, which to date have been poorly studied. Physical distancing represents another major research gap which needs to be addressed expediently, especially within the context of the COVID-19 pandemic setting as well as in future epidemic settings. The use of quarantine and screening at entry ports needs to be investigated in well-designed, high-quality studies. We found only one RCT of quarantine, and no trials of screening at entry ports or physical distancing. Given that this is one of the primary strategies applied globally in the face of the COVID-19 pandemic, future trials should be conducted within the context of this pandemic, as well as in future epidemics with other respiratory viruses of less virulence.

The variable quality and small scale of some studies is known from descriptive studies (Aiello 2002; Fung 2006; WHO 2006b), and systematic reviews of selected interventions (Meadows 2004). In summary, more high-quality studies are needed to evaluate the most effective strategies to implement successful physical interventions in practice, both on a small scale and at a population level. Finally, we emphasise that more attention should be paid to describing and quantifying the harms of the interventions assessed in this review and their relationship with compliance.

ACKNOWLEDGEMENTS

Thanks to the following people for commenting on the draft protocol and review: Anne Lyddiatt, Stephanie Kondos, Tom Sandora, Kathryn Glass, Max Bulsara, Rick Shoemaker, and Allen Cheng. Thanks also to the following people for translating non-English language trials for the draft review: Jørgen Lous for translating a Danish paper and extracting data, Ryuki Kassai who translated a Japanese paper, and Taixiang Wu who translated several Chinese papers. We thank the following people for commenting on the 2009, 2010, and 2011 updated reviews, respectively: for 2009, Anne Lyddiatt, Thomas Sandora, Michael Broderick, Sree Nair, and Allen Cheng; for 2010, Carmem Pessoa da Sailva and Sergey Eremin; and for 2011, Amy Zelmer, Tom Sandora, Sree Nair, and Allen Cheng. Drs Aiello and Larson provided additional information on their trials for the 2010 update. Dr V Shukla, Dr J Conly, and K Lee prepared the GRADE tables using GRADEprofiler software. Drs Carmem Pessoa da Silva and Thomas Haustein provided linguistic assistance for the 2010 update.

We gratefully acknowledge funding for the 2009 update from the UK National Institute for Health Research (NIHR) and the National Health and Medical Research Council (NHMRC) of Australia and from WHO for the 2010 update. We also thank Ruth Foxlee and Alex Rivetti for constructing the search strategies for the previous review versions, and Bill Hewak and Adi Prabhala for extracting data in the original review. Finally, we thank Sree Nair, who co-authored previous versions of this review.

For this 2020 update, we thank Dr Elizabeth Gibson for assistance with describing the intervention details of the included trials. We also wish to thank the following people for commenting on the draft update: Dr CJ Cates, Reader in Evidence Based Medicine, SGUL, Dr Teresa Neeman, Dr Robert Ware, Dr Janet Wale, and Prof Allen Cheng.

CHARACTERISTICS OF STUDIES

Characteristics of included studies *[ordered by study ID]*

Aelami 2015

Study characteristics	
Methods	A prospective cross-sectional study conducted during the Hajj season 2012. Pilgrims were randomised into 2 groups. The intervention group received education on personal hygiene including a hygienic package containing alcohol-based hand rub (gel or spray), surgical masks, soap, paper handkerchiefs, and user instructions; the control group did not receive any intervention. ILI was defined as the presence of at least 2 of the following during their stay: fever, cough, and sore throat. Questionnaires including demographic and clinical information were distributed amongst trained physicians before departure from Iran.
Participants	Total enrolled: 664 Iranian pilgrims (306 in the intervention group and 358 in the control group) Inclusion criteria: not reported Exclusion criteria: not reported

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Aelami 2015 *(Continued)*

Interventions	Hygiene education and package. See Table 1 for details.
Outcomes	ILI defined as the presence of at least 2 of the following during their stay: fever, cough, and sore throat. No safety outcomes were reported.
Notes	This is an abstract, therefore few details were reported.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Insufficient details provided
Allocation concealment (selection bias)	Unclear risk	Insufficient details provided
Blinding of participants and personnel (performance bias) All outcomes	High risk	Unblinded study
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	Insufficient details provided
Incomplete outcome data (attrition bias) All outcomes	Unclear risk	Insufficient details provided
Selective reporting (reporting bias)	Unclear risk	Insufficient details provided

Aiello 2010

Study characteristics

Methods	Cluster-RCT assessing the effects of hand sanitiser and masks versus masks or no intervention on ILI symptoms. The trial was conducted in university halls of residence with more than 100 student residents in a US university during the 2006 to 2007 influenza "season". The study lasted 6 weeks. The units of randomisation were 7 of the 15 halls. 1 hall was very large (1240 residents), and the 6 remaining ones, which had between 110 and 830 residents, were combined into 2 clusters roughly equivalent in size. The 3 clusters were then randomised by random extraction of the clustered halls' names out of a container. The largest hall (single-cluster) was randomised to the mask and hand sanitiser arm; the 4-halls cluster received masks; and the remaining 2 halls were assigned as controls.
Participants	A total of 1297 with completed baseline survey and at least 1 weekly survey result were analysed (face mask and hand hygiene group = 367; face mask–only group = 378; control group = 552). Inclusion criteria: aged 18 or more, willing to wear mask and use alcohol-based hand sanitiser, have a throat swab specimen collected when ill, and complete the baseline and weekly surveys over the 6-week study period Exclusion criteria: individuals reporting a skin allergy to alcohol were excluded

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Aiello 2010 *(Continued)*

	Recruitment of students began in 26 November, but the trial did not go "live" with distribution of intervention materials until 22 January 2007 when the first case of influenza was confirmed on campus by laboratory tests. Enrolment continued until 16 February 2007, and the study was completed on 16 March 2007. During the study period there was a 1-week break when the majority of residents left campus. There were 1327 eligible participants, 1297 of which had a complete baseline survey and at least 1-weekly survey result. It is unclear what the ineligibility criteria were for the 30 missing (1327 minus 1297), but the explanation may be in the appendix.
Interventions	Alcohol-based hand sanitiser (62% ethyl alcohol in a gel base) in a squeeze bottle and TECNOL procedure masks with ear loops (KC Ltd) and educational material or masks and educational material or no intervention. Compliance was encouraged within halls and outside. Sleep wearing was optional. All participants received basic video-linked instruction on cough etiquette and hand sanitation. At baseline and weekly during the study, participants were asked to fill in a web-based survey collecting demographic and ILI symptom data. This was supplemented by direct observation of compliance by staff. Compliance with "optimal handwashing" (at least 20 seconds 5 or more times a day) was significantly higher in the sanitiser-and-mask arm.
Outcomes	Laboratory details are described in appendix. Effectiveness: ILI, defined as cough and at least 1 constitutional symptom (fever/feverishness, chills, headache, myalgia). ILI cases were given contact nurses' phone numbers to record the illness and paid USD 25 to provide a throat swab. 368 participants had ILI, and 94 of these had a throat swab analysed by PCR. 10 of these were positive for influenza (7 for A and 3 for B). Safety: N/A
Notes	The authors conclude that "These findings suggest that face masks and hand hygiene may reduce respiratory illnesses in shared living settings and mitigate the impact of the influenza A (H1N1) pandemic". This conclusion is based on a significantly lower level of ILI incidence in the mask and hand sanitiser arm compared to the other 2 arms after adjustment for covariates (30% to 50% less in arm 1 compared to controls in the last 2 weeks of the study). Comparison with the ILI rate of the control arm may not be a reflection of the underlying rate of ILI because the intervention arm received instruction on hand sanitation and hand etiquette. The play of adjustments is unclear. The intracluster correlation coefficient is reported in the footer of Table 4. Its very small size suggests lack of clustering within halls. The role of spring break is mentioned in the Discussion, as are the results of this study compared to other studies included in our review (Cowling 2008 and MacIntyre 2009). The authors report that 147 of 1297 participants (11.3%) had ILI symptoms "at baseline" and were excluded from analysis. During the 6 weeks of the study, 368 of 1150 participants (32%) had ILI. This averages out at about 5% per week. It is unclear what the term "at baseline" means; presumably this means during the 2 to 3 weeks of participant enrolment. If this is so, the reason for the triggering of the interventions (tied to influenza isolation) are obscure, as the trial is supposedly about ILI, and an ILI outbreak was already under way "at baseline".

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Described as randomised, but sequence generation not reported
Allocation concealment (selection bias)	High risk	The residence hall units were randomised by blindly selecting a uniform ticket with the name of each hall out of a container (A.S.M. and A.A.) for randomisation assignment to each study arm.

Aiello 2010 *(Continued)*

Blinding of participants and personnel (performance bias) All outcomes	High risk	Unblinded study
Blinding of outcome assessment (detection bias) All outcomes	Low risk	Outcome assessors blinded.
Incomplete outcome data (attrition bias) All outcomes	Low risk	Attrition is reported as follows: 9, 11, and 19 ineligible and 26, 52, and 21 lost to follow-up (respectively by arm), for a total of 39 and 99 for each reason for attrition. In total, 1297 (97%) of 1331 participants completed a baseline and at least 1-weekly survey. The text reports an ITT analysis with only 1 ILI episode included by participant. No reasons for the attrition of participants and swab volunteers are reported (were the swabs taken from a random sample or not?).
Selective reporting (reporting bias)	High risk	There is no information on the causes of ILI other than the reporting on the 10 influenza PCR-positive swabs of 94 out of 368 students with ILI. This is a very low rate (and the Discussion confirms that the influenza season was mild), but investigation of the other known causes of ILI is not even mentioned in the text. This is especially important because stress, alcohol intake levels, and influenza vaccination were a significant predictor of ILI symptoms (Table 1). The reason for selective testing and/or reporting of influenza viruses tests over the other causes of ILI are unclear, especially as the study objective was focused on ILI. The text is also difficult to follow, weaving the reporting of ILI and influenza without a clear rationale.

Aiello 2012

Study characteristics	
Methods	During the 2007 to 2008 influenza season, 1111 students residing in university residence halls were cluster-randomised by residence house (N = 37) to either face mask and hand hygiene, face mask only, or control arms. Discrete time survival analysis using generalised models estimated rate ratios according to study arm, each week and cumulatively over the 6-week intervention period, for clinically verified ILI and laboratory-confirmed influenza A or B.
Participants	A total of 1187 young adults living in 37 residence halls, randomly assigned to 1 of 3 groups for 6 weeks: face mask use (n = 392), face masks with hand hygiene (n = 349), control (n = 370) Inclusion criteria: aged 18 or more, willing to wear mask and use alcohol-based hand sanitiser, have a throat swab specimen collected when ill, and complete the baseline and weekly surveys over the 6-week study period Exclusion criteria: individuals reporting a skin allergy to alcohol were excluded
Interventions	Participants were assigned to face mask and hand hygiene, face mask only, or control group during the study. See Table 1 for details.
Outcomes	Clinically verified ILI: case definition (presence of cough and at least 1 or more of fever/feverishness, chills, or body aches) Laboratory-confirmed influenza A or B. Throat swab specimens were tested for influenza A or B using RT-PCR.

	No safety outcomes reported.
Notes	This study has the same trial registration number as the Aiello 2010 study; the study was funded by government and pharmaceutical industry.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Computer generation of sequence described.
Allocation concealment (selection bias)	Low risk	All residence houses in each of the residence halls were randomised prior to the intervention implementation.
Blinding of participants and personnel (performance bias) All outcomes	High risk	No blinding for study participants and personnel
Blinding of outcome assessment (detection bias) All outcomes	Low risk	Outcome assessors blinded.
Incomplete outcome data (attrition bias) All outcomes	Low risk	Attrition low and similar in each group
Selective reporting (reporting bias)	Low risk	2 outcomes specified and reported.

Aiello 2010

Study characteristics

Methods	Cluster-RCT assessing the effects of hand sanitiser and masks versus masks or no intervention on ILI symptoms. The trial was conducted in university halls of residence with more than 100 student residents in a US university during the 2006 to 2007 influenza "season". The study lasted 6 weeks. The units of randomisation were 7 of the 15 halls. 1 hall was very large (1240 residents), and the 6 remaining ones, which had between 110 and 830 residents, were combined into 2 clusters roughly equivalent in size. The 3 clusters were then randomised by random extraction of the clustered halls' names out of a container. The largest hall (single-cluster) was randomised to the mask and hand sanitiser arm; the 4-halls cluster received masks; and the remaining 2 halls were assigned as controls.
Participants	A total of 1297 with completed baseline survey and at least 1 weekly survey result were analysed (face mask and hand hygiene group = 367; face mask–only group = 378; control group = 552). Inclusion criteria: aged 18 or more, willing to wear mask and use alcohol-based hand sanitiser, have a throat swab specimen collected when ill, and complete the baseline and weekly surveys over the 6-week study period Exclusion criteria: individuals reporting a skin allergy to alcohol were excluded Recruitment of students began in 26 November, but the trial did not go "live" with distribution of intervention materials until 22 January 2007 when the first case of influenza was confirmed on campus by laboratory tests. Enrolment continued until 16 February 2007, and the study was completed on 16 March 2007. During the study period there was a 1-week break when the majority of residents left cam-

Aiello 2010 *(Continued)*

	pus. There were 1327 eligible participants, 1297 of which had a complete baseline survey and at least 1-weekly survey result. It is unclear what the ineligibility criteria were for the 30 missing (1327 minus 1297), but the explanation may be in the appendix.
Interventions	Alcohol-based hand sanitiser (62% ethyl alcohol in a gel base) in a squeeze bottle and TECNOL procedure masks with ear loops (KC Ltd) and educational material or masks and educational material or no intervention. Compliance was encouraged within halls and outside. Sleep wearing was optional. All participants received basic video-linked instruction on cough etiquette and hand sanitation. At baseline and weekly during the study, participants were asked to fill in a web-based survey collecting demographic and ILI symptom data. This was supplemented by direct observation of compliance by staff. Compliance with "optimal handwashing" (at least 20 seconds 5 or more times a day) was significantly higher in the sanitiser-and-mask arm.
Outcomes	Laboratory details are described in appendix. Effectiveness: ILI, defined as cough and at least 1 constitutional symptom (fever/feverishness, chills, headache, myalgia). ILI cases were given contact nurses' phone numbers to record the illness and paid USD 25 to provide a throat swab. 368 participants had ILI, and 94 of these had a throat swab analysed by PCR. 10 of these were positive for influenza (7 for A and 3 for B). Safety: N/A
Notes	The authors conclude that "These findings suggest that face masks and hand hygiene may reduce respiratory illnesses in shared living settings and mitigate the impact of the influenza A (H1N1) pandemic". This conclusion is based on a significantly lower level of ILI incidence in the mask and hand sanitiser arm compared to the other 2 arms after adjustment for covariates (30% to 50% less in arm 1 compared to controls in the last 2 weeks of the study). Comparison with the ILI rate of the control arm may not be a reflection of the underlying rate of ILI because the intervention arm received instruction on hand sanitation and hand etiquette. The play of adjustments is unclear. The intracluster correlation coefficient is reported in the footer of Table 4. Its very small size suggests lack of clustering within halls. The role of spring break is mentioned in the Discussion, as are the results of this study compared to other studies included in our review (Cowling 2008 and MacIntyre 2009). The authors report that 147 of 1297 participants (11.3%) had ILI symptoms "at baseline" and were excluded from analysis. During the 6 weeks of the study, 368 of 1150 participants (32%) had ILI. This averages out at about 5% per week. It is unclear what the term "at baseline" means; presumably this means during the 2 to 3 weeks of participant enrolment. If this is so, the reason for the triggering of the interventions (tied to influenza isolation) are obscure, as the trial is supposedly about ILI, and an ILI outbreak was already under way "at baseline".

Alzaher 2018

Study characteristics

Methods	A cluster-RCT conducted amongst girls attending 4 primary schools between January and March 2018. The participants attended a hand hygiene workshop. The schoolgirls' absences were followed up for 5 weeks. Incidence rate, percentage of absence days, and absence rate were calculated for total and upper respiratory infections absences.
Participants	A total of 496 schoolgirls aged of 6 to 12 years, attending 4 public primary girls' schools in the city of Riyadh, Saudi Arabia between January and March 2018. Students were randomised to education group (n = 234) or control group (n = 262). Exclusion criteria: not reported
Interventions	Hand hygiene workshop. See Table 1 for details.
Outcomes	Incidence rate, percentage of absence days, and absence rate were calculated for total and upper respiratory infections absences. The episode of URIs was defined as having 2 of the following symptoms for a day or 1 of the symptoms for 2 or more consecutive days: 1) a runny nose, 2) a stuffy or blocked nose or noisy breathing, 3) sneezing, 4) a cough, 5) a sore throat, and 6) feeling hot, having a fever or a chill. No safety outcomes reported.
Notes	Source of funding unclear

Arbogast 2016

Study characteristics	
Methods	A 13.5-month prospective cluster-RCT executed with alcohol-based hand sanitiser in strategic workplace locations and personal use (intervention group) and brief hand hygiene education (both groups). 4 years of retrospective data were collected for all participants.
Participants	Data for a total of 1183 participants were analysed (intervention group = 525, control group = 607). Inclusion criteria: all employees at 3 facilities who were 18 years of age or older, were enrolled in the company health insurance coverage, did not transfer between sites, and worked onsite full time (≥ 32 hours) were eligible for the study Exclusion criteria: not reported
Interventions	Alcohol-based hand sanitiser in strategic workplace locations and personal use (intervention group) and brief hand hygiene education (both groups). See Table 1 for details.
Outcomes	(1) The number of healthcare insurance claims, for a defined set of preventable illnesses, per participant per year, and (2) absenteeism, defined as the number of sick episodes per participant per year Claims based on ICD-9 codes No safety outcomes reported.
Notes	Industry funded; only 2 clusters (1 per group) included, hence study data not included in meta-analysis.

Azor-Martinez 2016

Study characteristics	
Methods	Randomised, controlled, and open study with an 8-month follow-up. The experimental group washed their hands with soap and water, together with using hand sanitiser, and the control group followed their usual handwashing procedures. Absenteeism rates due to URIs were compared between the 2 groups through a multivariate Poisson regression analysis. The per cent of days missed in both groups were compared with a z test.
Participants	A sample of 1341 (intervention group = 621, control group = 720) Inclusion criteria: children 4 to 12 years old, attending 5 state schools in Almeria (Spain) whose parents/guardians had signed an informed consent document Exclusion criteria: children who had any of the following chronic illnesses that predisposed them to infection: neoplasia, primary and secondary immunodeficiencies, cystic fibrosis, chronic treatment with high doses of steroids or immunosuppressants
Interventions	Hand-washing workshops of 2-hour duration. The experimental group washed their hands with soap and water together with using hand sanitiser, whilst the control group followed usual hand-washing procedures. See Table 1 for details.
Outcomes	Absenteeism rates due to URIs Per cent of days missed Respiratory illness was defined by 2 of the following symptoms during 1 day, or 1 of the symptoms for 2 consecutive days: (1) runny nose; (2) stuffy or blocked nose or noisy breathing; (3) cough; (4) feeling hot or feverish or having chills; (5) sore throat; or (6) sneezing. A school absenteeism case (episode) was defined as when a child failed to attend school due to an URI. Common infectious illnesses, such as conjunctivitis, and skin infections were not included. Other causes for absenteeism, such as doctors' appointments, family vacations, and accident injuries, were also excluded.

Ban 2015

Study characteristics	
Methods	"Group randomised" trial. Only 2 clusters, which were 2 kindergartens in Xiantao City, Hubei Province, China
Participants	Data for a total of 393 participants were analysed (intervention group = 194, control group = 199). 5 classes (221 children) randomly selected from 1 kindergarten in the intervention group and 6 classes (244 children) randomly selected from another kindergarten in the control group. Children were aged 5 or under. There were 72 exclusions from the analysis.
Interventions	Intervention group: hand hygiene and surface-cleaning education and provision of products for kindergarten and home use. Control group: usual practice. See Table 1 for details.
Outcomes	Respiratory illness, defined as: 2 or more of the following: fever, cough and expectoration, runny nose and nasal congestion, collected by parental questionnaire. Axillary temperature higher than 37.3 °C or the range of temperature fluctuation is more than 1 °C. 'Cough and expectoration' were defined as 3 or more coughs in a single hour and lasting for 4 or more hours in a single day, with or without expectoration. 'Runny nose and nasal congestion' were defined as a runny nose lasting for 4 or more hours in 1 day, with or without nasal congestion.

Notes	

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	High risk	Method not described, and only 2 clusters.
Allocation concealment (selection bias)	Unclear risk	Method not described.
Blinding of participants and personnel (performance bias) All outcomes	High risk	Unblinded study
Blinding of outcome assessment (detection bias) All outcomes	High risk	Unblinded study
Incomplete outcome data (attrition bias) All outcomes	High risk	Parental report, and parents were aware of treatment allocation
Selective reporting (reporting bias)	High risk	Attrition reported and balanced between groups, but high rate of attrition in a trial with small numbers of participants.

Barasheed 2014

Study characteristics

Methods	Pilot, non-blinded, parallel, cluster-RCT
Participants	22 tents were randomly selected from the Australian pilgrims camped in Mina, during Hajj in 2011; 12 tents were allocated to the mask group and 10 tents to the control group. A total of 164 Australian pil-

Barasheed 2014 *(Continued)*

	grims were recruited: 75 in the mask group (39 'cases' and 36 'contacts') and 89 in the control group (36 'cases' and 53 'contacts'). Inclusion criteria for index case: 1) Australian pilgrims of any gender aged > 15 years who attend the Hajj 2011, and 2) have symptoms of respiratory infection for 3 days. For close tent contact: 1) Australian pilgrims of any gender aged 15 years or more who attend the Hajj 2011, and 2) pilgrims who share the same tent and sleep "immediately close" to the index case. Exclusion criteria: for index case: 1) pilgrims who do not suffer from symptoms of respiratory infection, 2) pilgrims who present with symptoms of respiratory infection for > 3 days, and 3) children aged less than 15 years. For close tent contact: 1) pilgrims who are symptomatic at presentation, 2) pilgrims who are not close tent contacts of an index case, and 3) children aged less than 15 years. Only 10% to 15% of potential participants took part in the study.
Interventions	"supervised mask use" versus "no supervised mask use". See Table 1 for details.
Outcomes	Laboratory: 2 nasal swabs from all ILI cases and contacts, 1 for influenza POCT using the QuickVue Influenza (A+B) assay (Quidel Corporation, San Diego, USA) and 1 for later nucleic acid testing for influenza and other respiratory viruses. However, there was a problem with getting POCT on time during Hajj. Effectiveness: to assess the effectiveness of face masks in the prevention of transmission of ILI. ILI was defined as subjective (or proven) fever plus 1 respiratory symptom (e.g. dry or productive cough, runny nose, sore throat, shortness of breath). Safety: none planned or reported
Notes	The study was conducted from 4 November 2011 to 10 November 2011. Funding: government (Qatar National Research Fund (QNRF)) Compliance with face mask use by pilgrims was 56 of 75 (76%) in the mask group and 11 of 89 (12%) in the control group (P < 0.001). The proportion of face mask user in the 'mask' tents was 76% for both males (19/25) and females (38/50). The most often reported reason for not wearing face masks was discomfort (15%).

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Insufficient information provided.
Allocation concealment (selection bias)	Unclear risk	"tents were randomised to either intervention group (supervised mask tent) or control group (no supervised mask tent) by an independent study coordinator who was not an investigator", but did not mention how
Blinding of participants and personnel (performance bias) All outcomes	Low risk	"Because advice from the Saudi Ministry of Hajj to all pilgrims included recommending the wearing of masks, all pilgrims, both cases and controls, were asked about mask-wearing"
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	Self-reported outcomes (nasal swab was performed for those who reported ILI symptoms and was not intended as systematic detection). ILI was defined as subjective (or proven) fever plus 1 respiratory symptom.
Incomplete outcome data (attrition bias) All outcomes	Low risk	No loss to follow-up, all numbers were reported from enrolment to analysis

Biswas 2019

Study characteristics	
Methods	Cluster-RCT in 24 primary schools in Dhaka to assess the effectiveness of hand sanitiser and a respiratory hygiene education intervention in reducing ILI and laboratory-confirmed influenza during June to September 2015. 12 schools were randomly selected to receive hand sanitiser and respiratory hygiene education, and 12 schools received no intervention. Field staff actively followed children daily to monitor for new ILI episodes (cough with fever) through school visits and by phone if a child was absent. When an illness episode was identified, medical technologists collected nasal swabs to test for influenza viruses.
Participants	A total of 10,855 students were enrolled in the study (intervention schools = 5077 children; control schools = 5778 children). Children aged 5 to 10 years educated in 24 randomly selected primary schools in Dhaka, Bangladesh Exclusion: schools that offered education above grade 5 because of differences in student populations, as well as schools that had previously received a hand or respiratory hygiene intervention
Interventions	Hand sanitiser and respiratory hygiene education versus no intervention. See Table 1 for details.
Outcomes	Incidence of ILI Incidence of laboratory-confirmed influenza (RT-PCR) An ILI episode was defined as measured fever ≥ 38 °C or subjective fever and cough. If a child was absent, the field staff followed up by phone to identify the reason for absenteeism and to determine if the child met the ILI case definition. If a child in a participating school had an ILI episode, a trained medical technologist visited the child's household to obtain consent from the child's parent/guardian and collect a nasal swab from the child within 48 hours of symptom onset. If it was outside the 48-hour window, the sample was not collected. No safety outcomes reported.

Canini 2010

Study characteristics

Methods	A cluster-RCT conducted in France during the 2008 to 2009 influenza season. Households were recruited during a medical visit of a household member with a positive rapid influenza A test and symptoms lasting less than 48 hours. Households were randomised either to the mask or control group for 7 days. In the intervention arm, the index case had to wear a surgical mask from the medical visit and for a period of 5 days. The trial was initially intended to include 372 households, but was prematurely interrupted after the inclusion of 105 households (306 contacts) following the advice of an independent steering committee. Generalised estimating equations were used to test the association between the intervention and the proportion of household contacts who developed an ILI during the 7 days following the inclusion.
Participants	A total of 105 households were randomised, which represented 148 contacts in the intervention arm and 158 in the control arm. The study was conducted in 3 French regions (Ile de France, Aquitaine, and Franche-Comté) and included households of size 3 to 8. Exclusion criteria: if index patient was treated for asthma or chronic obstructive pulmonary disease or was hospitalised
Interventions	Surgical mask versus no mask. See Table 1 for details.
Outcomes	The primary endpoint was the proportion of household contacts who developed an ILI during the 7 days following inclusion. Exploratory cluster-level efficacy outcome, the proportion of households with 1 or more secondary illness in household contacts.

Carabin 1999

Study characteristics

Methods	Cluster-RCT carried out in DCCs in the Canadian province of Quebec between 1 September 1996 and 30 November 1997 (15 months). The aim was to test the effects of a hygiene programme on the incidence of diarrhoea and fecal contamination (data not extracted) and on colds and URTIs. The design included before and after periods analysed to assess the Hawthorne effect of study participation on control DCCs. The unit of randomisation was DCC, but analysis was also carried out at classroom and single-child level. This is a common mistake in cluster-RCT analysis. DCCs were stratified by URTI incidence preceding the trial and randomised by location. Cluster coefficients are not reported.
Participants	A total of 1729 children aged 18 to 36 months in 47 DCCs (83 toddler classrooms) Inclusion criteria: presence of at least 1 sandbox and 1 play area and of at least 12 available toddler places For the autumn of 1997 intervention group (24 DCCs, 43 classrooms, and 414 children), control group (23 DCCs, 23 classrooms, and 374 children). It is not clear what is the distribution and data for the autumn of 1996.

Carabin 1999 *(Continued)*

Interventions	Training session (1 day) with washing of hands, toy cleaning, window opening, sand pit cleaning, and repeated exhortations to hand wash
Outcomes	Laboratory: N/A Effectiveness: diarrhoea and coliform contamination (data not extracted) Colds (nasal discharge with at least 1 of the following: fever, sneezing, cough, sore throat, earache, malaise, irritability) URTI (cold of at least 2 days' duration) Surveillance was carried out by educators, annotating absences or illness on calendars. Researchers also filled in a phone questionnaire with answers by DCC directors. Safety: N/A
Notes	Risk of bias: high (no description of randomisation; partial reporting of outcomes, numerators, and denominators) Notes: the authors conclude that the intervention reduced the incidence of colds (IRR 0.80, 95% CI 0.68 to 0.93). This was a confusingly written study with unclear interweaving of 2 study designs. For unclear reasons analysis was only carried out for the first autumn. Unclear why colds are not reported in the results. Cluster-coefficients and randomisation process were not described.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Block randomisation of DCC according to region, but sequence generation not reported
Allocation concealment (selection bias)	Unclear risk	Not described
Blinding of participants and personnel (performance bias) All outcomes	High risk	Blinding not possible (hygiene session plus educational material versus none)
Blinding of outcome assessment (detection bias) All outcomes	High risk	Unblinded
Incomplete outcome data (attrition bias) All outcomes	High risk	Originally 52 eligible DCCs with 89 classrooms agreed to take part, but 5 dropped out (2 closed, 1 was sold, 2 either did not provide data or the data were "unreliable", and 6 classrooms had insufficient data). 43 children failing to attend DCC for at least 5 days in the autumn were also excluded. ITT analysis was carried out including an additional DCC whose director refused to let staff attend the training session. No correction made for clustering.
Selective reporting (reporting bias)	High risk	Denominators unclear and not explained

Chard 2019

Study characteristics

Methods	Cluster-RCT conducted amongst 100 randomly selected primary schools lacking functional WASH facilities in Saravane Province, Lao People's Democratic Republic. Schools were randomly assigned to either

Chard 2019 *(Continued)*

	the intervention (n = 50) or comparison (n = 50) arm. Intervention schools received a school water supply, sanitation facilities, hand-washing facilities, drinking water filters, and behaviour change education and promotion. Comparison schools received the intervention after research activities had ended. At unannounced visits every 6 to 8 weeks, enumerators recorded pupils' roll-call absence, enrolment, attrition, progression to the next grade, and reported illness (diarrhoea, respiratory infection, conjunctivitis), and conducted structured observations to measure intervention fidelity and adherence. Stool samples were collected annually prior to de-worming and analysed for soil-transmitted helminth (STH) infection. In addition to our primary ITT analysis, we conducted secondary analyses to quantify the role of intervention fidelity and adherence on project impacts.
Participants	100 primary schools (50 intervention, 50 comparison) with a total of 3993 pupils were enrolled throughout the study period (intervention schools = 2021 pupils, control schools = 1972 pupils). Up to 40 pupils selected from grades 3 to 5 in each school using systematic stratified sampling, with grade and sex as the stratification variables. Pupils selected at baseline were followed throughout the entire study period; pupils who left the school due to abandonment or transfer were replaced at the beginning of the following academic year, maintaining equal grade and sex ratios when possible. Pupils who progressed from fifth to the sixth grade were replaced with pupils from grade 3 the following academic year.
Interventions	Water supply, sanitation facilities, hand-washing facilities, drinking water filters, and behaviour change education and promotion versus control. See Table 1 for details.
Outcomes	Primary impact of interest was pupil absence, measured by school-wide roll-call at each visit. Secondary health impacts included diarrhoea, symptoms of respiratory infection, and conjunctivitis/non-vision-related eye illness collected through pupil interviews. Pupils were considered to have symptoms of respiratory infection if they reported cough, runny nose, stuffy nose, or sore throat. No safety outcomes reported.
Notes	Funded by government and pharmaceutical industry

Correa 2012

Study characteristics	
Methods	Cluster-RCT in childcare facilities in Colombia from 16 April to 18 December 2008 (3 school terms) testing the effects of hand hygiene using an alcohol-based hand rub versus standard practice
Participants	42 childcare facilities in 6 towns in Colombia. A total of 1727 were enrolled (intervention group = 794 from 21 centres, control group = 933 from 21 centres). Inclusion criteria: licensed to care for 12 or more children aged 1 to 5 years for 8 hours a day, 5 times per week, and where availability of tap water was limited
Interventions	Intervention: alcohol-based hand wash as an addition to hand-washing Control: usual hand-washing practice See Table 1 for details.
Outcomes	ARI defined as: 2 or more of the following symptoms for at least 24 hours, lasting at least 2 days: runny, stuffy, or blocked nose or noisy breathing; cough; fever, hot sensation, or chills; and/or sore throat. Ear pain alone was considered an ARI.
Notes	

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	"...using the random function in Microsoft Excel™ (Microsoft Corp., Redmond, Washington, United States), random numbers (1 or 2) were generated and allotted 1:1 within each group. Finally, a researcher flipped a coin to decide which number would correspond to either arm (heads = 1, intervention; tails = 2, control)."

Cowling 2008

Study characteristics	
Methods	Cluster-RCT carried out in Hong Kong SARS between February and September 2007. The study assessed the effects of non-pharmaceutical interventions on the household transmission of influenza over a 9-day period. ILI cases whose family contacts had been symptom-free for at least 2 weeks rapid-tested for influenza A and B were used and randomised to 3 interventions. Randomisation was carried out in 2 different schedules (2:1:1 for the first 100 households, and subsequently 8:1:1), but it is unclear why and how this was done.
Participants	A total of 350 of 944 originally enrolled participants representing 122 households were analysed (control group = 71 households with 205 household contacts, face mask = 21 households with 61 household contacts, HH = 30 households with 84 household contacts). Inclusion criteria: residents of Hong Kong aged at least 2 years, reporting at least 2 symptoms of ILI ((such as fever ≥ 38 degrees, cough, headache, coryza, sore throat, muscle aches and pains) and positive influenza A+B rapid test and living in a household with at least 2 other individuals, none of whom had ILI in the preceding 14 days Households were excluded because subsequent laboratory testing (culture) was negative. Attrition was not explained.
Interventions	Households were randomised to either wearing face masks with education (as the control group plus education about face mask use) or hand-washing with special medicated soap (with alcohol sanitiser) with education (as the control group plus education about hand-washing) or education about general healthy lifestyle and diet (control group). The soap was distributed in special containers that were weighed at the start and end of the study. Interventions visits to the households were done on average 1 day after randomisation of index case household.
Outcomes	Laboratory: QuickVue RTI MDCK culture Samples were harvested using NTS, but the text refers to a second procedure from June 2007 onwards testing for non-influenza viruses, with no data reported. Effectiveness: secondary attack ratios (SAR): SAR is the proportion of household contacts of an index case who were subsequently ill with influenza (symptomatic contact individuals with at least 1 NTS positive for influenza by viral culture or PCR)

Cowling 2008 *(Continued)*

	3 clinical definitions were used for secondary analysis: 1. Fever ≥ 38 degrees, or at least 2 of following symptoms: headache, coryza, sore throat, muscle aches and pains 2. At least 2 of the following S/S: fever ≥ 37.8 degrees, cough, headache, sore throat, muscle aches and pains 3. Fever ≥ 37.8 degrees plus cough or sore throat Safety: no harms were reported in any of the arms
Notes	The trial authors conclude that "The secondary attack ratios were lower than anticipated, and lower than reported in other countries, perhaps due to differing patterns of susceptibility, lack of significant antigenic drift in circulating influenza virus strains recently, and/or issues related to the symptomatic recruitment design. Lessons learnt from this pilot have informed changes for the main study in 2008". Although billed as a pilot study, the text is highly confusing and at times contradictory. The intervention was delivered at a home visit up to 36 hours after the index case was seen in the outpatients. This is a long time and perhaps the reason for failure of the intervention. Practically, the intervention will have to be organised before even seeking medical care, i.e. people know to do it when the child gets sick at home.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Randomisation was computer generated by a biostatistician. "A pre-specified table of random numbers will be used to assign one of the three interventions to the household of the index case."
Allocation concealment (selection bias)	Low risk	The households of eligible study index patients were allocated to 3 groups in a 1:1:1 ratio under a block randomisation structure with randomly permuted block sizes of 18, 24, and 30 using a random-number generator. Allocation was concealed from treating physicians and clinics and implemented by study nurses at the time of the initial household visit.
Blinding of participants and personnel (performance bias) All outcomes	High risk	Participants and people who administered the interventions were not blinded to the interventions, but participants were not informed of the specific nature of the interventions applied to other participating households.
Blinding of outcome assessment (detection bias) All outcomes	High risk	Unblinded
Incomplete outcome data (attrition bias) All outcomes	High risk	Dropout was accounted for. Dropout from the randomised population was high: 32% in control group, 37.5% in hand hygiene group, and 39.4% in face mask and hand hygiene group. Reasons for dropout were distributed evenly across the 3 groups. Authors report follow-up as proportion of patients remaining in the study after initial dropout.
Selective reporting (reporting bias)	High risk	The choice of season, change in randomisation schedules, and unexplained dropouts amongst contacts; the use of QuickVue, which proved unreliable, reporting bias on non-influenza isolates resulted in a judgement of high risk of bias.

Cowling 2009

Study characteristics	
Methods	Cluster-RCT
Participants	A total of 407 index cases and 794 household contacts were analysed. Of 407 enrolled households, 322 received the allocated interventions as follows: 1. control group = 112 households with 346 contacts (only 91 households analysed with 279 contacts); 2. hand hygiene = 106 households with 329 contacts (only 85 households analysed with 257 contacts); 3. face mask + hand hygiene = 104 households with 340 contacts (only 83 households analysed with 258 contacts). Inclusion criteria: households in Hong Kong. Index cases from 45 outpatient clinics in both the private and public sectors across Hong Kong. They enrolled individuals who reported at least 2 symptoms of ARI (temperature 37.8 °C, cough, headache, sore throat, or myalgia); had symptom onset within 48 hours; and lived in a household with at least 2 other people, none of whom had reported ARI in the preceding 14 days. After giving informed consent, participants provided nasal and throat swab specimens. 2750 patients were eligible and tested between 2 January and 30 September 2008.
Interventions	Participants with a positive rapid-test result and their household contacts were randomly assigned to 1 of 3 study groups: control (lifestyle measures - 134 households), control plus enhanced hand hygiene only (136 households), and control plus face masks and enhanced hand hygiene (137 households) for all household members. No detailed description of the instructions was given to participants.
Outcomes	Influenza virus infection in household contacts, as confirmed by RT-PCR or diagnosed clinically after 7 days "The primary outcome measure was the secondary attack ratio at the individual level: that is, the proportion of household contacts infected with influenza virus. We evaluated the secondary attack ratio using a laboratory definition (a household contact with a nose and throat swab specimen positive for influenza by RT-PCR) as the primary analysis and 2 secondary clinical definitions of influenza based on self-reported data from the symptom diaries as secondary analyses." Statistical analysis: adjusted for clustering Results: no statistically significant difference in secondary attack ratio between groups in total population. Statistically significant reduction in RT-PCR confirmed influenza virus infections in the household contacts in 154 households in which the intervention was applied within 36 hours of symptom onset in the index patient. Adherence to hand hygiene was between 44% and 62%. Adherence of index patient to wearing a face mask between 15% and 49%.
Notes	"In an unintentional deviation from that protocol, 49 of the 407 randomly allocated persons had a household contact with influenza symptoms at recruitment (a potential co-index patient). We also randomly assigned 6 of 407 persons who had symptoms for slightly more than 48 hours." The trial authors conclude that "Hand hygiene and face masks seemed to prevent household transmission of influenza virus when implemented within 36 hours of index patient symptom onset. These findings suggest that non-pharmaceutical interventions are important for mitigation of pandemic and interpandemic influenza".

DiVita 2011

Study characteristics	
Methods	The impact of hand-washing promotion on the risk of household transmission of influenza, ILI, and fever was tested in rural Bangladesh. ILI was defined as fever in children < 5 years old and fever with cough or sore throat in individuals > 5 years old. Households were randomised to intervention or control. The intervention group received hand-washing stations with soap and daily hand-washing motivation at critical times for pathogen transmission, such as after coughing or sneezing. Daily surveillance was conducted, and household members with fever were tested for influenza viruses by PCR. Secondary attack ratios (SAR) were calculated for influenza, ILI, and fever in each arm. Logistic regression with generalised estimating equations was used to estimate the significance of the SAR comparison whilst controlling for clustering by household.
Participants	The study included 233 patient index cases (intervention group = 100, control group 133) with 2540 household contacts (intervention group = 134, control group = 1226). Inclusion criteria: index case patients (individuals who developed ILI within the previous 2 days and were the only symptomatic person in their household) as well as their household contacts
Interventions	Hand-washing stations with soap and daily hand-washing motivation versus control. See Table 1 for details.
Outcomes	SAR were calculated for influenza, ILI, and fever. ILI was defined as fever in children < 5 years old and fever with cough or sore throat in individuals > 5 years old. No safety outcomes reported.
Notes	Funding source unknown

Farr 1988a

Study characteristics

Methods	6-month cluster-RCT, controlled, double-blind of the efficacy of virucidal nasal tissues in the prevention of natural cold, conducted in Charlottesville, Virginia, USA. Many of the families were enrolled because 1 or more family members worked at the State Farm Insurance Company; the remaining families were recruited from the Charlottesville community by advertisement in a local newspaper. Families were randomly assigned by the sponsoring company to receive boxes of treated tissues, placebo tissues, or no tissues. The randomisation was performed by computer. Study participants and investigators were unaware of the type of tissues each family was randomised to receive. Blinding efficacy was tested using a questionnaire: the mothers in each family were asked twice if she believed her family was using virucidal or placebo tissues. Participants in the treated and placebo groups were instructed to use only tissues received through the study, whilst families in the additional control group without tissues were allowed to continue their

Farr 1988a *(Continued)*

	usual practice of personal hygiene. Each family member kept a daily listing of respiratory symptoms on a record card. A nurse epidemiologist visited each family monthly to encourage recording.
Participants	186 families, 58 in the active group, 59 in the placebo group, and 69 in the no-tissues group. A total of 302 families were originally recruited; 116 families who did not comply with the study protocol, lost their surveillance cards, could not complete the protocol were excluded from the analysis.
Interventions	Use of virucidal tissues versus placebo tissues versus no tissues. The treated tissues were impregnated with malic and citric acids and sodium lauryl sulphate, whilst placebo tissues contained saccharin.
Outcomes	Laboratory: serological evidence: no Effectiveness: respiratory illness Safety: N/A
Notes	The authors concluded that virucidal tissues have only a small impact on the overall rate of natural acute respiratory illnesses. The total illness rate was lower in families using virucidal tissues than in both of the other study groups, but only the difference between active and placebo groups was statistically significant (3.4 illness per person versus 3.9 for placebo group, P = 0.04, and 3.6 for the no-tissue control group, P = 0.2, and overall 14% to 5% reduction). The questionnaire results suggest that some bias may have been present since a majority of mothers in the virucide group believed they were receiving the 'active' tissues. Another possible explanation of the low effectiveness of virucidal tissues is poor compliance by children in use of the virucidal tissues. A well-designed and honestly reported study

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	"The randomisation was performed by computer in each trial." However, method of sequence generation is not stated.
Allocation concealment (selection bias)	Unclear risk	"In trial I, families were randomly assigned by the sponsoring company to receive boxes of treated tissues, placebo tissues or no tissues." "Families with one or two children were randomised in one stratum, and families with three or more children were randomised in a second stratum in trial I." Concealment of allocation not described
Blinding of participants and personnel (performance bias) All outcomes	Low risk	"Study participants and investigators were unaware of the type of tissues which each family was randomised to receive in both trials. In trial I, the mother in each family was asked twice if she believed her family was using active or placebo tissues, first after three months and then at the end of the study."
Blinding of outcome assessment (detection bias) All outcomes	Low risk	"Study participants and investigators were unaware of the type of tissues which each family was randomised to receive in both trials. In trial I, the mother in each family was asked twice if she believed her family was using active or placebo tissues, first after three months and then at the end of the study."
Incomplete outcome data (attrition bias) All outcomes	High risk	"A total of 116 of the 302 families were excluded from the analysis. Families were excluded if they lost their surveillance cards or did not conscientiously record data, did not comply with the study protocol, or simply could not complete the protocol for family reasons. It was discovered that families with five or more members had so many colds that it was not possible to distinguish primary and secondary illnesses. These large families were therefore excluded from the analysis in trial I and were excluded from enrolment in trial II."

Selective reporting (reporting bias)	Low risk	All indicated outcomes are reported.

Farr 1988b

Study characteristics	
Methods	6-month randomised, controlled, double-blind trial of the efficacy of virucidal nasal tissues in the prevention of natural cold, conducted in Charlottesville, Virginia, USA. Families were recruited from the Charlottesville community by advertisement in a local newspaper. Families were randomly assigned by the sponsoring company to receive either virucidal tissues or placebo-treated tissues. Stratified randomisation was performed by computer, and the strata were defined by total number in the family. Study participants and investigators were unaware of the type of tissues each family was randomised to receive. Each family member kept a daily listing of respiratory symptoms on a record card. A nurse epidemiologist visited each family monthly to encourage recording. In addition, a study monitor visited each family bimonthly to further encourage compliance and reporting of symptoms.
Participants	98 families, 58 in the active group and 40 in the placebo group. 231 families were initially recruited, 222 completed the trial, data of 98 families were analysed. The other families were excluded from the analysis because they complained of side effects (sneezing, etc.) or reported not using the tissues regularly.
Interventions	Use of virucidal tissues versus placebo tissues. The treated tissues were impregnated with malic and citric acids and sodium lauryl sulphate, whilst the placebo tissues contained succinic acid. Participants in the treated and placebo groups were instructed to only use tissues received through the study.
Outcomes	Laboratory: serological evidence: no Effectiveness: respiratory illness Safety: N/A
Notes	The study suggests that virucidal tissues have only a small impact on the overall rate of natural acute respiratory illnesses. The total illness rate was lower in families using virucidal tissues than in the other study group, but the difference between active and placebo groups was not statistically significant. There was a small, non-significant drop in illness rates across families (5%). The tissues appeared to be ineffective as the drop was confined to primary illness unaffected by tissue use. The placebo (succinic acid) was not inert, and was associated with cough and nasal burning. This impacted on allocation concealment. A well-designed and honestly reported study marred by transparent allocation

Risk of bias

Blinding of participants and personnel (performance bias) All outcomes	Low risk	"Study participants and investigators were unaware of the type of tissues which each family was randomised to receive in both trials."
Blinding of outcome assessment (detection bias) All outcomes	Low risk	"Study participants and investigators were unaware of the type of tissues which each family was randomised to receive in both trials."
Incomplete outcome data (attrition bias) All outcomes	High risk	"A total of 222 (of 231) families completed trial II; 9 families were terminated early (table 1). In 124 families, one or more family members reported not using the tissues regularly and/or reported having significant side effects. The data from these families were not analysed, leaving 58 families (177 persons) and 40 families (114 persons) for analysis in the virucide and placebo groups, respectively."
Selective reporting (reporting bias)	Low risk	All indicated outcomes are reported.

Feldman 2016

Study characteristics	
Methods	Prospective cluster-RCT. Ships from a single, central naval base. Ships were stratified by vessel classes (corvette, fast missile boat, and patrol boat).
Participants	All people participating in security operations, routine exercises, and patrol at a single, central naval base were eligible. The actual number of participants in the groups is not reported.
Interventions	Chlorhexidine gluconate (CHG) dispensers in addition to soap-and-water hand-washing versus soap-and-water hand-washing. See Table 1 for details.
Outcomes	Laboratory: bacterial palm cultures from 30 sailors from each group using a modified bag broth technique with sterile brain-heart broth, at 0 and 4 months (sample participants) Effectiveness: Primary outcome: incidence of infectious diseases reported by the computerised patient records system using ICD-9 diagnoses and grouped into diarrhoeal, respiratory, and skin infections; the number of sick call visits; and the number of sick leave and light-duty days incurred by the sailors Secondary outcome: subclinical morbidity (i.e. symptoms of self-reported infectious diseases) Safety: not reported
Notes	No report on adherence Funding: governmental (Israeli Defense Force Medical Corps) Study was conducted between May and September 2014 (4 months follow-up). CHG availability onboard the ships did not reduce the transmission of infectious diseases or colonisation.

Goodall 2014

Study characteristics	
Methods	A 2X2 factorial RCT with 4 treatment arms: 1. Vitamin D_3 and gargling 2. Placebo and gargling 3. Vitamin D_3 and no gargling 4. Placebo and no gargling
Participants	600 students from McMaster University, Hamilton, Ontario, Canada, randomised to the following: 1. Vitamin D and gargling (N = 150, analysed 135) 2. Vitamin D and no gargling (N = 150, 123 outcomes included in analysis) 3. Placebo and gargling (N = 150, 121 known outcomes included in analysis) 4. Placebo and no gargling (N = 150, 113 known outcomes included in analysis) Inclusion criteria: aged ≥ 17 years and lived with at least 1 student housemate. Exclusion criteria: students with contraindicated medical conditions (hypercalcaemia, parathyroid disorder, chronic kidney disease, use of anticonvulsants, malabsorption syndromes, sarcoidosis), who were currently or planning to become pregnant, who were taking ≥ 1000 international units (IU)/day vitamin D, or who were unable to swallow capsules
Interventions	See TIDieR Table (Table 9).
Outcomes	Laboratory (influenza assessed via weekly self-collected nasal swabs; only swabs for symptomatic participants were assessed). Lab-confirmed influenza was determined by testing the Day 1 nasal swabs using an in-house enterovirus/rhinovirus PCR and, if negative, a commercial multiplex PCR able to detect 16 respiratory viruses and viral subtypes (xTAG RVP FAST, Luminex, Austin TX).

Goodall 2014 *(Continued)*

	Clinical URTI assessed via weekly online surveys. Clinical URTI is defined as the participant's perception of cold in conjunction with 1 or more symptoms (runny/stuffy nose, congestion, cough, sneezing, sore throat, muscle aches, or fever). When participants reported symptoms but were uncertain if they were ill, adjudication was applied by 2 clinicians. Safety: None assessed/reported by the investigators.
Notes	Study was conducted during 2 periods: September to October in 2010 and 2011. Partial governmental funding

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	No description on how the randomisation sequence was generated
Allocation concealment (selection bias)	Low risk	Study used opaque, sealed, serially numbered envelopes. Envelopes were only accessed when both personnel were present.
Blinding of participants and personnel (performance bias) All outcomes	Low risk	Due to the nature of gargling with tap water, this intervention was not blinded. However, all other aspects of the study were blinded. Self-reported symptoms were adjudicated by 2 clinicians.
Blinding of outcome assessment (detection bias) All outcomes	Low risk	Except for gargling, all other participants and study personnel were blinded.
Incomplete outcome data (attrition bias) All outcomes	Low risk	Study flow chart and reasons for lost to follow-up are provided, imputation used for missing outcomes.
Selective reporting (reporting bias)	Low risk	All planned study outcomes were reported and match the published study protocol.

Gwaltney 1980

Study characteristics

Methods	Study assessed the effectiveness of aqueous iodine applied to the fingers in blocking hand transmission of experimental infection with rhinovirus from 1 volunteer to another. Healthy, young adult volunteers were recruited from the general population at the University of Virginia, Charlottesville. Volunteers were not informed about the contents of the hand preparation until after the study. 2 experiments were conducted to evaluate the virucidal activity of aqueous iodine applied to the fingers immediately before viral contamination. Another 2 experiments were conducted to determine whether there was sufficient residual activity of aqueous iodine after 2 hours to interrupt viral spread by the hand route. Volunteers who were donors of virus for the hand exposures were challenged intranasally on 3 consecutive days with the rhinovirus strain HH. Recipients were randomly assigned to receive iodine or placebo. The donors contaminated their hands with nasal secretions by finger to nose contact before the exposure. Hand contact was made between a donor and a recipient by stroking of the fingers for 10 seconds. Donors and recipients wore masks during the exposure period.

Gwaltney 1980 *(Continued)*

Participants	15 and 20 volunteers in 2 experiments
Interventions	Treatment of fingers with iodine versus placebo. The virucidal preparation used was aqueous iodine (2% iodine and 4% potassium iodide). The placebo was an aqueous solution of food colours.
Outcomes	Experimental rhinovirus infection reduced (P = 0.06) Laboratory: serological evidence Effectiveness: rhinovirus infection (based on serology, isolation, and clinical symptoms) with high-score clinical illness. Score was published elsewhere. Safety: N/A
Notes	Risk of bias: high (poor description of randomisation process, concealment, or allocation) Notes: the study suggests that aqueous iodine applied to the fingers was effective in blocking transmission by hand contact of experimental infection with rhinovirus for up to 2 hours after application (1 out 10 volunteers were infected compared to 6 out of 10 in the placebo preparation arm, P = 0.06 with Fisher's exact test). The effectiveness of iodine treatment of the fingers in interrupting viral transmission in volunteers recommends its use for attempting to block transmission of rhinovirus under natural conditions. Although the cosmetic properties of 2% aqueous iodine make it impractical for routine use, it can be used as an epidemiologic tool to study the importance of the hand transmission route and to develop an effective cosmetically acceptable hand preparation. A summarily reported study

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Insufficient information
Allocation concealment (selection bias)	Unclear risk	insufficient information
Blinding of participants and personnel (performance bias) All outcomes	Low risk	"The viricidal preparation used was aqueous iodine... . The placebo was an aqueous solution of food colors... mixed to resemble the color of iodine. An odor of iodine was given to the placebo... . Volunteers were not informed about the contents of the hand preparation until after the study."
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	It is not stated whether the outcome assessor was blinded or not.
Incomplete outcome data (attrition bias) All outcomes	Unclear risk	Insufficient information
Selective reporting (reporting bias)	Unclear risk	Insufficient information

Hartinger 2016

Study characteristics

Methods	Communities were randomised to a comprehensive intervention was an improved solid-fuel stove, installation of a kitchen sink with running water, solar drinking water disinfection, education on handwashing, and separating animals from the kitchen environment.

Hartinger 2016 *(Continued)*

Participants	534 children (267 in each group) in 51 communities (25 in intervention, 26 in control group). 250 children/households in the intervention group and 253 children/households in the control group were available for follow-up. Conducted in a rural farming area
Interventions	Environmental home-based intervention package consisting of improved solid-fuel stoves, kitchen sinks, solar disinfection of drinking water, and hygiene promotion. See Table 1 for details.
Outcomes	Laboratory: *Escherichia coli* (not relevant to this review) Effectiveness: weekly collection of daily diary data on illness. ARI was defined as child presenting cough or difficulty breathing, or both. ALRI was defined as child presenting cough or difficulty breathing, with a raised respiratory rate (> 50 per min in children aged 6 to 11 months and > 40 per min in children aged 12 months) on 2 consecutive measurements. Safety: none described in methods and none reported
Notes	The authors conclude that "combined home-based environmental interventions slightly reduced childhood diarrhoea, but the confidence interval included unity. Effects on growth and respiratory outcomes were not observed, despite high user compliance of the interventions. The absent effect on respiratory health might be due to insufficient household air quality improvements of the improved stoves and additional time needed to achieve attitudinal and behaviour change when providing composite interventions". Well-reported trial. Age of children not reported.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Covariate-constrained randomisation is mentioned, but method not described.
Allocation concealment (selection bias)	Unclear risk	Method not mentioned
Blinding of participants and personnel (performance bias) All outcomes	High risk	Unblinded
Blinding of outcome assessment (detection bias) All outcomes	High risk	Data collected by field worker and recorded by parent. All would be aware of allocation.
Incomplete outcome data (attrition bias) All outcomes	Low risk	Low attrition rate, reasons stated, balanced between groups.
Selective reporting (reporting bias)	Low risk	It is unlikely that other outcomes were measured but not reported.

Hubner 2010

Study characteristics	
Methods	A prospective, controlled, intervention-control group design to assess the epidemiological and economical impact of alcohol-based hand disinfectants use at workplace. Volunteers in public administrations in the municipality of the city of Greifswald were randomised into 2 groups. Participants in the intervention group were provided with alcoholic hand disinfection, the control group was unchanged. In all, 1230 person-months were evaluated.
Participants	Employees (n = 134) from the administration of the Ernst-Moritz-Arndt University Greifswald, the municipality of Greifswald and the state of Mecklenburg-Pomerania, were recruited for the study and randomised to intervention (N = 67) or control (N = 67). Final analysis was performed on 64 from the intervention and 65 from the control group. Inclusion criteria: all administrative officers, who did not already apply hand disinfection at work, were considered for participation and were invited by email or mail (n = 850). The 134 participants declared their written consent to participate and completed a pre-study survey with demographic, social, health, and work-related questions to provide data for randomisation. Exclusion criteria: employees that were already using hand disinfectants at work
Interventions	Alcohol-based hand disinfectants use at workplace versus usual hygiene. See Table 1 for details.
Outcomes	Respiratory and gastrointestinal symptoms and days of work were recorded based on a monthly questionnaire over 1 year.

Huda 2012

Study characteristics	
Methods	Poorly described cluster-RCT. Partial report of the SHEWA-B trial focused on changing 11 targeted behaviours in villages to measure the impact on diarrhoea and respiratory illness amongst children. Unit of randomisation is not clear, but was probably a village. A group of 10 to 17 households within a village were the participants, based on the household having at least 1 child under the age of 5.
Participants	A total of 1692 participants (intervention = 848, control = 844) at baseline and 1699 participants at 18 months (intervention = 849, control = 850) Households were eligible if they have a child < 5 years of age and a guardian agreed to participate.
Interventions	SHEWA-B programme targeting improved latrine coverage and usage, access to and use of arsenic-free water, and improved hygiene practices using soaps. See Table 1 for details.
Outcomes	Laboratory: none described in methods and none reported Effectiveness: ARI and diarrhoea. ARI defined as cough and fever or difficulty breathing and fever within 48 h prior to interview. Safety: none described in methods and none reported
Notes	The authors conclude that "The prevalence of childhood diarrhea and respiratory illness was similar in the intervention and control communities". Poorly reported trial

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Mentions random-number tables, but not clear if this was for random selection or randomisation
Allocation concealment (selection bias)	Unclear risk	Method not described
Blinding of participants and personnel (performance bias) All outcomes	High risk	Unblinded
Blinding of outcome assessment (detection bias) All outcomes	High risk	Data on illness were collected by a resident of the village, who was likely to know treatment allocation.
Incomplete outcome data (attrition bias) All outcomes	High risk	Not reported. No flow diagram
Selective reporting (reporting bias)	Unclear risk	Unlikely that other outcomes were measured and not reported

Ibfelt 2015 *(Continued)*

	practice. Swabbing for bacteria and respiratory viruses was conducted at baseline and the end of the intervention period.
Participants	12 nurseries in Copenhagen (intervention = 6, control = 6) with a total of 587 children aged 6 months to 3 years Not clear how many children were in each group. Data on illness collected at the individual level, and on presence of bacteria and viruses at the cluster level.
Interventions	Washing and disinfection of toys and linen every 2 weeks for 3 months. See Table 1 for details.
Outcomes	Laboratory: counts of bacteria (not relevant to this review) and 11 respiratory viruses at baseline and end of intervention period, taken from swabs of 10 predefined locations in playroom (7 locations) and toilet area (3 locations). Viruses were influenza A and B; coronavirus NL63229E, OC43, and HKU1; parainfluenza virus 1, 2, 3, and 4; rhinovirus; RSV A/B; adenovirus; enterovirus; parechovirus; metapneumovirus; and bocavirus. Testing by PCR Effectiveness: illness counts in the children. Absence due to sickness recorded daily with reason categorised, but no definitions of illness provided. Safety: none mentioned in methods and none reported
Notes	The authors conclude that "Although cleaning and disinfection of toys every two weeks can decrease the microbial load in nurseries, it does not appear to reduce sickness absence among nursery children". The results of the disinfection are reported as follows: "The most prevalent virus was coronavirus (97% positive samples), followed by bocavirus (96%), adenovirus (73%) and rhinovirus (46%). The intervention reduced the presence of adenovirus, rhinovirus and RSV approximately two- to five-fold [odds ratio (OR) 2.4, 95% confidence interval (CI) 1.1-5.0 for adenovirus; OR 5.3, 95% CI 2.3-12.4 for rhinovirus; OR 4.1, 95% CI 1.5-11.2 for RSV] compared with the control group. On the other hand, metapneumovirus was found significantly less often in the control group than in the intervention group. The intervention had no effect on the detection of other viruses. The fomites with the highest presence of respiratory virus were pillows and sofas, followed by toys and playroom tables. When looking at the samples from the toys alone, there was a significant decrease following the intervention in the intervention group compared with the control group for rhinovirus (OR 3.8, 95% CI 1.3-10.5; P = 0.01) and RSV (OR 5.2, 95% CI 1.1-23.8; P = 0.04), but not adenovirus". This a poorly reported cluster-RCT. Its importance lies in the surface viral prevalence data (which could have been overestimated by PCR) and the finding that even in the presence of high viral prevalence, sickness was lower in the control (no surface disinfection) arm. This suggests the absence of other factors that could activate surface respiratory viruses.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Method not mentioned
Allocation concealment (selection bias)	Unclear risk	Method not mentioned

Ide 2016

Study characteristics	
Methods	Randomised controlled study in Japan. Participants were randomly allocated into the catechin-treated (epigallocatechin gallate-treated) or non-treated face mask groups for 60 days from January to March 2016. Incidence of laboratory-confirmed influenza infection was measured and compared between groups using Fisher's exact test. Multivariate analysis was performed to calculate adjusted ORs and associated 95% CIs.
Participants	Participants included workers in a nursing home, a rehabilitation facility, and a hospital. A total of 234 participants were eligible for the study (catechin group, n = 118; control group, n = 116).
Interventions	Catechin-treated mask versus non-treated face mask. See Table 1 for details.
Outcomes	Incidence of laboratory-confirmed influenza infection Laboratory-confirmed influenza infection with viral antigen detected by immunochromatographic assay performed when participants reported ILI. No safety outcomes reported.
Notes	Government funded

Ide 2016

Study characteristics	
Methods	Randomised controlled study in Japan. Participants were randomly allocated into the catechin-treated (epigallocatechin gallate-treated) or non-treated face mask groups for 60 days from January to March 2016. Incidence of laboratory-confirmed influenza infection was measured and compared between groups using Fisher's exact test. Multivariate analysis was performed to calculate adjusted ORs and associated 95% CIs.
Participants	Participants included workers in a nursing home, a rehabilitation facility, and a hospital. A total of 234 participants were eligible for the study (catechin group, n = 118; control group, n = 116).
Interventions	Catechin-treated mask versus non-treated face mask. See Table 1 for details.
Outcomes	Incidence of laboratory-confirmed influenza infection Laboratory-confirmed influenza infection with viral antigen detected by immunochromatographic assay performed when participants reported ILI. No safety outcomes reported.
Notes	Government funded

Jacobs 2009

Study characteristics	
Methods	Open RCT lasting 77 days from January 2008 to test “superiority” of face masks in preventing "URTI". This term appears as an acronym in the introduction and is not explained. It is assumed that it stands for 'upper respiratory infections', but it is preceded in the text by the term 'common cold', which is also lacking a definition. Randomisation was carried out in blocks within each of 3 professional figures (physicians, nurses, and “co-medical” personnel).
Participants	33 HCWs mainly females aged around 34 to 37 in a tertiary healthcare hospital in Tokyo, Japan. HCW with “predisposing conditions” (undefined) to “URTI” and those taking antibiotics were excluded. A baseline descriptive survey was carried out including “quality of life”. 1 participant dropped out at end of week 1, but no reason is reported nor the allocation arm. Analysis was performed on 32 participants (mask = 17, no mask = 15).
Interventions	Surgical mask MA-3 (Osu Sangyo, Japan) during all phases of hospital work (n = 17) or no mask (n = 15) (except when specifically required by hospital SOPs)
Outcomes	Laboratory: N/A Effectiveness: URTI is defined on the basis of a symptoms score, with a score > 14 being a URTI according to Jackson’s 1958 criteria (“Jackson score”). These are not explained in text, although the symptoms are listed in Table 3 (any, sore throat, runny nose, stuffy nose, sneeze, cough, headache, ear ache, feel bad) together with their mean and scores SD by intervention arm. Safety: the text does not mention or report harms. These appear to be indistinguishable from URTI symptoms (e.g. headache which is reported as of significantly longer duration in the intervention arm). Compliance is self-reported as high (84.3% of participants).
Notes	The authors conclude that “Face mask use in healthcare workers has not been demonstrated to provide benefit in terms of cold symptoms or getting colds. A larger study is needed to definitively establish non-inferiority of no mask use”. This is a small, badly reported trial. The purpose of trials is to test hypotheses not to prove or disprove 'superiority' of interventions. There is no power calculation, and CIs are not reported (although there is a mention in Discussion). No accurate definitions of a series of important variables (e.g. URTI, runny nose, etc.) are reported, and the Jackson scores are not explained, nor their use in Japanese personnel or language validated.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Open RCT, but sequence generation not reported
Allocation concealment (selection bias)	Unclear risk	"Mask and no mask groups were formed using block randomisation of subjects within their respective job categories: nurses, doctors, and co-medical personnel." Concealment of allocation not described
Blinding of participants and personnel (performance bias) All outcomes	High risk	Unblinded study. Blinding not possible, as 1 group wore face masks
Blinding of outcome assessment (detection bias) All outcomes	High risk	Unblinded study
Incomplete outcome data (attrition bias) All outcomes	Low risk	1 dropout in each group accounted for. "Analyses were performed following the principles of intention-to-treat."
Selective reporting (reporting bias)	High risk	NB: influenza vaccine coverage was 100% in mask group and only 81% in the non-mask-wearing group.

Kotch 1994

Study characteristics

Methods	Pair-matched, cluster-RCT conducted from 19 October 1988 to 23 May 1989 in 24 childcare centres in North Carolina, USA The trial tested the effects of a hand-washing and environment sterilising programme on diarrhoea (data not extracted) and ARIs. Child daycare centres had to care for 30 children or less, at least 5 of whom had to be in nappies, and intending to stay open for at least another 2 years. Randomisation is not described, nor are cluster coefficients reported.
Participants	389 children aged 3 years or less in daycare for at least 20 hours a week. There were some withdrawals, but attrition of participants is not stated, only that in the end data for 31 intervention classrooms and 36 control classrooms were available. 291 children aged up to 24 months and 80 over 24 months took part. The text is very confusing, as 371 seems to be the total of the number of families that took part. No denominator breakdown by arm is reported, and numerators are only reported as new episodes per child-year.
Interventions	Structured hand-washing and environment (including surfaces, sinks, toilets, and toys) disinfecting programme with waterless disinfectant scrub
Outcomes	Laboratory: N/A Effectiveness: ARI (coughing, runny nose, wheezing, sore throat, or earache) Safety: N/A
Notes	Risk of bias: high (poor reporting of randomisation, outcomes, numerators and denominators)

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Kotch 1994 *(Continued)*

	Note: the authors conclude that the fully adjusted RR for prevention of ARIs was 0.94 (−2.43 to 0.66). A poorly reported study

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	"Pair-matched cluster-randomised, controlled trial", but sequence generation not reported
Allocation concealment (selection bias)	Unclear risk	Centres were matched in pairs and then randomly allocated to either intervention or control programmes. Allocation concealment was not reported.
Blinding of participants and personnel (performance bias) All outcomes	High risk	Not possible (intervention was training session)
Blinding of outcome assessment (detection bias) All outcomes	High risk	"The same staff who conducted the training unobtrusively recorded observations at 5-week intervals"
Incomplete outcome data (attrition bias) All outcomes	High risk	18 families were dropped, denominator not clear.
Selective reporting (reporting bias)	High risk	Denominators not clearly reported

Ladegaard 1999

Study characteristics

Methods	RCT with cluster-randomisation to intervention or control. Of 10 institutions, 2 were excluded because they wanted institutions to be comparable in uptake area (i.e. housing and income). Interventions were administered to children, parents, and teachers at the institutions.
Participants	Children 0 to 6 years old
Interventions	Multifaceted: information, t-shirts to the children with: "Clean hands - yes, thank you", performance of a fairytale "The princess who did not want to wash her hands", exercise in hand-washing, importance of clean and fresh air. The aims of the intervention were to: 1. increase the hygiene education of the daycare teachers; 2. motivate the children by practical learning to have better hand hygiene; and 3. inform the parents about better hand hygiene.
Outcomes	34% decrease in "sickness" (probably mostly gastroenteritis)
Notes	Risk of bias: only limited data available Note: the authors conclude that there was a 34% decrease in sickness in the intervention arm; this is probably overall sickness, as gastroenteritis is part of the outcomes (data not extracted). Only limited data available from translation by Jørgen Lous.

Larson 2010

Study characteristics	
Methods	Cluster block-randomised, controlled trial carried out between 20 November 2006 and 20 June 2008 in an upper Manhattan immigrant Latino neighbourhood ("19 month data collection period"). The study aimed at assessing the effects of education versus education and hand sanitiser use versus education and hand sanitiser use and common mask use against upper respiratory infections over a period of under 2 years. Follow-up was through an automated telephone system with a small financial incentive (USD 20) for those with 75% or more compliance. Those reporting an ILI received a visit within 48 hours for swabbing. An index case was someone who at the "onset day of illness nobody else in the household had been symptomatic within the previous five days". A secondary case for each episode "was any member of the household who developed symptoms within five days following the index case"; "The secondary attack rate was defined as the number of secondary cases recorded within 5 days of the onset of symptoms in the index case divided by the number of household members minus one". The text implies that the unit of observation was the episode ("study subjects contributed more than one episode in which they were considered to be the index case").
Participants	617 households were randomised to the education group (n = 211), the hand sanitiser group (n = 205), and the hand sanitiser and mask group (n = 201). There were 2708 participants, mostly adult Latino immigrants to the USA. Recruitment and allocation were carried out by household. There had to be at least 3 people living in the household, with at least 1 being a preschool or elementary school child, speaking English or Spanish, having a telephone, willingness to complete symptom assessments and have bimonthly home visits, and not using alcohol-based hand sanitiser routinely. Intracluster correlation coefficients are reported on page 179 of the manuscript.

Larson 2010 *(Continued)*

Interventions	Written Spanish or English language educational materials regarding the prevention and treatment of URTIs and influenza or the same educational materials and hand sanitiser (Purell, J&J), in large (8- and 4-ounce) and small (1-ounce) containers to be carried by individual household members to work or school, or the same interventions as well as regular surgical face masks (Procedure Face Masks for adults and children, Kimberly-Clark) with instructions for both the caretaker and the ill person to wear them when an ILI occurred in any household member. Replenishment of intervention stocks was done at the bimonthly home visit. Caretakers had to wear a mask for 7 days when within 3 feet of a symptomatic case. They were also encouraged to wear masks within 3 feet of any household member. Reinforcing phone calls were made 3 times in 6 days. The text clearly reports active influenza vaccine promotion during the bimonthly visits. (“The home visit to each household was made every 2 months to minimise study dropout, reinforce adherence to the assigned intervention, replenish product supplies and record use of supplies, answer questions, and correct ongoing misconceptions. At each visit, new educational materials regarding URTI prevention and treatment and influenza vaccination were distributed.” (PDF page 3). Also just before the Discussion as follows: “Influenza vaccination rates: There was an increase between the baseline and exit interview in all three groups that reported 50% of more of members receiving influenza vaccine (pre- versus post-intervention for each group: 21.1% and 40.8% in the Education group, 19.0% and 57.1% in the hand sanitiser group, and 22.4% and 43.5% in the hand sanitiser and face mask group (P = 0.001). Additionally, those in the hand sanitiser group reported a significantly greater increase than the other 2 groups, controlling for baseline rates (P = 0.002)”) Coverage was unequal across groups, no information on the progressive impact of the vaccine, or indeed the nature of the vaccine(s) is reported. Apparently the first season was mild and the vaccine mismatched, compliance with the trial interventions was low in Arm 3, and a local epidemic of *Staphylococcus aureus* meant that the control group started washing hands. The trial authors report no effect on reporting rates of vaccine coverage by arms, but with so many confounders who knows?
Outcomes	Laboratory: PCR carried out on samples from deep nasal swabs for influenza and the most common other pathogens (RSV, rhinovirus, enterovirus, parainfluenza viruses, etc.). The text describing the results of the swabbing is confusing, but in general appears to be non-random “Households reported 669 episodes of ILI (0 to 5 per individual)". Of the 234 deep nasal swabs obtained, 33.3% (n = 78) tested positive for influenza: 43.6% (n = 34) were influenza A and 56.4% (n = 44) were influenza B. Amongst the 66.7% who tested negative for influenza, 30.8% (48/156) tested positive for other viruses: 7 for respiratory syncytial virus, 9 for parainfluenza, 11 for enterovirus, 10 for rhinovirus, 6 for adenovirus, and 5 for metapneumovirus. Swabs were not obtained from the remaining 435 reported ILI episodes for the following reasons: 72.0% (n = 313) did not meet the CDC definition of an ILI and were therefore included in the URTI symptom count; 21.4% of episodes (n = 93) were reported after 48 hours of ILI onset or the participant refused to be swabbed; and the research staff were unable to reach the participant in 6.7% of episodes (n = 29). As no definition of URTI is given, it is unclear what kind of biases were introduced by the non-swabbing of the 313/435 “not meeting CDC definition”. Effectiveness: ILI (CDC definition): “temperature of 37.8°C or more and cough and/or sore throat in the absence of a known cause other than influenza” URTI only referred to as “Viral upper respiratory infections (URTIs)”. Safety: N/A
Notes	The authors conclude that “the Hand Sanitizer group was significantly more likely to report that no household member had symptoms (P,0.01), but there were no significant differences in rates of infection by intervention group in multivariate analyses. Knowledge improved significantly more in the Hand Sanitizer group (P,0.0001). The proportion of households that reported >50% of members receiving influenza vaccine increased during the study (P,0.001). Despite the fact that compliance with mask wearing was poor, mask wearing as well as increased crowding, lower education levels of caretakers, and index cases 0–5 years of age (compared with adults) were associated with significantly lower sec-

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Larson 2010 *(Continued)*

ondary transmission rates (all P,0.02). In this population, there was no detectable additional benefit of hand sanitiser or face masks over targeted education on overall rates of URTIs, but mask wearing was associated with reduced secondary transmission and should be encouraged during outbreak situations. During the study period, community concern about methicillin-resistant *Staphylococcus aureus* was occurring, perhaps contributing to the use of hand sanitiser in the Education control group, and diluting the intervention's measurable impact".

The study is at high risk of bias. Randomisation and reasons for dropout are not described. Differentials in cluster characteristics across arms point to randomisation not having worked, and the confounding effects of a postrandomisation staphylococcal scare are difficult to judge. Symptom-driven follow-up gives no idea of the effects on asymptomatic ILI/influenza. Poor definitions (URTI?). There are unexplained dropouts, and the analysis plan is unclear. Finally, the very small number of cases of influenza and an unclear swabbing attrition may introduce further elements of confounding.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	"Cluster block randomised, controlled trial", but sequence generation not reported
Allocation concealment (selection bias)	Unclear risk	"Households were block randomised into one of three groups" Allocation concealment not reported
Blinding of participants and personnel (performance bias) All outcomes	High risk	Blinding of participants and personnel was not possible.
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	Blinding of outcome assessment is not stated.
Incomplete outcome data (attrition bias) All outcomes	High risk	In control group households (n = 211), 26 dropped out and 37 did not consent. In hand sanitiser group households (n = 205), 21 dropped out and 36 did not consent. In hand sanitiser and face mask group households (n = 201), 19 dropped out and 35 did not consent. Reasons for dropout were not described.
Selective reporting (reporting bias)	Unclear risk	617 of 772 eligible households were randomised.

Little 2015

Study characteristics

Methods	Individuals sharing a household by mailed invitation through general practices in England were recruited. After consent, participants were randomised online by an automated computer-generated random-number program to receive either no access or access to a bespoke automated web-based intervention that maximised hand-washing intention, monitored hand-washing behaviour, provided tailored feedback, reinforced helpful attitudes and norms, and addressed negative beliefs. Participants were enrolled into an additional cohort (randomised to receive intervention or no intervention) to assess whether the baseline questionnaire on hand-washing would affect hand-washing behav-

Little 2015 *(Continued)*

	iour. Participants were not masked to intervention allocation, but statistical analysis commands were constructed masked to group. The primary outcome was number of episodes of RTIs in index participants in a modified intention-to-treat population of randomly assigned participants who completed follow-up at 16 weeks.
Participants	344 physician offices were recruited over a wide area of England, and 20,066 participants were enrolled and randomised to intervention (N = 16,086) and control (N = 10,026). Modified ITT was performed on 16,908 participants who completed the follow-up questionnaire at 16 weeks (intervention = 8241 and control = 8667). Inclusion criteria: adult patients (aged 18 years or older) identified from computerised lists in general practitioner (GP) practices in England, for whom there was at least 1 other individual living in the household who was willing to report illness to the index person Exclusion criteria: patients with severe mental problems (e.g. major uncontrolled depression or schizophrenia, dementia, or severe mental impairment) or who were terminally ill, and those reporting a skin complaint that would restrict hand-washing
Interventions	Automated web-based intervention that maximised hand-washing intention, monitored hand-washing behaviour, provided tailored feedback, reinforced helpful attitudes and norms, and addressed negative beliefs. Control no access to intervention web pages. See Table 1 for details.
Outcomes	The primary outcome was the number of index individuals that reported 1 or more RTIs (including ILI) at 16 weeks. Secondary: duration of symptoms, transmission of respiratory infections, gastrointestinal infections, attendance at the practice, and use of health service resources Infections self-reported by participants. RTI defined as 2 symptoms of an RTI for at least 1 day or 1 symptom for 2 consecutive days. Definition of ILI was a high temperature (feeling very hot or very cold; or measured temperature > 37.5 °C), a respiratory symptom (sore throat, cough, or runny nose), and a systemic symptom (headache, severe fatigue, severe muscle aches, or severe malaise). No safety outcomes reported.
Notes	Government funded

Larson 2010

Study characteristics	
Methods	Cluster block-randomised, controlled trial carried out between 20 November 2006 and 20 June 2008 in an upper Manhattan immigrant Latino neighbourhood ("19 month data collection period"). The study aimed at assessing the effects of education versus education and hand sanitiser use versus education and hand sanitiser use and common mask use against upper respiratory infections over a period of under 2 years. Follow-up was through an automated telephone system with a small financial incentive (USD 20) for those with 75% or more compliance. Those reporting an ILI received a visit within 48 hours for swabbing. An index case was someone who at the "onset day of illness nobody else in the household had been symptomatic within the previous five days". A secondary case for each episode "was any member of the household who developed symptoms within five days following the index case"; "The secondary attack rate was defined as the number of secondary cases recorded within 5 days of the onset of symptoms in the index case divided by the number of household members minus one". The text implies that the unit of observation was the episode ("study subjects contributed more than one episode in which they were considered to be the index case").
Participants	617 households were randomised to the education group (n = 211), the hand sanitiser group (n = 205), and the hand sanitiser and mask group (n = 201). There were 2708 participants, mostly adult Latino immigrants to the USA. Recruitment and allocation were carried out by household. There had to be at least 3 people living in the household, with at least 1 being a preschool or elementary school child, speaking English or Spanish, having a telephone, willingness to complete symptom assessments and have bimonthly home visits, and not using alcohol-based hand sanitiser routinely. Intracluster correlation coefficients are reported on page 179 of the manuscript.
Interventions	Written Spanish or English language educational materials regarding the prevention and treatment of URTIs and influenza or the same educational materials and hand sanitiser (Purell, J&J), in large (8- and 4-ounce) and small (1-ounce) containers to be carried by individual household members to work or school, or the same interventions as well as regular surgical face masks (Procedure Face Masks for adults and children, Kimberly-Clark) with instructions for both the caretaker and the ill person to wear them when an ILI occurred in any household member. Replenishment of intervention stocks was done at the bimonthly home visit.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Larson 2010 *(Continued)*

	Caretakers had to wear a mask for 7 days when within 3 feet of a symptomatic case. They were also encouraged to wear masks within 3 feet of any household member. Reinforcing phone calls were made 3 times in 6 days. The text clearly reports active influenza vaccine promotion during the bimonthly visits. ("The home visit to each household was made every 2 months to minimise study dropout, reinforce adherence to the assigned intervention, replenish product supplies and record use of supplies, answer questions, and correct ongoing misconceptions. At each visit, new educational materials regarding URTI prevention and treatment and influenza vaccination were distributed." (PDF page 3). Also just before the Discussion as follows: "Influenza vaccination rates: There was an increase between the baseline and exit interview in all three groups that reported 50% of more of members receiving influenza vaccine (pre- versus post-intervention for each group: 21.1% and 40.8% in the Education group, 19.0% and 57.1% in the hand sanitiser group, and 22.4% and 43.5% in the hand sanitiser and face mask group (P = 0.001). Additionally, those in the hand sanitiser group reported a significantly greater increase than the other 2 groups, controlling for baseline rates (P = 0.002)") Coverage was unequal across groups, no information on the progressive impact of the vaccine, or indeed the nature of the vaccine(s) is reported. Apparently the first season was mild and the vaccine mismatched, compliance with the trial interventions was low in Arm 3, and a local epidemic of *Staphylococcus aureus* meant that the control group started washing hands. The trial authors report no effect on reporting rates of vaccine coverage by arms, but with so many confounders who knows?
Outcomes	Laboratory: PCR carried out on samples from deep nasal swabs for influenza and the most common other pathogens (RSV, rhinovirus, enterovirus, parainfluenza viruses, etc.). The text describing the results of the swabbing is confusing, but in general appears to be non-random "Households reported 669 episodes of ILI (0 to 5 per individual)". Of the 234 deep nasal swabs obtained, 33.3% (n = 78) tested positive for influenza: 43.6% (n = 34) were influenza A and 56.4% (n = 44) were influenza B. Amongst the 66.7% who tested negative for influenza, 30.8% (48/156) tested positive for other viruses: 7 for respiratory syncytial virus, 9 for parainfluenza, 11 for enterovirus, 10 for rhinovirus, 6 for adenovirus, and 5 for metapneumovirus. Swabs were not obtained from the remaining 435 reported ILI episodes for the following reasons: 72.0% (n = 313) did not meet the CDC definition of an ILI and were therefore included in the URTI symptom count; 21.4% of episodes (n = 93) were reported after 48 hours of ILI onset or the participant refused to be swabbed; and the research staff were unable to reach the participant in 6.7% of episodes (n = 29). As no definition of URTI is given, it is unclear what kind of biases were introduced by the non-swabbing of the 313/435 "not meeting CDC definition". Effectiveness: ILI (CDC definition): "temperature of 37.8°C or more and cough and/or sore throat in the absence of a known cause other than influenza" URTI only referred to as "Viral upper respiratory infections (URTIs)". Safety: N/A
Notes	The authors conclude that "the Hand Sanitizer group was significantly more likely to report that no household member had symptoms (P,0.01), but there were no significant differences in rates of infection by intervention group in multivariate analyses. Knowledge improved significantly more in the Hand Sanitizer group (P,0.0001). The proportion of households that reported >50% of members receiving influenza vaccine increased during the study (P,0.001). Despite the fact that compliance with mask wearing was poor, mask wearing as well as increased crowding, lower education levels of caretakers, and index cases 0–5 years of age (compared with adults) were associated with significantly lower secondary transmission rates (all P,0.02). In this population, there was no detectable additional benefit of hand sanitiser or face masks over targeted education on overall rates of URTIs, but mask wearing was associated with reduced secondary transmission and should be encouraged during outbreak situations. During the study period, community concern about methicillin-resistant *Staphylococcus aureus* was occurring, perhaps contributing to the use of hand sanitiser in the Education control group, and diluting the intervention's measurable impact". The study is at high risk of bias. Randomisation and reasons for dropout are not described. Differentials in cluster characteristics across arms point to randomisation not having worked, and the confounding

Larson 2010 *(Continued)*

effects of a postrandomisation staphylococcal scare are difficult to judge. Symptom-driven follow-up gives no idea of the effects on asymptomatic ILI/influenza. Poor definitions (URTI?). There are unexplained dropouts, and the analysis plan is unclear. Finally, the very small number of cases of influenza and an unclear swabbing attrition may introduce further elements of confounding.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	"Cluster block randomised, controlled trial", but sequence generation not reported
Allocation concealment (selection bias)	Unclear risk	"Households were block randomised into one of three groups" Allocation concealment not reported
Blinding of participants and personnel (performance bias) All outcomes	High risk	Blinding of participants and personnel was not possible.
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	Blinding of outcome assessment is not stated.
Incomplete outcome data (attrition bias) All outcomes	High risk	In control group households (n = 211), 26 dropped out and 37 did not consent. In hand sanitiser group households (n = 205), 21 dropped out and 36 did not consent. In hand sanitiser and face mask group households (n = 201), 19 dropped out and 35 did not consent. Reasons for dropout were not described.
Selective reporting (reporting bias)	Unclear risk	617 of 772 eligible households were randomised.

Little 2015

Study characteristics

Methods	Individuals sharing a household by mailed invitation through general practices in England were recruited. After consent, participants were randomised online by an automated computer-generated random-number program to receive either no access or access to a bespoke automated web-based intervention that maximised hand-washing intention, monitored hand-washing behaviour, provided tailored feedback, reinforced helpful attitudes and norms, and addressed negative beliefs. Participants were enrolled into an additional cohort (randomised to receive intervention or no intervention) to assess whether the baseline questionnaire on hand-washing would affect hand-washing behaviour. Participants were not masked to intervention allocation, but statistical analysis commands were constructed masked to group. The primary outcome was number of episodes of RTIs in index participants in a modified intention-to-treat population of randomly assigned participants who completed follow-up at 16 weeks.
Participants	344 physician offices were recruited over a wide area of England, and 20,066 participants were enrolled and randomised to intervention (N = 16,086) and control (N = 10,026).

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Little 2015 *(Continued)*

	Modified ITT was performed on 16,908 participants who completed the follow-up questionnaire at 16 weeks (intervention = 8241 and control = 8667). Inclusion criteria: adult patients (aged 18 years or older) identified from computerised lists in general practitioner (GP) practices in England, for whom there was at least 1 other individual living in the household who was willing to report illness to the index person Exclusion criteria: patients with severe mental problems (e.g. major uncontrolled depression or schizophrenia, dementia, or severe mental impairment) or who were terminally ill, and those reporting a skin complaint that would restrict hand-washing
Interventions	Automated web-based intervention that maximised hand-washing intention, monitored hand-washing behaviour, provided tailored feedback, reinforced helpful attitudes and norms, and addressed negative beliefs. Control no access to intervention web pages. See Table 1 for details.
Outcomes	The primary outcome was the number of index individuals that reported 1 or more RTIs (including ILI) at 16 weeks. Secondary: duration of symptoms, transmission of respiratory infections, gastrointestinal infections, attendance at the practice, and use of health service resources Infections self-reported by participants. RTI defined as 2 symptoms of an RTI for at least 1 day or 1 symptom for 2 consecutive days. Definition of ILI was a high temperature (feeling very hot or very cold; or measured temperature > 37.5 °C), a respiratory symptom (sore throat, cough, or runny nose), and a systemic symptom (headache, severe fatigue, severe muscle aches, or severe malaise). No safety outcomes reported.
Notes	Government funded

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Participants were automatically randomly assigned by the intervention software, but sequence generation not described.
Allocation concealment (selection bias)	Low risk	Participants were automatically randomly assigned by the intervention software.
Blinding of participants and personnel (performance bias) All outcomes	High risk	Unblinded study
Blinding of outcome assessment (detection bias) All outcomes	High risk	Unblinded study
Incomplete outcome data (attrition bias) All outcomes	High risk	High attrition that was different in the 2 groups
Selective reporting (reporting bias)	Low risk	Specified outcomes reported.

Loeb 2009

Study characteristics	
Methods	Open non-inferiority RCT carried out to compare the surgical mask with the N95 respirator in protecting healthcare workers against influenza. The trial was carried out between 2008 (enrolment started in September and follow-up on 12 January 2009) and 23 April 2009 (when all HCWs caring for febrile patients were told to wear an N95 respirator) because of the appearance of novel A/H1N1). The trial trigger was the beginning of the influenza season, defined as isolation of 2 or more viruses in a district in the same week. Following the 2003 SARS outbreak, all Ontario nurses caring for febrile patients (38 °C or more and new onset cough or SOB) had to wear surgical masks. The randomisation (carried out in blocks of 4 by centre) then consisted of either confirmation to same-maker surgical mask wear or N95 respirator wear. Investigators and laboratory staff were blind to allocation status, but for obvious reasons (the visible difference in interventions), participants were unblinded. "The criterion for non-inferiority was met if the lower limit of the 95% confidence interval (CI) for the reduction in incidence (N95 respirator minus surgical group) was greater than -9%". So this is the non-inferiority margin. It is assumed that the "minus surgical group" means minus surgical mask group.
Participants	Consenting nurses (n = 446 randomised) aged a mean of 36.2 years working full time (≥ 37 hours/week) in 23 acute units (a mix of paediatric, A&E, and acute medical units) in 8 hospitals in Ontario, Canada. 225 were randomised to the surgical mask and 221 to the N95 respirator. There were 13 and 11 dropouts, respectively from each arm (all accounted for), plus 21 and 19 lost to follow-up; 11 in each arm gave no reason, the others are accounted for. There were no deaths. The final total of 212 and 210 was included in the analysis. Table 1 reports the demographic data of participants by arm, which appear comparable.
Interventions	Surgical masks (as standard wear by the standard distributor) or fit–tested N95 respirator. All nurses wore gloves or gowns in the presence of a febrile patient.
Outcomes	Laboratory RT-PCR paired sera with 4-fold antibody rise from baseline (only for unvaccinated) nurses Effectiveness: follow-up (lasting a mean of around 97 days for both arms) was carried out twice-weekly on a web-based instrument. Nurses with new symptoms were asked to swab a nostril if any of the following signs or symptoms had developed: fever (temperature ≥ 38 °C), cough, nasal congestion, sore throat, headache, sinus problems, muscle aches, fatigue, earache, ear infection, or chills. The text defines influenza with laboratory confirmation, and separately reports criteria for swab triggering and a definition of ILI ("Influenza-like illness was defined as the presence of cough and fever: a temperature ≥ 38°C"). But this is not formally linked to influenza in the text, as it appears that primary focus was the detection of laboratory-confirmed influenza (either by RT-PCR or serology). Additional outcome data sought were work-related absenteeism and physician visits for respiratory illness. Secondary outcomes included detection of the following non-influenza viruses by PCR: parainfluenza virus types 1, 2, 3, and 4; respiratory syncytial virus types A and B; adenovirus; metapneumovirus; rhinovirus-enterovirus; and coronaviruses OC43, 229E, SARS, NL63, and HKU1. Audits to assess nurse compliance with the interventions were carried out in the room of each patient cared for. The text reports that 50 and 48 nurses in the surgical mask and N95 groups, respectively, had laboratory confirmation of influenza infection, indicating non-inferiority. Interestingly, non-inferiority seemed to be applicable both to seasonal viruses and nH1N1 viruses (as 8% and 11.9% were serologically positive to nH1N1). This finding is explained either by seeding or cross reaction with seasonal H1N1. Equivalent conclusions could be drawn for nurses with complete follow-up. Non-inferiority was applicable also to other ILI agents identified. None of the 52 individuals with positive isolates met the criteria for ILI. All cases of ILI were confirmed as having influenza (9 and 2 respectively). This means that all the 11 cases of ILI had influenza, but that most of those with a laboratory diagnosis of influenza did not have cough and fever. For example, the text reports that "Of the 44 nurses in each group who had influenza diagnosed by serology, 29 (65.9%) in the surgical mask group and 31 (70.5%) in the N95 respirator group had no symptoms". By implication, of the 88 nurses with antibody rises, 28 had symptoms of some kind, i.e. two-thirds were asymptomatic. Absenteeism was 1 versus 39 episodes in the mask ver-

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Loeb 2009 *(Continued)*

	sus respirator arms. No episodes of LRTI were recorded. The number of family contacts with ILI were the same for each arm (45 versus 47). Physician visits were similar in both groups. Safety: no AEs are reported
Notes	The authors conclude that "Among nurses in Ontario tertiary care hospitals, use of a surgical mask compared with a N95 respirator resulted in non-inferior rates of laboratory-confirmed influenza". This a well-designed and conducted trial with credible conclusions. The only comment is that the focus in the analysis on influenza (symptomatic and asymptomatic) is not well-described, although the rationale is clear (interruption of transmission).

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	"Randomisation was performed centrally ....", but method of sequence generation not described.
Allocation concealment (selection bias)	Low risk	"...by an independent clinical trials coordinating group such that investigators were blind to the randomisation procedure and group assignment and was stratified by centre in permuted blocks of 4 participants."
Blinding of participants and personnel (performance bias) All outcomes	High risk	"It was not possible to conceal the identity of the N95 respirator or the surgical mask since manipulating these devices would interfere with their function"
Blinding of outcome assessment (detection bias) All outcomes	Low risk	Outcome assessment blinded: "Laboratory personnel conducting hemagglutinin inhibition assays, polymerase chain reaction (PCR), and viral culture for influenza were blinded to allocation."
Incomplete outcome data (attrition bias) All outcomes	Low risk	21 of 225 randomised to mask group and 19 of 221 randomised to N95 group were lost to follow-up, reasons reported. Study stopped early: "We had planned to stop the study at the end of influenza season. However, because of the 2009 influenza A(H1N1) pandemic, the study was stopped on April 23, 2009, when the Ontario Ministry of Health and Long-Term Care recommended N95 respirators for all healthcare workers taking care of patients with febrile respiratory illness."
Selective reporting (reporting bias)	Low risk	All outcomes reported.

Longini 1988

Study characteristics

Methods	Cluster-controlled, double-blind, randomised trial to assess the efficacy of virucidal tissues in interrupting family transmission of rhinovirus and influenza virus. The study was carried out in the community of Tecumseh, Michigan, USA during the period of 25 November 1984 to 28 April 1985. However, the authors only report results for the period of 13 January to 23 March 1985, when a high circulation of influenza A H3N2 and rhinovirus was detected.
Participants	296 households were enrolled, but 5 households were eliminated from the analysis for "technical reasons". The analysis was carried out in households with 3 to 5 members. The authors report data on 143 households randomised to virucidal tissues and 148 to placebo tissue. The average age in households

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Longini 1988 *(Continued)*

	was around 22, and the difference between arms was not significant. Randomisation was carried out by the sponsor, and tissues were pre-packed in coded boxes with no other identifying features and delivered to households at the beginning of the study period.
Interventions	Disposable 3-layered virucidal tissues (citric and malic acids with sodium lauryl sulphate in the middle layer) or placebo (succinic acid in the middle layer) tissues. They were used to blow the nose and for coughing or sneezing into. Households were also stratified by level of tissue use. Tissue use was significantly higher in the intervention arm (82% versus 71%).
Outcomes	Laboratory: yes - viral culture from nasal and throat swabs from symptomatic participants Effectiveness: ARI (with a proportion of laboratory-confirmed diagnosis in non-randomly chosen participants with symptoms lasting 2 days or more) Follow-up and surveillance was carried out using a telephone questionnaire. Safety: N/A
Notes	Risk of bias: high (inappropriate choice of placebo) Note: the authors conclude that virucidal tissues were up to 36.9% effective in preventing transmission of ARIs as measured by secondary attack rates (18.7% versus 11.8%). This finding was not statistically significant, but may well have been affected by the lack of do-nothing community controls. This a well-designed, well-written study despite the unexplained attrition of 5 families, the lack of reporting of cluster coefficients, and the differential in tissue use between the 2 arms, which raises questions about the robustness of double-blinding. Particularly notable is the discussion on the low generalisability of results from the study from the placebo arm given that even the inert barrier of the tissues is likely to have limited spread. Also, the lengths to which the authors went to obtain allocation concealment and maintenance of double-blind conditions

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	"Treated and placebo tissues were randomly assigned ..." Sequence generation not reported
Allocation concealment (selection bias)	Low risk	"Treated and placebo tissues were randomly assigned by the sponsor to 296 participating households stratified by household size, such that roughly half the households would receive treated tissues. Thus, the investigators were unaware of the assignment of treated tissues."
Blinding of participants and personnel (performance bias) All outcomes	Low risk	"Treated and placebo tissues were randomly assigned by the sponsor to the randomly assigned 296 households stratified by household size... The type of tissue was identified by code, and the boxes in which tissues were contained were not marked with any specific identifiers. Therefore, the study was double-blinded."
Blinding of outcome assessment (detection bias) All outcomes	Low risk	"The investigators were unaware of the assignment of the treated tissues"
Incomplete outcome data (attrition bias) All outcomes	Unclear risk	296 households eligible. "The final sample used for analysis consisted of 143 households in the treatment group and 148 households in the placebo group."
Selective reporting (reporting bias)	High risk	"The analysis of secondary spread was restricted to households of three to five members for technical reasons, which eliminated five households." "The two groups were almost identical in composition."

Luby 2005

Study characteristics	
Methods	Partly double-blind, cluster-RCT carried out during 15 April 2002 to 5 April 2003 in Karachi, Pakistan. The trial assessed the effects of mother and child hand-washing on the incidence of respiratory infections, impetigo (data not extracted), and diarrhoea (data not extracted). Randomisation took place by computer-generated random numbers in 3 phases. 1. 25 neighbourhoods were assigned to hand-washing and 11 to standard practice. 2. 300 households were assigned to using antiseptic soap. 3. 300 households were assigned to using plain soap. 4. 306 households were assigned to standard practice. 5. 1523 children younger than 15 years were assigned to using antiseptic soap. 6. 1640 children younger than 15 years were assigned to using plain soap. 7. 1528 children younger than 15 years were assigned to standard practice. Soaps were of identical weight, colour, and smell and were packed centrally with a coded packing case matched to households containing 96 bars. Neither fieldworkers nor participants were aware of the content. Control arm households were visited with the same frequency as intervention household but were given books and pens. Codes were held centrally by the manufacturer and broken after the end of the trial to allow analysis.
Participants	Householders of slums in Karachi. Of the 1523 children younger then 15 years assigned to using antiseptic soap, 117 dropped out (1 died, 51 were born in, and 65 aged out) = 1406; 504 were aged less than 5. Of 1640 children younger then 15 years assigned to using plain soap, 117 dropped out (3 died, 44 were born in, and 70 aged out) = 1523; 517 were aged less than 5. Of 1528 children younger then 15 years assigned to standard practice, 125 dropped out (3 died, 40 were born in, and 82 aged out) = 1403; 489 were aged less than 5.
Interventions	Instruction programme and antibacterial soap containing 1.2% triclocarban, or ordinary soap to be used throughout the day by householders, or standard procedure
Outcomes	Laboratory: N/A Effectiveness: 1. Number of new respiratory illness per person per week 2. Pneumonia (cough or difficulty in breathing with a respiratory rate of > 60 min in children less than 60 days old, > 50 min in those less than 1 year old, and > 40 min for those aged 1 to 5 years) Follow-up was weekly with household interview and direct observation. Children aged less than 5 were weighed, and the report presents stratification of results by child weight. Safety: N/A
Notes	Risk of bias: low (cluster coefficients and analysis by unit of randomisation provided) Note: the authors conclude that "handwashing" neighbourhoods has significantly fewer episodes of respiratory disease than controls (e.g. 50% less cough). "Handwashing" children aged less than 5 had 50% fewer episodes of pneumonia than controls (−65% to −35%). However, there was no difference in respiratory illness between types of soap. The report is confusing, with a shifting focus between children age groups. The impression reading is of an often rewritten manuscript. There is some loss of data (e.g. in the results by weight, i.e. risk group) because of lack of clarity on denominators. Despite this, the trial is a landmark.
Risk of bias	

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Luby 2005 *(Continued)*

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Randomisation took place by computer-generated random numbers in 3 phases.
Allocation concealment (selection bias)	Low risk	"One of the investigators (SL) who did not participate in recruiting neighbourhoods or households programmed a spreadsheet to randomly generate the integers of a 1 or a 2. He applied the random numbers sequentially to the list of neighbourhoods. Neighbourhoods with a 1 were assigned to control, and those with a 2 were assigned to handwashing promotion. Random assignment continued until neighbourhoods consisted of at least 600 handwashing promotion households and 300 control households were assigned."
Blinding of participants and personnel (performance bias) All outcomes	Low risk	"The antibacterial soap ... contained 1-2% triclocarban as an antibacterial substance. The plain soap was identical to the antibacterial soap except that it did not contain triclocarban... . Neither the fieldworkers nor the families knew whether soaps were antibacterial or plain."
Blinding of outcome assessment (detection bias) All outcomes	Low risk	"Neither the fieldworkers nor the families knew whether soaps were antibacterial or plain."
Incomplete outcome data (attrition bias) All outcomes	Unclear risk	89% of the study population followed up, but no data on the clusters.
Selective reporting (reporting bias)	Low risk	"At baseline, households in the three intervention groups were similar."

MacIntyre 2009

Study characteristics	
Methods	Prospective cluster-RCT carried out in Sydney, Australia, to assess the use of surgical masks, P2 masks, and no masks in preventing ILI in households. The study was carried out during the 2 winter seasons of 2006 and 2007 (August to the end of October 2006 and June to the end of October 2007). “Gaussian random effects were incorporated in the model to account for the natural clustering of persons in households"
Participants	290 adults from 145 families. 47 households (94 enrolled adults and 180 children) were randomised to the surgical mask group, 46 (92 enrolled adults and 172 children) to the P2 mask group, and 52 (104 enrolled adults and 192 children) to the no-mask (control) group.
Interventions	Use of surgical masks and P2 mask versus no mask. The P2 mask is described as very cumbersome.
Outcomes	Laboratory: serological evidence Effectiveness: ILI (described as fever, history of fever or feeling feverish in the past week, myalgia, arthralgia, sore throat, cough, sneezing, runny nose, nasal congestion, headache) However, a positive laboratory finding for influenza converts the ILI definition into one of influenza. Safety: N/A
Notes	The study authors conclude that adherence to mask use significantly reduced the risk for ILI-associated infection, but < 50% of participants wore masks most of the time. They concluded that household use of face masks is associated with low adherence and is ineffective for controlling seasonal respiratory disease. Compliance was by self-report, therefore likely to be an underestimate.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

MacIntyre 2009 *(Continued)*

The primary outcome was ILI or lab-positive illness. This showed no effect.
Sensitivity analysis by adherence showed that under the assumption that the incubation period is equal to 1 day (the most probable value for the 2 most common viruses isolated, influenza (21) and rhinovirus (26)), adherent use of P2 or surgical masks significantly reduces the risk for ILI infection, with a hazard ratio = 0.26 (95% CI 0.09 to 0.77; P = 0.015). No other covariate was significant. Under the less likely assumption that the incubation period is equal to 2 days, the quantified effect of complying with P2 or surgical mask use remains strong, although borderline significant; hazard ratio was 0.32 (95% CI 0.11 to 0.98; P = 0.046). The study was underpowered to determine if there was a difference in efficacy between P2 and surgical masks (Table 5). The study conclusion appears to be a post hoc data exploration. Regardless of this, the study message is that respirator use in a family setting is unlikely to be effective as compliance is difficult unless there is a situation of real impending risk.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	"Participating households were randomised to 1 of 3 arms by a secure computerised randomisation process", but sequence generation not described.
Allocation concealment (selection bias)	Unclear risk	Not reported
Blinding of participants and personnel (performance bias) All outcomes	High risk	"Study participants and trial staff were not blinded, as it is not technically possible to blind the mask type to which participants were randomised."
Blinding of outcome assessment (detection bias) All outcomes	Low risk	"However, laboratory staff were blinded to the arm of randomisation."
Incomplete outcome data (attrition bias) All outcomes	Low risk	143 of 145 randomised families were analysed; 2 families in the control group were lost to follow-up during the study, for which no reasons were given.
Selective reporting (reporting bias)	Low risk	No differences between groups at baseline

MacIntyre 2011

Study characteristics

Methods	A cluster-RCT of 1441 HCWs in 15 Beijing hospitals was performed during the 2008 to 2009 winter. Participants wore masks or respirators during the entire work shift for 4 weeks. Outcomes included CRI, ILI, laboratory-confirmed respiratory virus infection, and influenza. A convenience no-mask/respirator group of 481 health workers from 9 hospitals was compared.
Participants	Participants (N = 1441) were hospital HCWs aged > 18 years from the emergency departments and respiratory wards of 15 hospitals. These wards were selected as high-risk settings in which repeated and multiple exposures to respiratory infections are expected. Participants were randomised to medical mask (N = 492 staff from 5 hospitals), N95 fit-tested masks (N = 461 staff from 5 hospitals), and N95 non-fit-tested mask (N = 488 staff from 5 hospitals).
Interventions	Fit-tested N95 respirators versus non-fit-tested N95 respirators versus medical masks. See Table 1 for details.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

MacIntyre 2011 *(Continued)*

Outcomes	Clinical respiratory illness, defined as 2 or more respiratory symptoms or 1 respiratory symptom and a systemic symptom Influenza-like illness, defined as fever ≥ 38 °C plus 1 respiratory symptom (i.e. cough, runny nose, etc.) Laboratory-confirmed viral respiratory infection (detection of adenoviruses, human metapneumovirus, coronavirus 229E/NL63, parainfluenza viruses 1, 2, and 3, influenza viruses A and B, respiratory syncytial virus A and B, rhinovirus A or B, and coronavirus OC43/HKU1 by multiplex PCR) Laboratory-confirmed influenza A or B Adherence with mask or respirator use. Reported problems associated with using the masks or respirators
Notes	Funding source unknown; control arm not randomised so has been ignored

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Randomisation process (using a secure computerised randomisation program), but sequence generation not described
Allocation concealment (selection bias)	Low risk	Hospitals randomised prior to inclusion of participants.
Blinding of participants and personnel (performance bias) All outcomes	High risk	Unblinded study
Blinding of outcome assessment (detection bias) All outcomes	High risk	Unblinded study
Incomplete outcome data (attrition bias) All outcomes	Low risk	No loss to follow-up
Selective reporting (reporting bias)	Low risk	Specified outcomes reported.

MacIntyre 2013

Study characteristics

Methods	A cluster-RCT
Participants	A total of 1669 nurses and doctors from 68 emergency departments and respiratory wards of 19 Beijing hospitals were included. Inclusion criteria: any nurse or doctor aged 18 years or older who worked full time in the emergency or respiratory wards was eligible. Exclusion: HCWs if they (1) were unable or refused to consent; (2) had beards, long moustaches, or long facial hair stubble; (3) had a current respiratory illness, rhinitis, and/or allergy; or (4) worked part time or did not work in the aforementioned wards or departments Final analysis was performed on 572 staff and 24 wards in medical mask group, 516 staff and 20 wards in the targeted N95 mask group, and 581 staff and 24 wards in the N95 mask group.

MacIntyre 2013 *(Continued)*

Interventions	Quote: "Masks used in the study were the 3M Standard Tie-On Surgical Mask (catalog number mask 1817; 3M, St. Paul, MN) and the 3M Health Care N95 Particulate Respirator (catalog number 1860; 3M)... . Participants wore the mask or respirator on every shift after being shown how to fit and wear it. Participants were supplied daily with either three masks for the medical mask arm or two N95 respirators. Participants using N95 respirators underwent a fit testing procedure using a 3M FT-30 Bitrex Fit Test Kit according to the manufacturer's instructions (3M)." See Table 1 for details.
Outcomes	Laboratory: 1. Laboratory-confirmed viral respiratory infection in symptomatic participants, defined as detection of adenoviruses; human metapneumovirus; coronaviruses 229E/NL63 and OC43/HKU1; parainfluenza viruses 1, 2, and 3; influenza viruses A and B; respiratory syncytial viruses A and B; or rhinoviruses A/B by nucleic acid testing (NAT) using a commercial multiplex polymerase chain reaction (Seegen, Inc., Seoul, Korea). 2. Laboratory-confirmed influenza A or B in symptomatic participants. 3. Laboratory-confirmed bacterial colonisation in symptomatic participants, defined as detection of *Streptococcus pneumoniae*, *Legionella*, *Bordetella pertussis*, chlamydia, *Mycoplasma pneumoniae*, or *Haemophilus influenzae* type B by multiplex polymerase chain reaction (Seegen, Inc.). Effectiveness: CRI, defined as 2 or more respiratory symptoms or 1 respiratory symptom and a systemic symptom. ILI, defined as fever (38 °C) plus 1 respiratory symptom Safety: adverse effects measured using a semi-structured questionnaire. Investigators stated that there was higher reported adverse effects and discomfort of N95 respirators compared with the other 2 arms. In terms of comfort, 52% (297 of 571) of the medical mask arm reported no problems, compared with 62% (317 of 512) of the targeted arm and 38% (217 of 574) of the N95 arm (P < 0.001).
Notes	Compliance with the product was highest in the targeted N95 arm (82%; 422 of 516), then the medical mask arm (66%; 380 of 572), and the N95 arm (57%; 333 of 581); these differences were statistically significant (P < 0.001). The period study conducted: 28 December 2009 to 7 February 2010 Funding: unclear

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	"using a secure computerized randomization program", but sequence generation not described
Allocation concealment (selection bias)	Unclear risk	No information provided.
Blinding of participants and personnel (performance bias) All outcomes	Low risk	Outcome was objectively assessed with lab confirmation in addition to clinical illness.
Blinding of outcome assessment (detection bias) All outcomes	Low risk	"Laboratory outcomes are reported for all subjects (with at least one respiratory symptom or fever) tested, and then for the subset meeting the CRI definition"
Incomplete outcome data (attrition bias) All outcomes	Low risk	No loss to follow-up. Flow chart and text match, investigators conducted ITT and PP analysis. All the outcomes were accounted for amongst all participants.

Study characteristics	
Methods	A cluster-RCT of cloth masks compared with medical masks in healthcare workers in 14 secondary-/tertiary-level hospitals in Hanoi, Vietnam. Hospital wards were randomised to: medical masks, cloth masks, or a control group (usual practice, which included mask wearing). Participants used the mask on every shift for 4 consecutive weeks.
Participants	1607 hospital HCWs aged ≥ 18 years working full time in selected high-risk wards. Medical mask group (n = 580 HCWs), cloth mask group (n = 569 HCWs), control group (n = 458 HCWs)
Interventions	Medical masks, cloth masks, or a control group. See Table 1 for details.
Outcomes	Clinical respiratory illness, influenza-like illness, and laboratory-confirmed respiratory virus infection 1. Clinical respiratory illness, defined as 2 or more respiratory symptoms or 1 respiratory symptom and a systemic symptom 2. Influenza-like illness, defined as fever ≥ 38 °C plus 1 respiratory symptom 3. Laboratory-confirmed viral respiratory infection. Laboratory confirmation was by nucleic acid detection using multiplex reverse transcriptase PCR (RT-PCR) for 17 respiratory viruses. Adverse events associated with mask use
Notes	Government funded

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**

Methods	Cluster-RCT to examine medical mask use as source control for people with respiratory illness in 6 major hospitals in 2 districts of Beijing, China. Index cases with ILI were randomly allocated to medical mask (n = 123) and control arms (n = 122). Since 43 index cases in the control arm also used a mask during the study period, an as-treated post hoc analysis was performed by comparing outcomes amongst household members of index cases who used a mask (mask group) with household members of index cases who did not use a mask (no mask group).
Participants	245 index cases with ILI (medical mask = 123, control group = 122) and 597 household contacts (medical mask = 302, control group = 295)
Interventions	Medical mask versus no mask (control). See Table 1 for details.
Outcomes	Clinical respiratory illness, ILI, and laboratory-confirmed viral respiratory infection 1. Clinical respiratory illness, defined as 2 or more respiratory symptoms (cough, nasal congestion, runny nose, sore throat, or sneezes) or 1 respiratory symptom and a systemic symptom (chill, lethargy, loss of appetite, abdominal pain, muscle or joint aches). 2. ILI, defined as fever ≥ 38 °C plus 1 respiratory symptom. 3. Laboratory-confirmed viral respiratory infection, defined as detection of adenoviruses, human metapneumovirus, coronaviruses 229E/NL63 and OC43/HKU1, parainfluenza viruses 1, 2, and 3, influenza viruses A and B, respiratory syncytial virus A and B, or rhinovirus A/B by nucleic acid testing using a commercial multiplex PCR. No safety outcomes reported.

McConeghy 2017 *(Continued)*

Methods	Pilot study of comprehensive intervention (education, cleaning of surfaces, audit and feedback) to staff of nursing homes versus usual care. Pair-matched cluster-randomised design with only 5 clusters (nursing homes) in each group
Participants	10 nursing homes in Colorado, USA Intervention group = 481 long-stay residents and control group = 380 'Long-stay' defined as resident at least 90 days prior to baseline, or recently readmitted after previous long stay.
Interventions	A multifaceted hand-washing/surface-cleaning intervention comprised of 1) 1-hour online educational module focused on how to prevent infections; 2) provided with an "essential bundle" of 7 products, ranging from hand sanitiser gel and foam to antiviral facial tissues, disinfecting spray, and hand and face wipe and recommendation to use 4 skin cream and wipe products; 3) audit and feedback system. See Table 1 for details.
Outcomes	Laboratory: surface cultures mentioned in Methods, but no results given Effectiveness: LRTI, all infections, hospitalisation, use of antibiotics (not relevant to this review) Safety: none mentioned in Methods and no results given
Notes	The authors conclude that "This multifaceted hand-washing and surface cleaning intervention was designed to reduce infection rates among nursing homes residents. In our 10-facility randomized, matched pair pilot study, we observed program compliance and satisfaction along with reductions in surface bacterial counts, but did not observe a statistically significant reduction in infection rates, antimicrobial use, or hospitalizations". Very poorly reported study with results not explained, summarised in Table 3 as RDs. Denominators and attrition are unclear.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Method not described
Allocation concealment (selection bias)	Unclear risk	Method not described

Millar 2016

Study characteristics	
Methods	Cluster-RCT, open-label study, factorial design
Participants	Around 30,000 healthy, male army trainees aged 18 to 42 years at Fort Benning, Georgia were included. Inclusion criteria: trainees assigned to 1 of the 6 selected training battalions, trainees who present with an SSTI at the clinic or the hospital, provide informed consent. Exclusion criteria: fails to meet inclusion criteria. No denominator breakdown by arm is reported.
Interventions	Promotion of hand-washing in addition to a once-weekly application of chlorhexidine-based body wash. See Table 1 for details.
Outcomes	This study was nested in a large field-based RCT and utilised clinic-based medical records. Laboratory: none Effectiveness: incidence of ARI at 20 months. The case definition was any occurrence of the following ICD-9 symptom or disease-specific codes: 460 to 466, 480 to 488, and specifically 465.9, 482.9, 486, and 487.1. Safety: adverse effects neither planned nor reported by the investigators
Notes	The period study conducted: May 2010 to January 2012 Funding: government

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	Low risk	"computer-generated random numbers to 1 of the 3 study groups"
Allocation concealment (selection bias)	Unclear risk	No information provided.
Blinding of participants and personnel (performance bias) All outcomes	High risk	The study was open-label and self-reporting of ARI. It is planned as secondary objective of an original trial. Data abstractors were blinded to group assignment.
Blinding of outcome assessment (detection bias) All outcomes	Low risk	Data abstractors were blinded to group assignment.
Incomplete outcome data (attrition bias) All outcomes	High risk	There is a statistically significant difference between attrition rates in the 3 groups. The reasons for attrition are briefly reported in Table 1 of the original study (Ellis and colleagues 2014), but are unlikely to be related to the outcomes of this study. ARI cases were captured utilising clinic-based medical records, but this outcome is not prespecified in the protocol.

Miyaki 2011

Study characteristics	
Methods	A quasi-cluster-RCT
Participants	A total of 15,134 assigned to intervention (N = 6634 workers) and control (N = 8500 workers) Inclusion criteria: all general employees (aged 19 to 72 years in 2009) of 2 sibling companies of a major car industry in Kanagawa Prefecture, Japan. All workers who regularly reported to the workplace were included, regardless of treatment for chronic diseases. All employees have the same health insurance plan and were followed up in the same way.
Interventions	"The intervention involved asking workers whose family members developed an influenza-like illness (ILI) to stay at home. If any co-habiting family members showed signs of influenza-like illness (ILI), employees ... were asked to stay at home voluntarily until 5 days has passed since the resolution of the ILS symptoms or 2 days after alleviation of fever." See Table 1 for details.
Outcomes	Workroom: influenza A test kit (rapid test) Effectiveness: assess the effectiveness of household quarantine in reducing the incidence of influenza A H1N1. ILI was defined as a body temperature greater than 38 °C or more than 1 °C above the normal temperature accompanied with more than 2 of these symptoms: nasal mucus, pharyngeal pain, cough, chills or heat sensation Safety: the incidence of influenza A H1N1 amongst workers who were told to stay home if a family member developed ILI was higher (relative risk of 2.17; P < 0.001) compared to control group. No other safety measures/harms reported. Compliance: quote: "our intervention was not compulsory; we only asked the employees to leave the workplace for a while on full pay, and we succeeded in getting all workers' agreement. In our case, explaining that the home waiting policy might be beneficial to the whole workers and help to avoid stopping the manufacturing lines (explaining it is for the benefit of the public) and guaranteeing payment during the leave (financial support) helped them to obey our request."
Notes	Period study conducted: 1 July 2009 to 19 February 2010 Unfunded

Risk of bias		
Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	Unclear risk	No information given.

Morton 2004

Study characteristics

Methods	Cross-over study to evaluate the effectiveness of an alcohol gel as an adjunct to regular hand-washing for decreasing absenteeism amongst elementary children by reducing specific communicable diseases such cold, flu, and conjunctivitis. The study was conducted in an elementary school in New England, USA. In the cross-over design, classrooms in each grade level were randomised to begin as the experimental group (alcohol gel) or the control group (regular hand-washing). A study protocol for hand hygiene was introduced following the germ unit education. The hand-washing product was a soap-and-water alternative that is approximately 60% ethyl alcohol. In phase 1 (46 days) children in 9 classrooms were in the experimental group, and children in 8 classrooms were in the control group. After a 1-week washout period when no children had access to the alcohol gel, phase 2 (47 days) started, and the classroom that had participated before as experimental group passed into the control group and vice versa. Data were collected by the parents, who informed the secretary or the school nurse of the reasons for a child's absence, including symptoms of any illness. Respiratory illnesses were defined by symptoms of URTI.
Participants	253 children, 120 girls and 133 boys, from kindergarten to 3rd grade. Of the eligible 285 students, 32 children dropped out (10 due to skin irritation and 22 because of lack of parental consent). No denominator breakdown by arm is reported because the study used a cross-over design.
Interventions	Use of an alcohol gel as an adjunct to regular hand-washing and educational programme versus regular hand-washing and educational programme
Outcomes	Laboratory: no

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Morton 2004 *(Continued)*

	Effectiveness: days of absences from school for respiratory illness Safety: N/A
Notes	Risk of bias: high (no description of randomisation; partial reporting of outcomes, numerators and denominators) Note: the authors conclude that significantly fewer children became ill whilst using the alcohol gel as an adjunct to regular hand-washing than when using regular hand-washing only (decreased school absenteeism of 43% with the use of alcohol gel on top of hand-washing). The authors also described, as a limitation of the study, the fact that the school nurse served as the data collector, which could be perceived as bias in measurement of the outcome variable. Randomisation and allocation are not described; no cluster coefficients were reported; and attrition was not taken into consideration during the analysis. Unit of randomisation and analysis are different. No reporting by arm. No ORs, no CIs reported.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Insufficient information
Allocation concealment (selection bias)	Unclear risk	Insufficient information
Blinding of participants and personnel (performance bias) All outcomes	Unclear risk	"A cross-over design was used. In the crossover design, classrooms in each grade level were randomized to begin as the experimental group (regular hand washing)."
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	"The school nurse served as the data collector for the duration of the study. This could be perceived as bias in the measurement of the outcome variable, absenteeism related to infectious illness."
Incomplete outcome data (attrition bias) All outcomes	Unclear risk	Insufficient information
Selective reporting (reporting bias)	Unclear risk	Insufficient information

Najnin 2019

Study characteristics

Methods	Cluster-RCT, parallel assignment
Participants	Residents of the high-risk, cholera-prone study areas. Low-income communities in Mirpur area of urban Dhaka defined by low per capita income, poor sanitation, unsafe water use, sharing of water source, and poor living conditions. 90 geographic clusters were included, with 30-metre buffer zones. A total of 7842 households, with 52,237 individuals analysed Vaccine-only area: data were analysed for 1965 households consisting of 13,148 individuals Vaccine-plus-behaviour-change area: data were analysed for 3886 households consisting of 25,566 individuals Control area: data were analysed for 1991 households consisting of 13,523 individuals

Najnin 2019 *(Continued)*

	Study criteria from published protocol: Inclusion criteria: apparently healthy residents of selected vaccination sites, aged 1 year and above, non-pregnant women, written informed consent Exclusion criteria: age less than 1 year and pregnant women
Interventions	Hand-washing and water treatment promotion. See Table 1 for details.
Outcomes	Laboratory: none used Effectiveness: prevalence of respiratory illness. People were classified as having respiratory illness if they reported having fever plus either cough or nasal congestion or fever plus breathing difficulty in the past 2 days of unannounced home visits: in each intervention group and amongst those who had soap/soapy water with water present in the hand-washing station (35% of all groups combined) versus those without this (regardless of the intervention group). Planned secondary outcome: prevalence of reported respiratory illness during 2-year intervention period Safety: no adverse effects planned or reported
Notes	The period study conducted: 2011 to 2013 Funding: government and private Bill & Melinda Gates Foundation

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Computer-generated randomisation sequence was used to allocate 90 geographical clusters to 1 of 3 groups. Before randomisation, clusters were stratified blocked into 2 categories according to the distance to the hospital. (parent article: Lancet. 2015 Oct 3;386(10001):1362-1371)
Allocation concealment (selection bias)	Unclear risk	No information provided.
Blinding of participants and personnel (performance bias) All outcomes	High risk	All trial participants and investigators were aware of group assignment. Several in and out migrations across all groups before, after, and during outcome monitoring, and large number of changes in intervention areas
Blinding of outcome assessment (detection bias) All outcomes	High risk	Several in and out migrations across all groups before, after, and during outcome monitoring, and large number of changes in intervention areas
Incomplete outcome data (attrition bias) All outcomes	High risk	High migration movement. This could have distorted the baseline characteristics even more. Very hard to assess because the numbers in the index paper are different from the parent paper (Qadri 2015). In addition to that, for each intervention, data were analysed for 15% to 30% of those allocated on start date. Each group started with approximately 80,000 people; the number analysed is much lower (237,216 people were in the study area on start date of outcome monitoring, the total number analysed across all groups was 52,237). No info about data on migrated individuals or on those who changed intervention areas was dealt with? Also data for prevalence of ARI adjusted for age and wealth were not shown. The outcome is addressed in the 2 days preceding an unannounced visit. This means that if there was a respiratory illness in the past week it would not have been reported. Moreover, these monthly unannounced visits were done to a different set of participants in each group!

Selective reporting (reporting bias)	High risk	Published protocol does not include respiratory illness as an outcome.

Morton 2004

Study characteristics

Methods	Cross-over study to evaluate the effectiveness of an alcohol gel as an adjunct to regular hand-washing for decreasing absenteeism amongst elementary children by reducing specific communicable diseases such cold, flu, and conjunctivitis. The study was conducted in an elementary school in New England, USA. In the cross-over design, classrooms in each grade level were randomised to begin as the experimental group (alcohol gel) or the control group (regular hand-washing). A study protocol for hand hygiene was introduced following the germ unit education. The hand-washing product was a soap-and-water alternative that is approximately 60% ethyl alcohol. In phase 1 (46 days) children in 9 classrooms were in the experimental group, and children in 8 classrooms were in the control group. After a 1-week washout period when no children had access to the alcohol gel, phase 2 (47 days) started, and the classroom that had participated before as experimental group passed into the control group and vice versa. Data were collected by the parents, who informed the secretary or the school nurse of the reasons for a child's absence, including symptoms of any illness. Respiratory illnesses were defined by symptoms of URTI.
Participants	253 children, 120 girls and 133 boys, from kindergarten to 3rd grade. Of the eligible 285 students, 32 children dropped out (10 due to skin irritation and 22 because of lack of parental consent). No denominator breakdown by arm is reported because the study used a cross-over design.
Interventions	Use of an alcohol gel as an adjunct to regular hand-washing and educational programme versus regular hand-washing and educational programme
Outcomes	Laboratory: no Effectiveness: days of absences from school for respiratory illness Safety: N/A
Notes	Risk of bias: high (no description of randomisation; partial reporting of outcomes, numerators and denominators) Note: the authors conclude that significantly fewer children became ill whilst using the alcohol gel as an adjunct to regular hand-washing than when using regular hand-washing only (decreased school absenteeism of 43% with the use of alcohol gel on top of hand-washing). The authors also described, as a limitation of the study, the fact that the school nurse served as the data collector, which could be perceived as bias in measurement of the outcome variable. Randomisation and allocation are not described; no cluster coefficients were reported; and attrition was not taken into consideration during the analysis. Unit of randomisation and analysis are different. No reporting by arm. No ORs, no CIs reported.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Insufficient information
Allocation concealment (selection bias)	Unclear risk	Insufficient information
Blinding of participants and personnel (performance bias)	Unclear risk	"A cross-over design was used. In the crossover design, classrooms in each grade level were randomized to begin as the experimental group (regular hand washing)."

Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	"The school nurse served as the data collector for the duration of the study. This could be perceived as bias in the measurement of the outcome variable, absenteeism related to infectious illness."
Incomplete outcome data (attrition bias) All outcomes	Unclear risk	Insufficient information
Selective reporting (reporting bias)	Unclear risk	Insufficient information

Najnin 2019

Study characteristics	
Methods	Cluster-RCT, parallel assignment
Participants	Residents of the high-risk, cholera-prone study areas. Low-income communities in Mirpur area of urban Dhaka defined by low per capita income, poor sanitation, unsafe water use, sharing of water source, and poor living conditions. 90 geographic clusters were included, with 30-metre buffer zones. A total of 7842 households, with 52,237 individuals analysed Vaccine-only area: data were analysed for 1965 households consisting of 13,148 individuals Vaccine-plus-behaviour-change area: data were analysed for 3886 households consisting of 25,566 individuals Control area: data were analysed for 1991 households consisting of 13,523 individuals Study criteria from published protocol: Inclusion criteria: apparently healthy residents of selected vaccination sites, aged 1 year and above, non-pregnant women, written informed consent Exclusion criteria: age less than 1 year and pregnant women
Interventions	Hand-washing and water treatment promotion. See Table 1 for details.
Outcomes	Laboratory: none used Effectiveness: prevalence of respiratory illness. People were classified as having respiratory illness if they reported having fever plus either cough or nasal congestion or fever plus breathing difficulty in the past 2 days of unannounced home visits: in each intervention group and amongst those who had soap/soapy water with water present in the hand-washing station (35% of all groups combined) versus those without this (regardless of the intervention group). Nicholson 2014

Study characteristics	
Methods	Cluster-RCT
Participants	70 low-income communities in Mumbai, India (35 communities per arm) were randomised to intervention arm (N = 1025) and control arm (N = 1026). Households located in low-income urban communities in west and south Mumbai, India. Each household contains 1 target child in the first year of a municipal school (typically aged 5 years).
Interventions	Combination of hand-washing promotion with provision of free soap aimed at 5-year-olds with provision of free soap. See Table 1 for details.
Outcomes	Laboratory: none reported Effectiveness: Primary outcomes: episodes of diarrhoea, ARIs, and school absences amongst target children, and episodes of diarrhoea and ARIs among their families

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Nicholson 2014 *(Continued)*

	Secondary outcomes: episodes of eye infections, vomiting, abscesses or boils, headaches, and earache Operational definitions for all the illnesses were taken from *Black's Medical Dictionary* (MacPherson 1999). ARIs as "pneumonia, cough, fever, chest pain and shortness of breath, cold, inflammation of any or all of the airways, that is, nose, sinuses, throat, larynx, trachea and bronchi" Safety: no safety measures planned or reported by the investigators
Notes	The period study conducted: 22 October 2007 to 2 August 2008 Funding: multinational corporate company (Unilever plc.)

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	High risk	Coin tossing used, which could have led to a large imbalance.
Allocation concealment (selection bias)	Low risk	"a coin toss was used to assign one community in each pair to intervention and one to control"
Blinding of participants and personnel (performance bias) All outcomes	High risk	Participants knew to which arm they had been recruited. Households were removed from the study if they provided no data for 5 consecutive weeks.
Blinding of outcome assessment (detection bias) All outcomes	High risk	Data collectors were independent of the behaviour change intervention. Each was assigned exclusively to either households in the intervention group or to control households. However, communities, where very low literacy levels exist, were replaced after randomisation.
Incomplete outcome data (attrition bias) All outcomes	High risk	Data for non-completers were available and similar across groups. ITT and PP were performed. However, households were removed from the study if they provided no data for 5 consecutive weeks.
Selective reporting (reporting bias)	Unclear risk	No information to judge

Pandejpong 2012

Study characteristics

Methods	Cluster-RCT, single study centre
Participants	Children (total number = 1437) were randomised to alcohol hand gel every 60 minutes (N = 452 children), every 120 minutes (N = 447 children), and once before lunch (N = 540 children). Inclusion criteria: all children in a large private school in suburban Bangkok, Thailand, all ages, both genders with parental consent to participate. Exclusion criteria: an allergy to alcohol hand gel
Interventions	3 disinfection interventions: Alcohol hand gel applied every 60 minutes vs every 120 minutes vs once before lunch (3 groups). The current school standard for hand hygiene (q lunch group). See Table 1 for details.
Outcomes	Laboratory: none

Priest 2014 *(Continued)*

Participants	Study included children aged 5 to 11 years at 68 primary schools in New Zealand. Schools were randomised to hand sanitiser + education session arm (34 schools and 8859 children) and education session arm (34 schools and 7386 children). Inclusion criteria: School-level inclusion: at least 100 children of primary school age (school years 1 to 6; children will generally range in age from 5 years to 11 years) at November 2008. Schools that are not currently using hand sanitiser products or are willing to not use them for the period of the trial. Schools are within the City boundaries of Christchurch, Dunedin, or Invercargill in New Zealand. The principal of the school consents to the school being included in the trial. Not ''special schools'' (e.g. schools for children with deafness or disability) and either not currently using hand sanitiser products or willing to not use them for the period of the trial if they were randomised to the control group were eligible to participate in the trial. Student-level inclusion (follow-up children): children were eligible to participate in the follow-up group, for whom more detailed information on absences was collected, if they attended a school year 1 to 6 class in 1 of the included schools at the beginning of the second school term in 2009 (the end of April), and their caregivers completed the consent form indicating that they were willing to be telephoned following their child's absences and that they were able to take part in telephone interviews in English Exclusion criteria: School-level exclusion: special needs schools Student-level exclusion (follow-up children): children of the principal investigators and study personnel of the trial. Or, children of families that the principal of the primary school directs us not to approach
Interventions	Hand sanitiser provision (in addition to hand hygiene education session also provided to control group) in schoolchildren. See Table 1 for details.
Outcomes	Laboratory: none Effectiveness: Primary outcome: the incidence rate of absence episodes from school (reported by the parents during telephone calls) due to any illness during the study period (winter term) Secondary outcomes: assessing whether hand sanitiser was effective in reducing the: 1. incidence rate of respiratory illness absence episodes, 2. incidence rate of gastrointestinal illness absence episodes, 3. incidence rate of absence for any reason, 4. length of illness episode, 5. length of illness absence episode, and 6. incidence rate of subsequent illness amongst other children or adults in the household. Definition of respiratory illness: at least 2 of the following caregiver-reported symptoms for 1 day, or 1 of the following symptoms for 2 days (but not fever alone): runny nose, stuffy or blocked nose or noisy breathing, cough, fever, sore throat, or sneezing Safety: examined whether the use of hand sanitiser was associated with an increased risk of any skin reactions during the intervention period. Skin reactions: dryness, redness, flakiness, itchiness, eczema, and any other skin reactions
Notes	The period study conducted: 27 April to 25 September 2009 Funding: government (Health Research Council of New Zealand)

Radonovich 2019

Study characteristics	
Methods	Cluster-RCT, multicentre, pragmatic effectiveness trial
Participants	Study included 280 clusters randomly assigned to N95 respirators (189 clusters and 1993 HCPs) and medical masks (191 clusters and 2058 HCPs). All participants in a cluster worked in the same outpatient clinic or outpatient setting. All participants were permitted to participate for 1 or more years and gave written consent for each year of participation. Inclusion criteria: healthcare workers in outpatient settings serving adult and paediatric patients with a high prevalence of acute respiratory illness. Participants were aged at least 18 years and employed at 1 of the 7 participating health systems, and self-identified as routinely positioned within 6 feet (1.83 m) of patients. Participants were full-time employees (defined as direct patient care for approximately ≥ 24 hours weekly) and worked primarily at the study site (defined as ≥ 75% of working hours). Exclusion criteria: medical conditions precluding safe participation or anatomic features that could interfere with respirator fit, such as facial hair or third-trimester pregnancy. Participants self-identified race and sex using fixed categories; these variables were collected because facial anthropometrics related to race and sex may influence N95 respirator fit.
Interventions	Fit-tested N95 respirators versus medical masks when near patients with respiratory illness. See Table 1 for details.
Outcomes	Laboratory. Primary outcome: the incidence of laboratory-confirmed influenza, defined as: 1. detection of influenza A or B virus by RT-PCR in an upper respiratory specimen collected within 7 days of symptom onset; 2. detection of influenza from a randomly obtained swab from an asymptomatic participant; and 3. influenza seroconversion (symptomatic or asymptomatic), defined as at least a 4-fold rise in haemagglutination inhibition antibody titres to influenza A or B virus between pre-season and postseason serological samples deemed not attributable to vaccination. Effectiveness. Secondary outcomes: the incidence of 4 measures of viral respiratory illness or infection as follows: 1. acute respiratory illness with or without laboratory confirmation; 2. laboratory-detected respiratory infection, defined as detection of a respiratory pathogen by PCR or serological evidence of infection with a respiratory pathogen during the study surveillance period(s), which was added to the protocol prior to data analysis; 3. laboratory-confirmed respiratory illness, identified as previously described (defined as self-reported acute respiratory illness plus the presence of at least PCR–confirmed viral pathogen in a specimen collected from the upper respiratory tract within 7 days of the reported symptoms and/or at least a 4-fold rise from pre-intervention to postintervention serum antibody titres to influenza A or B virus; and 4. influenza-like illness, defined as temperature of at least 100 °F (37.8 °C) plus cough and/or a sore throat, with or without laboratory confirmation.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Radonovich 2019 *(Continued)*

	Safety: no serious study-related adverse events were reported. 19 participants reported skin irritation or worsening acne during years 3 and 4 at 1 site in the N95 respirator group.
Notes	The study was conducted from September 2011 to May 2015, with final follow-up on 28 June 2016. Funding: government Compliance: adherence was reported on daily surveys 22,330 times in the N95 respirator group and 23,315 times in the medical mask group. “Always” was reported 14,566 (65.2%) times in the N95 respirator group and 15,186 (65.1%) times in the medical mask group; “sometimes” 5407 (24.2%) times in the N95 respirator group and 5853 (25.1%) times in the medical mask group; “never” 2272 (10.2%) times in the N95 respirator group and 2207 (9.5%) times in the medical mask group; and “did not recall” 85 (0.4%) times in the N95 respirator group and 69 (0.3%) times in the medical mask group. Participant-reported adherence could not be assessed in 784 participants (31.2%) in the N95 respirator group and 822 (30.8%) in the medical mask group (P = 0.84) because of lack of response to surveys or lack of adherence opportunities (i.e. participants did not encounter an individual with respiratory signs or symptoms). Analysed post hoc, participant adherence was reported as always or sometimes 89.4% of the time in the N95 respirator group and 90.2% of the time in the medical mask group.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Computer-generated random sequences by an individual not involved in the study implementation and data analyses. Used stratified randomisation
Allocation concealment (selection bias)	Low risk	Used constrained randomisation
Blinding of participants and personnel (performance bias) All outcomes	Low risk	The participants cannot be blinded, but it seems that all the measures otherwise were the same with meticulous follow-up. Besides, the primary outcome was lab based (an objective outcome), which is unlikely to be affected by of lack of blinding. Investigators were blinded to the randomisation until completion of the study and analysis.
Blinding of outcome assessment (detection bias) All outcomes	Low risk	Primary outcome is laboratory-confirmed diagnosis.
Incomplete outcome data (attrition bias) All outcomes	Low risk	"Missing outcomes were imputed using standard multiple imputation techniques, creating multiple imputed data sets with no missing values for each analysis"
Selective reporting (reporting bias)	Low risk	Reported study outcomes matched the published protocol. Every outcome was accounted for.

Primary outcome: the incidence of laboratory-confirmed influenza, defined as: 1. detection of influenza A or B virus by RT-PCR in an upper respiratory specimen collected within 7 days of symptom onset; 2. detection of influenza from a randomly obtained swab from an asymptomatic participant; and 3. influenza seroconversion (symptomatic or asymptomatic), defined as at least a 4-fold rise in haemagglutination inhibition antibody titres to influenza A or B virus between pre-season and postseason serological samples deemed not attributable to vaccination. Effectiveness. Secondary outcomes: the incidence of 4 measures of viral respiratory illness or infection as follows: 1. acute respiratory illness with or without laboratory confirmation; 2. laboratory-detected respiratory infection, defined as detection of a respiratory pathogen by PCR or serological evidence of infection with a respiratory pathogen during the study surveillance period(s), which was added to the protocol prior to data analysis; 3. laboratory-confirmed respiratory illness, identified as previously described (defined as self-reported acute respiratory illness plus the presence of at least PCR–confirmed viral pathogen in a specimen collected from the upper respiratory tract within 7 days of the reported symptoms and/or at least a 4-fold rise from pre-intervention to postintervention serum antibody titres to influenza A or B virus; and 4. influenza-like illness, defined as temperature of at least 100 °F (37.8 °C) plus cough and/or a sore throat, with or without laboratory confirmation. Safety: no serious study-related adverse events were reported. 19 participants reported skin irritation or worsening acne during years 3 and 4 at 1 site in the N95 respirator group.
Notes	The study was conducted from September 2011 to May 2015, with final follow-up on 28 June 2016. Funding: government Compliance: adherence was reported on daily surveys 22,330 times in the N95 respirator group and 23,315 times in the medical mask group. “Always” was reported 14,566 (65.2%) times in the N95 respirator group and 15,186 (65.1%) times in the medical mask group; “sometimes” 5407 (24.2%) times in the N95 respirator group and 5853 (25.1%) times in the medical mask group; “never” 2272 (10.2%) times in the N95 respirator group and 2207 (9.5%) times in the medical mask group; and “did not recall” 85 (0.4%) times in the N95 respirator group and 69 (0.3%) times in the medical mask group. Participant-reported adherence could not be assessed in 784 participants (31.2%) in the N95 respirator group and 822 (30.8%) in the medical mask group (P = 0.84) because of lack of response to surveys or lack of adherence opportunities (i.e. participants did not encounter an individual with respiratory signs or symptoms). Analysed post hoc, participant adherence was reported as always or sometimes 89.4% of the time in the N95 respirator group and 90.2% of the time in the medical mask group.
Risk of bias

Radonovich 2019 *(Continued)*

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Computer-generated random sequences by an individual not involved in the study implementation and data analyses. Used stratified randomisation
Allocation concealment (selection bias)	Low risk	Used constrained randomisation
Blinding of participants and personnel (performance bias) All outcomes	Low risk	The participants cannot be blinded, but it seems that all the measures otherwise were the same with meticulous follow-up. Besides, the primary outcome was lab based (an objective outcome), which is unlikely to be affected by of lack of blinding. Investigators were blinded to the randomisation until completion of the study and analysis.
Blinding of outcome assessment (detection bias) All outcomes	Low risk	Primary outcome is laboratory-confirmed diagnosis.
Incomplete outcome data (attrition bias) All outcomes	Low risk	"Missing outcomes were imputed using standard multiple imputation techniques, creating multiple imputed data sets with no missing values for each analysis"
Selective reporting (reporting bias)	Low risk	Reported study outcomes matched the published protocol. Every outcome was accounted for.

Ram 2015

Study characteristics	
Methods	RCT
Participants	377 household compounds (index cases) completed the study. Control arm has 184 compounds with 1607 contacts, and intervention group has 193 compounds with 1814 contacts. Final analysis was performed on 193 index cases and 1661 contacts in the intervention group and 184 index cases and 1498 contacts in the control group. In 2009, index case-patients with symptom onset within 7 days preceding enrolment were eligible. Eligibility criteria changed in 2010 to include index case-patient with symptom onset within 48 hours preceding enrolment. Inclusion criteria: 1. Individuals ≥ 5 years old: ILI, defined as history of fever and either cough or sore throat with fever onset within the previous 24 hours. 2. Individuals < 5 years old: any child with acute fever with onset within the previous 24 hours. 3. Return to home within 24 hours of presentation to Upazilla Health Complex, Jahurul Islam Medical College Hospital or the local pharmacies, i.e. the index case cannot be admitted for treatment. If admitted, the patient would not be eligible. 4. No fever in any bari resident during the 7 days preceding the patient's presentation to hospital (see definition below). 5. At least 2 individuals (in addition to the index case-patient) who intend to reside in the bari during the subsequent 20 days. 6. Residence within 30 minutes travel time (1-way) from the Upazilla Health Complex or Jahurul Islam Medical College Hospital or the local pharmacy. Exclusion criteria: compounds were excluded if any compound member(s) was reported to have fever within 3 days before index case-patient enrolment. At another time point, compounds were excluded

Ram 2015 *(Continued)*

	if any primary household member was reported to have fever (fever occurring within 48 hours prior to enrolment recorded).
Interventions	Promoting intensive hand-washing in households to prevent transmission of ILI. See Table 1 for details.
Outcomes	Laboratory: PCR for influenza A and B, with further subtyping of influenza A isolates for all ILI amongst contacts Effectiveness: incidence of ILI. An age-based definition of ILI was used as follows. 1. For individuals > 5 years old, ILI was defined as history of fever with cough or sore throat. 2. For children < 5 years old, ILI was defined as fever (the authors used this relatively liberal case definition in order to include influenza cases with atypical presentations in children). Safety: no safety data planned or reported by investigators
Notes	Inclusion/exclusion criteria changed 3 times during the study conduct. The period study conducted: June 2009 to December 2010 Funding: government

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Block randomisation, with a block size of 4, in order to promote random and even allocation of household compounds to the 2 treatment arms. The list of random assignments was generated by an investigator with no contact with the participants.
Allocation concealment (selection bias)	Low risk	Once baseline data collection was complete, the data collector notified the field research officer, who consulted the block randomisation list to make the assignment of the household compound to intervention or control.
Blinding of participants and personnel (performance bias) All outcomes	High risk	Relied on symptom reporting from the head of family. Inclusion/exclusion criteria changed 3 times during the study conduct. Given the provision of a hand-washing station as part of the intervention, it was not possible to ensure blinding of participants, intervention staff, or data collectors.
Blinding of outcome assessment (detection bias) All outcomes	High risk	Relied on symptom reporting from the head of family. Inclusion/exclusion criteria changed 3 times during the conduct of the study. Given the provision of a hand-washing station as part of the intervention, it was not possible to ensure blinding of participants, intervention staff, or data collectors.
Incomplete outcome data (attrition bias) All outcomes	Low risk	Flow chart followed all households an individuals from recruitment to analysis.
Selective reporting (reporting bias)	Low risk	The specified outcomes are clearly accounted for. Investigators report all outcomes for each modified enrolment.

Roberts 2000

Study characteristics	
Methods	Open cluster-RCT carried out between March and November 1996 (the Southern Hemisphere winter season) in 23 childcare centres caring for a minimum of 50 children 10 hours a day, 5 days a week in Australia. The study assessed the effects of an Australian national hand-washing programme compared to standard procedure. Randomisation was according to a random-number table, and cluster coefficients are reported.
Participants	Children (299 in the intervention arm and 259 in the control arm) aged 3 or younger attending the centres at least 3 days a week. Attrition was 51 children in the intervention arm and 72 children in the control arm due mainly to staff leaving the centres.
Interventions	Hand-washing programme with training for staff and children. It is unclear whether any extra hand-cleansing agents were used, as GloGerm (?) is mentioned when it was used in a preliminary study.
Outcomes	Laboratory: N/A Effectiveness: ARI (runny nose, cough, and blocked nose) Follow-up was via a parental phone interview every 2 weeks. Safety: N/A
Notes	Risk of bias: low (cluster coefficients and analysis by unit of randomisation) Note: the authors conclude that although there was no overall decrease in respiratory illness (RR 0.95, 95% CI 0.89 to 1.01), in children up to 24 months the decrease was statistically significant (RR 0.90, 95% CI 0.83 to 0.97). The authors speculated that this was because maximum benefits are likely from this age group due to their limited ability to wipe their nose and hands without a structured programme. Analyses by 3 compliance levels are also reported. A so-so reported and well-conducted trial
Risk of bias

Random sequence generation (selection bias)	Low risk	Randomisation was according to a random-number table.
Allocation concealment (selection bias)	Unclear risk	Not reported
Blinding of participants and personnel (performance bias) All outcomes	High risk	It was not possible to blind the intervention.
Blinding of outcome assessment (detection bias) All outcomes	Low risk	"The observer was not informed of the content of the training sessions or the intervention status of the centres."
Incomplete outcome data (attrition bias) All outcomes	Unclear risk	Recruitment rate 88% (23 of 26 CCCs); loss to follow-up not clear, as no denominator given
Selective reporting (reporting bias)	Low risk	Centres were comparable at baseline.

Sandora 2005

Study characteristics	
Methods	Single-blind, cluster-RCT carried around the Boston area, USA, in the period of November 2002 to April 2003. The trial tested the effects of using a hand sanitiser and a programme of instruction on the transmissions of GI infections (data not extracted) and ARIs in families. Units of randomisation were child-care centres and were carried out on enrolment by an investigator using random block size generated by computer. Assignment was single-blind (i.e. investigator blinded to the status of the centre). Cluster correlation was 0.01.
Participants	292 families with 1 or more children aged 6 months to 5 years who were in child care for 10 or more hours a week 155 children in 14 centres were allocated to the intervention arm and 137 children in 12 centres to the control arm**.** The mean age was 3 to 2.7 years. Attrition was respectively 15 (3 lost to follow-up and 12 who discontinued the intervention) and 19 (8 lost to follow-up and 11 who discontinued the intervention). ITT analysis was carried out.
Interventions	Alcohol-based hand sanitiser with biweekly hand hygiene educational materials over 5 months versus biweekly educational material on healthy diet
Outcomes	Effectiveness: ARI (2 of the following symptoms for 1 day or 1 of the following symptoms for 2 days: runny nose, cough, sneezing, stuffy or blocked nose, fever, sore throat). An illness episode had to be separated by 2 symptom-free days from a previous episode. A secondary illness was when it followed a similar illness in another family member by 2 to 7 days. Follow-up was by means of biweekly phone calls to caregivers. Safety: dry skin (71 reports), stinging (11 reports), bad smell (7 reports), dislike (2 reports), allergic reaction (2 reports), slippery feel (1 report), and irritation (20 reports)
Notes	Risk of bias: low Note: the authors conclude that although the rate of GI illnesses was significantly lower in the intervention group, the IRR was not significantly different for ARIs (0.97, 95% CI 0.72 to 1.30). Compliance and droplet route spread may account for this apparent lack of effect. A well-reported trial

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	"Random assignments were generated by computer using a permuted-blocks design with random block sizes."
Allocation concealment (selection bias)	Low risk	"Assignments were concealed in opaque envelopes, and centers were assigned to control or intervention groups by a study investigator as they were enrolled."
Blinding of participants and personnel (performance bias) All outcomes	High risk	"Teachers in the intervention classrooms were responsible for encouraging the use of the disinfecting wipes and hand sanitizer according to the study protocol ... Given that no placebo was provided and sanitizer use was recorded, neither families nor data collectors could be blinded as to the group assignment of the family."
Blinding of outcome assessment (detection bias) All outcomes	High risk	"Given that no placebo was provided and sanitizer use was recorded, neither families nor data collectors could be blinded as to the group assignment of the family."
Incomplete outcome data (attrition bias) All outcomes	Low risk	Attrition was 15 in intervention arm (3 lost to follow-up and 12 who discontinued the intervention) and 19 in the control arm (8 lost to follow-up and 11 who discontinued the intervention). ITT analysis was carried out.
Selective reporting (reporting bias)	Unclear risk	Well-reported

Sandora 2008

Study characteristics

Methods	Cluster-RCT carried out in a single elementary school system located in Avon, Ohio, USA to assess the effectiveness of a multifactorial infection-control intervention, including alcohol-based hand sanitiser and surface disinfection, in reducing absenteeism caused by gastrointestinal and respiratory illnesses amongst elementary school students. The study also aimed to describe the viral and bacterial contamination of common surfaces in the school classroom and to assess the impact of an environmental disinfectant on the presence of selected viruses and bacteria on these surfaces. Clustering was described as "teams of 3-4 classes depending on the class year".
Participants	A total of 363 students in 15 different classrooms were eligible to participate and received letters about the study. A sample of 285 of these students provided written informed consent and were randomly assigned to the intervention group (146) or to the control group (139) and contributed to final analysis. No students were lost to follow-up or discontinued the intervention during the study period. Baseline demographic characteristics were similar in the intervention and control groups. Most families were white and non-Hispanic and in excellent or very good health at baseline.
Interventions	Alcohol-based hand sanitiser to use at school and quaternary ammonium wipes to disinfect classroom surfaces daily for 8 weeks versus usual hand-washing and cleaning practices
Outcomes	Laboratory: Serological evidence: no Swabs for bacteria and viruses from 3 types of classroom surfaces were taken.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Sandora 2008 *(Continued)*

	Effectiveness: Respiratory illness defined as days absent as measured by a (blinded) school worker who routinely recorded reason for absenteeism either for gastrointestinal or respiratory causes. Safety: N/A
Notes	The authors conclude that the multifaceted intervention that included alcohol-based hand sanitiser use and disinfection of common classroom surfaces reduced absenteeism from gastrointestinal illness amongst elementary school students. The intervention did not impact on absenteeism from respiratory illness. In addition, norovirus was detected less frequently on classroom surfaces in the group receiving the intervention. The study is of good quality with low risk of bias. The authors checked compliance by counting discarded wipes. Reasons given for the apparent lack of effect against ARIs but good effect on GI illness are that disinfecting the classroom surfaces (daily at lunchtime with alkali) was important, as were the alcohol wipes. The authors measured the norovirus concentration on surfaces and found this to be reduced. Other reasons may be that droplets are not affected by this method, or that contamination of hands by respiratory infections is likely to be continuous (in orofaecal transmission is mostly at the time of defecation).

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	"The allocation sequence was generated by computer ..."
Allocation concealment (selection bias)	Unclear risk	"...and teams were assigned to study groups by a study investigator (Dr Shih)." Blinding of allocation cannot be guaranteed.
Blinding of participants and personnel (performance bias) All outcomes	High risk	Not possible
Blinding of outcome assessment (detection bias) All outcomes	Low risk	"All of the students absences were recorded in the usual fashion by the school employee who normally answers this dedicated telephone line. This employee was blinded to the group assignment of the child."
Incomplete outcome data (attrition bias) All outcomes	Low risk	No students were lost to follow-up or discontinued the intervention during the study period.
Selective reporting (reporting bias)	Unclear risk	Well-reported

Satomura 2005

Study characteristics

Methods	RCT. Randomisation was achieved by simple computer-generated random digit. Allocation was concealed using sealed, opaque envelopes. Not clear if there was a central randomisation centre. Post hoc exchange of envelopes was prevented by writing both the name of each participant and the number on the envelope he/she drew before breaking the seal. Participants were not blinded to the intervention; however, disease incidence was determined by 1 study physician who was not informed of the results of assignment. Analysis was done based on the intention-to-treat principle. The study targeted community healthcare all over Japan and was conducted between December 2002 and March 2003 for a follow-up period of 60 days.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Satomura 2005 *(Continued)*

Participants	387 participants at 18 sites were recruited, 384 were included in the analysis: water gargling (N = 122), povidone-iodine gargling (N = 132), and control (N = 130). Follow-up was completed on 338 participants. Attrition was fully explained for URTI analysis; however, 2 participants were not accounted for in the ILI analysis. 46 participants did not complete the follow-up due to either discontinuation of diary use (n = 9) or contracting ILI (n = 37). Of the 37 participants with ILI, 11 were in the povidone-iodine group, 12 in the water group, and 14 in the control group. Analysis was performed on 35 participants (Kitamura 2007).
Interventions	Participants were randomised to 1 of the following: water gargling, n = 122 (20 mL of water for about 15 seconds 3 times consecutively, at least 3 times a day); povidone-iodine gargling, n = 133 (20 mL of 15 to 30 times diluted 7% povidone-iodine (as indicated by the manufacturer) in the same way as water gargling); and control, n = 132 (retain their previous gargling habits). All groups were asked to fill a daily gargling diary (standardised form to record: gargling habits, hand-washing, and influenza complaints). The frequency of gargling in the water group was higher (3.6); the frequency of hand-washing was similar amongst the 3 groups. URTI symptom was classified according to Jackson methods. Diary recording was continued throughout the follow-up period and for 1 week after the onset of URTI. ILI was reported separately.
Outcomes	Laboratory: none Effectiveness: Primary outcome: incidence of first URTI. Index cases were defined as all of the following conditions: 1. both nasal and pharyngeal symptoms, 2. severity of at least 1 symptom increased by 2 grades or more, and 3. worsening of a symptom of 1 increment or more for > 3 days. Secondary outcome: severity of URTI of the incident cases was assessed by grading each symptom during the initial 7 days after the onset of URTI in numeric scores: none = 0, mild = 1, moderate = 2, and severe = 3 ILI was defined as both developing a fever of 38 °C or higher and worsening arthralgia in addition to some respiratory symptoms (Kitamura 2007). Safety: no harm was reported. However, 2 participants in the povidone-iodine group switched to water gargling (analysed in their assignment group).
Notes	The authors concluded that simple water gargling is effective in preventing URTIs amongst healthy people. However, no statistically significant difference was observed against ILIs. The study was well-conducted; blinding would have added to the validity of the results. In addition, the study was not powered enough to detect a statistically significant preventative effect against ILI. The study demonstrates that in addition to hand-washing, simple gargling even with water can reduce URTI, but not ILI. However, during periods of endemic influenza, multiple inexpensive and simple modalities (hand-washing, masks, gargling) can be utilised together to reduce infection and transmission. Overall, the reporting of the 2 combined studies together is highly confusing. In the first study (Satomura 2005), the main outcome is URTI defined as fever and arthralgia. The second study (which is a presentation of further data from the 2005 publication in the guise of a short report) introduces the outcome ILI with a definition similar to that of URTI in the first study but referring to the earlier outcome as common cold. Also of note is reporting of significance without confidence intervals. Overall, this potentially important study should be repeated with a larger denominator. Unclear risk of bias because of confused reporting and absence of double-blinding

Blinding of outcome assessment (detection bias) All outcomes	Low risk	"To prevent post hoc exchange of the envelopes, local administrators wrote down both the name of each subject and the number on the envelope he/she drew before breaking the seal."
Incomplete outcome data (attrition bias) All outcomes	Low risk	338 of 385 randomised followed up; reasons reported.
Selective reporting (reporting bias)	Unclear risk	Confusing reporting

Savolainen-Kopra 2012

Study characteristics	
Methods	Open cluster-RCT, 3-arm intervention trial
Participants	A total of 21 clusters (683 individuals) were randomised to implement hand hygiene with soap and water (257 individuals), alcohol-based hand rub (202 individuals), or control (224 individuals). The study was conducted in distinct office work units in 6 corporations in the Helsinki Region that together employed some 10,000 staff. All employees (age ≥ 18 years, both genders) were contacted by email survey. Inclusion criteria: "Volunteers working in defined units" Exclusion criteria: "Persons with open wounds or chronic eczema in hands" The designated 21 study clusters were identified as operationally distinct working units, each containing at least 50 people.
Interventions	Hand hygiene with soap and water and standardised instructions on how to limit the transmission of infections. Usual hand hygiene (control). See Table 1 for details.
Outcomes	Laboratory: "Between November 2008 and May 2010, the seven occupational health clinics serving the six participating corporations were advised to collect, using standard techniques, two to three respiratory samples per week from typical RTI patients and also faecal samples from a few representative patients with gastrointestinal symptoms when a GIT outbreak was suspected. The samples could originate from the study participants and also from work units not included in the study. In the laboratory, viral nucleic acids were extracted with well-characterized commercial kits and tested by validated real-time PCR methods to detect influenza A and B viruses, respiratory syncytial virus, parainfluenza virus types 1, 2, and 3, adenoviruses, human rhinoviruses and human enteroviruses from respiratory specimens, and norovirus from faecal specimens (detailed descriptions of the test procedures are available from the authors)."

	Effectiveness: Predefined primary endpoints: 1. Number of reported infection episodes in a cluster per total reported weeks. 2. Number of reported sick leave episodes in a cluster per total reported weeks. Secondary endpoints and outcome measures: 1. Number of days with reported symptoms of RTI and/or GTI in a cluster within a time frame of 100 reporting weeks. 2. Number of days-off due to own RTI or GTI in a cluster within a time frame of 100 reporting weeks. Safety: reported 0 adverse events
Notes	The period study conducted: January 2009 to May 2010 Funding: government

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Insufficient information
Allocation concealment (selection bias)	Low risk	"clusters were matched and randomized prior to onset of the interventions"
Blinding of participants and personnel (performance bias) All outcomes	High risk	The interventions were not blinded to any party involved (i.e. the study group, participants, or the occupational health services). Subjective reporting of disease episodes
Blinding of outcome assessment (detection bias) All outcomes	High risk	Subjective reporting of disease episodes
Incomplete outcome data (attrition bias) All outcomes	High risk	24% loss to follow-up. However, new recruiting in most clusters; the total number of reporting participants at the end of the trial was 91.7% compared to that at the beginning. Attrition was reported, and 76% of volunteers who started reporting continued to do so until the end of the study. Because of new recruiting in most clusters, the total number of reporting participants at the end of the trial was 626, or 91.7%, compared to that at the beginning. This means that 15.7% of the participants were replaced during the study!!! Raw data on the effects of the interventions on the occurrence of respiratory infections and vomiting/diarrhoea diseases were not reported. Zero adverse effects were reported.
Selective reporting (reporting bias)	Low risk	All planned outcomes were reported.

Random sequence generation (selection bias)	Low risk	Randomisation was according to a random-number table.
Allocation concealment (selection bias)	Unclear risk	Not reported
Blinding of participants and personnel (performance bias) All outcomes	High risk	It was not possible to blind the intervention.
Blinding of outcome assessment (detection bias) All outcomes	Low risk	"The observer was not informed of the content of the training sessions or the intervention status of the centres."
Incomplete outcome data (attrition bias) All outcomes	Unclear risk	Recruitment rate 88% (23 of 26 CCCs); loss to follow-up not clear, as no denominator given
Selective reporting (reporting bias)	Low risk	Centres were comparable at baseline.

Sandora 2005

Study characteristics

Methods	Single-blind, cluster-RCT carried around the Boston area, USA, in the period of November 2002 to April 2003. The trial tested the effects of using a hand sanitiser and a programme of instruction on the transmissions of GI infections (data not extracted) and ARIs in families. Units of randomisation were child-care centres and were carried out on enrolment by an investigator using random block size generated

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Sandora 2005 *(Continued)*

	by computer. Assignment was single-blind (i.e. investigator blinded to the status of the centre). Cluster correlation was 0.01.
Participants	292 families with 1 or more children aged 6 months to 5 years who were in child care for 10 or more hours a week 155 children in 14 centres were allocated to the intervention arm and 137 children in 12 centres to the control arm**.** The mean age was 3 to 2.7 years. Attrition was respectively 15 (3 lost to follow-up and 12 who discontinued the intervention) and 19 (8 lost to follow-up and 11 who discontinued the intervention). ITT analysis was carried out.
Interventions	Alcohol-based hand sanitiser with biweekly hand hygiene educational materials over 5 months versus biweekly educational material on healthy diet
Outcomes	Effectiveness: ARI (2 of the following symptoms for 1 day or 1 of the following symptoms for 2 days: runny nose, cough, sneezing, stuffy or blocked nose, fever, sore throat). An illness episode had to be separated by 2 symptom-free days from a previous episode. A secondary illness was when it followed a similar illness in another family member by 2 to 7 days. Follow-up was by means of biweekly phone calls to caregivers. Safety: dry skin (71 reports), stinging (11 reports), bad smell (7 reports), dislike (2 reports), allergic reaction (2 reports), slippery feel (1 report), and irritation (20 reports)
Notes	Risk of bias: low Note: the authors conclude that although the rate of GI illnesses was significantly lower in the intervention group, the IRR was not significantly different for ARIs (0.97, 95% CI 0.72 to 1.30). Compliance and droplet route spread may account for this apparent lack of effect. A well-reported trial

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	"Random assignments were generated by computer using a permuted-blocks design with random block sizes."
Allocation concealment (selection bias)	Low risk	"Assignments were concealed in opaque envelopes, and centers were assigned to control or intervention groups by a study investigator as they were enrolled."
Blinding of participants and personnel (performance bias) All outcomes	High risk	"Teachers in the intervention classrooms were responsible for encouraging the use of the disinfecting wipes and hand sanitizer according to the study protocol ... Given that no placebo was provided and sanitizer use was recorded, neither families nor data collectors could be blinded as to the group assignment of the family."
Blinding of outcome assessment (detection bias) All outcomes	High risk	"Given that no placebo was provided and sanitizer use was recorded, neither families nor data collectors could be blinded as to the group assignment of the family."
Incomplete outcome data (attrition bias) All outcomes	Low risk	Attrition was 15 in intervention arm (3 lost to follow-up and 12 who discontinued the intervention) and 19 in the control arm (8 lost to follow-up and 11 who discontinued the intervention). ITT analysis was carried out.
Selective reporting (reporting bias)	Unclear risk	Well-reported

Sandora 2008

Study characteristics	
Methods	Cluster-RCT carried out in a single elementary school system located in Avon, Ohio, USA to assess the effectiveness of a multifactorial infection-control intervention, including alcohol-based hand sanitiser and surface disinfection, in reducing absenteeism caused by gastrointestinal and respiratory illnesses amongst elementary school students. The study also aimed to describe the viral and bacterial contamination of common surfaces in the school classroom and to assess the impact of an environmental disinfectant on the presence of selected viruses and bacteria on these surfaces. Clustering was described as "teams of 3-4 classes depending on the class year".
Participants	A total of 363 students in 15 different classrooms were eligible to participate and received letters about the study. A sample of 285 of these students provided written informed consent and were randomly assigned to the intervention group (146) or to the control group (139) and contributed to final analysis. No students were lost to follow-up or discontinued the intervention during the study period. Baseline demographic characteristics were similar in the intervention and control groups. Most families were white and non-Hispanic and in excellent or very good health at baseline.
Interventions	Alcohol-based hand sanitiser to use at school and quaternary ammonium wipes to disinfect classroom surfaces daily for 8 weeks versus usual hand-washing and cleaning practices
Outcomes	Laboratory: Serological evidence: no Swabs for bacteria and viruses from 3 types of classroom surfaces were taken. Effectiveness: Respiratory illness defined as days absent as measured by a (blinded) school worker who routinely recorded reason for absenteeism either for gastrointestinal or respiratory causes. Safety: N/A
Notes	The authors conclude that the multifaceted intervention that included alcohol-based hand sanitiser use and disinfection of common classroom surfaces reduced absenteeism from gastrointestinal illness amongst elementary school students. The intervention did not impact on absenteeism from respiratory illness. In addition, norovirus was detected less frequently on classroom surfaces in the group receiving the intervention. The study is of good quality with low risk of bias. The authors checked compliance by counting discarded wipes. Reasons given for the apparent lack of effect against ARIs but good effect on GI illness are that disinfecting the classroom surfaces (daily at lunchtime with alkali) was important, as were the alcohol wipes. The authors measured the norovirus concentration on surfaces and found this to be reduced. Other reasons may be that droplets are not affected by this method, or that contamination of hands by respiratory infections is likely to be continuous (in orofaecal transmission is mostly at the time of defecation).

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	Low risk	"The allocation sequence was generated by computer ..."
Allocation concealment (selection bias)	Unclear risk	"...and teams were assigned to study groups by a study investigator (Dr Shih)." Blinding of allocation cannot be guaranteed.
Blinding of participants and personnel (performance bias) All outcomes	High risk	Not possible

Sandora 2008 *(Continued)*

Blinding of outcome assessment (detection bias) All outcomes	Low risk	"All of the students absences were recorded in the usual fashion by the school employee who normally answers this dedicated telephone line. This employee was blinded to the group assignment of the child."
Incomplete outcome data (attrition bias) All outcomes	Low risk	No students were lost to follow-up or discontinued the intervention during the study period.
Selective reporting (reporting bias)	Unclear risk	Well-reported

Satomura 2005

Study characteristics	
Methods	RCT. Randomisation was achieved by simple computer-generated random digit. Allocation was concealed using sealed, opaque envelopes. Not clear if there was a central randomisation centre. Post hoc exchange of envelopes was prevented by writing both the name of each participant and the number on the envelope he/she drew before breaking the seal. Participants were not blinded to the intervention; however, disease incidence was determined by 1 study physician who was not informed of the results of assignment. Analysis was done based on the intention-to-treat principle. The study targeted community healthcare all over Japan and was conducted between December 2002 and March 2003 for a follow-up period of 60 days.
Participants	387 participants at 18 sites were recruited, 384 were included in the analysis: water gargling (N = 122), povidone-iodine gargling (N = 132), and control (N = 130). Follow-up was completed on 338 participants. Attrition was fully explained for URTI analysis; however, 2 participants were not accounted for in the ILI analysis. 46 participants did not complete the follow-up due to either discontinuation of diary use (n = 9) or contracting ILI (n = 37). Of the 37 participants with ILI, 11 were in the povidone-iodine group, 12 in the water group, and 14 in the control group. Analysis was performed on 35 participants (Kitamura 2007).
Interventions	Participants were randomised to 1 of the following: water gargling, n = 122 (20 mL of water for about 15 seconds 3 times consecutively, at least 3 times a day); povidone-iodine gargling, n = 133 (20 mL of 15 to 30 times diluted 7% povidone-iodine (as indicated by the manufacturer) in the same way as water gargling); and control, n = 132 (retain their previous gargling habits). All groups were asked to fill a daily gargling diary (standardised form to record: gargling habits, hand-washing, and influenza complaints). The frequency of gargling in the water group was higher (3.6); the frequency of hand-washing was similar amongst the 3 groups. URTI symptom was classified according to Jackson methods. Diary recording was continued throughout the follow-up period and for 1 week after the onset of URTI. ILI was reported separately.
Outcomes	Laboratory: none Effectiveness: Primary outcome: incidence of first URTI. Index cases were defined as all of the following conditions: 1. both nasal and pharyngeal symptoms, 2. severity of at least 1 symptom increased by 2 grades or more, and 3. worsening of a symptom of 1 increment or more for > 3 days. Secondary outcome: severity of URTI of the incident cases was assessed by grading each symptom during the initial 7 days after the onset of URTI in numeric scores: none = 0, mild = 1, moderate = 2, and severe = 3

Satomura 2005 *(Continued)*

	ILI was defined as both developing a fever of 38 °C or higher and worsening arthralgia in addition to some respiratory symptoms (Kitamura 2007). Safety: no harm was reported. However, 2 participants in the povidone-iodine group switched to water gargling (analysed in their assignment group).
Notes	The authors concluded that simple water gargling is effective in preventing URTIs amongst healthy people. However, no statistically significant difference was observed against ILIs. The study was well-conducted; blinding would have added to the validity of the results. In addition, the study was not powered enough to detect a statistically significant preventative effect against ILI. The study demonstrates that in addition to hand-washing, simple gargling even with water can reduce URTI, but not ILI. However, during periods of endemic influenza, multiple inexpensive and simple modalities (hand-washing, masks, gargling) can be utilised together to reduce infection and transmission. Overall, the reporting of the 2 combined studies together is highly confusing. In the first study (Satomura 2005), the main outcome is URTI defined as fever and arthralgia. The second study (which is a presentation of further data from the 2005 publication in the guise of a short report) introduces the outcome ILI with a definition similar to that of URTI in the first study but referring to the earlier outcome as common cold. Also of note is reporting of significance without confidence intervals. Overall, this potentially important study should be repeated with a larger denominator. Unclear risk of bias because of confused reporting and absence of double-blinding

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	"Group assignment was based on simple computer-generated random digits..."
Allocation concealment (selection bias)	Low risk	"By an individual drawing of sealed opaque envelopes, subjects were randomly assigned to the following three groups" "allocation was completely concealed from study administrators"
Blinding of participants and personnel (performance bias) All outcomes	High risk	Not blinded
Blinding of outcome assessment (detection bias) All outcomes	Low risk	"To prevent post hoc exchange of the envelopes, local administrators wrote down both the name of each subject and the number on the envelope he/she drew before breaking the seal."
Incomplete outcome data (attrition bias) All outcomes	Low risk	338 of 385 randomised followed up; reasons reported.
Selective reporting (reporting bias)	Unclear risk	Confusing reporting

Savolainen-Kopra 2012

Study characteristics

Methods	Open cluster-RCT, 3-arm intervention trial
Participants	A total of 21 clusters (683 individuals) were randomised to implement hand hygiene with soap and water (257 individuals), alcohol-based hand rub (202 individuals), or control (224 individuals).

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Savolainen-Kopra 2012 *(Continued)*

	The study was conducted in distinct office work units in 6 corporations in the Helsinki Region that together employed some 10,000 staff. All employees (age ≥ 18 years, both genders) were contacted by email survey. Inclusion criteria: "Volunteers working in defined units" Exclusion criteria: "Persons with open wounds or chronic eczema in hands" The designated 21 study clusters were identified as operationally distinct working units, each containing at least 50 people.
Interventions	Hand hygiene with soap and water and standardised instructions on how to limit the transmission of infections. Usual hand hygiene (control). See Table 1 for details.
Outcomes	Laboratory: "Between November 2008 and May 2010, the seven occupational health clinics serving the six participating corporations were advised to collect, using standard techniques, two to three respiratory samples per week from typical RTI patients and also faecal samples from a few representative patients with gastrointestinal symptoms when a GIT outbreak was suspected. The samples could originate from the study participants and also from work units not included in the study. In the laboratory, viral nucleic acids were extracted with well-characterized commercial kits and tested by validated real-time PCR methods to detect influenza A and B viruses, respiratory syncytial virus, parainfluenza virus types 1, 2, and 3, adenoviruses, human rhinoviruses and human enteroviruses from respiratory specimens, and norovirus from faecal specimens (detailed descriptions of the test procedures are available from the authors)." Effectiveness: Predefined primary endpoints: 1. Number of reported infection episodes in a cluster per total reported weeks. 2. Number of reported sick leave episodes in a cluster per total reported weeks. Secondary endpoints and outcome measures: 1. Number of days with reported symptoms of RTI and/or GTI in a cluster within a time frame of 100 reporting weeks. 2. Number of days-off due to own RTI or GTI in a cluster within a time frame of 100 reporting weeks. Safety: reported 0 adverse events
Notes	The period study conducted: January 2009 to May 2010 Funding: government

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Insufficient information
Allocation concealment (selection bias)	Low risk	"clusters were matched and randomized prior to onset of the interventions"
Blinding of participants and personnel (performance bias) All outcomes	High risk	The interventions were not blinded to any party involved (i.e. the study group, participants, or the occupational health services). Subjective reporting of disease episodes
Blinding of outcome assessment (detection bias)	High risk	Subjective reporting of disease episodes

Savolainen-Kopra 2012 *(Continued)*
All outcomes

Incomplete outcome data (attrition bias) All outcomes	High risk	24% loss to follow-up. However, new recruiting in most clusters; the total number of reporting participants at the end of the trial was 91.7% compared to that at the beginning. Attrition was reported, and 76% of volunteers who started reporting continued to do so until the end of the study. Because of new recruiting in most clusters, the total number of reporting participants at the end of the trial was 626, or 91.7%, compared to that at the beginning. This means that 15.7% of the participants were replaced during the study!!! Raw data on the effects of the interventions on the occurrence of respiratory infections and vomiting/diarrhoea diseases were not reported. Zero adverse effects were reported.
Selective reporting (reporting bias)	Low risk	All planned outcomes were reported.

Simmerman 2011

Study characteristics	
Methods	Randomised controlled study
Participants	Study recruited 348 households and 885 members and randomised them as follows: 1. Control (index household = 119, with 302 family members) 2. Hand-washing (index household = 119, with 292 family members) 3. Hand-washing and face mask (index household = 110, with 291 family members) The household members of children (index cases) presenting with ILI at the outpatient department of the Queen Sirikit National Institute of Child Health (QSNICH) in Bangkok, the largest public paediatric hospital in Thailand Inclusion criteria: For index cases: children aged 1 month through 15 years, residents of the Bangkok metropolitan area, and had an onset of illness < 48 hours before respiratory specimens tested positive for influenza by an RIDT that was later confirmed by qualitative real-time RT-PCR (rRT-PCR) Eligible index cases' households must have had at least 2 other members aged ≥ 1 month who planned to sleep inside the house for a period of at least 21 days from the time of enrolment. Exclusion criteria: For index cases: children at high risk for severe influenza complications (e.g. chronic lung disease, renal disease, and long-term aspirin therapy) and those treated with influenza antiviral medications Excluded households: those with any member reporting an ILI that preceded the index case by 7 days or less and households where any member had received influenza vaccination during the preceding 12 months
Interventions	Hand-washing, or hand-washing plus paper surgical face mask, or control. See Table 1 for details.
Outcomes	Laboratory: To identify index cases: QuickVue Influenza A+B rapid diagnostic kit (Quidel Co., San Diego, CA, USA), followed by rRT-PCR for influenza viral RNA Index cases and contacts tested with nasal swab and throat swab both processed for rRT-PCR.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Simmerman 2011 *(Continued)*

	2 blood samples for antibody seroconversion collected on Days 1 and 21 (seroconversion defined as a fourfold rise in HI titre between paired sera for any of the antigens assayed). Effectiveness: Laboratory-confirmed secondary influenza virus infections amongst household members described as the secondary attack rate (SAR). A secondary influenza virus infection was defined as a positive rRT-PCR result on Days 3 or 7 or a fourfold rise in influenza HI antibody titres with the virus type and sub-type matching the index case. SAR for ILI defined by the WHO as fever plus cough or sore throat, based on self-reported symptoms. Safety: no safety measures planned or reported by the investigators Adherence: participants in the control arm reported an average of 3.9 hand-washing episodes/day (on Day 7), whilst participants in the hand-washing arm reported an average of 4.7 hand-washing episodes/day (95% CI 4.3 to 5.0; P = 0.002 compared to controls), and participants in the hand-washing plus face mask arm reported 4.9 episodes/day (95% CI 4.5 to 5.3; P < 0.001 compared to controls). In the intervention arms, parents had the highest reported daily hand-washing frequency (5.7, 95% CI 5.3 to 6.0) followed by others (4.8, 95% CI 4.3 to 5.3), siblings (4.3, 95% CI 3.7 to 4.8), and the index cases (4.1, 95% CI 3.8 to 4.4). There was no difference in the average amount of soap used in a week in the hand-washing arm (54 mL per person) and the hand-washing plus face mask arm (58.1 mL per person) (P = 0.15). 289 participants in the hand-washing plus face mask arm used an average of 12 masks per person per week (median 11, IQR 7 to 16) and reported wearing a face mask a mean of 211 minutes/day (IQR 17 to 317 minutes/day). Parents wore their masks for a median of 153 (IQR 40 to 411) minutes per day, far more than other relations (median 59; IQR 9 to 266), the index patients themselves (median 35; IQR 4 to 197), or their siblings (median 17; IQR 6 to 107). The study authors note that differences in average usage may be an attenuated measure of appropriate use in relation to the actual unmeasured exposure risk such as proximity to the index case.
Notes	The period study conducted: April 2008 and August 2009 Funding: government

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	"Randomization was achieved using a block randomization method using a list of blocks each with 12 household IDs, four of which were assigned to each of the three study arms."
Allocation concealment (selection bias)	Unclear risk	"A study coordinator assigned each household to one study arm after consent was obtained"
Blinding of participants and personnel (performance bias) All outcomes	Low risk	Recruiting clinicians were blinded to the allocation of the specific intervention. The participants were not blinded, but it is unlikely that the outcome would have been affected by lack of blinding.
Blinding of outcome assessment (detection bias) All outcomes	Low risk	The primary outcome is a laboratory-confirmed influenza.
Incomplete outcome data (attrition bias) All outcomes	Low risk	Household flow chart provided with reasons for exclusions, all numbers provided. Analysis was done by ITT and PP.
Selective reporting (reporting bias)	Low risk	All outcomes are accounted for in the ITT analysis of the results.

Stebbins 2011

Study characteristics	
Methods	Cluster-RCT, open-label
Participants	Study included 3360 students from 10 Pittsburgh elementary schools. Intervention arm (5 schools, 1695 people) and control arm (5 schools, 1665 people) No inclusion or exclusion criteria were provided.
Interventions	Training in hand and respiratory (cough) hygiene. Hand sanitiser was provided and encouraged to be used regularly. See Table 1 for details.
Outcomes	Laboratory: Primary outcome: laboratory-confirmed influenza (RT-PCR) amongst children presenting with ILIs leading to their absence from school 2 nasal swabs were obtained using test manufacturer-approved sterile Dacron swabs. 1 swab was employed for influenza testing using the QuickVue Influenza A+B test (Quidel Corp, San Diego, CA). The second nasal swab was delivered on cold pack to the University of Pittsburgh Medical Center Clinical Virology Laboratory, Pittsburgh, PA for RT-PCR testing (performed within 48 hours). The RT-PCR used viral nucleic acid extract (EasyMag; bioMerieux, Durham, NC) and primer/probe sequences for influenza A, influenza B, and influenza A H1 and H3 subtypes (CDC, Atlanta GA). Effectiveness: Secondary outcome: absence episodes and cumulative days of absence due to ILI, any illness, and all causes Safety: none mentioned
Notes	The period study conducted: 1 November 2007 through 24 April 2008 Funding: unclear

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	"constrained randomization algorithm"
Allocation concealment (selection bias)	Low risk	"Random allocation of schools to two arms was created by Dr. Cummings and concealed until intervention assignment". "At the beginning of the school year parents and guardians were given the opportunity to decline participation"
Blinding of participants and personnel (performance bias) All outcomes	High risk	Unblinded
Blinding of outcome assessment (detection bias) All outcomes	Low risk	In 76% and 78% of illness in intervention and control group were laboratory confirmed. ILI is objectively defined.

Suess 2012

Study characteristics	
Methods	Cluster-RCT, open-label, parallel design
Participants	Study sample included 84 households randomised as follows: 1. 30 control (index cases = 30, household contact = 82) 2. 26 mask group (index cases = 26, household contact = 69) 3. 28 mask and hand hygiene group (index cases = 28, household contact = 67) Inclusion criteria: patients presenting to general practitioners or family physicians at the study sites within 2 days of symptom onset; had a positive rapid antigen test for influenza (later to be confirmed by quantitative RT-PCR (qRT-PCR); and was at least 2 years old. Index cases also had to be the only household member suffering from respiratory disease within 14 days prior to symptom onset. Exclusion criteria were pregnancy, severely reduced health status, and HIV infection. 1-person households were also not eligible or inclusion.
Interventions	Quote: "facemask and practising intensified hand hygiene (MH group), wearing facemask only (M group) and none of the 2 (control group)". See Table 1 for details.
Outcomes	Primary outcomes: SAR of laboratory-confirmed (qRT-PCR) influenza infection amongst household members (secondary infection cases) presenting with ILI within the observation period (8 days from the date of onset). ILI was defined as fever (> 38.0 °C) + cough or sore throat. Nasal wash specimens (or if these were not possible, nasal swabs) from all participating household members Effectiveness: Secondary outcomes: laboratory-confirmed influenza infection in a household contact (secondary infection cases). The study authors defined a symptomatic secondary influenza virus infection as a laboratory-confirmed influenza infection in a household member who developed fever (> 38.0 °C), cough, or sore throat during the observation period. They termed all other secondary cases as subclinical. A

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Suess 2012 *(Continued)*

	secondary outcome measure was the occurrence of ILI as defined by WHO as fever plus cough or sore throat. Safety: study reported that the majority of participants (107/172, 62%) did not report any problems with mask-wearing. This proportion was significantly higher in the group of adults (71/100, 71%) compared to the group of children (36/72, 50%) (P = 0.005). The main problem reported by participants (adults as well as children) was "heat/humidity" (18/34, 53% of children; 10/29, 35% of adults) (P = 0.1), followed by "pain" and "shortness of breath" when wearing a face mask.
Notes	Period study conducted: November 2009 to April 2011 Funding: governmental Adherence: in general, daily adherence was good, reaching a plateau of over 50% in nearly all groups (M and MH groups; 2009/10 and 2010/11) from the third day on (by then the intervention had been implemented in all households). A gradual decline towards lower adherence began around the sixth day of the index patient's illness.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	"prepared lists of random numbers with Microsoft Excel 2003 (Mircosoft™ Cooperation, Seattle, USA) which were divided between the three intervention groups. Each participating physician received a list of random numbers with the interventions represented in a 1:1:1 ratio"
Allocation concealment (selection bias)	Low risk	"the participating physician received a list of random numbers with the interventions represented in a 1:1:1 ratio. Eligible index patients were randomly assigned a number, which was then communicated to the study center. The resulting intervention was only communicated to the households with the physicians. Intervention material was given to the study sites in closed boxes marked only with the randomisation number. Recruiting physicians were not aware of the allocation of the numbers to the interventions and the boxes for the three intervention arms looked identical. After randomisation, participants were given their box by the physician's assistants"
Blinding of participants and personnel (performance bias) All outcomes	Unclear risk	Outcomes are very objective and therefore unlikely to be influenced by lack of blinding. In addition, “physicians (as well as laboratory personnel) blinded from the randomisation results”.
Blinding of outcome assessment (detection bias) All outcomes	Low risk	“physicians (as well as laboratory personnel) blinded from the randomisation results”. Outcomes are very objective and therefore unlikely to be influenced by lack of blinding.
Incomplete outcome data (attrition bias) All outcomes	Low risk	No loss to follow-up. Daily follow-up home visits over the short period of data collection (8 days)
Selective reporting (reporting bias)	Low risk	The follow-up period is very short (8 days) with very good coverage, and the criteria for defining the outcome are highly objective. All planned outcomes were reported.

Suess 2012 *(Continued)*

Methods	Cluster-RCT, open-label, parallel design
Participants	Study sample included 84 households randomised as follows: 1. 30 control (index cases = 30, household contact = 82) 2. 26 mask group (index cases = 26, household contact = 69) 3. 28 mask and hand hygiene group (index cases = 28, household contact = 67) Inclusion criteria: patients presenting to general practitioners or family physicians at the study sites within 2 days of symptom onset; had a positive rapid antigen test for influenza (later to be confirmed by quantitative RT-PCR (qRT-PCR); and was at least 2 years old. Index cases also had to be the only household member suffering from respiratory disease within 14 days prior to symptom onset. Exclusion criteria were pregnancy, severely reduced health status, and HIV infection. 1-person households were also not eligible or inclusion.
Interventions	Quote: "facemask and practising intensified hand hygiene (MH group), wearing facemask only (M group) and none of the 2 (control group)". See Table 1 for details.
Outcomes	Primary outcomes: SAR of laboratory-confirmed (qRT-PCR) influenza infection amongst household members (secondary infection cases) presenting with ILI within the observation period (8 days from the date of onset). ILI was defined as fever (> 38.0 °C) + cough or sore throat. Nasal wash specimens (or if these were not possible, nasal swabs) from all participating household members Effectiveness: Secondary outcomes: laboratory-confirmed influenza infection in a household contact (secondary infection cases). The study authors defined a symptomatic secondary influenza virus infection as a laboratory-confirmed influenza infection in a household member who developed fever (> 38.0 °C), cough, or sore throat during the observation period. They termed all other secondary cases as subclinical. A secondary outcome measure was the occurrence of ILI as defined by WHO as fever plus cough or sore throat. Safety: study reported that the majority of participants (107/172, 62%) did not report any problems with mask-wearing. This proportion was significantly higher in the group of adults (71/100, 71%) compared to the group of children (36/72, 50%) (P = 0.005). The main problem reported by participants (adults as well as children) was "heat/humidity" (18/34, 53% of children; 10/29, 35% of adults) (P = 0.1), followed by "pain" and "shortness of breath" when wearing a face mask.
Notes	Period study conducted: November 2009 to April 2011 Funding: governmental Adherence: in general, daily adherence was good, reaching a plateau of over 50% in nearly all groups (M and MH groups; 2009/10 and 2010/11) from the third day on (by then the intervention had been implemented in all households). A gradual decline towards lower adherence began around the sixth day of the index patient's illness.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	"prepared lists of random numbers with Microsoft Excel 2003 (Mircosoft™ Co-operation, Seattle, USA) which were divided between the three intervention groups. Each participating physician received a list of random numbers with the interventions represented in a 1:1:1 ratio"
Allocation concealment (selection bias)	Low risk	"the participating physician received a list of random numbers with the interventions represented in a 1:1:1 ratio. Eligible index patients were randomly assigned a number, which was then communicated to the study center. The resulting intervention was only communicated to the households with the

Suess 2012 *(Continued)*

		physicians. Intervention material was given to the study sites in closed boxes marked only with the randomisation number. Recruiting physicians were not aware of the allocation of the numbers to the interventions and the boxes for the three intervention arms looked identical. After randomisation, participants were given their box by the physician's assistants"
Blinding of participants and personnel (performance bias) All outcomes	Unclear risk	Outcomes are very objective and therefore unlikely to be influenced by lack of blinding. In addition, "physicians (as well as laboratory personnel) blinded from the randomisation results".
Blinding of outcome assessment (detection bias) All outcomes	Low risk	"physicians (as well as laboratory personnel) blinded from the randomisation results". Outcomes are very objective and therefore unlikely to be influenced by lack of blinding.
Incomplete outcome data (attrition bias) All outcomes	Low risk	No loss to follow-up. Daily follow-up home visits over the short period of data collection (8 days)
Selective reporting (reporting bias)	Low risk	The follow-up period is very short (8 days) with very good coverage, and the criteria for defining the outcome are highly objective. All planned outcomes were reported.

Talaat 2011

Study characteristics	
Methods	Cluster-RCT
Participants	Children (N = 44,451) in the first 3 primary grades from 60 governmental elementary schools in Cairo, Egypt were included and randomised to 30 schools in the intervention arm (N = 20,882 students) and 30 control schools (N = 23,569 students). No exclusion criteria provided.
Interventions	Students were required to wash their hands at least twice during the school days for about 45 seconds, followed by proper rinsing and drying on a clean towel. Campaign material was developed, and posters were placed near sinks in the classroom and playground to encourage hand-washing with soap and water upon arriving at school, before and after meals, using the bathroom, and after coughing and sneezing. See Table 1 for details.
Outcomes	Laboratory: point-of-care influenza A and B viruses using QuickVue (QuickVue; Quidel Corp., San Diego, CA, USA). School nurses collected nasal swabs from children who visited the school clinic with ILI, and only for students who had prior written approval of a parent. Effectiveness: rates of absenteeism caused by ILI and laboratory-confirmed influenza. ILI defined as fever > 38 °C and either cough or sore throat. Safety: none planned or reported by the investigators
Notes	The period study conducted: 16 February to 12 May 2008 Funding: unclear

Risk of bias		
Bias	**Authors' judgement**	**Support for judgement**

Temime 2018

Study characteristics	
Methods	2-arm cluster-RCT
Participants	All residents and staff of 27 privately held chains of nursing homes owned by Korian. 26 nursing homes (13 per arm), with an average of 80 residents per nursing home, were included in the study.
Interventions	"The intervention was based on a bundle of HH-related measures aimed at NH staff, residents, visitors, and outside care providers. These measures included facilitated access to handrub solution using pocket-sized containers and new dispensers, a campaign to promote HH with posters and event organization, the formation of local work groups in each NH to work on HH guidelines, and staff education using e-learning on infection control and HH training performed by the same nurse for all NHs." See Table 1 for details.
Outcomes	Laboratory: none used Effectiveness: Primary outcomes: incidence rate of ARIs and AGE reported in the context of episodes of clustered cases, defined as at least 5 cases within 4 days amongst nursing home residents or staff. ARIs were defined as the combination of at least 1 respiratory symptom with 1 symptom of systemic infection. AGE was defined as the sudden onset of diarrhoea or vomiting in the absence of a non-infectious aetiology.

Turner 2004a *(Continued)*

Methods	Double-blind RCT conducted by Hill Top Research, Inc., Winnipeg, Canada, to assess the efficacy of acids with virucidal activity for the inactivation of virus and prevention of experimental rhinovirus colds. Participants in good health, aged 18 to 60, were recruited from Winnipeg and surrounding communities for participation. Qualified participants were randomised to treatment with vehicle (62% ethanol, 1% ammonium lauryl sulphate, and 1% Klucel), vehicle containing 3.5% salicylic acid, or vehicle containing 1% salicylic acid and 3.5% pyroglutamic acid. The volunteers' hands were disinfected, and then test product was applied to both hands of participant. 15 minutes after application, the fingerprints of each hand were contaminated with rhinovirus type 39. The volunteers touched conjunctiva and the nasal mucosa only with the right hand. Viral contamination of the fingers was assessed in the left hands of the volunteers, and viral infection was assessed by culture of nasal lavage specimens and blood samples.
Participants	85 volunteers; 31 control group, 27 used vehicle with 3.5% salicylic acid, 27 used vehicle with 1% salicylic acid and 3.5% pyroglutamic acid
Interventions	Use of salicylic acid versus salicylic acid and pyroglutamic acid versus "placebo" substance
Outcomes	Laboratory: yes Effectiveness: rhinovirus type 39 infection Safety: N/A
Notes	Risk of bias: unclear (no description of randomisation process, concealment or allocation) Note: the authors concluded that organic acids commonly used in over-the-counter skin care and cosmetic products have substantial virucidal activity against rhinovirus. These preparations provided effective residual antiviral activity on the hands. The virucidal effect of these hand treatments resulted in a reduction in the incidence of rhinovirus infection in the treated volunteers (P = 0.025). The utility of this observation in the natural setting remains to be determined. The volunteers were not allowed to use their hands in the interval between the hand treatment and the virus challenge, so the effect of normal use of the hands on the virucidal activity of these organic acids is not known. Similarly, the virus challenge method used in these experiments may not simulate the natural setting in all aspects. The effect of nasal secretions that would be transferred with the virus in the natural setting on the activity of the acids or on the transmission of virus was not tested in the model. We are unsure as to the practical significance of this study and the generalisability of its results to the real world. Poorly reported study

Turner 2004b

Study characteristics

Methods	Double-blind RCT conducted by Hill Top Research, Inc., Winnipeg, Canada, to assess the residual virucidal activity of a skin cleanser wipe and its effectiveness in preventing experimental rhinovirus colds. Participants in good health, aged 18 to 60 years, were recruited from Winnipeg and surrounding communities for participation. The residual activity of a skin cleanser wipe containing 4% pyroglutamic acid formulated with 0.1% benzalkonium chloride was tested. The negative control treatment was 62% ethanol. Benzalkonium chloride had been previously tested and was found to have no virucidal activity. Volunteers were randomly assigned to use the control preparation or the active preparation. The study material was applied to hands with a towelette. 15 minutes later, when the fingers were completely dry, the fingertips of each hand of the control participants and the volunteers in the active treatment group were contaminated with rhinovirus type 39. An additional volunteer in the active group was challenged with virus 1 hour after application, and the final group of volunteers was challenged 3 hours after application. Viral infection was assessed by culture of nasal lavage specimens and blood samples.
Participants	122 volunteers; 30 in control group, 92 in active group (30 tested after 15 minutes, 30 after 1 hour, 32 after 2 hours)
Interventions	Use of a skin cleanser wipe containing 4% pyroglutamic acid formulated with 0.1% benzalkonium chloride versus skin cleanser wipe containing ethanol
Outcomes	Laboratory: yes Effectiveness: rhinovirus type 39 infection Safety: N/A
Notes	Risk of bias: unclear (no description of randomisation process, concealment or allocation)

Selective reporting (reporting bias)	High risk	Poorly reported

Turner 2012

Study characteristics

Methods	Randomised controlled clinical trial
Participants	A total of 212 participants were enrolled (116 in the treatment group, 96 in the control group). Healthy adult volunteers aged > 18 years from the University of Virginia community Written informed consent was obtained, and volunteers were compensated for participation. Exclusion: individuals with skin conditions that would interfere with safety evaluations or medical conditions that could impact the person's well-being or affect study results, and those whose occupations required frequent hand-washing
Interventions	Antiviral hand treatment containing 2% citric acid, 2% malic acid, and 62% ethanol (n = 116) or to a no-treatment control group (n = 96). The hand treatment was applied every 3 hours and after hand-washing whilst the participants were awake. See Table 1 for details.
Outcomes	Laboratory: PCR using AmpliTaq Gold DNA Polymerase from Applied Biosystems Effectiveness: reduction of rhinovirus-induced common colds; comparison of the number of RV-associated illnesses per 100 participants in the control group with that in the treatment group over 9 weeks. Definitions: a common cold illness was defined as the presence of any of the symptoms of nasal obstruction, rhinorrhoea, sore throat, or cough on at least 3 consecutive days. Illnesses separated by at least 3 symptom-free days were considered to be separate illnesses. Rhinovirus infection was defined as the detection of RV in nasal lavage. All volunteers were seen weekly for nasal lavage, and specimens were assayed by PCR for the presence of RV. PCR–positive specimens separated by at least 8 days and at least 1 negative PCR specimen were considered to be separate infections. RV-associated illnesses were based on detection of RV either at the time of the illness or at the first weekly visit after the illness. Safety: hand irritation occurred in 11 of the 116 volunteers (9%) in the treatment group, which met protocol criteria for removal from the study. An additional 8 participants who did not meet these protocol criteria voluntarily withdrew due to hand irritation. There was no hand irritation in the control group. No other adverse effects of the study treatment were noted.

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	"A randomization code generated using commercially available software was provided by the sponsor"
Allocation concealment (selection bias)	Low risk	"staff at the study site assigned sequential subject numbers as they enrolled volunteers into the study, and treatment assignment was determined by the subject number."
Blinding of participants and personnel (performance bias) All outcomes	Low risk	The outcomes are unlikely to be influenced by lack of blinding.
Blinding of outcome assessment (detection bias) All outcomes	Low risk	"Personnel who conducted the laboratory assays were blinded to study groups and to whether the specimen was from a routine or illness related visit"
Incomplete outcome data (attrition bias) All outcomes	Low risk	Attrition (and reasons for it) was reported. Study outcomes reported as ITT and PP.
Selective reporting (reporting bias)	Low risk	All planned outcomes in study protocol were reported on.

White 2001

Study characteristics

Methods	Double-blind, placebo-controlled, cluster-RCT that took place in 3 schools in California during March to April 1999. The study assessed the incremental value of using an alcohol hand rub together with water-and-soap hand-washing. Both arms were administered an educational programme beginning 2 weeks prior to start of the trial. Randomisation was by classroom, and the placebo hand rub was indistinguishable from the active ingredient. Details of randomisation are not given.
Participants	Of the 72 classes originally recruited, lack of compliance (use of supplementary product at least 3 times a day) reduced the classes to 32 (16 in both arms) and a total of 769 participants aged 5 to 12 (381 students who received the sanitiser, and 388 who received the placebo).
Interventions	Pump-activated antiseptic hand rub with benzalkonium chloride (SAB) (Woodward Laboratories) or inert placebo that "virtually" looked the same in batches of 4 colour-coded bottles. School staff, parents, and participants were blinded.
Outcomes	Laboratory: testing of virucidal and bactericidal activity of the active compound Effectiveness: ARI (cough, sneezing, sinus trouble, bronchitis, fever, red eye, headache, mononucleosis, acute exacerbations of asthma) Gastrointestinal and other illnesses (data not extracted) Follow-up and observation was carried out by classroom staff, and illnesses were described by parents.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

White 2001 *(Continued)*

	Safety: 7 students dropped out because of mild sensitivity to the rub
Notes	Risk of bias: high (no description of randomisation; partial reporting of outcomes, numerators and denominators) Note: the authors conclude that addition of the rub led to a 30% to 38% decrease of illness and absenteeism (RR for illness absence incidence 0.69, RR for absence duration 0.71). Very high attrition, unclear randomisation procedure, educational programme and use of placebo hand rub make generalisability of the results debatable. No confidence intervals reported.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	"randomised trial", but sequence generation not described
Allocation concealment (selection bias)	Unclear risk	Not described
Blinding of participants and personnel (performance bias) All outcomes	Low risk	"To distinguish content, both the active and placebo formulations were distributed in four color-coded groups of 1oz spritz bottles. The content were and distribution patters were only know to the researchers and were indecipherable by the school staff or students."
Blinding of outcome assessment (detection bias) All outcomes	Low risk	"Teachers were responsible for recording attendance for each day during the study"
Incomplete outcome data (attrition bias) All outcomes	High risk	Partial reporting of outcomes, numerators and denominators
Selective reporting (reporting bias)	High risk	Poor reporting

Yeung 2011

Study characteristics

Methods	Clustered-RCT of a hand hygiene intervention involving pocket-sized containers of alcohol-based hand rub for the control of infections in long-term care facilities. Staff hand hygiene adherence was directly observed, and residents' infections necessitating hospitalisation were recorded. After a 3-month preintervention period, long-term care facilities (LTCFs) were randomised to receive pocket-sized containers of alcohol-based gel, reminder materials, and education for all HCWs (treatment group) or to receive basic life support education and workshops for all HCWs (control group). A 2-week intervention period (1 to 15 April 2007) was followed by 7 months of postintervention observations.
Participants	6 out of 7 community-based, private or semiprivate, residential LTCFs in Hong Kong agreed to participate and were randomised to: 1. hand hygiene group (3 LTCFs, 73 nursing staff and 244 residents analysed); or 2. control group (3 LTCFs, 115 nursing staff and 379 residents analysed). All were nursing homes serving an elderly population. All LTCFs were situated in different regions of Hong Kong, including urban and rural areas. The targets of the intervention were all full- and part-time HCWs at these LTCFs.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Yeung 2011 *(Continued)*

	The LTCFs employed 3 types of HCWs: nurses, nursing assistants, and physiotherapists.
Interventions	Pocket-sized containers of alcohol-based gel, reminder materials, and education (intervention group) or basic life-support education and workshop (control group). See Table 1 for details.
Outcomes	Rates of infection (requiring hospitalisation) Outbreaks Death due to infection Diagnoses of infection coded into 6 categories, all of which were common endemic infections in LTCFs: 1. pneumonia, 2. urinary tract infection, 3. septicaemia, 4. skin or soft-tissue infection (including cellulitis or pressure sores), 5. gastroenteritis, and 6. fever. Infections recorded in death certificates were also included, regardless of whether the resident had been hospitalised. The causes of death were categorised as due to infection, not due to infection, or unknown. If the primary or the secondary diagnosis on the death certificate belonged to 1 of the 6 endemic infection categories, the death was coded as due to infection. No safety outcomes reported.
Notes	University and industry funded

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	No details provided.
Allocation concealment (selection bias)	Unclear risk	No details provided.
Blinding of participants and personnel (performance bias) All outcomes	High risk	Unblinded study
Blinding of outcome assessment (detection bias) All outcomes	High risk	Unblinded study
Incomplete outcome data (attrition bias) All outcomes	Low risk	No loss to follow-up
Selective reporting (reporting bias)	Unclear risk	No protocol available

Zomer 2015

Study characteristics	
Methods	Cluster-RCT
Participants	71 daycare centres (36 intervention DCCs, and 35 control) in Rotterdam-Rijnmond, Gouda and Leiden in the Netherlands Study enrolled 545 children (intervention = 278, control = 267). Inclusion/exclusion criteria: children who attended the DCC at least 2 days a week; were aged between 6 months and 3.5 years at start of the trial; intended to attend the DCC throughout the study period; and if their parents consented, were Dutch-speaking, and had access to email or regular post. Children were excluded if they had a chronic illness or medication that predisposed them to infection, a sibling taking part in the trial (i.e. 1 child per family could be included), or if they started attending CCC after the beginning of the trial).
Interventions	4 components: 1. HH products, paper towel dispensers, soap, alcohol-based hand sanitiser, and hand cream were provided for 6 months. 2. Training and a booklet outlining the training. 3. 2 team training sessions aimed at specific HH improvement activities. 4. Posters and stickers for caregivers and children as reminders. See Table 1 for details.
Outcomes	Laboratory: none Effectiveness: incidence of respiratory infections in children monitored by parents. The common cold was defined as a blocked or runny nose with at least 1 of the following symptoms: coughing, sneezing, fever, sore throat, or earache. Safety: none planned or reported by the investigators
Notes	The period study conducted: September 2011 to April 2012 Funding: mixed. The Netherlands Organisation for Health Research and Development (ZonMw). Dispensers and refills were sponsored by SCA Hygiene Products, Sweden.

Risk of bias

Bias	**Authors' judgement**	**Support for judgement**
Random sequence generation (selection bias)	Low risk	"Stratified randomization is performed by assigning each DCC to one of six strata based on size (i.e. small < 46 children per day versus large ≥ 46 children per day) and geographic location (i.e. highly urban versus urban versus slightly/non-urban). DCCs are assigned to either intervention or control group by means of computer generation with a 1:1 ratio in each of the strata"
Allocation concealment (selection bias)	Unclear risk	No information provided.
Blinding of participants and personnel (performance bias) All outcomes	High risk	Outcome is subjective.
Blinding of outcome assessment (detection bias)	High risk	Symptoms were reported by parents, no validation.

Study	Reason for exclusion
Gore 2001	Summary of Dyer 2000. (Dyer 2000 was a prospective, cluster open-label cross-over cohort study included in the previous version of this review (2011). Non-RCTs were removed in this 2020 update).
Gostin 2003	Not an analytical study
Gralton 2010	Review
Guinan 2002	It would appear that 9 classes took part and "acted as their own controls", but it is not clear if there was cross-over of classes or not. In addition, the outcome is combined gastrointestinal/respiratory. The clue lies in the presence of a nested economic analysis which shows considerable savings in time for staff and pupils if the soap is used: in other words this is a (covert) publicity study.
Gupta 2005	Economic model - no new data
Gwaltney 1982	No breakdown of cases given by arm.
Han 2003	Non-comparative
Hayden 1985	This is an RCT with laboratory-induced colds, small numbers, and uncertain numerators, but almost certainly because of the unique laboratory conditions (placebo tissues not being a placebo at all) of impossible generalisation. It was a pilot to the far bigger trial by Farr 1988a; Farr 1988b.
Hendley 1988	Inappropriate intervention
Hens 2009	Model
Heymann 2009	Already included in review as Heymann 2004. (Heymann 2004 was a controlled before and after study included in the previous version of this review (2011). Non-RCTs were removed in this 2020 update).
Hilburn 2003	No ARI/viral outcomes (e.g. URTIs)
Hilmarsson 2007	Animal study
Hirsch 2006	Study tested pharmacological interventions.
Ho 2003	Descriptive review
Hsieh 2007	Mathematical model
Hugonnet 2007	Letter without any data
Jiang 2003	2 papers that are probably different versions of the same paper: Jiang SP, Huang LW, Wang JF, Wu W, Yin SM, Chen WX, et al. A study of the architectural factors and the infection rates of healthcare workers in isolation units for severe acute respiratory syndrome. Chung-Hua Chieh Ho Ho Hu Hsi Tsa Chih [Chinese Journal of Tuberculosis & Respiratory Diseases]. 26(10):594-7, 2003 Oct
Johnson 2009	Outcomes are non-clinical.
Jones 2005	Historical account
Kaydos-Daniels 2004	Not an analytical study
Kelso 2009	Model

NCT03454009

Study name	Appropriate time-interval application of alcohol hand gel on reducing influenza-like illness among preschool children: a randomized, controlled trial
Methods	This is a comprehensive randomised cluster hand-hygiene improvement intervention to reduce self-reported ARI/ILI and GI illness, absenteeism, presenteeism and related behavioural and attitudinal change over a 90-day trial. The intervention group will receive hand hygiene supplies and a variety of educational materials, including environmental posters in common areas. The control group will perform their usual hygiene activities and will not receive an intervention. Identical weekly surveys will be administered to the intervention and control groups to measure self-reported illness, absenteeism, presenteeism, along with behaviour and attitudes measured at specified intervals during the study. The intervention and control groups were randomised by work floors before the onset of the enrolment period. It is hypothesised that employees in the intervention group will experience reduced self-reported illness, absenteeism, and presenteeism along with improved protective hygiene behaviours and related attitudes, relative to those in the control group over the 90-day trial.
Participants	Inclusion criteria: 1. At least 18 years of age or older 2. No known allergies to alcohol or surface disinfecting wipes 3. Works at least 30% of office hours at the study host site 4. Consent to receiving emails from Kent State University Exclusion criteria: 1. Under 18 years of age 2. Known allergies to alcohol or surface disinfecting wipes 3. Works less than 30% of office hours at the study host site 4. Does not consent to receiving emails from Kent State University
Interventions	The intervention group will receive hand hygiene supplies and a variety of educational materials, including environmental posters in common areas. The control group will perform their usual hygiene activities and will not receive an intervention.
Outcomes	Self-reported ARI/ILI and GI illness, absenteeism, presenteeism and related behavioural and attitudinal change over a 90-day trial
Starting date	5 February 2018
Contact information	Maggie Stedman-Smith, PhD, Kent State University College of Public Health

NCT04267952

Study name	Hand hygiene intervention program on primary school students' health outcomes and absenteeism in school
Methods	Study Type: interventional (clinical trial) Estimated enrolment: 200 participants Allocation: randomised Intervention model: parallel assignment Masking: single (participant) Masking description: participation will not know whether they are in the experimental or control group
Participants	Inclusion criteria: primary school student (especially third- and fourth-class student) Exclusion criteria: people with chronic disease
Interventions	Experimental: first group Hand hygiene intervention programme prepared by using planned behaviour theory will be applied to the students in this group. Active comparator: second group Students in this group will be given classic hand hygiene training.
Outcomes	Primary outcome measure: children with symptoms of infection will be referred to the family physician to have a rapid antigen test and to report the result to the researcher. 10 identified upper respiratory tract symptoms (fever, sore throat, runny nose, etc.) will be recorded weekly by family of children. The researcher will receive symptom information from the family via weekly SMS. The number of days the child does not attend school due to illness and the percentage of absenteeism 1. Group A streptococcal infections in rapid antigen test (time frame: total 20 weeks) 2. Incidence of symptoms of acute upper respiratory tract infection (time frame: total 20 weeks) 3. School absenteeism (time frame: total 20 weeks) Secondary outcome measures: Glogerm gel applied hands will shine areas containing micro-organisms. Contamination rate will be calculated by taking a photo of the hands and performing brightness analysis in Adobe Photoshop program. 1. Pollution rate of hands (time frame: from date of randomisation until the date of first documented progression assessed up to 7 months)
Starting date	9 September 2019
Contact information	Contact: Uyanık +905068949969; gulcinyelten@hotmail.com
Notes	Recruitment is ongoing. Last update in ClinicalTrials.gov was 13 February 2020. NCT04267952

NCT04296643

Study name	Medical masks vs N95 respirators for COVID-19

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

NCT04296643 *(Continued)*

Methods	A RCT in which nurses will be randomised to either medical masks or N95 respirators when providing medical care to patients with COVID-19. This Canadian multicentre RCT will assess whether medical masks are non-inferior to N95 respirators when nurses provide care involving non-aerosol generating procedures. Nurses will be randomised to either use of a medical mask or to a fit-tested N95 respirator when providing care for patients with febrile respiratory illness. The primary outcome is laboratory confirmed COVID-19 amongst nurse participants.
Participants	Inclusion criteria: 1. Nurses who work > 37 hours per week in medical, emergency, paediatric units Exclusion criteria: 1. Nurses with 1 or more comorbidities 2. Nurses who cannot pass an N95 respirator fit-test
Interventions	Experimental: medical mask Medical mask worn when providing care to patient with febrile respiratory illness Active comparator: N95 respirator N95 respirator worn when providing care to patient with febrile respiratory illness
Outcomes	Primary outcome measures: 1. Number of participants with RT-PCR confirmed COVID-19 infection 2. RT-PCR confirmed COVID-19 infection (time frame: 6 months) Secondary outcome measures: 1. Number of participants with acute respiratory illness 2. Number of participants with absenteeism 3. Number of participants with lower respiratory infection 4. Number of participants with pneumonia 5. Number of participants with ICU admission 6. Number of participants needing mechanical ventilation 7. Number of participants that died
Starting date	Started 2 April 2020

Notes	NCT04296643

NCT04337541

Study name	Reduction in COVID-19 infection using surgical facial masks outside the healthcare system
Methods	Parallel RCT
Participants	18 years of age and older. The participants recruited are people working outside of their home, who have not previously been infected with COVID-19 and who do not wear facial masks (e.g. healthcare personnel) when working. They will be randomised for: 1. normal behaviour according to the authority's recommendations; or

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

NCT04337541 *(Continued)*

	2. normal behaviour according to the authority's recommendations and use of facial masks.
Interventions	All participants will follow authority recommendations and be randomised to either wear facial masks or not. They will perform swab-test if they experience symptoms during the study as well as at the end of study. Participants will be instructed in using the facial mask consistently when outside their home (and at home when receiving visits from others). The instruction is given in writing and via an instruction video. The participants will be contacted once weekly to optimise compliance. It will be registered if the participants are diagnosed with COVID-19. Participants will perform antibody screening at study start and end. Participants who do not test positive for COVID-19 during the study period will perform a swab self-test if experiencing symptoms or when the study ends (instruction video).
Outcomes	Primary outcome: reduction in COVID-19 infection frequency Secondary outcome: number of participants testing positive in antibody screening at study start and study end, respectively
Starting date	2 April 2020

NCT04471766

Study name	Evaluation of locally produced cloth face mask on COVID-19 and respiratory illnesses prevention at the community level - a cluster-RCT
Methods	Study type: interventional (clinical trial) Estimated enrolment: 66,000 participants Allocation: randomised Intervention model: parallel assignment Masking: single (outcomes assessor) Primary purpose: prevention
Participants	Ages eligible for study: 10 years and older (child, adult, older adult) Sexes eligible for study: all Accepts healthy volunteers: no Criteria Inclusion criteria: 1. Household resident 2. Age 10 years and older Exclusion criteria: 1. Refusal to participate
Interventions	Experimental: certified cloth face mask plus preventive information

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

NCT04471766 *(Continued)*

	Active comparator: information on COVID-19 prevention
Outcomes	Self-reported main symptoms of COVID-19 (3 or more of fever, cough, fatigue, shortness of breath, loss of smell/taste) Consultation for COVID-19 like illness or reported positive test, or both Self reported COVID-19 like illness plus hospitalisation or death Any death during the follow-up period: 1. Reported COVID-19 like illness (time frame: 4 months' follow-up) 2. Consultation (time frame: 4 months' follow-up) 3. Severe illness (time frame: 4 months' follow-up) 4. Mortality (time frame: 4 months' follow-up)
Starting date	Estimated study start date: July 2020
Contact information	Amabelia Rodrigues, PhD, 00245966078659; a.rodrigues@bandim.org
Notes	The number of cases of COVID-19 is still increasing, and transmission of SARS-CoV-2 seems to occur mainly through person-to-person transmission through respiratory droplets, indirect contact with infected people and surfaces. The use of face masks is recommended as a public health measure, but in many settings only domestic cloth made masks are available to the majority of the people. However, masks can be of different quality, and very little is known about the utility of cloth face masks at the community level. In Bandim Health Project's Health and Demographic Surveillance System we will evaluate the effect of providing locally produced cloth face masks on the severity of COVID-19 like illness and mortality in an urban population. The locally produced cloth mask is made according to a laboratory-certified model and will be provided to the intervention group alongside information of how the risk of transmission can be reduced. The control group will receive information alone. Follow-up will be implemented through telephone calls and postepidemic home visits.

Wang 2015

Study name	A cluster-RCT to test the efficacy of face masks in preventing respiratory viral infection among Hajj pilgrims
Methods	Cluster-randomised trial, randomising worshippers' accommodation tents during several seasons of the Hajj pilgrimage in Saudi Arabia. In the intervention tents, free face masks will be distributed to be worn for 7 days.
Participants	Pilgrims to the Hajj
Interventions	Standard surgical masks distributed free of charge to pilgrims in the intervention accommodation tents. Control group receives no intervention.
Outcomes	Flu-like illness, recorded in diaries, with laboratory confirmation where possible
Starting date

Table 1. Description of interventions in included studies, using the items from the Template for Intervention Description and Replication (TIDieR) checklist

Author, year	Brief name	Recipient	Why	What (materials)	What (procedures)	Who provided	How	Where	When and how much	Tailoring	Modification of intervention throughout trial	Strategies to improve or maintain intervention fidelity	Extent of intervention fidelity
Masks compared to either no masks or different mask types													
Barasheed 2014	Supervised mask use	Religious pilgrims ≥ 15 years	Prevent respiratory virus infections at mass gatherings through mask use	Plain surgical face masks (3M Standard Tie-On Surgical Mask, Cat No: 1816) manufactured by 3M company, USA; 5 masks per day Written instructions on face mask use Special polythene bags for disposal	Masks provided to index case and their contacts with advice on mask use (before prayers, in seminars, and after meals). Written instructions provided on face mask use, need to change them, and disposal.	Not described, presumably the medical researchers	Face-to-face provision of masks, instructions, and reminders	Tents of pilgrimage site (Mina Valley, Saudi Arabia)	Advice on mask use given throughout pilgrimage stay (5 days)	None reported.	None reported.	The medical researchers followed pilgrims each day to remind participants about recording their mask usage in health diary.	Face mask use: mask group: 56/75 (76%), control group: 11/89 (12%) (P < 0.001) 76% of intervention tents wore masks. 10 of 75 (13%) pilgrims in 'mask' tents wore face masks during sleep.
Canini 2010	Surgical face masks	Householders (over 5 years)	Limit transmission of influenza transmission by large	Initial supply of 30 masks: for adults and children > 10: surgery masks with earloops, 3 plys, anti fog (AEROKYN, LCH medical products, Paris, France)	Masks given immediately on home visit by attending general practitioner with demonstration of proper use	General practitioners	Face-to-face individually	Households in France	One-off provision of masks worn for 5 days	None described.	None described.	Not described, but reported mask usage was measured	34/51 (66%) wore masks > 80% of the duration.

											hy-giene.		
Priest 2014	Hand sanitiser provision (in addition to hand hygiene education session also provided to control group)	Primary schools and their students, teachers, and administrative staff	Reduce person-to-person community transmission of infectious disease by targeting improved and additional hand hygiene of school children through supervised hand sanitiser provision as an alternative to improving and maintaining bathroom facilities	‘‘No touch’’ dispensers (> 60% ethanol) for each classroom that dispensed dose when hands were placed under an infrared sensor Supply of top-up sanitiser as needed	Dispensers installed into each classroom. Teachers asked to ensure that the children used sanitiser at particular times and to oversee general use (McKenzie 2010). Weekly classroom visits to top-up of sanitiser and measure quantity used 30-minute in-class hand hygiene education session provided (also to control group) plus instruction in hand sanitiser use.	School liaison research assistants topped-up sanitiser. Teachers	Installation of dispensers to classrooms Supervision of children by teachers delivered face-to-face individually and as a class.	City schools in New Zealand	20 weeks (2 school terms) Sanitiser to be used by students at least after coughing/sneezing, blowing their nose, and as they leave for morning break and for lunch break. Approximately 0.45 mL of sanitiser dispensed per wash. Weekly top-up of sanitiser	Children were able to use the sanitiser at any time they wished as well as at key times (McKenzie 2010).	Change of sanitiser after week 10 to flavourless type of the same % ethanol in 41 of 396 classrooms (10%) (in 9 of 34 schools) due to children tasting it when eating, affecting use.	Weekly classroom visits by school liaison research assistants who recorded quantity of sanitiser used Total amount of sanitiser per classroom was measured. Compliance defined as dispensing a volume equivalent to at least 45 mL per child of hand sanitiser solution over the trial period.	100% dispensing 45 mL per child Average hand sanitiser dispensed/child for 34 schools: 94 mL Median classroom difference in sanitiser usage between first 10 weeks and second 10 weeks amongst classes that switched products was 220 mL.

Najnin 2019 (see also Qadri 2015 for further details)	2 active interventions: A. Combined cholera vaccine and 'behaviour change communication' intervention B. Cholera vaccine-alone group	Low-income households and compounds	Prevent or reduce transmission of respiratory illness based on the Integrated Behavioural Model for Water Sanitation and Hygiene (IBM-WASH) theoretical framework (Dreibelbis 2013; Hulland 2013)	A. and B. Cholera vaccine ShanChol™ (Shantha Biotechnics-Sanofi, India) A. Following hardware per compound: a. Hand-washing hardware: (i) Bucket with a tap (provided free of charge) (ii) Soapy water bottle (mixture of a commercially available sachet of powdered detergent (~USD 0.03) with 1.5 L of water in a plastic bottle with a hole punched in the cap) supplied by participating compounds (iii) Bowl to collect rinse water after washing hands (see photo in text or in Najnin 2017 doi.org/10.1093/ije/dyx187) b. Water treatment hardware:	A. and B. Provision of cholera vaccine (2 doses at least 14 days apart) Provision of hand-washing hardware and behaviour change communication activities Encouragement of hand-washing after defecation, after cleaning child's anus, and before preparing food Encouragement to add chlorine to own water vessels Benefits were again explained. Follow-up visits by health promoters	Dushtha Shasthya Kendra (DSK), an NGO, delivered the hardware and behavioural intervention (through community health promoters). Separate data collectors observed soap avail-	Handwashing and water treatment hardware mostly delivered at the compound level in person. Behaviour change communication messages were delivered both at	Households and compounds (where several households share a common water source, kitchen, and toilets) in Bangladesh	Behaviour change communication messages delivered first (within 3 months of cholera vaccination). Point-of-use water hardware provided 3 months later. Follow-up health promoter visits 3 times in 2 months after hardware installation, then 2 times/month (over nearly 2 years).	Hardware-related problems (breakage/leakage) were addressed on health promoter follow-up visits.	None described.	Unannounced home visits by data collectors who observed presence of soap/soapy water and water in most convenient place for handwashing (either reserved in a container or available at the tap) Residual chlorine was measured indicating uptake of chlorine dispenser.	Presence of soap / soapy water and water: A. Handwashing group compounds: 45% (1,729 / 3,886); B. Vaccine-only group compound: 22% (438 / 1,965); C. Control: 28% (556 / 1991) Residual chlorine present in stored drinking water of 4% (160/3886) of households in the vac-

							also not described.						
Ide 2014	2 active interventions (no control): A. Green tea gargling B. Water gargling	High school students	Prevent influenza spread and infection in high school students who are at increased risk from close interaction through gargling as a non-pharmaceutical intervention, specifically green tea containing highly bioactive catechin (-)-epigallocatechin gallate, with possible anti-influenza virus properties	A. Bottled green tea (500 mL) containing a catechin concentration of 37 ± 0.2 mg/dL, including approximately 18% (-)-epigallocatechin gallate (manufactured by the Kakegawa Tea Merchants Association). Concentration measured by high-performance liquid chromatography based on the average concentration in 10 bottles from the same production lot (September 2011) used for gargling in the study. B. Tap water	A. Provision of green tea B. Advice to gargle with tap water and not to gargle green tea during study A. and B. Advice to gargle at least 3 times/day (after arriving at school, after lunch, and after school) Consumption of green tea and other tea was not restricted for either group. Safety monitoring carried out throughout the study (not further described).	Materials supplied by researchers. High schools' vice principals and head teachers assisted with safety monitoring.	Green tea supplied individually to students. Mode of gargling advice not described.	High schools in Japan	Gargling 3 times/day for 90 days	None described.	None described.	Daily questionnaire included questions about daily adherence to gargling regimen. Adherence rate of gargling at or above 75%, and absence of green tea gargling when in the water gargling group.	Gargling adherence rate: green tea group: 73.7%; water group: 67.2%

Table 2. Results from trials of hand hygiene compared to control

Study	Comparison (see Table 1 for details of interventions)	Reported outcomes	Results
Alzaher 2018 cluster-RCT Saudi Arabia	Hand-washing workshop and posters vs usual practice	% absence days due to URI	0.39% and 0.72% in intervention group schools; 0.86% and 1.39% in control schools
Arbogast 2016 cluster-RCT USA	Hand sanitiser + wipes + hand foam vs none Both groups received education + signage about hand-washing	1. Health insurance claims for preventable illnesses per employee 2. Absences per employee	1. 0.30 claims in intervention; 0.37 in control (27% relative reduction; P = 0.03) 2. 1.45 in intervention; 1.53 in control (5.0% relative reduction in intervention; P = 0.30)
Azor-Martinez 2016 RCT Spain	Hand-washing with soap and water plus hand sanitiser vs usual hand-washing practices	% absence days due to URI	1.15% in intervention; 1.68% in control. Significantly lower in intervention (P < 0.001)
Azor-Martinez 2018 cluster-RCT Spain	Education and hand hygiene with soap and water vs hand hygiene with sanitiser vs usual hand-washing procedures	1. URI incidence rate ratio (primary) 2. Percentage difference in absenteeism days	1. HH soap vs control 0.94 (95% CI 0.82 to 1.08); HH sanitiser vs control 0.77 (95% CI 0.68 to 0.88); HH soap vs HH sanitiser 1.21 (95% CI 1.06 to 1.39) 2. HH soap 3.9% vs control 4.2% (P < 0.001); HH sanitiser 3.25% vs control 4.2% (P = 0.026); HH soap 3.9% vs HH sanitiser 3.25% (P < 0.001)
Biswas 2019 cluster-RCT Bangladesh	Hand sanitiser and respiratory hygiene education and cough/sneeze hygiene vs no intervention	1. ILI incidence rate (at least 1 episode) 2. Laboratory-confirmed influenza	1. 22 per 1000 student-weeks in intervention; 27 per 1000 student-weeks in control, not statistically significantly different 2. 3 per 1000 student-weeks in intervention; 6 per 1000 student-weeks in control, P = 0.01
Correa 2012 cluster-RCT Colombia	Alcohol-based hand sanitiser in addition to hand-washing vs usual hand-washing practice	ARIs in 3rd trimester of follow-up	Hazard ratio for intervention to control 0.69 (95% CI 0.57 to 0.83)
Cowling 2008 cluster-RCT Hong Kong	Hand hygiene (36 households) vs face mask (mask) vs education (control)	Secondary attack rate for: 1. laboratory-confirmed influenza; 2. ILI definition 1; 3. ILI definition 2; 4. ILI definition 3.	1. HH 0.06; mask 0.07; control 0.06 2. HH 0.18; mask 0.18; control 0.18 3. HH 0.11; mask 0.10; control 0.11 4. HH 0.04; mask 0.08; control 0.04
Cowling 2009 cluster-RCT Hong Kong	Hand hygiene (HH) vs face mask + hand hygiene (HH + mask) vs education (control)	Secondary attack rate for: 1. laboratory-confirmed influenza;	1. HH 5; HH + mask 7; control 10 2. HH 16; HH + mask 21; control 19 3. HH 4; HH + mask 7; control 5

Table 8. Summary of main results of the review for the primary outcomes

Interventions	RCT/cluster-RCT (N = 67)
Medical/surgical masks	**Masks (medical/surgical) compared to no masks** 9 trials no effect on ILI (RR 0.99, 0.82 to 1.18) (Aiello 2010; Barasheed 2014; Canini 2010; Cowling 2008; Jacobs 2009; MacIntyre 2009; MacIntyre 2015; MacIntyre 2016; Suess 2012); 6 trials no effect on laboratory-confirmed influenza 95% CI RR 0.84 (0.61 to 1.17) (Aiello 2012; Cowling 2008; MacIntyre 2009; MacIntyre 2015; MacIntyre 2016; Suess 2012); 2 trials in HCWs no effect on ILI (RR 0.37, 0.05 to 2.50) (Jacobs 2009; MacIntyre 2015). **Medical/surgical masks vs other (non-N95) masks:** 1 trial more ILI with cloth mask (RR 13.25, 1.74 to 100.97) (MacIntyre 2015); 1 trial no effect of catechin-treated masks on influenza (adjusted OR 2.35, 0.40 to 13.72) (Ide 2016).
N95 respirator	**N95 respirators compared to medical/surgical masks** 3 trials no difference for clinical respiratory illness (RR 0.70, 0.45 to 1.10) (MacIntyre 2011; MacIntyre 2013; Radonovich 2019); 4 trials no difference for ILI (95% CI RR 0.81, 0.62 to 1.05) (Loeb 2009; MacIntyre 2009; MacIntyre 2011; Radonovich 2019); 4 trials no difference for laboratory-confirmed influenza (95% CI RR 1.06, 0.81 to 1.38) (Loeb 2009; MacIntyre 2009; MacIntyre 2011; Radonovich 2019). 4 studies conducted in HCWs, 3 trials no difference for clinical respiratory illness (RR 0.70, 0.45 to 1.10) (MacIntyre 2011; MacIntyre 2013; Radonovich 2019); 3 trials no difference for ILI (RR 0.64, 0.32 to 1.31) (Loeb 2009; MacIntyre 2011; Radonovich 2019); 3 trials no difference for laboratory-confirmed ILI (RR 1.02, 0.73 to 1.43) (Loeb 2009; MacIntyre 2011; Radonovich 2019).
Hand hygiene	**Hand hygiene compared to control** 16 trials found effect on combined outcome (ARI or ILI or influenza) (RR 0.89, 0.84 to 0.95) (Azor-Martinez 2018; Biswas 2019; Correa 2012; Cowling 2008; Cowling 2009; Hubner 2010; Larson 2010; Little 2015; Millar 2016; Nicholson 2014; Ram 2015; Roberts 2000; Sandora 2005; Simmerman 2011; Stebbins 2011; Zomer 2015); 7 trials effect on ARI (RR 0.84, 0.82 to 0.86) (Azor-Martinez 2018; Correa 2012; Larson 2010; Little 2015; Millar 2016; Nicholson 2014; Sandora 2005); 10 trials no effect on ILI

Table 8. Summary of main results of the review for the primary outcomes *(Continued)*

	(RR 0.98, 0.85 to 1.13) (Biswas 2019; Cowling 2008; Cowling 2009; Hubner 2010; Larson 2010; Little 2015; Ram 2015; Roberts 2000; Simmerman 2011; Zomer 2015); 8 trials no effect on laboratory-confirmed influenza (RR 0.91, 95% CI 0.63 to 1.30) (Biswas 2019; Cowling 2008; Cowling 2009; Hubner 2010; Larson 2010; Ram 2015; Simmerman 2011; Stebbins 2011)
Hand hygiene + medical/surgical masks	**Hand hygiene + medical/surgical masks compared to control** 7 trials no effect on ILI (95% CI RR 0.97, 0.80 to 1.19) (Aelami 2015; Aiello 2010; Aiello 2012; Cowling 2009; Larson 2010; Simmerman 2011; Suess 2012); 4 trials no effect on laboratory-confirmed influenza (RR 0.97, 0.69 to 1.36) (Cowling 2009; Larson 2010; Simmerman 2011; Suess 2012). **Hand hygiene + medical/surgical masks compared to hand hygiene** 3 trials no effect on ILI (RR 1.03, 0.69 to 1.53) or laboratory-confirmed influenza (RR 0.99, 0.69 to 1.44) (Cowling 2009; Larson 2010; Simmerman 2011).
Soap + water compared to sanitiser, and comparisons of different types of sanitiser	**Soap + water compared to sanitiser, and comparisons of different types of sanitiser** 1 trial hand sanitiser was more effective than soap and water (Azor-Martinez 2018); 1 trial there was no difference (Savolainen-Kopra 2012). 2 trials in children antiseptic was more effective (Morton 2004; White 2001); 1 trial in children antiseptic = soap (Luby 2005). 1 trial hand sanitisers were better than placebo, but no difference between sanitisers (Turner 2004a); 1 trial no difference between different wipes (Turner 2004b).
Surface/object disinfection (with or without hand hygiene) compared to control	**Surface/object disinfection compared to control** 2 trials were effective on ARI (Ban 2015; Carabin 1999); 1 trial was effective for viruses detected on surface (Ibfelt 2015); 2 trials showed no difference in ARIs (Kotch 1994; McConeghy 2017).
Disinfection of living quarters	-
Complex interventions	**Complex interventions compared to control** 4 trials in low-income countries found no effect on respiratory viral illness (Chard 2019; Hartinger 2016; Huda 2012; Najnin 2019).
Physical interventions (masks, gloves, gowns combined)	-
Gloves	-
Gowns	-
Physical distancing	-
Quarantine in the community	**Quarantine compared to control** 1 trial effective for influenza (Cox hazard ratio 0.799, 95% CI 0.66 to 0.97) (Miyaki 2011).
Eye protection	-
Gargling	**Gargling compared to control** 1 trial gargling with tap water was effective, povidone-iodine was not effective (Satomura 2005); 1 trial gargling with green tea was not more effective than tap water (Ide 2014); 1 trial gargling with water was not effective (Goodall 2014); pooling of 2 trials no effect of gargling (RR 0.91, 95% CI 0.63 to 1.31) (Goodall 2014; Satomura 2005).
Virucidal tissues	**Virucidal tissues compared to control**

Table 8. Summary of main results of the review for the primary outcomes *(Continued)*

	1 trial had a small effect (Farr 1988a) ("The study authors conclude that virucidal tissues have only a small impact upon the overall rate of natural acute respiratory illnesses"); 2 trials non-significant difference (Farr 1988b; Longini 1988).
Nose wash	-

ARI: acute respiratory infection
CI: confidence interval
HCW: healthcare worker
ILI: influenza-like illness
OR: odds ratio
RCT: randomised controlled trial
RR: risk ratio

Table 9. Trial authors' outcome definitions

	Study	Outcomes definitions
Masks (n = 13)		
1.	Cowling 2008 cluster-RCT Hong Kong	Laboratory: QuickVue Influenza A+B rapid test Viral culture on MDCK (Madin-Darby canine kidney cells) Samples were harvested using NTS, but the text refers to a second procedure from June 2007 onwards with testing for influenza viruses on index participants with a negative QuickVue result but a fever ≥ 38 °C who were also randomised and further followed up. Data on clinical signs and symptoms were collected for all participants, and an additional NTS was collected for later confirmation of influenza infection by viral culture. It is noteworthy that dropout was higher in households of index participants who had a negative result on the rapid influenza test (25/44, 57%) compared to those who had a positive result (45/154, 29%). Effectiveness: secondary attack ratios (SAR): SAR is the proportion of household contacts of an index case who subsequently were ill with influenza (symptomatic contact individuals with at least 1 NTS positive for influenza by viral culture or PCR) 3 clinical definitions were used for secondary analysis: 1. fever ≥ 38 °C or at least 2 of the following symptoms: headache, coryza, sore throat, muscle aches and pains; 2. at least 2 of the following S/S: fever ≥ 37.8 °C, cough, headache, sore throat and muscle aches and pains; and 3. fever of ≥ 37.8 °C plus cough or sore throat. Safety: harms were not mentioned as an outcome in the methods, but it was reported in the results that there were no adverse events.
2.	Jacobs 2009 RCT Japan	Laboratory-confirmation not reported. Effectiveness: URTI is defined on the basis of a symptom score with a score > 14 being a URTI according to Jackson's 1958 criteria ("Jackson score"). These are not explained in text, although the symptoms are listed in Table 3 (any, sore throat, runny nose, stuffy nose, sneeze, cough, headache, earache, feel bad) together with their mean and scores (SD) by intervention arm. Safety: the text does not mention or report harms. These appear to be indistinguishable from URTI symptoms (e.g. headache, which is reported as of significantly longer duration in the intervention arm). Compliance is self-reported as high (84.3% of participants).

Table 9. Trial authors' outcome definitions *(Continued)*

3.	Loeb 2009 cluster-RCT HCW Canada	Clinical respiratory illness, influenza-like illness, and laboratory-confirmed respiratory virus infection. 1. Clinical respiratory illness, defined as 2 or more respiratory symptoms or 1 respiratory symptom and a systemic symptom. 2. Influenza-like illness, defined as fever ≥ 38 °C plus 1 respiratory symptom. 3. Laboratory-confirmed viral respiratory infection. Laboratory confirmation was by nucleic acid detection using multiplex RT-PCR for 17 respiratory viruses. Safety: harms were not mentioned as an outcome in the methods, but it is stated in the results that no adverse events were reported by participants.
4.	MacIntyre 2009 cluster-RCT Australia	Eligibility criteria were stipulated as follows: 1. the household contained > 2 adults > 16 years of age and 1 child 0 to 15 years of age; 2. the index child had fever (temperature > 37.8 °C) and either a cough or sore throat; 3. the child was the first and only person to become ill in the family in the previous 2 weeks; 4. adult caregivers consented to participate in the study; and 5. the index child was not admitted to the hospital. Definitions used for outcomes: 1. ILI defined by the presence of fever (temperature > 37.8 °C), feeling feverish or a history of fever, > 2 symptoms (sore throat, cough, sneezing, runny nose, nasal congestion, headache), or 1 of the symptoms listed plus laboratory confirmation of respiratory viral infection. 2. Laboratory confirmation: multiplex RT-PCR tests to detect influenza A and B and RSV, PIV types 1–3, picornaviruses (enteroviruses or rhinoviruses), adenoviruses, coronaviruses 229E and OC43, and hMPV plus ≥ 1 sym Effectiveness: presence of ILI or a laboratory diagnosis of respiratory virus infection within 1 week of enrolment. Safety: harms not mentioned as an outcome in the methods, but it is reported in the results that more than 50% of participants reported concerns with mask wearing, mainly that wearing a face mask was uncomfortable, but there were no significant differences between the P2 (N95) and surgical mask groups. Other concerns were that the child did not want the parent wearing a mask.
5.	Aiello 2010 cluster-RCT USA	Laboratory details are described in appendix. Effectiveness: ILI, defined as cough and at least 1 constitutional symptom (fever/feverishness, chills, headache, myalgia). ILI cases were given contact nurses phone numbers to record the illness and paid USD 25 to provide a throat swab. 368 participants had ILI, 94 of which had a throat swab analysed by PCR. 10 of these were positive for influenza (7 for A and 3 for B), respectively by arm 2, 5 and 3 using PCR, 7 using cell culture. Safety: no outcomes on harms planned or reported.
6.	Canini 2010 cluster-RCT USA	The primary endpoint was the proportion of household contacts who developed an ILI during the 7 days following inclusion. Exploratory cluster-level efficacy outcome, the proportion of households with 1 or more secondary illness in household contacts. A temperature over 37.8 °C with cough or sore throat was used as primary clinical case definition. The authors also used a more sensitive case definition based on a temperature over 37.8 °C or at least 2 of the following: sore throat, cough, runny nose, or fatigue.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Table 9. Trial authors' outcome definitions *(Continued)*

		Safety: adverse reactions due to mask wearing were reported, with 38 (75%) participants in the intervention arm experiencing discomfort with mask use due to warmth (45%), respiratory difficulties (33%), and humidity (33%). Children wearing children face masks reported feeling pain more frequently than other participants wearing adult face masks (P = 0.036).
7.	Aiello 2012 cluster-RCT in halls of residence in the USA	Clinically verified ILI - case definition (presence of cough and at least 1 or more of fever/feverishness, chills, or body aches) Laboratory-confirmed influenza A or B. Throat swab specimens were tested for influenza A or B using real-time PCR. Safety: no outcomes on harms planned or reported.
8.	Barasheed 2014 cluster-RCT Saudi Arabia	Laboratory: 2 nasal swabs from all ILI cases and contacts. 1 for influenza POCT using the QuickVue Influenza (A+B) assay (Quidel Corporation, San Diego, USA) and 1 for later NAT for influenza and other respiratory viruses. However, there was a problem with getting POCT on time during Hajj. Effectiveness: to assess the effectiveness of face masks in the prevention of transmission of ILI. ILI was defined as subjective (or proven) fever plus 1 respiratory symptom (e.g. dry or productive cough, runny nose, sore throat, shortness of breath). Safety: no outcomes on harms planned or reported.
9.	MacIntyre 2011 cluster-RCT China	Clinical respiratory illness Influenza-like illness Laboratory-confirmed viral respiratory infection Laboratory-confirmed influenza A or B 1. Clinical respiratory illness, defined as 2 or more respiratory or 1 respiratory symptom and a systemic symptom. 2. Influenza-like illness, defined as fever ≥ 38 °C plus 1 respiratory symptom (i.e. cough, runny nose, etc.). 3. Laboratory-confirmed viral respiratory infection (detection of adenoviruses, human metapneumovirus, coronavirus 229E/NL63, parainfluenza viruses 1, 2, and 3, influenza viruses A and B, respiratory syncytial virus A and B, rhinovirus A/B and coronavirus OC43/HKU1 by multiplex PCR). 4. Laboratory-confirmed influenza A or B. 5. Adherence with mask/respirator use. Safety: adherence and adverse effects of mask wearing were collected at exit interviews 4 weeks' poststudy. Significantly higher adverse events with N95 respirator compared to medical mask for discomfort, headache, difficulty breathing, nose pressure, trouble communicating, not wearing, and unspecified "other" side effects. Over 50% of those wearing N95 respirators reported adverse events. Of those wearing medical masks versus N95 respirators, 85.5% (420/491) versus 47.4% (447/943) reported no adverse events (P < 0.001), respectively.
10.	MacIntyre 2013 cluster-RCT China	Laboratory: 1. Laboratory-confirmed viral respiratory infection in symptomatic participants, defined as detection of adenoviruses; human metapneumovirus; coronaviruses 229E/NL63 and OC43/HKU1; parainfluenza viruses 1, 2, and 3; influenza viruses A and B; respiratory syncytial viruses A and B; or rhinoviruses A/B by NAT using a commercial multiplex PCR (Seegen, Inc., Seoul, Korea). 2. Laboratory-confirmed influenza A or B in symptomatic participants.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Table 9. Trial authors' outcome definitions *(Continued)*

		3. Laboratory-confirmed bacterial colonisation in symptomatic participants, defined as detection of *Streptococcus pneumoniae*, *Legionella*, *Bordetella pertussis*, *Chlamydia*, *Mycoplasma pneumoniae*, *or Haemophilus influenzae* type B by multiplex PCR (Seegen, Inc.). Effectiveness: clinical respiratory illness defined as 2 or more respiratory symptoms or 1 respiratory symptom and a systemic symptom. ILI defined as fever (38 °C) plus 1 respiratory symptom. Safety: adverse effects measured using a semi-structured questionnaire. Investigators stated that there was higher reported adverse effects and discomfort of N95 respirators compared with the other 2 arms. In terms of comfort, 52% (297 of 571) of the medical mask arm reported no problems, compared with 62% (317 of 512) of the targeted arm and 38% (217 of 574) of the N95 arm (P < 0.001).
11.	MacIntyre 2015 cluster-RCT Vietnam	Clinical respiratory illness, influenza-like illness, and laboratory-confirmed respiratory virus infection. 1. Clinical respiratory illness, defined as 2 or more respiratory symptoms or 1 respiratory symptom and a systemic symptom. 2. Influenza-like illness, defined as fever ≥ 38 °C plus 1 respiratory symptom. 3. Laboratory-confirmed viral respiratory infection. Laboratory confirmation was by nucleic acid detection using multiplex RT-PCR for 17 respiratory viruses. Safety: adverse events associated with face mask use were reported in 40.4% (227/562) of HCWs in the medical/surgical mask arm and 42.6% (242/568) in the cloth mask arm (P = 0.45). The most frequently reported adverse events were: general discomfort (35.1%; 397/1130) and breathing problems (18.3%; 207/1130). The rate of ILI was higher in the cloth mask arm compared to medical/surgical masks (RR 13.25, 95% CI 1.74 to 100.97).
12.	MacIntyre 2016 cluster-RCT China	Clinical respiratory illness, influenza-like illness, and laboratory-confirmed viral respiratory infection. 1. Clinical respiratory illness, defined as 2 or more respiratory symptoms (cough, nasal congestion, runny nose, sore throat, or sneezes) or 1 respiratory symptom and a systemic symptom (chill, lethargy, loss of appetite, abdominal pain, muscle or joint aches). 2. Influenza-like illness, defined as fever ≥ 38 °C plus 1 respiratory symptom. 3. Laboratory-confirmed viral respiratory infection, defined as detection of adenoviruses, human metapneumovirus, coronaviruses 229E/NL63 and OC43/HKU1, parainfluenza viruses 1, 2, and 3, influenza viruses A and B, respiratory syncytial virus A and B, or rhinovirus A/B by NAT using a commercial multiplex PCR. Safety: no outcomes on harms planned or reported.
13.	Radonovich 2019 cluster-RCT USA	Laboratory. Primary outcome: incidence of laboratory-confirmed influenza, defined as: 1. detection of influenza A or B virus by RT-PCR in an upper respiratory specimen collected within 7 days of symptom onset; 2. detection of influenza from a randomly obtained swab from an asymptomatic participant; and 3. influenza seroconversion (symptomatic or asymptomatic), defined as at least a 4-fold rise in haemagglutination inhibition antibody titres to influenza A or B virus between pre-season and postseason serological samples deemed not attributable to vaccination. Effectiveness. Secondary outcomes: incidence of 4 measures of viral respiratory illness or infection as follows:

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Table 9. Trial authors' outcome definitions *(Continued)*

		1. acute respiratory illness with or without laboratory confirmation; 2. laboratory-detected respiratory infection, defined as detection of a respiratory pathogen by PCR or serological evidence of infection with a respiratory pathogen during the study surveillance period(s), which was added to the protocol prior to data analysis; and 3. laboratory-confirmed respiratory illness, identified as previously described (defined as self-reported acute respiratory illness plus the presence of at least PCR–confirmed viral pathogen in a specimen collected from the upper respiratory tract within 7 days of the reported symptoms and/or at least a 4-fold rise from pre-intervention to postintervention serum antibody titres to influenza A or B virus). Influenza-like illness, defined as temperature of at least 100 °F (37.8 °C) plus cough and/or a sore throat, with or without laboratory confirmation. Safety: 19 participants reported skin irritation or worsening acne during years 3 and 4 at 1 site in the N95 respirator group.
Hand and hygiene (n = 32)		
14.	Alzaher 2018 cluster-RCT Saudi Arabia	Episode of URI was defined as having 2 of the following symptoms for a day or 1 of the symptoms for 2 or more consecutive days: 1) a runny nose, 2) a stuffy or blocked nose or noisy breathing, 3) sneezing, 4) a cough, 5) a sore throat, and 6) feeling hot, having a fever or a chill.
15.	Arbogast 2016 cluster-RCT USA	ICD-9 used: 46611: acute bronchiolitis due to respiratory syncytial virus, 46619: acute bronchiolitis due to other infectious organisms, 4800: pneumonia due to adenovirus, 4809: viral pneumonia, unspecified, 4870: influenza with pneumonia, 07999: unspecified viral infection, 4658: acute upper respiratory infections of other multiple sites, 4659: acute upper respiratory infections of unspecified site, 4871: influenza with other respiratory manifestations.
16.	Azor-Martinez 2016 RCT Spain	Upper respiratory illness was defined as 2 of the following symptoms during 1 day, or 1 of the symptoms for 2 consecutive days: (1) runny nose; (2) stuffy or blocked nose or noisy breathing; (3) cough; (4) feeling hot or feverish or having chills; (5) sore throat; or (6) sneezing.
17.	Azor-Martinez 2018 RCT Spain	Respiratory illness (RI) was defined as the presence of 2 of the following symptoms during 1 day or the presence of 1 of the symptoms for 2 consecutive days: (1) runny nose, (2) stuffy or blocked nose or noisy breathing, (3) cough, (4) feeling hot or feverish or having chills, (5) sore throat, or (6) sneezing. ICD-10 and ICD-9 diagnosis codes used: nonspecific upper respiratory tract infection (465.9), otitis media (382.9), pharyngotonsillitis (463), lower respiratory tract infections (485 and 486), acute bronchitis (490), and bronchiolitis (466.19). Study authors combined the bronchopneumonia code (485) and pneumonia code (486) under the label "lower respiratory tract infections." If > 1 antibiotic was prescribed during an episode, they used the first prescription for analysis. The final diagnosis was done by the medical researchers on the basis of the symptoms described above and a review of the medical history of children with RIs.
18.	Biswas 2019 cluster-RCT Bangladesh	Influenza-like illness: an ILI episode was defined as measured fever > 38 °C or subjective fever and cough. Laboratory-confirmed influenza Nasal swabs for real-time RT-PCR.
19.	Correa 2012	Acute respiratory infection was defined as 2 or more of the following symptoms for at least 24 hours, lasting at least 2 days: runny, stuffy, or blocked nose or noisy

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Table 9. Trial authors' outcome definitions *(Continued)*

	cluster-RCT Colombia	breathing; cough; fever, hot sensation, or chills; and/or sore throat. Ear pain alone was considered ARI alternately.
20.	Cowling 2009 cluster-RCT Hong Kong	Laboratory-confirmed of influenza virus infection by RT-PCR for influenza A and B virus. Clinical influenza-like illness: used 2 clinical definitions of influenza based on self-reported data from the symptom diaries as secondary analyses. The first definition of clinical influenza was at least 2 of the following signs and symptoms: temperature 37.8 °C or greater, cough, headache, sore throat, and myalgia; the second definition was temperature 37.8 °C or greater plus cough or sore throat.
21.	DiVita 2011 (conference abstract) RCT Bangladesh	Influenza-like illness was defined as fever in children < 5 years old and fever with cough or sore throat in individuals > 5 years old.
22.	Feldman 2016 cluster-RCT Israel	Infectious diseases grouped into diarrhoeal, respiratory, and skin infection. Based on ICD-9, but no supplementary material was accessible for further definition (Supplementary Material C lists all ICD-9 diagnoses tallied in this "outcome").
23.	Gwaltney 1980 RCT USA	Viral cultures and serology if rhinovirus in laboratory-inoculation
24.	Hubner 2010 RCT Germany	Assessing illness rates due to common cold and diarrhoea. Collecting data on illness symptoms (common cold, sinusitis, sore throat, fever, cough, bronchitis, pneumonia, influenza, diarrhoea) and associated absenteeism at the end of every month. Definitions of symptoms were given to the participants as part of the individual information at the beginning of the study. Whilst most symptoms are quite self-explanatory, "influenza" and "pneumonia" are specific diagnoses that were confirmed by professional diagnosis only. Similarly, (self-) diagnosis of "fever" required objective measurement with a thermometer.
25.	Ladegaard 1999 RCT Denmark	Laboratory: serological evidence Effectiveness: influenza-like illness (described as fever, history of fever or feeling feverish in the past week, myalgia, arthralgia, sore throat, cough, sneezing, runny nose, nasal congestion, headache). However, a positive laboratory finding for influenza converts the ILI definition into one of influenza.
26.	Larson 2010 cluster-RCT USA	Study goals: rates of symptoms and secondary transmission of URIs, incidence of virologically confirmed influenza, knowledge of prevention and treatment strategies for influenza and URIs, and rates of influenza vaccination. 1. Laboratory-confirmed influenza: nasal swabs to test for influenza types A and B as well as other common respiratory viruses by rapid culture (R-Mix, Diagnostic Hybrids, Inc., Athens, OH, USA). PCR and subtyping of the samples was done during the second half of the second year of the study. 2. Influenza-like illness: CDC definition of ILI from the Sentinel Physicians' Network was used to determine when masks should be worn: "temperature of ≥37.8°C and cough and/or sore throat in the absence of a known cause other than influenza".

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Table 9. Trial authors' outcome definitions *(Continued)*

		3. Episodes of URI = upper respiratory infection: not clear, no explicitly stated definition, reported that the most commonly reported URI symptoms are cough or rhinorrhoea.
27.	Little 2015 RCT England	Respiratory tract infections defined as 2 symptoms of an RTI for at least 1 day or 1 symptom for 2 consecutive days. For reported ILI, study authors did not use WHO or CDC definitions because these definitions require measured temperature, and thus were not appropriate (participants were not included after a clinical examination), and they did not use the European Centre for Disease Prevention and Control definition (1 systemic and 1 respiratory symptom) because, according to the international influenza collaboration, this definition does not necessarily differentiate ILI from a common cold. Influenzanet suggests making high temperature a separate element. Their pragmatic definition of ILI therefore required a high temperature (feeling very hot or very cold; or measured temperature > 37.5 °C), a respiratory symptom (sore throat, cough, or runny nose), and a systemic symptom (headache, severe fatigue, severe muscle aches, or severe malaise).
28.	Luby 2005 RCT Pakistan	Defined pneumonia in children according to the WHO clinical case definition: cough or difficulty breathing with a raised respiratory rate (> 60 per minute in individuals younger than 60 days old, > 50 per minute for those aged 60 to 364 days, and > 40 per minute for those aged 1 to 5 years)
29.	Millar 2016 cluster-RCT USA	Medically attended, outpatient cases of acute respiratory infection in the study population. The case definition was any occurrence of the following International Classification of Disease, 9 Revision, Clinical Modification (ICD-9) symptom or disease-specific codes: 460-466, 480-488, and specifically 465.9, 482.9, 486, and 487.1. **Acute respiratory infections (460 to 466)** 460 Acute nasopharyngitis (common cold) 461 Acute sinusitis 462 Acute pharyngitis 463 Acute tonsillitis 464 Acute laryngitis and tracheitis 465 Acute upper respiratory infections of multiple or unspecified sites 466 Acute bronchitis and bronchiolitis **Pneumonia and influenza (480 to 488)** 480 Viral pneumonia 481 Pneumococcal pneumonia (*Streptococcus pneumoniae* pneumonia) 482 Other bacterial pneumonia 483 Pneumonia due to other specified organism 484 Pneumonia in infectious diseases classified elsewhere 485 Bronchopneumonia, organism unspecified 486 Pneumonia, organism unspecified 487 Influenza 488 Influenza due to identified avian influenza virus 465.9 Acute upper respiratory infections of unspecified site

Table 9. Trial authors' outcome definitions *(Continued)*

		482.9 Bacterial pneumonia NOS 487.1 Diagnosis of influenza with other respiratory manifestations
30.	Morton 2004 cluster-RCT Cross-over study USA	Respiratory illnesses defined by symptoms of upper respiratory infections such as nasal congestion, cough, or sore throat, in any combination, with or without fever
31.	Nicholson 2014 cluster-RCT India	Acute respiratory infections Operational definitions for all the illnesses were taken from Black's Medical Dictionary. ARIs defined as "Pneumonia, cough, fever, chest pain and shortness of breath, cold, inflammation of any or all of the airways, that is, nose, sinuses, throat, larynx, trachea and bronchi".
32.	Pandejpong 2012 cluster-RCT Thailand	Influenza-like illness defined if 2 or more symptoms of stuffy nose, cough, fever or chills, sore throat, headache, diarrhoea, presence of hand, foot, or mouth ulcers.
33.	Priest 2014 cluster-RCT New Zealand	Respiratory illness was defined as an episode of illness that included at least 2 of the following caregiver-reported symptoms for 1 day, or 1 of these symptoms for 2 days (but not fever alone): runny nose, stuffy or blocked nose or noisy breathing, cough, fever, sore throat, or sneezing.
34.	Ram 2015 RCT Bangladesh	Influenza-like illness Age-specific definitions of ILI. For individuals ≥ 5 years old, ILI was defined as history of fever with cough or sore throat. For children < 5 years old, ILI was defined as fever; study authors used this relatively liberal case definition in order to include influenza cases with atypical presentations in children. Laboratory-confirmed influenza infection Oropharyngeal swabs from index case patients for laboratory testing for influenza. All swabs were tested by PCR for influenza A and B, with further subtyping of influenza A isolates.
35.	Roberts 2000 cluster-RCT Australia	The symptoms of acute upper respiratory illness elicited from parents were: a runny nose, a blocked nose, and cough. Study authors used a definition of colds based on a community intervention trial of virucidal impregnated tissues. A cold was defined as either 2 symptoms for 1 day or 1 of the respiratory symptoms for at least 2 consecutive days, but not including 2 consecutive days of cough alone. Study authors defined a new episode of a cold as the occurrence of respiratory symptoms after a period of 3 symptom-free days.
36.	Sandora 2005 cluster-RCT USA	The overall rates of secondary respiratory and GI illness. Respiratory illness was defined as 2 of the following symptoms for 1 day or 1 of the symptoms for 2 consecutive days: (1) runny nose; (2) stuffy or blocked nose or noisy breathing; (3) cough; (4) fever, feels hot, or has chills; (5) sore throat; and (6) sneezing. An illness was considered new or separate when a period of at least 2 symptom-free days had elapsed since the previous illness. An illness was defined as a secondary case when it began 2 to 7 days after the onset of the same illness type (respiratory or GI) in another household member.

Table 9. Trial authors' outcome definitions *(Continued)*

37.	Savolainen-Kopra 2012 cluster-RCT Finland	Nasal and pharyngeal stick samples from participants with respiratory symptoms
38.	Simmerman 2011 cluster-RCT Thailand	Influenza-like illness defined by WHO as fever plus cough or sore throat, based on self-reported symptoms. Laboratory-confirmed secondary influenza virus infections amongst household members described as the secondary attack rate. The secondary influenza virus infection was defined as a positive rRT-PCR result on days 3 or 7 or a four-fold rise in influenza HI antibody titres with the virus type and subtype matching the index case.
39.	Stebbins 2011 cluster-RCT USA	The primary outcome was an absence episode associated with an influenza-like illness that was subsequently laboratory confirmed as influenza A or B. The following CDC definition for ILI was used: fever ≥ 38 °C with sore throat or cough.
40.	Talaat 2011 cluster-RCT Egypt	Nasal swab for QuickVue test for influenza A and B viruses. Influenza-like illness (defined as fever > 38 °C and either cough or sore throat).
41.	Temime 2018 cluster-RCT France	ARIs were defined as the combination of at least 1 respiratory symptom and 1 symptom of systemic infection.
42.	Turner 2004b RCT Canada	Virologic assays
43.	Turner 2012 RCT USA	Laboratory-confirmed rhinovirus infection by PCR assay. Common cold illness was defined as the presence of any of the symptoms of nasal obstruction, rhinorrhoea, sore throat, or cough on at least 3 consecutive days. Illnesses separated by at least 3 symptom-free days were considered as separate illnesses.
44.	Yeung 2011 cluster-RCT Hong Kong	Pneumonia
45.	Zomer 2015 cluster-RCT Netherlands	Incidence of gastrointestinal and respiratory infections in children monitored by parents. The common cold was defined as a blocked or runny nose with at least 1 of the following symptoms: coughing, sneezing, fever, sore throat, or earache.
Hand hygiene and masks (n = 6)		
46.	Aelami 2015 (conference abstract)	Influenza-like illness was defined as the presence of at least 2 of the following during their stay: fever, cough, and sore throat.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Table 9. Trial authors' outcome definitions *(Continued)*

	RCT Saudi Arabia	Safety: no outcomes on harms planned or reported.
47.	Aiello 2010 cluster-RCT USA	Influenza-like illness case definition (presence of cough and at least 1 constitutional symptom (fever/feverishness, chills, or body aches). Safety: no outcomes on harms planned or reported.
48.	Cowling 2009 cluster-RCT Hong Kong	2 clinical definitions of influenza. First definition was at least 2 of the following signs and symptoms: temperature 37.8 °C or greater, cough, headache, sore throat, and myalgia. The second was temperature 37.8 °C or greater plus cough or sore throat. Safety: no outcomes on harms planned or reported.
49.	Larson 2010 cluster-RCT USA	Study goals: rates of symptoms and secondary transmission of URIs, incidence of virologically confirmed influenza, knowledge of prevention and treatment strategies for influenza and URIs, and rates of influenza vaccination. 1. Laboratory-confirmed influenza: nasal swabs to test for influenza types A and B as well as other common respiratory viruses by rapid culture (R-Mix, Diagnostic Hybrids, Inc., Athens, OH, USA). PCR and subtyping of the samples was done during the second half of the second year of the study. 2. Influenza-like illness: CDC definition of ILI from the Sentinel Physicians' Network was used to determine when masks should be worn: "temperature of ≥37.8°C and cough and/or sore throat in the absence of a known cause other than influenza". 3. Episodes of URI = upper respiratory infection: not clear, no explicitly stated definition, reported that the most commonly reported URI symptoms are cough or rhinorrhoea. Safety: no outcomes on harms planned or reported.
50.	Simmerman 2011 cluster-RCT Thailand	Laboratory-confirmed secondary influenza virus infections amongst household members described as the secondary attack rate. The secondary influenza virus infection was defined as a positive rRT-PCR result on days 3 or 7 or a four-fold rise in influenza HI antibody titres with the virus type and subtype matching the index case. Influenza-like illness defined by WHO as fever plus cough or sore throat, based on self-reported symptoms. Safety: no outcomes on harms planned or reported.
51.	Suess 2012 cluster-RCT Germany	Quantitative RT-PCR for samples of nasal wash. Influenza virus infection as a laboratory-confirmed influenza infection in a household member who developed fever (> 38.0 °C), cough, or sore throat during the observation period. Also secondary outcome measure of the occurrence of ILI as defined by WHO as fever plus cough or sore throat. Safety: the study reported that the majority of participants (107/172, 62%) did not report any problems with mask wearing. This proportion was significantly higher in the group of adults (71/100, 71%) compared to the group of children (36/72, 50%) (P = 0.005). The main problem stated by participants (adults and children) was "heat/humidity" (18/34, 53% of children; 10/29, 35% of adults) (P = 0.1), followed by "pain" and "shortness of breath" when wearing a face mask.

Table 9. Trial authors' outcome definitions *(Continued)*

52.	Ban 2015 cluster-RCT China	Acute respiratory illness classified as the appearance of 2 or more of the following symptoms: fever, cough and expectoration, runny nose and nasal congestion.
53.	Carabin 1999 cluster-RCT Canada	The presence of nasal discharge (runny nose) accompanied by 1 or several of the following symptoms: fever, sneezing, cough, sore throat, ear pain, malaise, irritability. A URTI was defined as a cold for 2 consecutive days.
54.	Chard 2019 cluster-RCT Laos	Pupils were considered to have symptoms of respiratory infection if they reported cough, runny nose, stuffy nose, or sore throat.
55.	Ibfelt 2015 cluster-RCT Denmark	Laboratory confirmation of 16 respiratory viruses: influenza A; influenza B; coronavirus NL63229E, OC43 and HKU1; parainfluenza virus 1, 2, 3, and 4; rhinovirus; RSV A/B; adenovirus; enterovirus; parechovirus; and bocavirus using quantitative PCR
56.	Kotch 1994 RCT USA	Respiratory symptoms include coughing, runny nose, wheezing or rattling in the chest, sore throat, or earache.
57.	McConeghy 2017 RCT USA	Classified infections as lower respiratory tract infections (i.e. pneumonia, bronchitis, or chronic obstructive pulmonary disease exacerbation) or other.
58.	Sandora 2008 cluster-RCT USA	RI was defined as an acute illness that included > 1 of the following symptoms: runny nose, stuffy or blocked nose, cough, fever or chills, sore throat, or sneezing.
59.	White 2001 DB-RCT USA	RI was defined as: cough, sneezing, sinus trouble, bronchitis, fever alone, pink-eye, headache, mononucleosis, and acute exacerbation of asthma.
Other (miscellaneous) interventions (n = 4)		
60.	Hartinger 2016 cluster-RCT Peru	ARI was defined as a child presenting cough or difficulty breathing, or both. ALRI was defined as a child presenting cough or difficulty breathing, with a raised respiratory rate > 50 per minute in children aged 6 to 11 months and > 40 per minute in children aged > 12 months on 2 consecutive measurements. An episode was defined as beginning on the first day of cough or difficulty breathing and ending with the last day of the same combination, followed by at least 7 days without those symptoms.
61.	Huda 2012 cluster-RCT Bangladesh	Study authors classified acute respiratory illness as having cough and fever or difficulty breathing and fever within 48 h prior to interview.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Table 9. Trial authors' outcome definitions *(Continued)*

62.	Najnin 2019 cluster-RCT Bangladesh	Classified participants as having respiratory illness if they reported having fever plus either cough or nasal congestion or fever plus breathing difficult.
63.	Satomura 2005 RCT Japan	Upper respiratory tract infection defined as all of the following conditions: 1. both nasal and pharyngeal symptoms; 2. severity of at least 1 symptom increased by 2 grades or more; and 3. worsening of a symptom of 1 increment or more for > 3 days. Because of the difference in the mode of transmission, study authors excluded influenza-like diseases featured by moderate or severe fever; anti-influenza vaccination in the preseason and arthralgia, and treated them separately. The incidence was determined by 1 study physician who was blinded to group assignment.
Virucidal tissues (n = 2)		
64.	Farr 1988a cluster-RCT USA trial 1 and trial 2	RI defined as: occurrence of at least 2 respiratory symptoms on the same day or the occurrence of a single respiratory symptom on 2 consecutive days (except for sneezing). The respiratory symptoms were as follows: sneezing, nasal congestion, nasal discharge, sore throat, scratchy throat, hoarseness, coughing, malaise, headache, feverishness, chilliness and myalgia.
65.	Longini 1988 DB-PC RCT USA	Respiratory illness defined as 1 or more of the following symptoms occurring during the course of acute episode: coryza, sore throat or hoarseness, earache, cough, pain on respiration, wheezy breathing or phlegm from the chest.

ALRI: acute lower respiratory infection
ARIs: acute respiratory infections
CDC: Centers for Disease Control and Prevention
CI: confidence interval
cluster-RCT: cluster-randomised controlled trial
CRI: clinical respiratory illness
DB-PC: double-blind, placebo-controlled
DB-RCT: double-blind randomised controlled trial
GI: gastrointestinal
HCW: healthcare workers
HI: haemagglutinin
hMPV: human metapneumo virus
ICD-9: International Classification of Disease, 9th Revision, Clinical Modification
ICD-10: International Classification of Disease, 10th Revision, Clinical Modification
ILI: influenza-like illness
NAT: nucleic acid testing
NOS: not otherwise specified
NTS: nasal and throat swab
PCR: polymerase chain reaction
PIV: parainfluenza virus
POCT: point-of-care testing
RCT: randomised controlled trial
RI: respiratory infection
RR: risk ratio
rRT-PCR: real-time reverse transcriptase polymerase chain reaction
RSV: respiratory syncytial virus
RTI: respiratory tract infection

Appendix 5. Previous search strategies (pre-2010)

Details of the 2010 update and the search strategy used in the original review and the 2009 search strategy updates for MEDLINE, CENTRAL, EMBASE and CINAHL

In the 2010 update we searched, as we have done previously, the Cochrane Central Register of Controlled Trials (CENTRAL) 2010, Issue 3, which includes the Acute Respiratory Infections Group's Specialised Register, MEDLINE (April 2009 to October week 2, 2010), EMBASE (April 2009 to October 2010) and CINAHL (January 2009 to October 2010). Details of previous searches are in Appendix 1. In addition, to include more of the literature of low-income countries in this update, we ran searches in LILACS (2008 to October 2010), Indian MEDLARS (2008 to October 2010) and IMSEAR (2008 to October 2010).

We used the following search strategy (updated to include new and emerging respiratory viruses) to search MEDLINE and CENTRAL. We combined the MEDLINE search strategy with the Cochrane Highly Sensitive Search Strategy for identifying randomised trials in MEDLINE: sensitivity- and precision-maximising version (2008 revision) (Ovid format) (Lefebvre 2011). We also included an additional search strategy based on the work of Fraser, Murray and Burr (Fraser 2006) to identify observational studies.

(influenza or flu or common cold or rhinovirus or coronavirus or adenovirus or severe acute respiratory syndrome or sars or respiratory syncytial virus or rsv or parainfluenza or enterovirus or bocavirus or metapneumovirus or parvovirus or parechovirus) and (handwashing or hand washing or hand hygiene or sanitizer or sanitiser or cleanser or disinfectant or gloves or masks or mask or protective clothing or protective devices or patient isolation or barrier or curtain or partition or cross infection or disease control or infection control or school or schools or bans or banning or banned or ban or distancing or quarantine or isolation or spatial separation or cohorting or cohort isolation)

In the first publication of this review we searched the Cochrane Central Register of Controlled Trials (CENTRAL) (The Cochrane Library 2006, issue 4); MEDLINE (1966 to November 2006); OLDMEDLINE (1950 to 1965); EMBASE (1990 to November 2006) and CINAHL (1982 to November 2006). The MEDLINE search terms were modified for OLDMEDLINE, EMBASE and CINAHL.

In this 2009 update we searched the Cochrane Central Register of Controlled Trials (CENTRAL) (The Cochrane Library 2009, issue 2); Ovid MEDLINE (2006 to May Week 1 2009); OLDMEDLINE (1950 to 1965); Ovid EMBASE (2006 to Week 18, 2009) and Ovid CINAHL (2006 to May Week 1 2009).

WHAT'S NEW

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Date	Event	Description
1 April 2020	New citation required and conclusions have changed	There is now sufficient randomised controlled trial (RCT) evidence to show that hand hygiene is likely to provide a modest-benefit. Uncertainty remains for the other interventions. Further RCT evidence is needed.
1 April 2020	New search has been performed	Searches updated. In this 2020 update we only searched for RCTs and cluster-RCTs. We included 44 new trials (Aelami 2015; Aiello 2012; Alzaher 2018; Arbogast 2016; Azor-Martinez 2016; Azor-Martinez 2018; Ban 2015; Barasheed 2014; Biswas 2019; Canini 2010; Chard 2019; Correa 2012; DiVita 2011; Feldman 2016; Goodall 2014; Hartinger 2016; Hubner 2010; Huda 2012; Ibfelt 2015; Ide 2014; Ide 2016; Little 2015; MacIntyre 2011; MacIntyre 2013; MacIntyre 2015; MacIntyre 2016; McConeghy 2017; Millar 2016; Miyaki 2011; Najnin 2019; Nicholson 2014; Pandejpong 2012; Priest 2014; Radonovich 2019; Ram 2015; Savolainen-Kopra 2012; Simmerman 2011; Stebbins 2011; Suess 2012; Talaat 2011; Temime 2018; Turner 2012; Yeung 2011; Zomer 2015). We excluded 12 new trials (Azor-Martinez 2014; Bowen 2007; Chami 2012; Denbak 2018; Lennell 2008; Nandrup-Bus 2009; Patel 2012; Rosen 2006; Slayton 2016; Stedman-Smith 2015; Uhari 1999; Vessey 2007). We identified 5 new ongoing trials (NCT03454009; NCT04267952; NCT04296643; NCT04337541; Wang 2015) one of which – NCT04337541 - published as this review was going to press. We focused on RCTs and cluster-RCTs only and removed observational studies from this update.

HISTORY

Protocol first published: Issue 4, 2006
Review first published: Issue 4, 2007

Date	Event	Description
22 October 2010	New search has been performed	Searches conducted. We included 7 new trials: 4 randomised controlled trials and 3 non-randomised comparative studies. We excluded 36 new trials.
22 October 2010	New citation required but conclusions have not changed	We updated the review again at the behest of the World Health Organization (WHO). External sources of support amended. External support from the WHO. The WHO interim guidelines document on 'Infection Prevention and Control of Epidemic and Pandemic Prone Acute Respiratory Diseases in Health Care' was published in 2007 to provide infection control guidance to help prevent the transmission of acute respiratory diseases in health care. The update of these guidelines will be evidence-based, and an update of this review was requested to assist in informing the evidence base for the revision of the WHO guidelines. Dr John Conly, Dr Mark Jones, and Sarah Thorning joined the review team.
7 May 2009	New search has been performed	For the 2009 update, we included 3 cluster-randomised controlled trials, Cowling 2009; MacIntyre 2009; Sandora 2008, and 1

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Date	Event	Description
		individual randomised controlled trial (Satomura 2005, with its linked publication Kitamura 2007). We also included 1 retrospective cohort study (Foo 2006), 1 case-control study (Yu 2007), and 2 prospective cohort studies (Wang 2007; Broderick 2008). The content and conclusions of the 2007 review changed little, but the additional 8 studies add more information and certainty. Our meta-analysis remains unchanged as there were no new studies for pooling.
30 April 2009	New citation required but conclusions have not changed	New author joined the review team.
8 July 2008	Amended	Converted to new review format.
20 August 2007	Amended	Review first published Issue 4, 2007.

CONTRIBUTIONS OF AUTHORS

Tom Jefferson (TOJ), Chris Del Mar (CDM), and Liz Dooley (LD) were responsible for drafting the protocol.
TOJ, Eliana Ferroni (EF), Bill Hewak (BH), and Adi Prabhala (AP) extracted study data, and Sree Nair (SN) performed the analyses in the original review.

TOJ, EF, Lubna A Al-Ansary (LA), Ghada A Bawazeer (GB), and CDM adjudicated in data extraction in the 2009 update. Mieke van Driel (MvD) assisted in writing the review, updating with the most recent studies, and additional tables (apart from TiDIER). MvD constructed the summary of results table which was removed in the 2020 review update.

TOJ and John Conly (JMC) extracted data, and CDM checked extractions and arbitrated in the 2010 update. All three review authors checked the search strategy terms. Sarah Thorning (ST) designed and carried out the searches. All 2010 review authors contributed to the final report.

For the 2020 update:
Updated searches: ST
Co-ordinated the update: LD
Updated Background section: CDM
Designed Excel forms for extracting study characteristics and tested their usefulness/applicability: MJ
Screened titles and abstracts, excluded irrelevant citations: MJ
Excluded irrelevant citations based on title and text in the trial registry entry: ST
Excluded irrelevant citations based on titles/abstracts and the full-text articles: GB
Selection of studies: MvD, MJ, GB, JC
Data extraction and management: MJ, EF, LA, GB, TOJ, TH, EB
Assessment of risk of bias in the included studies: TOJ, EB, LA, GB, MJ, EF
Adjudicated data extraction: MJ
Data analysis: MJ, EB
Wrote the update: MJ, TOJ, LD, LA, JMC, EB, MVD, GB, TH, CDM, PG

DECLARATIONS OF INTEREST

Tom Jefferson: Tom Jefferson's full disclosure is available at restoringtrials.org/competing-interests-tom-jefferson/.
Chris B Del Mar: a grant from WHO paid to Bond University and a grant from UK National Institute for Health Research (NIHR) to be paid to Bond University on publication of the review in the Cochrane Library. Funding from National Health and Medical Research Council (NHMRC) for research on antibiotic resistance.
Liz Dooley: a grant from the World Health Organization (WHO) paid to Bond University and a grant from UK NIHR to be paid to Bond University on publication of the review in the Cochrane Library.
Eliana Ferroni: none known.
Lubna A Al-Ansary: none known.
Ghada A Bawazeer: none known.

Copyright © 2020 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

Mieke L van Driel: Dr van Driel has acted as a consultant for Therapeutic Guidelines Ltd and NPS Medicinewise, for which fees have been paid to her institution.
Mark A Jones: a grant from WHO paid to Bond University and a grant from UK NIHR to be paid to Bond University on publication of the review in the Cochrane Library.
Sarah Thorning: none known.
Elaine M Beller: this review was supported in part by research grants from the NHMRC, Australia, to the Institute for Evidence-Based Healthcare, Bond University.
Justin Clark: none known.
Tammy Hoffmann: a grant from WHO paid to Bond University and a grant from UK NIHR to be paid to Bond University on publication of the review in the Cochrane Library. Funding from NHMRC for research on antibiotic resistance.
Paul Glasziou: none known.
John M Conly: John Conly holds grants from the Canadian Institutes for Health Research on acute and primary care preparedness for COVID-19 in Alberta, Canada and was the primary local Investigator for a *Staphylococcus aureus* vaccine study funded by Pfizer for which all funding was provided only to the University of Calgary. He also received support from the Centers for Disease Control and Prevention (CDC) to attend an Infection Control Think Tank Meeting.

DIFFERENCES BETWEEN PROTOCOL AND REVIEW

We changed the title of the review in 2010 (see Published notes below).

For this 2020 update, we added one additional outcome: adverse events related to the intervention, and we split the outcomes into primary and secondary outcomes. We also focused only on RCTs and cluster-RCTs and removed observational studies.

NOTES

In Issue 1, 2010, the title of the review was changed from 'Interventions for the interruption or reduction of the spread of respiratory viruses' to 'Physical interventions to interrupt or reduce the spread of respiratory viruses'.

The original review was subsequently published as Jefferson T, Foxlee R, Del Mar C, Dooley L, Ferroni E, Hewak B, Prabhala A, Nair S, Rivetti A. Physical interventions to interrupt or reduce the spread of respiratory viruses: systematic review. BMJ 2008;336:77-80 and Jefferson T, Del Mar C, Dooley L, Ferroni E, Al-Ansary LA, Bawazeer GA, van Driel ML, Foxlee R, Rivetti A. Physical interventions to interrupt or reduce the spread of respiratory viruses: systematic review. BMJ 2009;339:b3675. DOI: 10.1136/bmj.b3675.

Nonpharmaceutical Measures for Pandemic Influenza in Nonhealthcare Settings—Personal Protective and Environmental Measures

Jingyi Xiao,[1] Eunice Y. C. Shiu,[1] Huizhi Gao, Jessica Y. Wong, Min W. Fong, Sukhyun Ryu, Benjamin J. Cowling

There were 3 influenza pandemics in the 20th century, and there has been 1 so far in the 21st century. Local, national, and international health authorities regularly update their plans for mitigating the next influenza pandemic in light of the latest available evidence on the effectiveness of various control measures in reducing transmission. Here, we review the evidence base on the effectiveness of nonpharmaceutical personal protective measures and environmental hygiene measures in nonhealthcare settings and discuss their potential inclusion in pandemic plans. Although mechanistic studies support the potential effect of hand hygiene or face masks, evidence from 14 randomized controlled trials of these measures did not support a substantial effect on transmission of laboratory-confirmed influenza. We similarly found limited evidence on the effectiveness of improved hygiene and environmental cleaning. We identified several major knowledge gaps requiring further research, most fundamentally an improved characterization of the modes of person-to-person transmission.

Influenza pandemics occur at irregular intervals when new strains of influenza A virus spread in humans (*1*). Influenza pandemics cause considerable health and social impact that exceeds that of typical seasonal (interpandemic) influenza epidemics. One of the characteristics of influenza pandemics is the high incidence of infections in all age groups because of the lack of population immunity. Although influenza vaccines are the cornerstone of seasonal influenza control, specific vaccines for a novel pandemic strain are not expected to be available for the first 5–6 months of the next pandemic. Antiviral drugs will be available in some locations to treat more severe infections but are unlikely to be available in the quantities that might be required to control transmission in the general community. Thus, efforts to control the next pandemic will rely largely on nonpharmaceutical interventions.

Most influenza virus infections cause mild and self-limiting disease; only a small fraction of case-patients require hospitalization. Therefore, influenza virus infections spread mainly in the community. Influenza virus is believed to be transmitted predominantly by respiratory droplets, but the size distribution of particles responsible for transmission remains unclear, and in particular, there is a lack of consensus on the role of fine particle aerosols in transmission (*2*,*3*). In healthcare settings, droplet precautions are recommended in addition to standard precautions for healthcare personnel when interacting with influenza patients and for all visitors during influenza seasons (*4*). Outside healthcare settings, hand hygiene is recommended in most national pandemic plans (*5*), and medical face masks were a common sight during the influenza pandemic in 2009. Hand hygiene has been proven to prevent many infectious diseases and might be considered a major component in influenza pandemic plans, whether or not it has proven effectiveness against influenza virus transmission, specifically because of its potential to reduce other infections and thereby reduce pressure on healthcare services.

In this article, we review the evidence base for personal protective measures and environmental hygiene measures, and specifically the evidence for the effectiveness of these measures in reducing transmission of laboratory-confirmed influenza in the community. We also discuss the implications of the evidence base for inclusion of these measures in pandemic plans.

Methods and Results

We conducted systematic reviews to evaluate the effectiveness of personal protective measures on influenza virus transmission, including hand hygiene, respiratory etiquette, and face masks, and a systematic review of surface and object cleaning as an environmental measure (Table 1). We searched 4 databases (Medline, PubMed, EMBASE, and CENTRAL) for literature in all languages. We aimed to identify randomized controlled trials (RCTs) of each measure for laboratory-confirmed influenza outcomes for each of the measures because RCTs provide the highest quality of evidence. For respiratory etiquette and surface and object cleaning, because of a lack of RCTs for laboratory-confirmed influenza, we also searched for RCTs reporting effects of these interventions on influenza-like illness (ILI) and respiratory illness outcomes and then for observational studies on laboratory-confirmed influenza, ILI, and respiratory illness outcomes. For each review, 2 authors (E.Y.C.S. and J.X.) screened titles and abstracts and reviewed full texts independently.

We performed meta-analysis for hand hygiene and face mask interventions and estimated the effect of these measures on laboratory-confirmed influenza prevention by risk ratios (RRs). We used a fixed-effects model to estimate the overall effect in a pooled analysis or subgroup analysis. No overall effect would be generated if there was considerable heterogeneity on the basis of I^2 statistic ≥75% (*6*). We performed quality assessment of evidence on hand hygiene and face mask interventions by using the GRADE (Grading of Recommendations Assessment, Development and Evaluation) approach (*7*). We provide additional details of the search strategies, selection of articles, summaries of the selected articles, and quality assessment (Appendix, https://wwwnc.cdc.gov/EID/article/26/5/19-0994-App1.pdf).

Personal Protective Measures

Hand Hygiene

We identified a recent systematic review by Wong et al. on RCTs designed to assess the efficacy of hand hygiene interventions against transmission of laboratory-confirmed influenza (*8*). We used this review as a starting point and then searched for additional literature published after 2013; we found 3 additional eligible articles published during the search period of January 1, 2013–August 13, 2018. In total, we identified 12 articles (*9*–*20*), of which 3 articles were from the updated search and 9 articles from Wong et al. (*8*). Two articles relied on the same underlying dataset (*16*,*19*); therefore, we counted these 2 articles as 1 study, which resulted in 11 RCTs. We further selected 10 studies with >10,000 participants for inclusion in the meta-analysis (Figure 1). We excluded 1 study from the meta-analysis because it provided estimates of infection risks only at the household level, not the individual level (*20*). We did not generate an overall pooled effect of hand hygiene only or of hand hygiene with or without face mask because of high heterogeneity in individual estimates (I^2 87 and 82%, respectively). The effect of hand hygiene combined with face masks on laboratory-confirmed influenza was not statistically significant (RR 0.91, 95% CI 0.73–1.13; I^2 = 35%, p = 0.39). Some studies reported being underpowered because of limited sample size, and low adherence to hand hygiene interventions was observed in some studies.

We further analyzed the effect of hand hygiene by setting because transmission routes might vary

Table 1. Summary of literature searches for systematic review on personal and environmental nonpharmaceutical interventions for pandemic influenza*

Types of interventions	No. studies identified	Study designs included†	Main findings
Hand hygiene	12	RCT	The evidence from RCTs suggested that hand hygiene interventions do not have a substantial effect on influenza transmission.
Respiratory etiquette	0	NA	We did not identify research evaluating the effectiveness of respiratory etiquette on influenza transmission.
Face masks	10	RCT	The evidence from RCTs suggested that the use of face masks either by infected persons or by uninfected persons does not have a substantial effect on influenza transmission.
Surface and object cleaning	3	RCT, observational studies	There was a limited amount of evidence suggesting that surface and object cleaning does not have a substantial effect on influenza transmission.

*NA, not available; RCT randomized controlled trial.
†In these systematic reviews, we prioritized RCTs, and only considered observational studies if there were a small number of RCTs. Our rationale was that with evidence from a larger number of RCTs, additional evidence from observational studies would be unlikely to change overall conclusions.

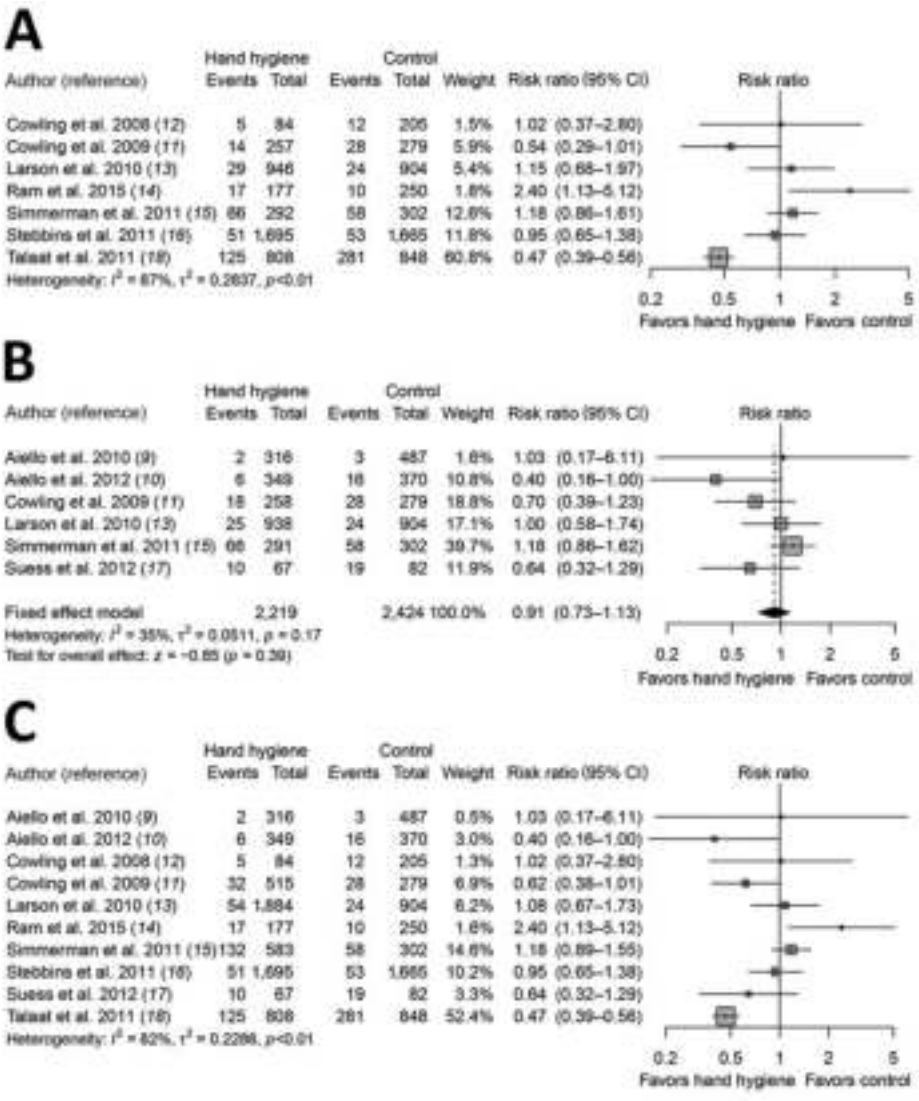

Figure 1. Meta-analysis of risk ratios for the effect of hand hygiene with or without face mask use on laboratory-confirmed influenza from 10 randomized controlled trials with >11,000 participants. A) Hand hygiene alone; B) hand hygiene and face mask; C) hand hygiene with or without face mask. Pooled estimates were not made if there was high heterogeneity (I^2 ≥75%). Squares indicate risk ratio for each of the included studies, horizontal line indicates 95% CIs, dashed vertical line indicates pooled estimation of risk ratio, and diamond indicates pooled estimation of risk ratio. Diamond width corresponds to the 95% CI.

in different settings. We found 6 studies in household settings examining the effect of hand hygiene with or without face masks, but the overall pooled effect was not statistically significant (RR 1.05, 95% CI 0.86–1.27; I^2 = 57%, p = 0.65) (Appendix Figure 4) (*11*–*15*,*17*). The findings of 2 studies in school settings were different (Appendix Figure 5). A study conducted in the United States (*16*) showed no major effect of hand hygiene, whereas a study in Egypt (*18*) reported that hand hygiene reduced the risk for influenza by >50%. A pooled analysis of 2 studies in university residential halls reported a marginally significant protective effect of a combination of hand hygiene plus face masks worn by all residents (RR 0.48, 95% CI 0.21–1.08; I^2 = 0%, p = 0.08) (Appendix Figure 6) (*9*,*10*).

In support of hand hygiene as an effective measure, experimental studies have reported that influenza virus could survive on human hands for a short time and could transmit between hands and contaminated surfaces (*2*,*21*). Some field studies reported that influenza A(H1N1)pdm09 and influenza A(H3N2) virus RNA and viable influenza virus could be detected on the hands of persons with laboratory-confirmed influenza (*22*,*23*), supporting the potential of direct and indirect contact transmission to play a role in the spread of influenza. Other experimental studies also demonstrated that hand hygiene could reduce or remove infectious influenza virus from human hands (*24*,*25*). However, results from our meta-analysis on RCTs did not provide evidence to support a protective effect of hand hygiene against transmission of laboratory-confirmed influenza. One study did report a major effect, but in this trial of hand hygiene in schools in Egypt, running water had to be installed and soap and hand-drying

material had to be introduced into the intervention schools as part of the project (*18*). Therefore, the impact of hand hygiene might also be a reflection of the introduction of soap and running water into primary schools in a lower-income setting. If one considers all of the evidence from RCTs together, it is useful to note that some studies might have underestimated the true effect of hand hygiene because of the complexity of implementing these intervention studies. For instance, the control group would not typically have zero knowledge or use of hand hygiene, and the intervention group might not adhere to optimal hand hygiene practices (*11*,*13*,*15*).

Hand hygiene is also effective in preventing other infectious diseases, including diarrheal diseases and some respiratory diseases (*8*,*26*). The need for hand hygiene in disease prevention is well recognized among most communities. Hand hygiene has been accepted as a personal protective measure in >50% of national preparedness plans for pandemic influenza (*5*). Hand hygiene practice is commonly performed with soap and water, alcohol-based hand rub, or other waterless hand disinfectants, all of which are easily accessible, available, affordable, and well accepted in most communities. However, resource limitations in some areas are a concern when clean running water or alcohol-based hand rub are not available. There are few adverse effects of hand hygiene except for skin irritation caused by some hand hygiene products (*27*). However, because of certain social or religious practices, alcohol-based hand sanitizers might not be permitted in some locations (*28*). Compliance with proper hand hygiene practice tends to be low because habitual behaviors are difficult to change (*29*). Therefore, hand hygiene promotion programs are needed to advocate and encourage proper and effective hand hygiene.

Respiratory Etiquette

Respiratory etiquette is defined as covering the nose and mouth with a tissue or a mask (but not a hand) when coughing or sneezing, followed by proper disposal of used tissues, and proper hand hygiene after contact with respiratory secretions (*30*). Other descriptions of this measure have included turning the head and covering the mouth when coughing and coughing or sneezing into a sleeve or elbow, rather than a hand. The rationale for not coughing into hands is to prevent subsequent contamination of other surfaces or objects (*31*). We conducted a search on November 6, 2018, and identified literature that was available in the databases during 1946–November 5, 2018. We did not identify any published research on the effectiveness of respiratory etiquette in reducing the risk for laboratory-confirmed influenza or ILI. One observational study reported a similar incidence rate of self-reported respiratory illness (defined by >1 symptoms: cough, congestion, sore throat, sneezing, or breathing problems) among US pilgrims with or without practicing respiratory etiquette during the Hajj (*32*). The authors did not specify the type of respiratory etiquette used by participants in the study. A laboratory-based study reported that common respiratory etiquette, including covering the mouth by hands, tissue, or sleeve/arm, was fairly ineffective in blocking the release and dispersion of droplets into the surrounding environment on the basis of measurement of emitted droplets with a laser diffraction system (*31*).

Respiratory etiquette is often listed as a preventive measure for respiratory infections. However, there is a lack of scientific evidence to support this measure. Whether respiratory etiquette is an effective nonpharmaceutical intervention in preventing influenza virus transmission remains questionable, and worthy of further research.

Face Masks

In our systematic review, we identified 10 RCTs that reported estimates of the effectiveness of face masks in reducing laboratory-confirmed influenza virus infections in the community from literature published during 1946–July 27, 2018. In pooled analysis, we found no significant reduction in influenza transmission with the use of face masks (RR 0.78, 95% CI 0.51–1.20; I^2 = 30%, p = 0.25) (Figure 2). One study evaluated the use of masks among pilgrims from Australia during the Hajj pilgrimage and reported no major difference in the risk for laboratory-confirmed influenza virus infection in the control or mask group (*33*). Two studies in university settings assessed the effectiveness of face masks for primary protection by monitoring the incidence of laboratory-confirmed influenza among student hall residents for 5 months (*9*,*10*). The overall reduction in ILI or laboratory-confirmed influenza cases in the face mask group was not significant in either studies (*9*,*10*). Study designs in the 7 household studies were slightly different: 1 study provided face masks and P2 respirators for household contacts only (*34*), another study evaluated face mask use as a source control for infected persons only (*35*), and the remaining studies provided masks for the infected persons as well as their close contacts (*11*–*13*,*15*,*17*). None of the household studies reported a significant reduction in secondary laboratory-confirmed influenza virus infections in the face

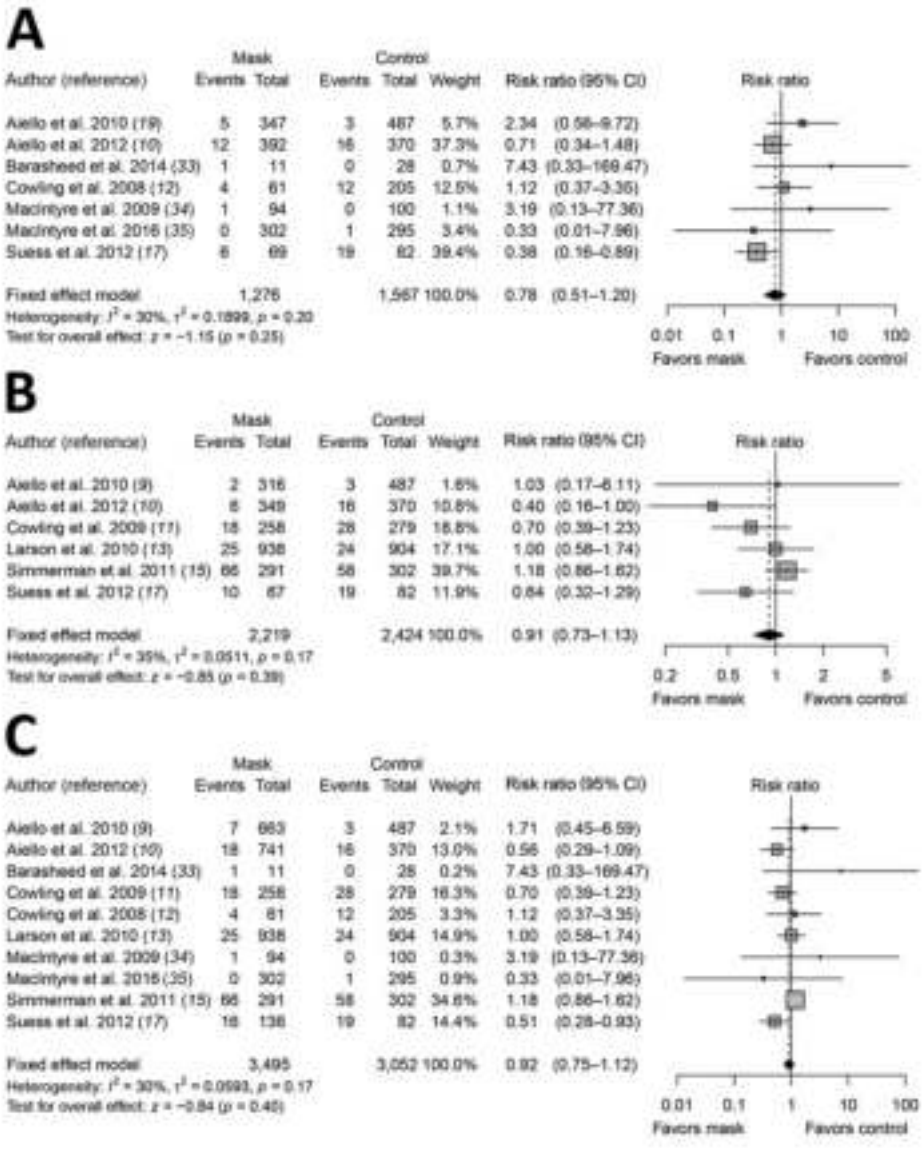

Figure 2. Meta-analysis of risk ratios for the effect of face mask use with or without enhanced hand hygiene on laboratory-confirmed influenza from 10 randomized controlled trials with >6,500 participants. A) Face mask use alone; B) face mask and hand hygiene; C) face mask with or without hand hygiene. Pooled estimates were not made if there was high heterogeneity (I^2 ≥75%). Squares indicate risk ratio for each of the included studies, horizontal lines indicate 95% CIs, dashed vertical lines indicate pooled estimation of risk ratio, and diamonds indicate pooled estimation of risk ratio. Diamond width corresponds to the 95% CI.

mask group (*11*–*13*,*15*,*17*,*34*,*35*). Most studies were underpowered because of limited sample size, and some studies also reported suboptimal adherence in the face mask group.

Disposable medical masks (also known as surgical masks) are loose-fitting devices that were designed to be worn by medical personnel to protect accidental contamination of patient wounds, and to protect the wearer against splashes or sprays of bodily fluids (*36*). There is limited evidence for their effectiveness in preventing influenza virus transmission either when worn by the infected person for source control or when worn by uninfected persons to reduce exposure. Our systematic review found no significant effect of face masks on transmission of laboratory-confirmed influenza.

We did not consider the use of respirators in the community. Respirators are tight-fitting masks that can protect the wearer from fine particles (*37*) and should provide better protection against influenza virus exposures when properly worn because of higher filtration efficiency. However, respirators, such as N95 and P2 masks, work best when they are fit-tested, and these masks will be in limited supply during the next pandemic. These specialist devices should be reserved for use in healthcare settings or in special subpopulations such as immunocompromised persons in the community, first responders, and those performing other critical community functions, as supplies permit.

In lower-income settings, it is more likely that reusable cloth masks will be used rather than

disposable medical masks because of cost and availability (*38*). There are still few uncertainties in the practice of face mask use, such as who should wear the mask and how long it should be used for. In theory, transmission should be reduced the most if both infected members and other contacts wear masks, but compliance in uninfected close contacts could be a problem (*12*,*34*). Proper use of face masks is essential because improper use might increase the risk for transmission (*39*). Thus, education on the proper use and disposal of used face masks, including hand hygiene, is also needed.

Environmental Measures

Surface and Object Cleaning

For the search period from 1946 through October 14, 2018, we identified 2 RCTs and 1 observational study about surface and object cleaning measures for inclusion in our systematic review (*40*–*42*). One RCT conducted in day care nurseries found that biweekly cleaning and disinfection of toys and linen reduced the detection of multiple viruses, including adenovirus, rhinovirus, and respiratory syncytial virus in the environment, but this intervention was not significant in reducing detection of influenza virus, and it had no major protective effect on acute respiratory illness (*41*). Another RCT found that hand hygiene with hand sanitizer together with surface disinfection reduced absenteeism related to gastrointestinal illness in elementary schools, but there was no major reduction in absenteeism related to respiratory illness (*42*). A cross-sectional study found that passive contact with bleach was associated with a major increase in self-reported influenza (*40*).

Given that influenza virus can survive on some surfaces for prolonged periods (*43*), and that cleaning or disinfection procedures can effectively reduce or inactivate influenza virus from surfaces and objects in experimental studies (*44*), there is a theoretical basis to believe that environmental cleaning could reduce influenza transmission. As an illustration of this proposal, a modeling study estimated that cleaning of extensively touched surfaces could reduce influenza A infection by 2% (*45*). However, most studies of influenza virus in the environment are based on detection of virus RNA by PCR, and few studies reported detection of viable virus.

Although we found no evidence that surface and object cleaning could reduce influenza transmission, this measure does have an established impact on prevention of other infectious diseases (*42*). It should be feasible to implement this measure in most settings, subject to the availability of water and cleaning products. Although irritation caused by cleaning products is limited, safety remains a concern because some cleaning products can be toxic or cause allergies (*40*).

Discussion

In this review, we did not find evidence to support a protective effect of personal protective measures or environmental measures in reducing influenza transmission. Although these measures have mechanistic support based on our knowledge of how influenza is transmitted from person to person, randomized trials of hand hygiene and face masks have not demonstrated protection against laboratory-confirmed influenza, with 1 exception (*18*). We identified only 2 RCTs on environmental cleaning and no RCTs on cough etiquette.

Hand hygiene is a widely used intervention and has been shown to effectively reduce the transmission of gastrointestinal infections and respiratory infections (*26*). However, in our systematic review, updating the findings of Wong et al. (*8*), we did not find evidence of a major effect of hand hygiene on laboratory-confirmed influenza virus transmission (Figure 1). Nevertheless, hand hygiene might be included in influenza pandemic plans as part of general hygiene and infection prevention.

We did not find evidence that surgical-type face masks are effective in reducing laboratory-confirmed influenza transmission, either when worn by infected persons (source control) or by persons in the general community to reduce their susceptibility (Figure 2). However, as with hand hygiene, face masks might be able to reduce the transmission of other infections and therefore have value in an influenza pandemic when healthcare resources are stretched.

It is essential to note that the mechanisms of person-to-person transmission in the community have not been fully determined. Controversy remains over the role of transmission through fine-particle aerosols (*3*,*46*). Transmission by indirect contact requires transfer of viable virus from respiratory mucosa onto hands and other surfaces, survival on those surfaces, and successful inoculation into the respiratory mucosa of another person. All of these components of the transmission route have not been studied extensively. The impact of environmental factors, such as temperature and humidity, on influenza transmission is also uncertain (*47*). These uncertainties over basic transmission modes and mechanisms hinder the optimization of control measures.

Table 2. Knowledge gaps for personal protective and environmental nonpharmaceutical interventions for pandemic influenza*

Intervention	Knowledge gaps	Suggested studies
Hand hygiene	There are major gaps in our knowledge of the mechanisms of person-to-person transmission of influenza, including the role of direct and indirect contact, the degree of viral contamination on hands and various types of surfaces in different settings, and the potential for contact transmission to occur in different locations and under different environmental conditions. There is little information on whether greater reductions in transmission could be possible with combinations of personal intervention (e.g., isolation away from family members as much as possible, plus using face masks and enhancing hand hygiene).	Additional high-quality RCTs of efficacy of hand hygiene against laboratory-confirmed influenza in other nonhealthcare settings, except households and university residential halls, would be valuable. In particular, studies in school settings are needed to solve the discrepancy between the two studies from the United States and Egypt.
Respiratory etiquette	There is no evidence about the quantitative effectiveness of respiratory etiquette against influenza virus.	RCTs of interventions to demonstrate the effectiveness of respiratory etiquette in reducing influenza transmission would be valuable.
Face mask	There are major gaps in our knowledge of the mechanisms of person-to-person transmission of influenza, including the importance of transmission through droplets of different sizes including small particle aerosols, and the potential for droplet and aerosol transmission to occur in different locations and with environmental conditions.	Additional high-quality RCTs of efficacy of face masks against laboratory-confirmed influenza would be valuable. Effectiveness of face masks or respirator use to prevent influenza prevention in special subpopulation, such as immunocompromised persons, would be valuable.
Surface and object cleaning	The effectiveness of different cleaning products in preventing influenza transmission–in terms of cleaning frequency, cleaning dosage, cleaning time point, and cleaning targeted surface and object material–remains unknown.	RCTs of interventions to demonstrate the effectiveness of surface and object cleaning in reducing influenza transmission would be valuable. Studies that can demonstrate the reduction of environmental detection of influenza virus through cleaning of surfaces and objects would also be valuable.

*RCT, randomized control trial.

In this review, we focused on 3 personal protective measures and 1 environmental measure. Other potential environmental measures include humidification in dry environments (*48*), increasing ventilation (*49*), and use of upper-room UV light (*50*), but there is limited evidence to support these measures. Further investigations on the effectiveness of respiratory etiquette and surface cleaning through conducting RCTs would be helpful to provide evidence with higher quality; evaluation of the effectiveness of these measures targeting specific population groups, such as immunocompromised persons, would also be beneficial (Table 2). Future cost-effectiveness evaluations could provide more support for the potential use of these measures. Further research on transmission modes and alternative interventions to reduce influenza transmission would be valuable in improving pandemic preparedness. Finally, although our review focused on nonpharmaceutical measures to be taken during influenza pandemics, the findings could also apply to severe seasonal influenza epidemics. Evidence from RCTs of hand hygiene or face masks did not support a substantial effect on transmission of laboratory-confirmed influenza, and limited evidence was available on other environmental measures.

This study was conducted in preparation for the development of guidelines by the World Health Organization on the use of nonpharmaceutical interventions for pandemic influenza in nonmedical settings.

This study was supported by the World Health Organization. J.X. and M.W.F. were supported by the Collaborative Research Fund from the University Grants Committee of Hong Kong (project no. C7025-16G).

About the Author

Ms. Xiao is a postgraduate student at the School of Public Health, University of Hong Kong, Hong Kong, China. Her primary research interests are influenza epidemiology and the dynamics of person-to-person transmission.

WHO	World Health Organization

Glossary

Contact tracing	Identification and follow-up of persons who may have come into contact with an infected person.
Closure	Halting the operation of an institution or business.
Isolation	Separation or confinement of a person who has or is suspected of having influenza virus infection, to prevent further infections.
Non-pharmaceutical /non-pharmacological interventions	Interventions that do not include pharmacological measures such as vaccines and antiviral drugs.
Personal protective measures	Measures to reduce personal risk of infection, such as hand washing and face masks.
Quarantine	Separation or restriction of the movement of persons who may be infected, based either on exposure to other infected people or on a history of travel to affected areas.
Movement restriction	Limitation on the movements of a person who has or is suspected of having an infection

EXECUTIVE SUMMARY

New influenza A viruses emerge in humans from time to time, causing global pandemics. The most recent influenza pandemic began in 2009 with the influenza A(H1N1)pdm09 virus. Public health measures against pandemic influenza include vaccines, antiviral drugs and non-pharmaceutical measures. Given that vaccines against novel pandemic strains are unlikely to be available in the early months of an influenza pandemic, and antiviral drugs are in short supply in many locations, non-pharmaceutical public health measures are often some of the most accessible interventions for community mitigation of a pandemic. Non-pharmaceutical interventions (NPIs) also have an important role in mitigating interpandemic influenza epidemics, which occur each winter in temperate locations and at varying times of the year in tropical and subtropical locations. These measures could reduce individuals' risk of infection, delay the epidemic peak, reduce the "height" of the epidemic peak, and spread cases over a long time period; each of these outcomes would contribute to reducing the overall impact of a pandemic or epidemic.

Here, we systematically review and evaluate the evidence base on the effectiveness and impact of community mitigation measures for pandemic and interpandemic influenza. This evidence base will contribute to updated public health guidelines for community mitigation measures for influenza. The scope of this review includes evidence on the effectiveness of interventions such as personal protective measures, environmental measures, social distancing measures, and travel-related measures. Consideration is also given to the feasibility of each intervention, including potential ethical issues.

We found that there is a limited evidence base on the effectiveness of non-pharmaceutical community mitigation measures. There are a number of high-quality randomized controlled trials demonstrating that personal measures (e.g. hand hygiene and face masks) have at best a small effect on transmission, with the caveat that higher compliance in a severe pandemic might improve efficacy. However, there are few randomized trials for other NPIs, and much of the evidence base is from observational studies and computer simulations. School closures can reduce transmission, but would need to be carefully timed to achieve mitigation objectives, while there may be ethical issues to consider. Travel-related measures are unlikely to be successful in most locations because current screening tools such as thermal scanners cannot identify presymptomatic and asymptomatic infections, and travel restrictions and travel bans are likely to have prohibitive economic consequences.

INTRODUCTION

Non-pharmacological interventions (NPIs) are often the most accessible interventions when a new pandemic influenza virus emerges and begins to spread, because of limited availability of antiviral drugs and delays in the availability of vaccines against the pandemic strain (1). These community mitigation measures may be able to slow the spread of infections in the community, delaying the peak in infections, reducing the size of the peak and spreading infections over a longer period of time (Fig. 1) (*2, 3*). Each of these consequences should contribute to reducing the overall impact of the epidemic or pandemic. Given that in some locations there could be limited surge capacity in hospitals (and particularly in intensive care beds), spreading infections over a longer time period could save lives, even if the total number of infections remained the same.

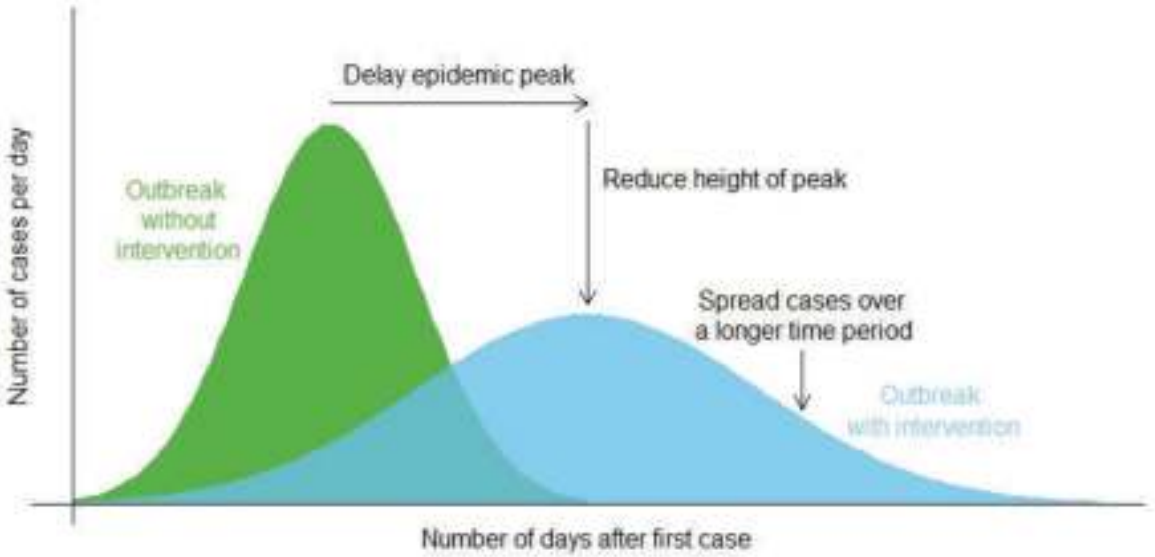

Fig. 1. Intended impact of non-pharmaceutical interventions on an influenza epidemic or pandemic by reducing person-to-person transmission

NPIs in non-health care settings usually focus on: reducing transmission by personal or environmental protective measures (e.g. hand hygiene); reducing the spread in the community populations (e.g. isolating and treating patients; closing schools and cancelling mass gatherings); limiting the international spread on travelling (e.g. travel screening and restriction); and public advice to the community (*4*). A number of health authorities have recently updated their reviews and guidelines on NPIs, including the United States (US) Centers for Disease Control and Prevention (CDC) (*2*), the European Centre for Disease Prevention and Control (*3*), the Australian Government Department of Health (*5*), the United Kingdom Department of Health (*6*), the Singapore Ministry of Health (*7*) and the Government of New Zealand (*8*).

This review examines the evidence base on each of the NPIs in community settings. While our focus is on the effectiveness of NPIs for mitigation of an influenza pandemic, the same measures may also be used in interpandemic influenza epidemics, which occur each winter in temperate locations and at varying times of the year in tropical and subtropical locations. In addition to NPIs in community settings, health authorities may also intervene in health care settings and systems, for example by establishing special influenza outpatient clinics, improving triage and isolation in hospitals, and cancelling non-essential surgeries. Health care system interventions are outside the scope of the present review of community mitigation measures.

The list of community mitigation measures is shown below. For each of the 18 listed NPIs, we first determined whether any systematic review had been published within the past 5 years (i.e. since January 2014), If there was a recently published review, we conducted a systematic review limited to studies published more recently than that review (starting from 1 year prior to the publication date), and updated that existing review. If we could not identify a systematic review of the NPI within the past 5 years, we conducted a full systematic review for the NPI. For the review of peer-reviewed articles, two independent reviewers screened all titles of studies identified by the search strategy for each of the NPIs, then reviewed the abstracts of the potentially relevant studies. If the studies described that NPI and its effectiveness against influenza transmission, the reviewers read the full-length text and extracted relevant data. Further discussion with a third reviewer was held if a consensus was not reached. We also evaluated the methodological quality of each of the studies using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach (*9*), based on the question of whether NPIs can reduce influenza transmission in the community. The quality of evidence was ranked for each study as high, moderate, low or very low, based on its risk of bias, consistency, directness, precision of the results and publication bias. Hence, we set the highest priority on randomized controlled trials (RCTs), then on observational studies and finally on simulation studies. If RCTs were reported, as a general principle we did not review observational studies or simulation studies, and if observational studies were reported, as a general principle we did not review simulation studies.

This report describes the evidence base on the effectiveness of each NPI. The specific targets of the evidence include but are not limited to reducing transmission, delaying the peak of the epidemic, spreading out infections over a longer time period, and reducing the total number of infections. This review of the evidence base will support the development of guidance on the use of NPIs for community mitigation. The NPIs reviewed in this report are listed below.

LIST OF NON-PHARMACEUTICAL PUBLIC HEALTH MEASURES

NPI	DEFINITION
Personal protective measures	**Personal hygiene measures to reduce the risk of acquiring or spreading respiratory infections.**
1. Hand hygiene	A personal measure aiming to reduce influenza transmission via direct or indirect contact by washing hands with soap and water or alcohol-based hand cleaners.
2. Respiratory etiquette	A personal measure aiming to reduce influenza transmission via respiratory droplets by covering nose and mouth with disposable tissues while coughing or sneezing.
3. Face masks	A personal measure aiming to reduce influenza transmission by wearing face mask of different types, including home-made masks, surgical and medical masks, or respirators with higher filtration rates. Masks can be worn by symptomatic or exposed persons to reduce onwards transmission (source control), or by uninfected persons in the community to reduce their risk of infection.

LIST OF NON-PHARMACEUTICAL PUBLIC HEALTH MEASURES

NPI	DEFINITION
Environmental measures	**Environmental hygiene measures to reduce the risk of acquiring or spreading influenza within an area.**
4. Surface and object cleaning	Routine cleaning of frequently used surfaces and objects to reduce influenza transmission.
5. Other environmental measures	Other measures to reduce risk of influenza transmission through the environment.
Social distancing measures	**Social measures to reduce the risk of acquiring or spreading respiratory infections in various community settings (e.g. homes, workplaces, schools, health care settings etc.)**
6. Contact tracing	The identification and follow-up of persons who may have come into contact with an infected person, usually in combination with quarantine of identified contacts.
7. Isolation of sick individuals	Reduction in virus transmission from an ill person to others by confining symptomatic individuals for a defined period either in a special facility or at home.
8. Quarantine of exposed individuals	Isolation of individuals who contacted a person with proven or suspected influenza, or travel history to an affected area, for a defined period after last exposure. Quarantined cases may be isolated.
9. School closure	Closure of schools either when virus transmission is observed in the school or community, or an early planned closure of schools before influenza transmission initiates.
10. Workplace closure	Closure of workplaces when virus transmission is observed in the workplace, or an early planned closure of workplaces before influenza transmission initiates.
11. Workplace measures	Measures to reduce influenza transmission in the workplace, or on the way to and from work, by decreasing frequency and length of social interactions.
12. Avoiding crowding	Measures to reduce influenza transmission in crowded areas (e.g. large meetings, conferences, and religious pilgrimages, national and international events).
Travel-related measures	**Measures including the provision of travel health advice, screening of travellers and restriction of travellers.**
13. Travel advice	Official government travel advice with legal and economic implications.
14. Entry and exit screening	Screening travellers for influenza symptoms to reduce the number of infectious individuals entering or leaving a country with infection, respectively, in order to delay the international spread of infection.

LIST OF NON-PHARMACEUTICAL PUBLIC HEALTH MEASURES

NPI	DEFINITION
15. Internal travel restrictions	Prevent or limit influenza transmission by restricting travel within a country.
16. Border closures	Prevent influenza entering a country by restricting travel to or from an affected area, in order to delay the international spread of infection.

SUPPORTING EVIDENCE FOR NPIS

Search strategy

Systematic reviews of NPIs were conducted using four databases (PubMed, EMBASE, MEDLINE and Cochrane Library) and the Cochrane Central Register of Controlled Trials (CENTRAL). The search strategy for each topic is given below.

MEASURES	SEARCH TERMS
1. Hand hygiene	#1: "hand hygiene" OR "hand washing" OR "handwashing" OR "hand-washing" OR "hand-wash" OR "hand wash" OR "handwash" OR "hand sanitize" OR "hand sanitizers" OR "hand sanitizer" OR "hand rub" OR "handrub" OR "hand rubbing" OR "hand cleansing" OR "hand cleans" OR "hand cleanser" OR "hand disinfectant" OR "hand disinfectants" OR "hand disinfection" OR "hand soap" OR "hand wipe" #2: "influenza" OR "flu" #3: #1 AND #2

1. PERSONAL PROTECTIVE MEASURES

1.1. Hand hygiene

Terminology
The definitions of relevant hand hygiene practices and products, and common terminology, are shown in Table 1 below.

Table 1. Definitions of hand hygiene terms

TERM	DEFINITION
Hand hygiene practices	
Hand hygiene	A general term referring to any action of hand cleansing, e.g. handwashing, antiseptic handwash, antiseptic hand rub, or surgical hand antisepsis (*10, 11*)
Hand cleansing	Action of performing hand hygiene for the purpose of physically or mechanically removing dirt, organic material, and/or microorganisms (*10*)
Handwashing	Washing hands with plain or antimicrobial soap and water (*10*)
Antiseptic handwashing	Washing hands with soap and water, or other detergents containing an antiseptic agent (*10*)
Antiseptic handrubbing (or handrubbing)	Applying an antiseptic handrub to all surfaces of the hands to reduce or inhibit the growth of microorganisms without the need for an exogenous source of water and requiring no rinsing or drying with towels or other devices (*10, 11*)
Hand disinfection	Hand disinfection is extensively used as a term in some parts of the world and can refer to antiseptic handwash, antiseptic handrubbing, hand antisepsis / decontamination / degerming, handwashing with an antimicrobial soap and water, hygienic hand antisepsis, or hygienic handrub (*10*)
Hand hygiene products	
Alcohol-based (hand) rub (or hand sanitizer)	An alcohol-containing preparation (liquid, gel or foam) designed for application to the hands to inactivate microorganisms and/or temporarily suppress their growth. Such preparations may contain one or more types of alcohol, other active ingredients with excipients, and humectants (*10*)

TERM	DEFINITION
Antimicrobial (medicated) soap	Soap (detergent) containing an antiseptic agent at a concentration sufficient to inactivate microorganisms and/or temporarily suppress their growth. The detergent activity of such soaps may also dislodge transient microorganisms or other contaminants from the skin to facilitate their subsequent removal by water (*10*)
Antiseptic hand wipe	A piece of fabric or paper pre-wetted with an antiseptic used for wiping hands to inactivate and/or remove microbial contamination. They may be considered as an alternative to washing hands with non-antimicrobial soap and water but, because they are not as effective at reducing bacterial counts on health care workers' hands as alcohol-based handrubs or washing hands with an antimicrobial soap and water, they are not a substitute for using an alcohol-based handrub or antimicrobial soap (*10*)
Plain soap	Plain soap refers to detergents that do not contain antimicrobial agents or contain low concentrations of antimicrobial agents that are effective solely as preservatives (*11*)
Other	
Visibly soiled hands	Hands showing visible dirt or visibly contaminated with proteinaceous material, blood, or other body fluids (e.g. faecal material or urine) (*11*)

Methods

We conducted a review of systematic reviews. PubMed, Medline, EMBASE and CENTRAL were searched for reviews until 1 August 2018. Review selection criteria were systematic reviews within 5 years studying the effect of hand hygiene interventions on prevention of laboratory-confirmed influenza in non-health care settings, regardless of language.

After identifying the most recent published systematic review (see below), we updated the search done in that published review in the same four databases through to 14 August 2018 using the same search terms. Study selection criteria were RCTs comparing the effect of hand hygiene interventions with no intervention in laboratory-confirmed influenza prevention in community settings. Study participants or clusters of participants were assigned prospectively into intervention and control groups using random allocation. A community setting was defined as an open setting without confinement or special care for the patients. Articles describing any hand hygiene related interventions were included. No language limits were applied.

Because of the availability of a reasonable number of randomized trials of hand hygiene, we did not extend the search to observational studies, but we did note the findings from earlier systematic reviews of observational studies of hand hygiene (*12-14*).

After data extraction, quality assessment of the evidence was done for included studies based on the GRADE framework. The research question was to study the effect of hand hygiene intervention on laboratory-confirmed influenza prevention.

Two independent reviewers (ZX and ES) reviewed retrieved titles and subsequent relevant abstracts independently. Titles or abstracts with any one of the reviewers' decision to include were included in next step. After title and abstract screening, two reviewers reviewed the full text based on the selection criteria. Data extraction and evidence quality assessment were also done by the reviewers. If a consensus was not reached, further discussion was held or opinion was obtained from the third independent reviewer.

Risk ratios (RRs) and their 95% confidence intervals (95% CIs) were calculated to estimate the effect of hand hygiene intervention on prevention of laboratory-confirmed influenza. Heterogeneity of each pooled and subgroup analysis was assessed by I2 statistics. The overall effect of each pooled and subgroup analysis was estimated by fixed-effect model. If the heterogeneity was high (I2 ≥ 75%), we did not estimate an overall pooled effect.

Results

We identified 225 reviews through the database search with our search terms, of which 172 reviews were screened out during by title and abstract screening. 46 reviews were excluded after full-text assessment that were not systematic reviews, not within the past 5 years, not based on RCTs, or had no hand hygiene intervention or no laboratory-confirmed influenza outcome. In total, seven reviews were included in our analysis, from which we identified nine eligible articles. The most recent systematic review and meta-analysis was published in 2014; it reviewed and analysed RCTs to study the effect of hand hygiene on the prevention of laboratory-confirmed influenza (*15*). The process of identifying these review articles is shown in Fig. 2.

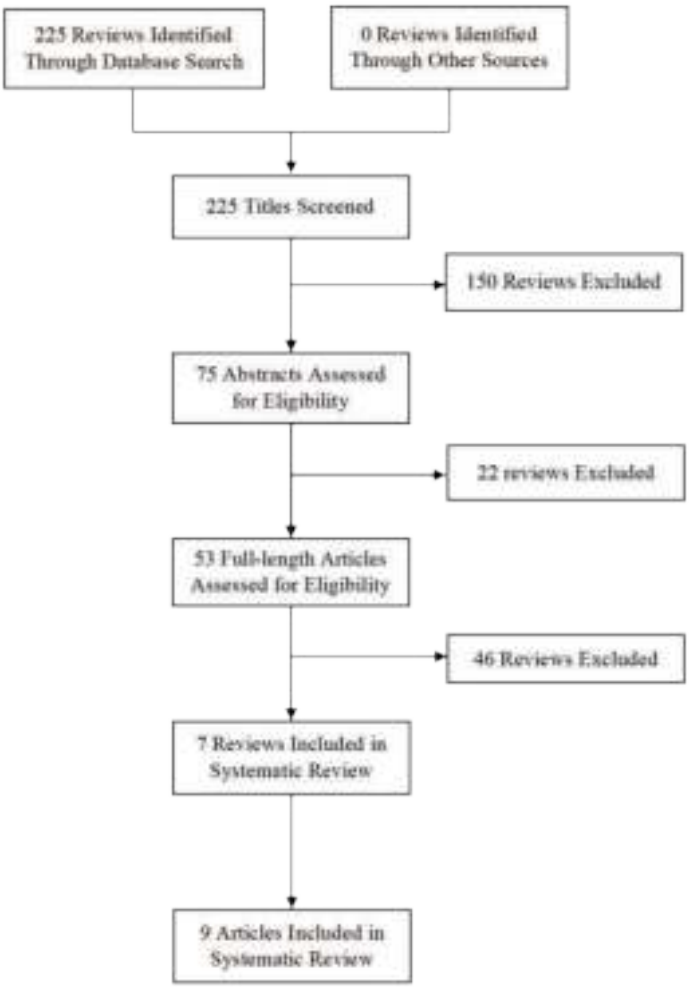

Fig. 2. The flow chart of hand hygiene review selection

In the additional search to update the systematic review by Wong et al. (*15*) that was published in 2014, 352 articles were identified from 1 January 2013 to 14 August 2018. At total of 319 articles were excluded in the title and abstract screening. 30 articles were excluded that were not RCTs, not done outside of health care settings, did not have a hand hygiene intervention or did not have a laboratory-confirmed influenza outcome. Three additional articles were identified since the publication of the review by Wong et al. (*15*). In total, 12 articles (11 studies; Azman et al. (*16*) and Stebbins et al. (*17*) were the same project during the same period but studied different questions) were included in our systematic review and 11 articles (10 studies; Levy et al. (*18*) only had household level secondary infection data but no individual level data) were included in the meta-analysis. The article selection flow is shown in Fig. 2.

Soap and education	1 (7)
Soap and face mask	2 (13)
Outcome assessed	
Laboratory-confirmed influenza	11 (100)

[a] More than one intervention for some studies.

Among the 11 included studies, 7 studies were in household settings, two in elementary schools and two in university residential halls. Included study information is shown in Table 2, and detailed study description and evidence quality assessment are shown in Table 3. The evidence profile for the outcomes is summarized in Table 4.

In the pooled analysis, hand hygiene with face mask (RR = 0.91, 95% CI: 0.73–1.13, p = 0.39, I2 = 35%) did not have a statistically significant protective effect in non-health care settings (Fig. 4) *(19-24)*. Some published studies noted that poor adherence to hand hygiene may lead to underestimation of the true effect of the intervention (*19, 21, 22*).

The relative importance of transmission modes of influenza may vary in different settings. In school settings, no total effect was generated due to high heterogeneity (Fig. 5) (*17, 25*). In a study in the United States of America (USA), there was no significant effect of hand hygiene with a point estimate of the risk ratio close to 1, whereas a large trial in Egypt reported a reduction of more than 50% in influenza cases in the intervention group.

Hand hygiene with face mask intervention contributed to 52% relative risk reduction (RR = 0.48, 95% CI: 0.21–1.08, p = 0.08, marginally significant, I2 = 0%) of laboratory-confirmed influenza infection in university residential hall (Fig. 6) (*20, 23*).

The efficacy of hand hygiene with or without face mask was insignificant (RR = 1.05, 95% CI: 0.86–1.27, p = 0.65, I2 = 57%) in household setting in the analysis (Fig. 7) (*19, 21, 22, 24, 26, 27*). Although the pooled analysis did not identify a significant effect of hand hygiene overall, some household transmission studies reported that implementing hand hygiene intervention earlier after onset in the index case might be more effective in preventing secondary cases in the household (*19, 24*).

Experimental studies found that influenza virus could not survive long on human hands (*28, 29*). Viable influenza virus could be transmitted from contaminated surfaces to human hands by rubbing (*30*). Simmerman cultured live influenza virus from a finger swab sample from a laboratory-confirmed influenza patient (*31*). This evidence suggested the biological plausibility of indirect contact transmission via contaminated hands of influenza. Experimental studies also claimed that hand hygiene practice (e.g. handwashing with water and soap, and handrubbing with alcohol-based handrub) is effective to inactivate or reduce viable influenza virus on human hands (*32-34*). These results highlighted the importance of hand hygiene and suggested that hand hygiene may be initiative to prevent influenza transmission.

Ethical considerations

There are no major ethical issues. Alcohol-based handrub might be not available in some locations due to religious objections, such as the situation of incompliance of hand hygiene recommendation among Muslim health care workers (35). Skin irritation by alcohol handrub is possible, although the irritant potential of alcohol-based handrub is very low (*36*). Low adherence to hand hygiene intervention was observed in some studies (*19, 21, 22, 26*).

Knowledge gaps

Our review identified 10 RCTs of hand hygiene against laboratory-confirmed influenza. The pooled estimate of the effectiveness of hand hygiene in household settings was close to the null, with a fairly narrow confidence interval (Fig. 7), and future studies are unlikely to move the pooled estimate far from the null even if individual trials done in the future show protective efficacy of hand hygiene. In schools, there are only two published trials, and there is a clear need for additional studies to resolve the discrepancy between those two studies from the USA and Egypt (*17, 25*), one of which showed a considerable effect of hand hygiene (Fig. 5).

A more basic knowledge gap is on mechanisms of person-to-person transmission of influenza, including virus survival on hands and different types of surfaces, and the potential for contact transmission to occur in different locations and with different environmental conditions. Randomized trials of hand hygiene can contribute to determining modes of influenza transmission because hand hygiene would primarily act against one specific mode of transmission (indirect contact) but not other modes (respiratory droplets of varying sizes) (*37*).

Table 3. Description of studies included in the review of hand hygiene

STUDY	STUDY DESIGN	STUDY PERIOD	POPULATION & SETTING	TRANSMISSION MODE	INTERVENTION	OUTCOME & FINDING	QUALITY OF EVIDENCE
Azman AS, 2013 (*16*)	Cluster-RCT School level	2007–2008 influenza season	3360 students from 10 elementary schools in Pittsburgh, USA	Primary and secondary	Hand sanitizer, soap and education	The primary transmission outcome refers to Stebbins, S. 2011; no significant difference in secondary ILI attack rate between intervention group and control group	Moderate
Levy JW, 2014 (*18*)	Cluster-RCT Household level	2009–2010	191 households with index children recruited from a public paediatric hospital in Bangkok, Thailand	Secondary	Handwashing; handwashing and face mask	Less secondary influenza infections in households in the intervention group than control group, but not statistically significant; handwashing reduces surface influenza RNA contamination	Moderate
Ram PK, 2015 (*27*)	Cluster-RCT Household level	2009–2010	384 households with index case-patients recruited from a hospital in Kishoregoni, Bangladesh	Secondary	Handwashing with soap and education	Handwashing promotion did not prevent secondary influenza infection in household setting	Moderate
Aiello AE, 2010 (*20*)	Cluster-RCT University residence hall level	2006–2007 influenza season	1297 participants recruited from7 residential halls in Michigan, USA	Primary	Hand sanitizer and face mask; face mask	The laboratory-confirmed influenza protective effect of intervention is not significant; but the intervention is significant in ILI reduction	Moderate
Aiello AE, 2012 (*23*)	Cluster-RCT University residence hall level	2007–2008 influenza season	1111 participants recruited from 5 residential halls in Michigan, USA	Primary	Hand sanitizer and face mask; face mask	Reductions in the rates of influenza in the intervention groups, but not significant; significant reduction in the rates of ILI	High
Cowling BJ, 2008 (*26*)	Cluster-RCT Household level	2007	198 households with index subjects recruited from outpatient clinics in Hong Kong SAR, China	Secondary	Hand sanitizer and education; face mask and education	No significant difference between intervention groups and control group in laboratory-confirmed influenza and clinical secondary attack rate	Moderate

STUDY	STUDY DESIGN	STUDY PERIOD	POPULATION & SETTING	TRANSMISSION MODE	INTERVENTION	OUTCOME & FINDING	QUALITY OF EVIDENCE
Cowling BJ, 2009 (*19*)	Cluster-RCT Household level	2008	259 households with index subjects recruited from outpatient clinics in Hong Kong SAR, China	Secondary	Hand sanitizer and education; hand sanitizer, face mask and education	Hand hygiene and face mask intervention prevent influenza transmission, but not statistically significant; among the households implementing interventions within 36 hours symptom onset of index cases, the interventions significantly reduce influenza transmission	Moderate
Larson EL, 2010 (*21*)	Cluster-RCT Household level	2006–2008	509 households were recruited in New York, USA	Primary	Hand sanitizer and education; hand sanitizer, face mask and education	There is no detectable benefit of hand hygiene, face mask and education intervention on influenza prevention	Moderate
Simmerman JM, 2011 (*22*)	Cluster-RCT Household level	2008–2009	442 households with index children recruited from a public paediatric hospital in Bangkok, Thailand	Secondary	Handwashing; handwashing and face mask	Hand hygiene and face mask intervention did not reduce influenza transmission	Moderate
Stebbins S, 2011 (*17*)	Cluster-RCT School level	2007–2008 influenza season	3360 students from 10 elementary schools in Pittsburgh, USA	Primary	Hand sanitizer, soap and education	"WHACK the Flu" programme did not reduce laboratory-confirmed influenza infection, but reduced absence episodes and laboratory-confirmed influenza A	Moderate
Suess T, 2011 (*24*)	Cluster-RCT Household level	2009–2010 pandemic season 2010–2011 influenza season	84 households with one influenza positive index case were recruited by general practitioners or paediatricians in Berlin, Germany	Secondary	Hand sanitizer and face mask; face mask	The interventions could reduce influenza transmission in household setting when implemented early and use properly	Moderate
Talaat M, 2011 (*25*)	Cluster-RCT School level	2008	44 451 students were enrolled from 60 elementary schools in Cairo, Egypt	Primary	Handwashing	Hand hygiene campaign effectively reduced different kinds of infectious disease, including laboratory-confirmed influenza	Moderate

ILI: influenza-like illness; RCT: randomized controlled trial; RNA: ribonucleic acid; SAR: Special Administrative Region; USA: United States of America.

Table 4. Grade evidence profile for hand hygiene

QUALITY ASSESSMENT							NO. OF PATIENTS		EFFECT		
No. of studies	Design	Risk of bias	Inconsistency	Indirectness	Imprecision	Other considerations	Hand hygiene with or without face mask	versus control	Risk ratio	Quality	Importance
Effect of hand hygiene intervention on prevention of laboratory-confirmed influenza											
10	Randomized trial [1]	No serious risk of bias [2,3,4]	Serious [5]	No serious indirectness [6]	Serious [7]	Strong association [8]	434/6442 (6.7%)	504/5392 (9.3%)	Risk ratio cannot be generated because of high heterogeneity	Moderate	Important

1 All studies were randomized trials.
2 All studies were cluster-RCTs at household, school and university residence level.
3 Five studies reported blinding of study staff including clinical staff, laboratory staff or recruiting physicians. Subjects of all studies were not blinded due to the nature of the study design.
4 Allocation concealment was adequate in all trials. Three studies used block randomization and seven studies used simple randomization.
5 High heterogeneity was observed in the pooled analysis (I2 > 50%).
6 Laboratory-confirmed influenza was the outcome for all studies.
7 Cowling B.J. 2008 and Suess T. 2011 reported insufficient number of participants. Cowling B.J. 2009 reported insufficient statistical power. Larson E.L. 2010 reported lower rate of illness was found compared to initial assumption. Simmerman J.M. 2011 reported did not reach the recruitment target. Talaat M. 2011 reported low rate of testing of students who were absent due to ILI.
8 Aiello AE (2012), rated as high-quality study, showed a large effect in favouring hand hygiene intervention – RR = 0.4.

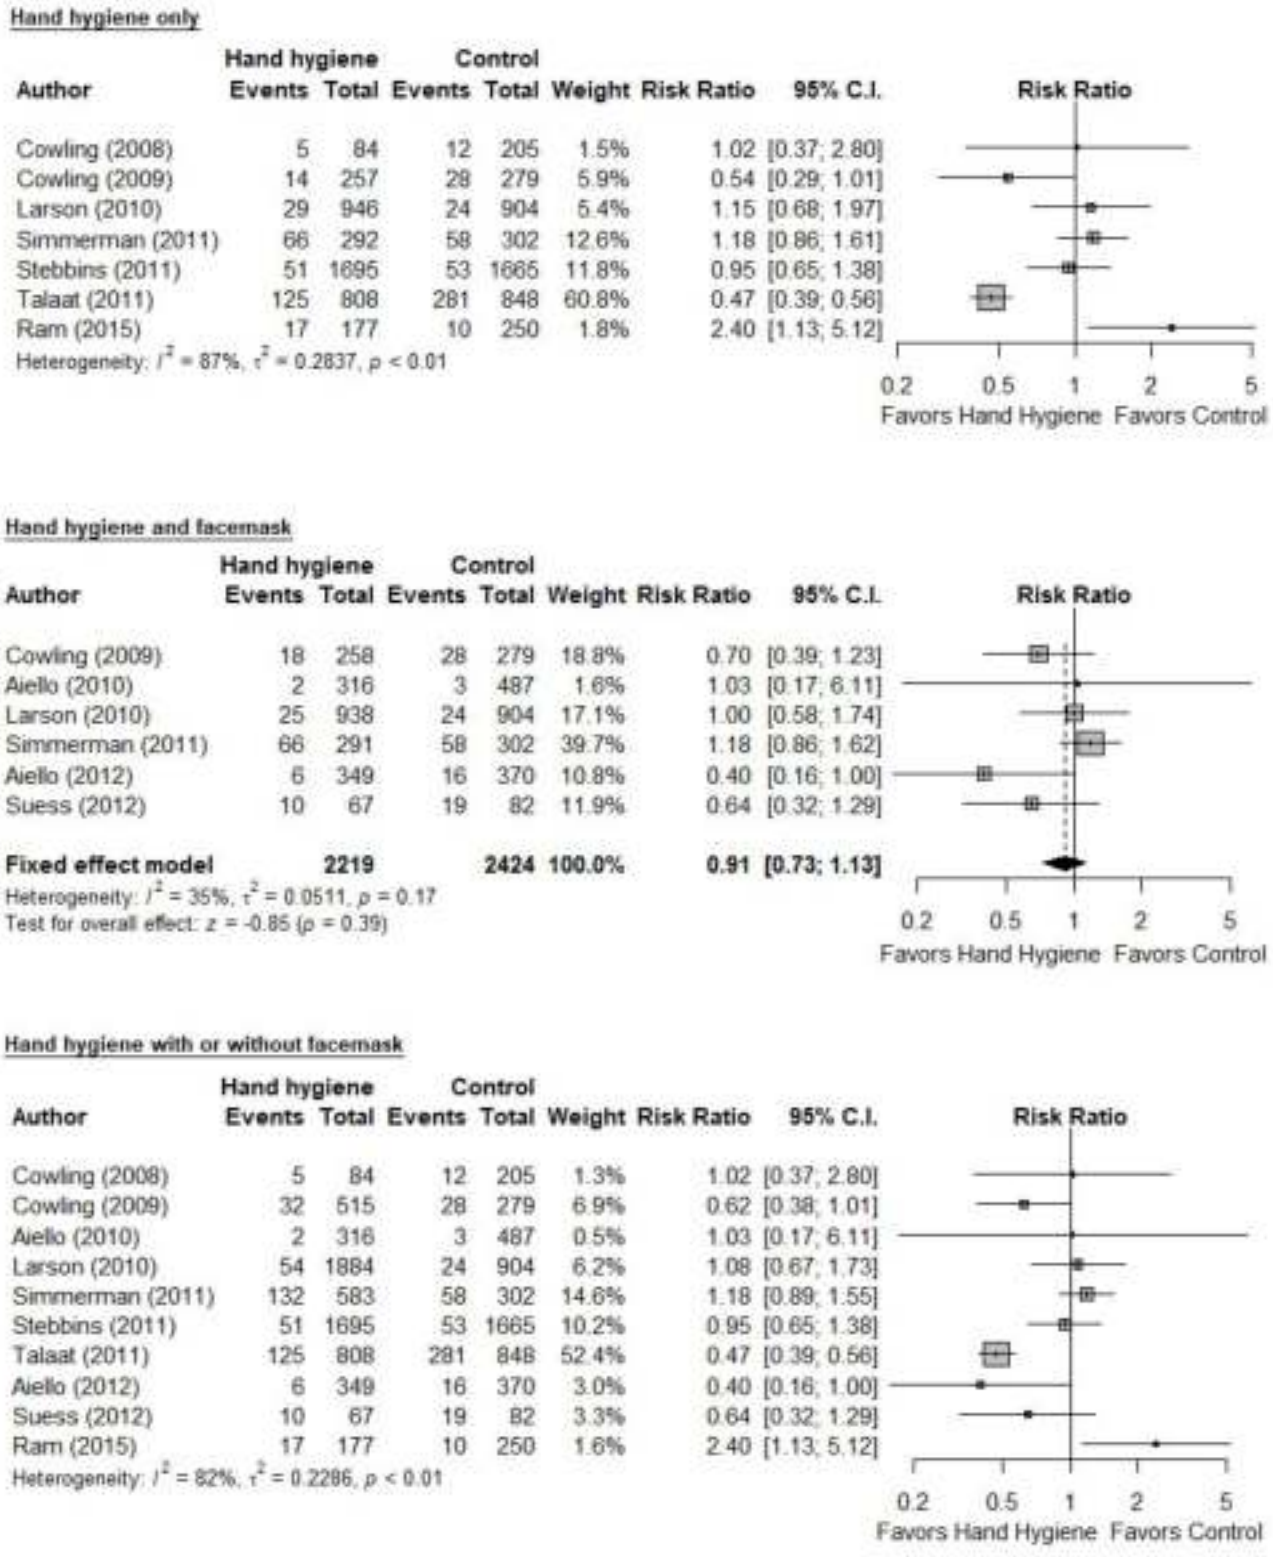

Fig. 4. Risk ratios for the effect of hand hygiene interventions with or without face mask on laboratory-confirmed influenza (pooled analysis)

Note: Total effect would not be estimated when heterogeneity is high (I2 ≥75%).

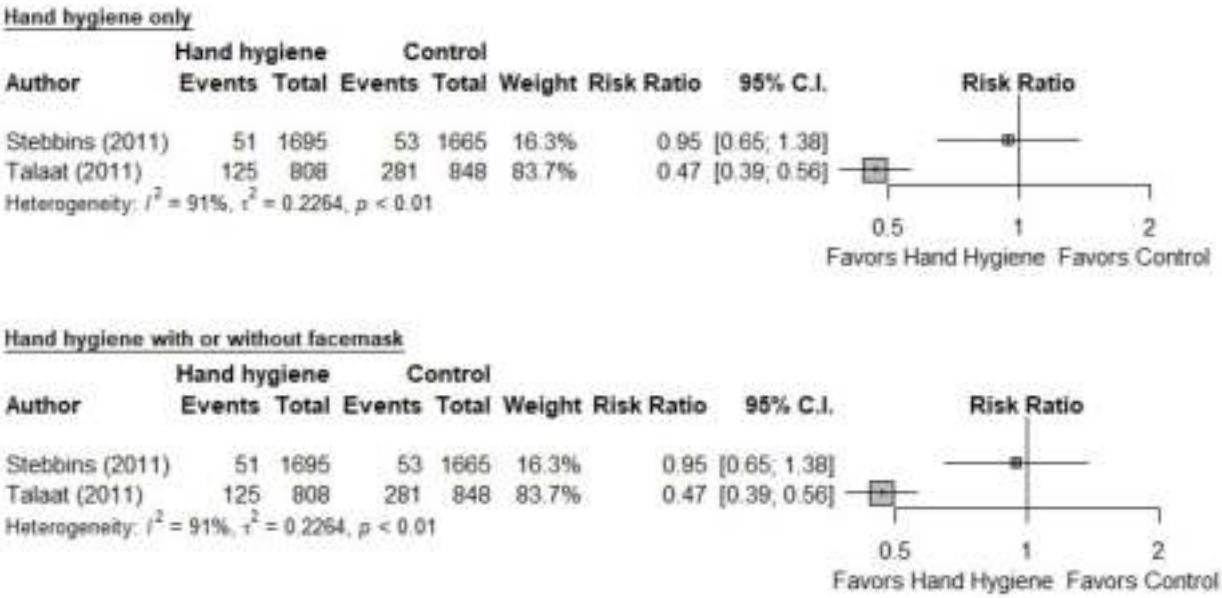

Fig. 5. Risk ratios for the effect of hand hygiene interventions with or without face mask on laboratory-confirmed influenza in elementary school setting

Note: Total effect would not be estimated when heterogeneity is high (I2 ≥ 75%).

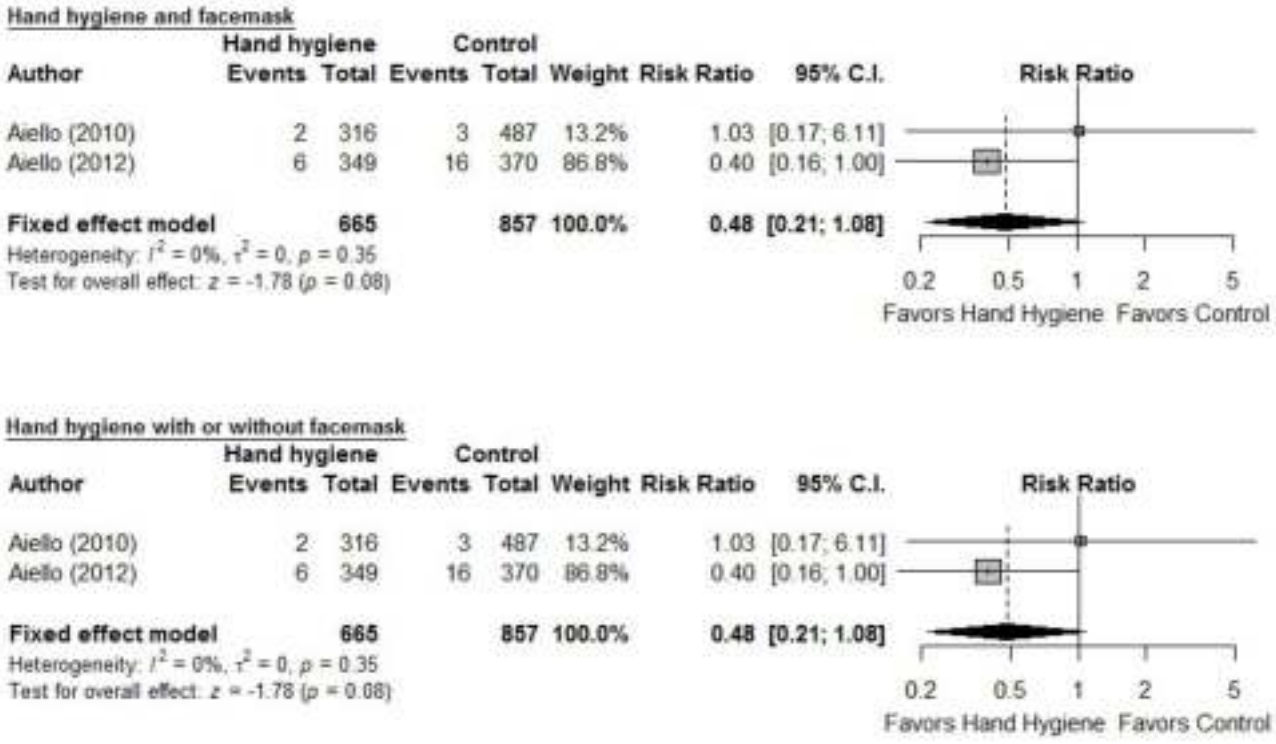

Fig. 6. Risk ratios for the effect of hand hygiene interventions with or without face mask on laboratory-confirmed influenza in university residential hall setting

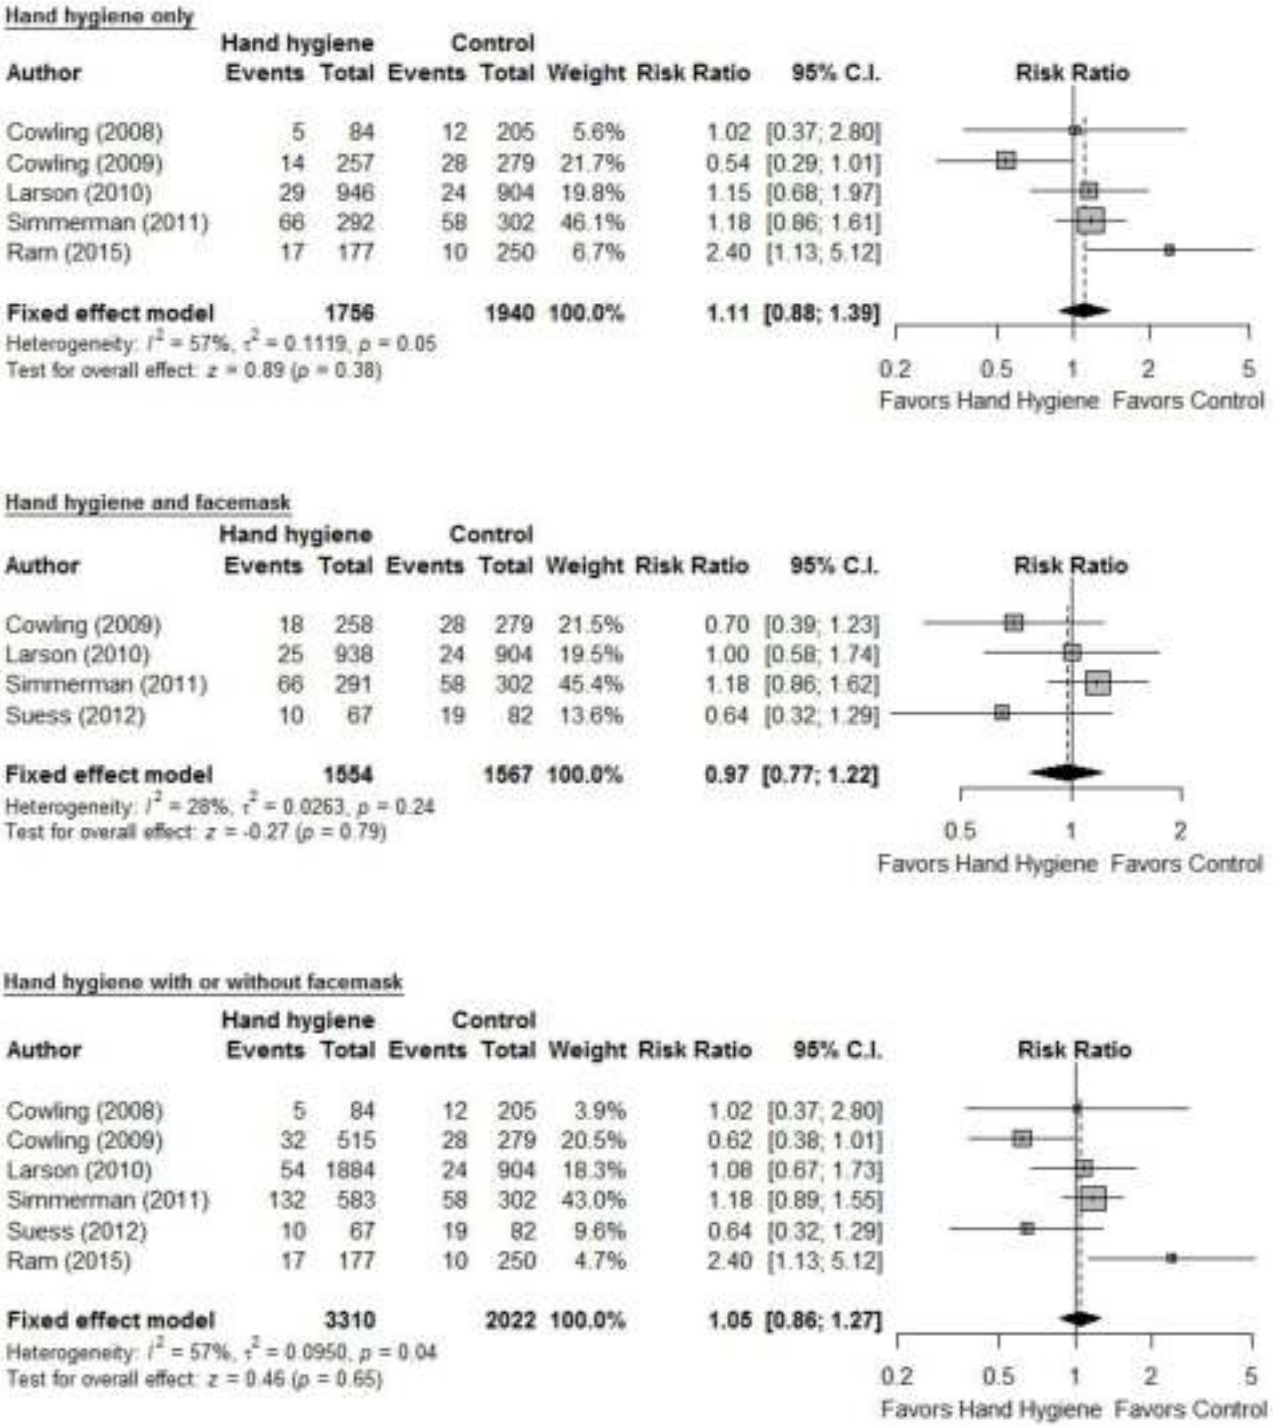

Fig. 7. Risk ratios for the effect of hand hygiene interventions with or without face mask on laboratory-confirmed influenza in household setting

1.2. Respiratory etiquette

Terminology

Definitions of respiratory etiquette are shown in Table 5.

Table 5. Definitions of respiratory etiquette terms

TERM	DEFINITION
Respiratory etiquette	Respiratory etiquette is also known as 'cough etiquette' (*38*). It is a simple hygiene practice to prevent person-to-person transmission of respiratory infections. Measures include (*39*): 1) Cover the mouth and nose with a tissue when coughing or sneezing 2) Find the nearest waste basket to dispose the used tissue immediately 3) Wash hands after touching respiratory secretions and/or contaminated objects

Methods

On 6 November 2018, we conducted a literature search in four databases: Medline (January 1946 to October 2018), PubMed (January 1950 to October 2018), EMBASE (1980 to October 2018), and CENTRAL (The Cochrane Library, 2018, Issue 5). Reference lists of retrieved articles were also reviewed for additional potential articles for this review. Articles of all languages were reviewed. Studies were selected if they investigated specifically the use of respiratory/ cough etiquette as the intervention along with the study outcome of laboratory-confirmed influenza virus infection. Studies that reported use of face mask as part of the respiratory etiquette were excluded because they will be covered in Section 1.3. Two independent reviewers (ES and SG) reviewed retrieved titles and subsequent relevant abstracts independently.

Results

A total of 80 articles were retrieved from four electronic databases after removing duplicate publications. Titles, abstract content and full text were subsequently reviewed for inclusion; 35 abstracts were selected for screening and then 18 full-text articles were assessed for eligibility. No studies were identified for this review to quantify the efficacy of respiratory etiquette with the outcome of laboratory-confirmed influenza. The flow chart is shown Fig. 8.

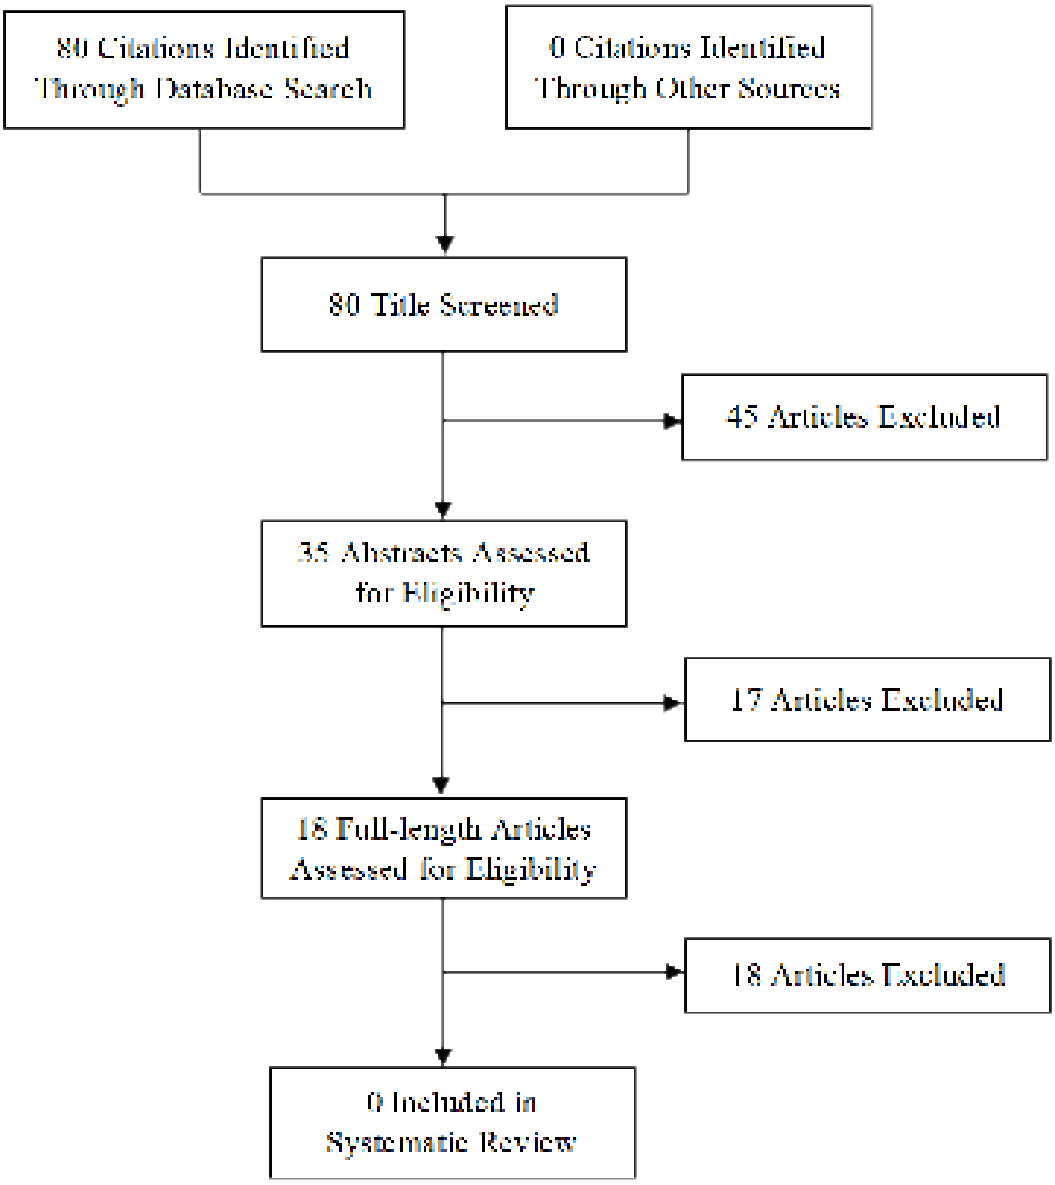

Fig. 8. Flow chart of the process and results of study selection

Balaban et al. reported a 2% reduction of self-reported respiratory illnesses, defined by one or more symptoms in cough, congestion, sore throat, sneezing or breathing problems, with the practice of cough etiquette among US pilgrims in the 2009 Hajj (*40*). Zayas et al. conducted an observational study to determine the effectiveness of respiratory etiquette manoeuvres in blocking the release of droplets or aerosols during coughing (*38*). They concluded the common respiratory etiquette (using surgical mask and hand, arm or sleeve, tissue) is not effective in blocking different diameter droplets to the surrounding environment and the majority of droplets dispersed to the environment when practicing the manoeuvre were < 1 µm.

Ethical considerations

No major ethical considerations. Cultural contexts may need to be considered when recommending specific actions such as covering coughs with hands or tissues.

Knowledge gaps

There is a need for further research in the best measures of respiratory etiquette for reducing influenza transmission (38).

1.3. Face masks

Terminology
Relevant terminology relating to face masks is shown in Table 6.

Table 6. Definitions of masks terms

TYPES OF MASKS	TERMINOLOGY
Clothing, scarf or rags tied over the nose and mouth	These are referred as alternative barriers to medical masks, but there is insufficient information available on their effectiveness *(41)*.
Cloth mask Face mask	Cloth masks can be referred to 'reusable masks made of cloth or any other fabric, including cotton, silk or muslin'*(42)* . Fitness of fabric and number of layers of a cloth mask determine its filtration capacity *(42)*. Cloth masks should be cleaned thoroughly between each use *(43)*. Washing with household detergent at normal temperature will be sufficient *(43)*.
Respirator	A face mask, also known as surgical, isolation, dental or medical procedure masks, is a loose-fitting, disposable device that covers the mouth and nose of the user, and helps block large-particle droplets, splashes, sprays or splatter that may contain infectious agents *(44)*. Face masks may also help reduce exposure of user's saliva and respiratory secretions to others *(44)*. They may come with or without a face shield and are not designed to be shared *(44)*. They are not designed to protect against breathing in small-particle aerosols that may contain viruses. Face masks should be used once and then disposed in the trash *(45)*. Respirator, also known as filtering facepiece respirator, is a personal protective device that covers the nose and mouth of the user, and helps reduce the risk of inhaling hazardous airborne particles (including dust particles and infectious agents), gases, or vapours on the user *(46)*. NIOSH in the USA certifies N, R and P series particulate filtering respirator types 95, 99 and 100 with minimum filtration efficiencies of 95, 99 and 99.97%, respectively. This certification is recognized by countries like Canada, Mexico and Chile. Several countries including Canada, Mexico and Chile. In Europe, respirators marked with 'Conformité Européen' (CE) such as FFP1 (class P1), FFP2 (class P2) and FFP3 (class P3) types meet minimum filtration efficiencies of 80, 94 and 99%, respectively *(47)*. A label 'NIOSH' is required to be printed on the NIOSH-approved products with other information including part, lot number and company name; A label 'CE' on the product indicates EC conformity *(47)*.

EC: European Community; NIOSH: National Institute for Occupational Safety and Health; USA: United States of America.

Methods

On 28 July 2018, we conducted a literature search in four databases: Medline (January 1946 to June 2018), PubMed (January 1950 to July 2018), EMBASE (1980 to June 2018), and CENTRAL (The Cochrane Library, 2018, Issue 5). Reference lists of retrieved articles were also reviewed for additional potential articles for this review. Articles of all languages were reviewed. Studies were selected if they were conducted in RCT in community settings such as households and schools, evaluated the use of face masks with or without the combination of other intervention as one intervention, and included the incidence of laboratory-confirmed influenza case as study outcome. Two independent reviewers (ES and ZX) reviewed retrieved titles and subsequent relevant abstracts independently.

Qualities of studies were assessed by GRADE with an aim to evaluate the efficacy of community-based face mask use in the prevention of laboratory-confirmed influenza virus infections.

Results

A total of 1100 articles were retrieved from four electronic databases after removing duplicate records. Titles, abstract content and full text were subsequently reviewed for inclusion; 10 relevant studies were identified for this review and meta-analysis to quantify the efficacy of community based use of face masks after excluding 89 articles by full-text assessment. The flow chart is shown in Fig. 9. Of 10 studies, seven were conducted in household settings (*19, 21, 22, 24, 26, 48, 49*), with two studies conducted in university residence halls (*20, 23*), and one study conducted in Hajj pilgrims (*50*). Nearly half of the studies evaluated the effect of face mask use with the practice of handwashing, therefore results were analysed in two groups: comparison of control group with intervention group of face mask use only; and comparison of control group with intervention group of face mask use with or without handwashing.

Among the 10 selected studies, two studies by MacIntyre et al. had a slightly different study design. One study enrolled families in which one person had laboratory-confirmed influenza, and only required the household contacts to wear face masks or P2 masks (equivalent to a N95 respirator) (48), whereas the other study required only the ill members to wear face mask to evaluate the protective effect of face mask if worn by the ill individual (i.e. source control) (*49*). In the remaining eight studies, every participant in the face mask intervention group was supposed to wear a face mask.

MacIntyre et al. compared the protective effect of face mask and P2 mask but found no significant difference in influenza-like illness (ILI) and laboratory-confirmed respiratory infections (influenza A and B virus, respiratory syncytial virus [RSV], human metapneumovirus [hMPV], adenovirus, human parainfluenza virus [PIV], coronavirus, rhinovirus, enterovirus or picornovirus); however, they reported a significant reduction in ILI if the mask was worn with good compliance in a secondary analysis (*48*).

Two studies by Aiello et al. were conducted in residence hall settings (*20, 23*). They randomized university residents by cluster (each residential hall forming a cluster unit) to face masks, enhanced hand hygiene, or both. They then measured the incidence of laboratory-confirmed influenza in students in each hall. The authors reported no significant difference in ILI and laboratory-confirmed influenza in these three randomized groups; however, they observed a significant reduction in ILI in the combined face mask and hand hygiene intervention group during the latter half of the study period in a secondary analysis.

Seven studies were conducted in household settings where a person with laboratory-confirmed influenza was recruited as a household index case, and the rate of secondary infections in the education group (control), mask group and/or hand hygiene group was monitored for illnesses and infections. All studies found no significant differences in the rate of laboratory-confirmed

influenza virus infections in contacts in the face mask arms, and some studies reported that low compliance of the use of NPIs could affect the results (*21*). One study reported a significant reduction in laboratory-confirmed influenza virus infections in contacts in the face mask and hand hygiene group in the subset of households where the intervention was applied within 36 hours of symptom onset in the index case (*24*).

Ten studies were pooled to conduct a meta-analysis to quantify the efficacy of community based use of face masks in the reduction of laboratory-confirmed influenza virus infection (Table 7). In the pooled analysis, there was a non-significant relative risk reduction of 22% (RR = 0.78, 95% CI: 0.51–1.20, I2 = 30%, p = 0.25) in the face mask group and 8% in the face mask group regardless of the addition of practice of hand hygiene (RR = 0.92, 95% CI: 0.75–1.12, I2 = 30%, p = 0.40). The evidence profile for face masks outcome is summarized in Table 8.

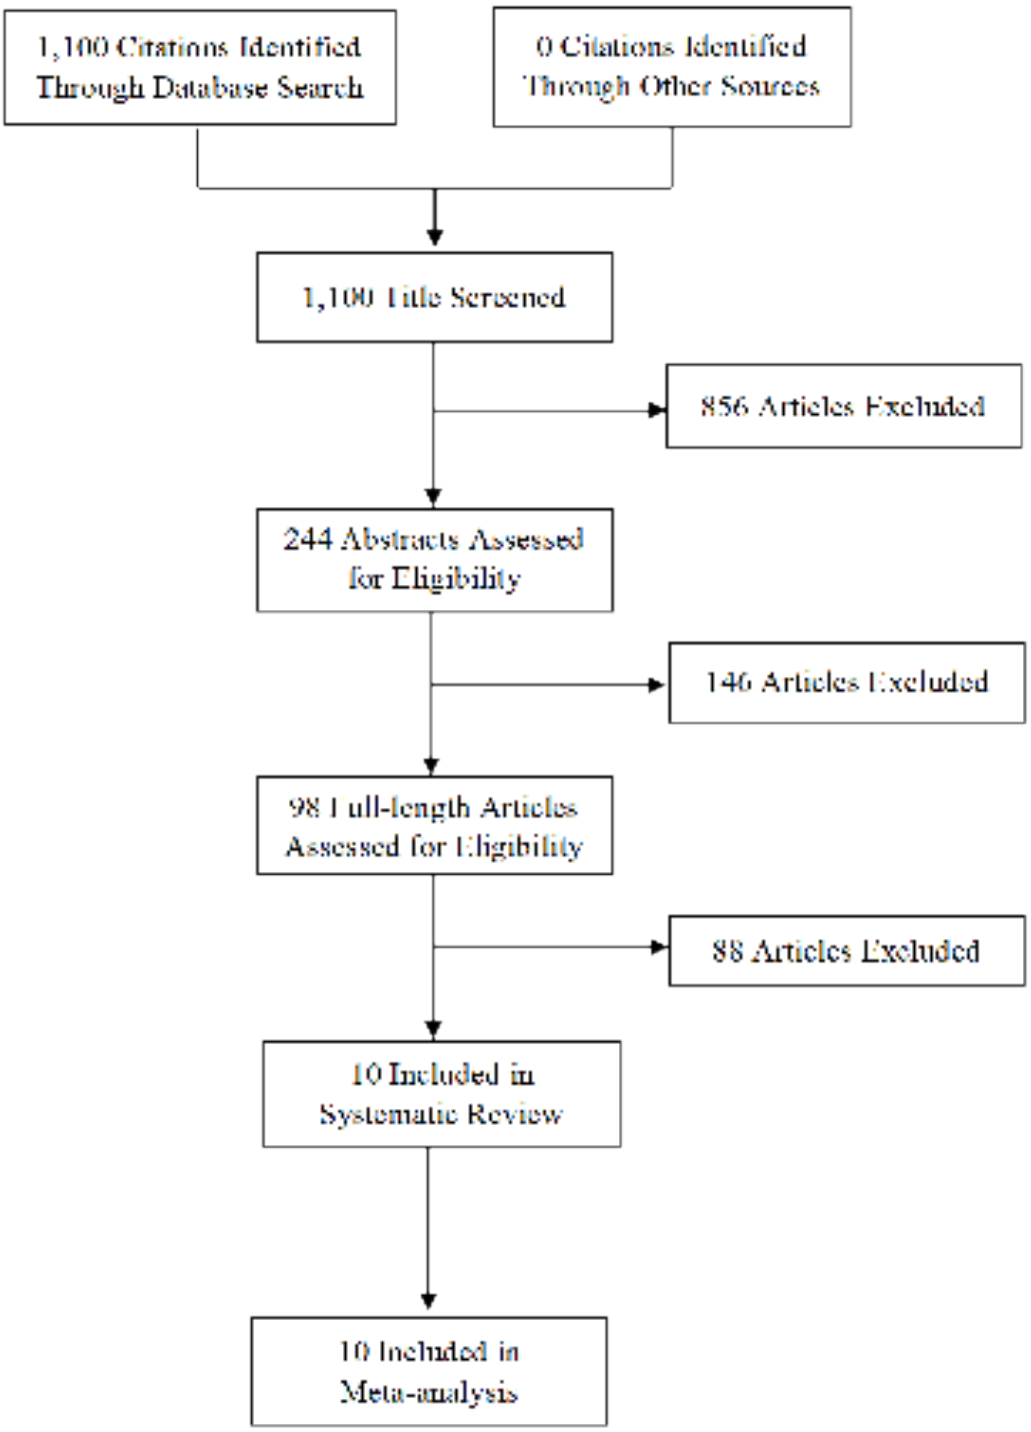

Fig. 9. The flow chart of the process and results of study selection

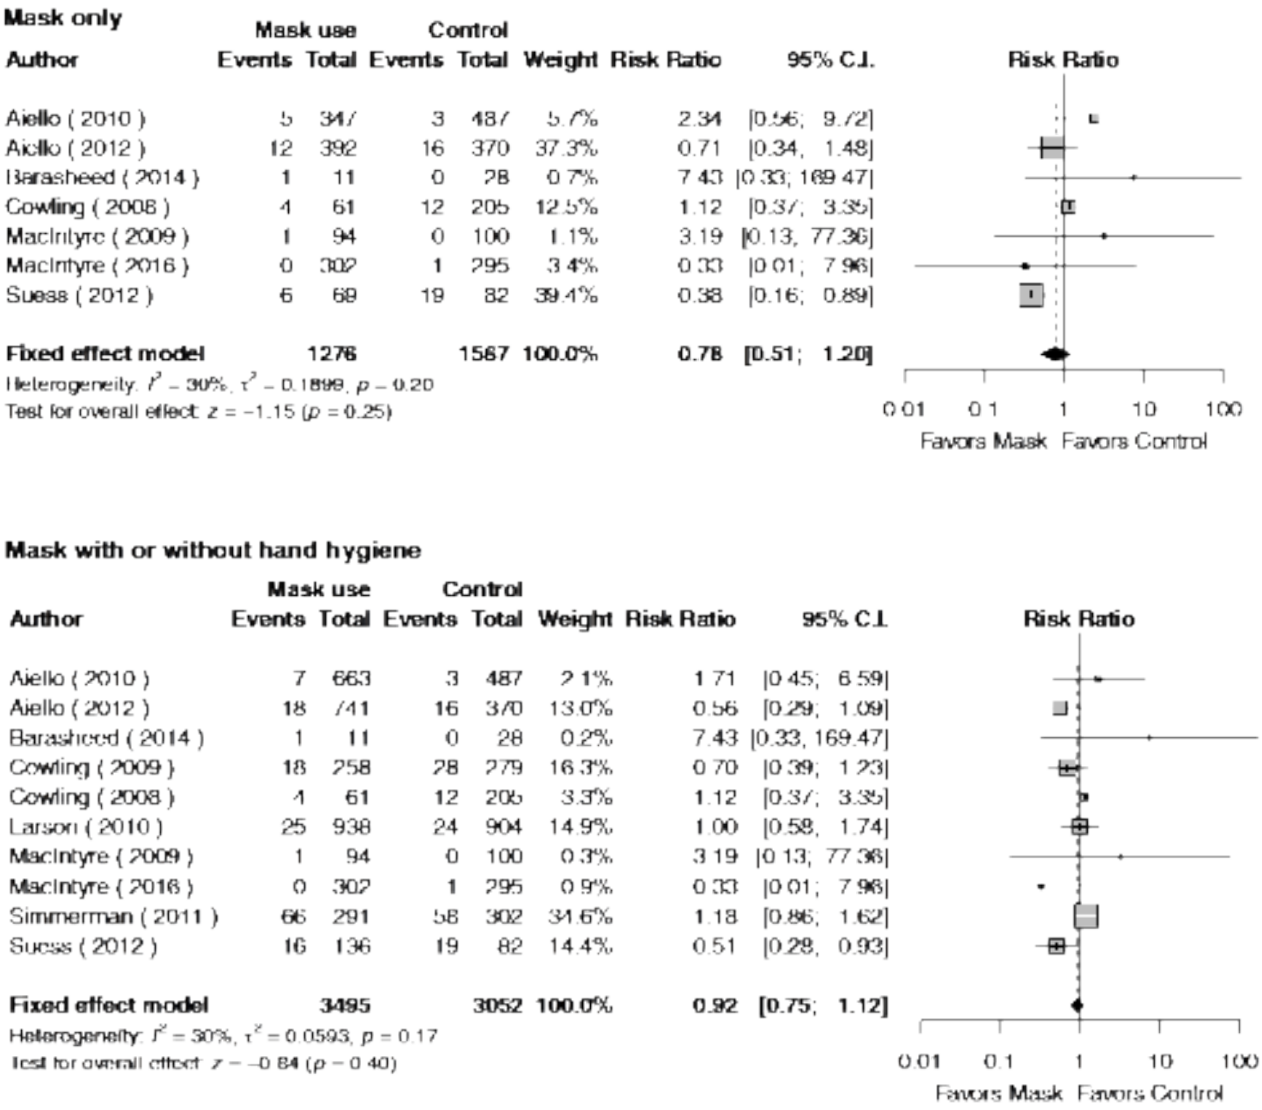

Fig. 10. Effects of face mask use interventions with or without enhanced hand hygiene on laboratory-confirmed influenza in 10 studies

Ethical considerations

No major ethical considerations. Masks may be more culturally acceptable in some locations than others, and a variety of factors may affect compliance.

Knowledge gaps

In the studies of face mask use with or without hand hygiene, the pooled estimate of the risk reduction against laboratory-confirmed influenza was 0.90 (95% CI: 0.75–1.12), which suggests that additional randomized trials would be less likely to identify a substantial protective efficacy of face masks. However, the majority of these studies were conducted in households in which at least one person was infected, and exposure levels might be relatively higher. Additional studies of face mask use in the general community would be valuable. While respirators should provide better protection against respiratory infections compared to face masks because of their higher filtration efficiency, a household randomized controlled study showed no difference in their effect on ILIs and laboratory-confirmed influenza virus infection (*48*). One issue is that respirators require fit testing for optimal performance, but fit testing facilities are not widely available in the community.

Table 7. Description of studies included in the review of face masks

STUDY	STUDY DESIGN	STUDY PERIOD	POPULATION & SETTING	INTERVENTION	OUTCOME & FINDING	QUALITY OF EVIDENCE
Aiello AE, 2010 (20)	Cluster-randomized intervention trial	Nov 2006 – Mar 2007	1437 university hall residents (USA)	Mask; Mask + Hand hygiene; control	Significant reduction in ILI during weeks 4–6 in mask and hand hygiene group compared to control; No significant reduction in ILI in mask and hand group or mask-only group or control	Moderate
Aiello AE, 2012(*23*)	Cluster-randomized interventional trial	Nov 2007 – Mar 2008	1178 university hall residents (USA)	Mask; Mask + Hand hygiene; control	No significant reduction in rates of laboratory-confirmed influenza in mask and hand group or mask-only group or control group	Moderate
Barasheed O, 2014 (*50*)	Non-blinded cluster-randomized trial	Nov 2011 – Nov 2011	164 Australian pilgrims (Saudi Arabia)	Mask; control	No significant difference in laboratory-confirmed influenza in two arms; protective effect against syndromic ILI compared to controls (31% versus 53%, p = 0.04)	Moderate
Cowling BJ, 2008 (*26*)	Cluster-randomized intervention trial	Feb 2007 – Sep 2007	198 laboratory-confirmed influenza case and their household contacts	Mask; Hand hygiene; control	No significant reduction in the secondary influenza attack rate in control, mask or hand group	Moderate
Cowling BJ, 2009 (*19*)	Cluster-randomized intervention trial	Jan 2008 – Sep 2008	407 laboratory-confirmed influenza case and 794 household members	Mask; Mask + Hand hygiene; control	No significant difference in rates of laboratory-confirmed influenza in hand-only or mask and hand group	Moderate
Larson EL, 2010 (*21*)	Cluster-randomized intervention trial	Nov 2006 – Jul 2008	617 households	Mask + Hand hygiene; Hand hygiene; control	No significant reduction in rates of laboratory-confirmed influenza in control, hand, mask or hand group	Moderate
MacIntyre CR, 2009 (*48*)	Cluster-randomized intervention trial	Aug 2006 – Oct 2006 & Jun 2007 – Oct 2007	145 laboratory-confirmed influenza case and their adult household contacts	Surgical mask; P2 mask; control	No significant difference in rate of laboratory-confirmed influenza in control, face mask or P2 mask group	Moderate
MacIntyre CR, 2016 (*49*)	Cluster-randomized intervention trial	Nov 2013 – Jan 2014	245 ILI index case and 597 household contacts	Mask; control	Clinical respiratory illness, ILI and laboratory-confirmed viral infections were lower in the mask arm compared to control, but results were not statistically significant	Moderate
Simmerman JM, 2011) (*22*)	Cluster-randomized intervention trial	Apr 2008 – Aug 2009	465 laboratory-confirmed influenza case and their household contacts	Mask + Hand hygiene; hand hygiene; control	No significant reduction in rate of secondary influenza infection in control, hand, mask or hand group	Moderate
Suess (2012) (*24*)	Cluster-randomized intervention trial	Nov 2009 – Jan 2010 & Jan 2011 – Apr 2011	84 laboratory-confirmed influenza case and 218 household contacts	Mask; Mask + Hand; control	No significant difference in rate of laboratory-confirmed influenza in control, mask, mask or hand group	Moderate

ILI: influenza-like illness; USA: United States of America.

Table 8. Grade evidence profile for face masks

QUALITY ASSESSMENT							NO. OF PATIENTS		EFFECT		
No. of studies	Design	Risk of bias	Inconsistency	Indirectness	Imprecision	Other considerations	Mask	Control	Risk ratio	Quality	Importance
10	RCT [1,2]	No serious risk of bias [3,4]	No serious inconsistency [5]	No serious indirectness	Serious [6]	None	156/3495	161/3052	0.92 (0.75,1.12)	Moderate	Important

RCT: randomized controlled trial.

1 All studies were randomized trials.
2 All studies were cluster-RCTs at household and university residence level.
3 Eight studies reported blinding of study staffs including clinical staff, laboratory staff or recruiting physicians. Subjects of all studies were not blinded.
4 Three studies used block randomization; six studies used computer program to generate the randomization order and one study used ticket-picking for selection.
5 Moderate heterogeneity was observed in the pooled analysis.
6 Six studies did not have sufficient sample size in each intervention group; 3 studies reported insufficient statistical power; one study reported insufficient detection of influenza case.

2. ENVIRONMENTAL MEASURES

2.1. Surface and object cleaning

Methods

We conducted a systematic review on the effect of surface and object cleaning in preventing influenza virus infections in non-health care settings. PubMed, Medline, EMBASE and CENTRAL were searched for articles on 15 October 2018.

Study selection criteria were studies reporting the effect of surface and object cleaning intervention with no intervention in preventing influenza virus infections in community settings. RCTs and other types of epidemiological studies were included if they aimed to study the effect of surface and object cleaning on laboratory-confirmed influenza, ILI or respiratory illness. Simulation studies, recommendations, and commentaries or editorials were excluded. A community setting was defined as an open setting without confinement and special care for the patients. Articles describing any surface and object cleaning related interventions were included. No language limits were applied.

Two independent reviewers (ZX and ES) reviewed titles, abstracts and full texts. After confirmed included studies, data extraction and evidence quality assessment were performed by the reviewers. The GRADE framework was used to evaluate the effect of surface and object cleaning on influenza.

Results

There were 484 articles retrieved through database search. 462 articles were excluded through title and abstract screening. In the full-text assessment, 19 articles were screened out due to no surface and object cleaning intervention or no specific respiratory infection outcome. Finally, three articles were included in the systematic review to study the effectiveness of surface and object cleaning to prevent influenza infection. The article selection flow is shown in Fig. 11.

A cross-sectional study showed that bleach use in households was significantly associated with an increased in the rate of self-reported influenza (influenza data were obtained from self-administered questionnaires and the paper did not specify whether it was laboratory-confirmed influenza or ILI), and the authors hypothesized that this might due to the immunosuppressive properties of bleach (*51*). An RCT with disinfection of toys and linen in day care nurseries found a reduction in the detections of viruses in the environment, but no significant effect on influenza virus specifically and no significant reduction in acute respiratory illnesses among children *(52)*. Another RCT conducted in elementary schools demonstrated that hand hygiene with alcohol-based hand sanitizer and surface disinfection with quaternary ammonium wipes intervention could reduce gastrointestinal illness absenteeism, but not respiratory illness absenteeism (*53*). Detailed data extraction is shown in Table 9 below.

Experimental studies found that laboratory-grown influenza virus could survive on common surfaces and objects (e.g. stainless steel, wood, plastic, cloth and banknotes) from community settings for a few hours and up to 1 week (*28, 30, 54-56*). Influenza virus RNA could be detected by polymerase chain reaction (PCR) on surfaces and objects in household, school and airport settings in the field studies (*31, 52, 57-60*). Killingley et al. found viable influenza virus in the environment with laboratory-confirmed influenza individuals (*59*). These results suggested the biological plausibility that influenza virus could transmit via the fomite route. And the results from some experimental studies showed that disinfection process with different disinfection products (e.g. ethanol and 1-propanol) was effective to inactivate or reduce infectious influenza virus on surfaces (*61-63*), which suggested the importance of surface and object cleaning in influenza transmission prevention.

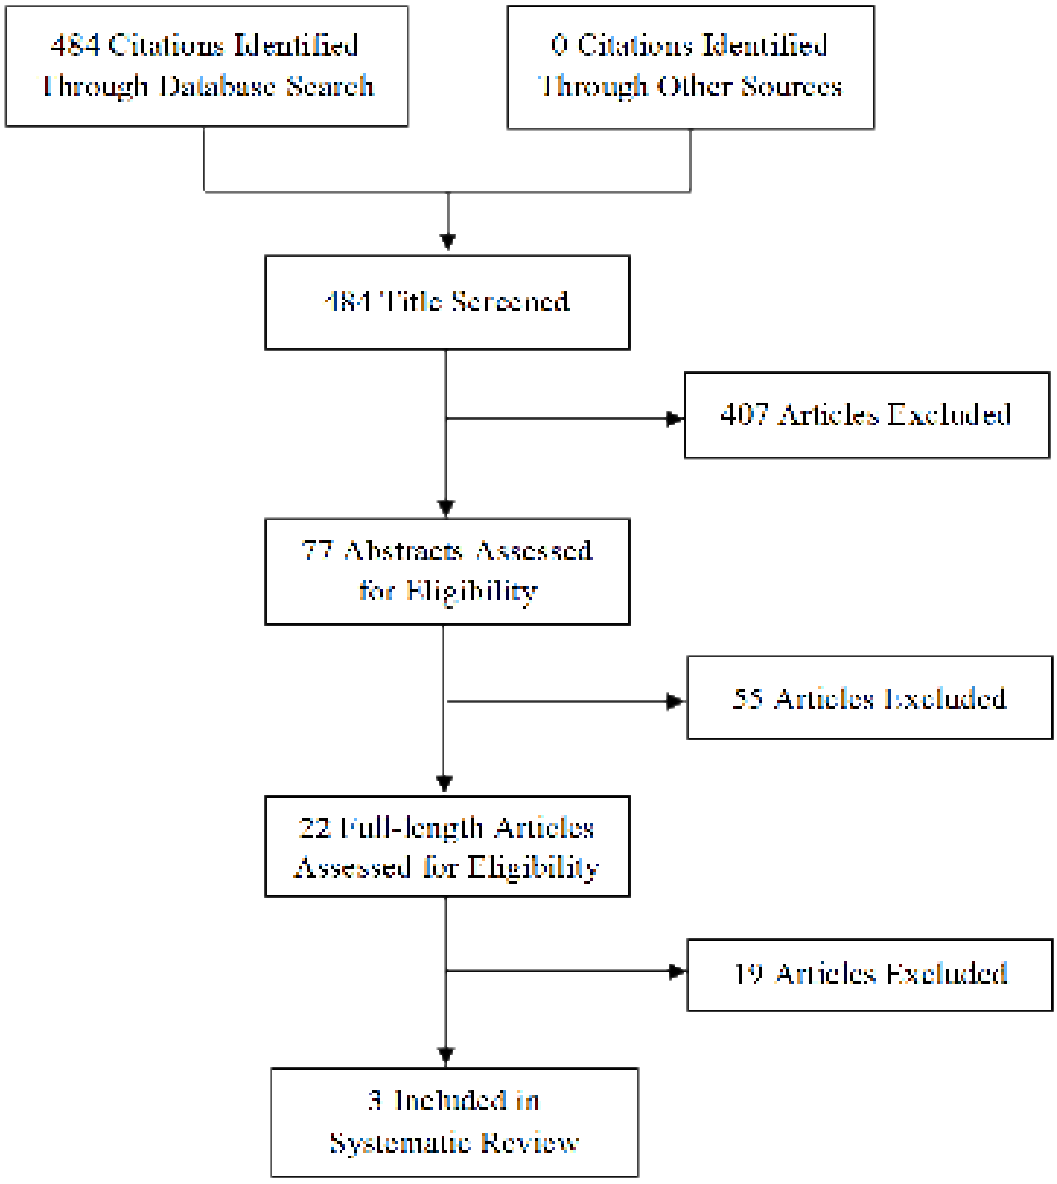

Fig. 11. The flow chart of surface and object cleaning articles selection

Ethical considerations

Disinfection product selection is a major issue, especially in public settings. Some disinfectants are irritants and may lead to adverse effect in sensitive population (*51*), and some disinfectants with alcohol may not be applicable in some countries or regions due to religious objections (*35*). In addition, the safety of cleaning personnel should also be considered. Proper training should be provided for the cleaning personnel, including proper use of the disinfectant (usage, dosage and time) and precautions before cleaning, such as wearing protective clothing.

Knowledge gaps

Only three studies were included in our systematic review and only two of them were RCTs. More trials are needed to study the effect of surface and object cleaning on influenza prevention. The best evidence for pandemic preparedness would be provided by studies in which the outcome is laboratory-confirmed influenza, rather than acute respiratory infections. Studies in various settings (e.g. household, school, workplace and public place) are also needed. The effect of different disinfection products to prevent influenza virus infection in terms of disinfection frequency, disinfection dosage, disinfection time point, and disinfection targeted surface and object material remained unknown.

Table 9. Description of studies included in the review of surface and object cleaning

STUDY	STUDY DESIGN	STUDY PERIOD	POPULATION & SETTING	INTERVENTION	OUTCOME MEASURE	MAIN FINDING	QUALITY OF EVIDENCE
Casas L, 2015 (*51*)	Cross-sectional study	2008–2010	9102 students from schools in Spain, Netherlands and Finland	Environment cleaning with bleach	Self-reported influenza	Passive contact with cleaning bleach in the household may increase the risk of respiratory and other infections in children, which may adversely affect the health of school-age children	Very low
Ibfelt T, 2015 (*52*)	Cluster-RCT	Autumn 2012 – April 2013	Twelve day-care nurseries (caring for 587 children) in Copenhagen, Denmark	Disinfection of toys	Respiratory infections and surface sample influenza virus detection	Frequently disinfection of toys could reduce environmental microbial presence, but not significantly reduce respiratory sickness of nursery children	Low
Sandora TJ, 2008 (*53*)	Cluster-RCT	March-May 2006	285 students from elementary schools in Avon, Ohio, USA	Hand hygiene and surface cleaning	Respiratory illness	Surface disinfection reduced gastrointestinal related absenteeism among school-age children, but not respiratory illness-related ones	Low

RCT: randomized controlled trial; USA: United States of America.

2.2. (*1*) Other environmental measures (UV light)

Terminology

The definition of ultraviolet (UV) light is shown in Table 10.

Table 10. Definition of UV light terms

TERM	DEFINITION
Ultraviolet light (UV light)	UV light is electromagnetic radiation that can be categorized into three groups by wavelength bands *(64)*: 1) UV-A (400–315 nm): It can be used for various purposes like pest control or identifying counterfeit banknotes. 2) UV-B (315–280 nm): It is known for the development of skin cancer. 3) UV-C (280–100 nm): It is used for disinfection of drinking water and sterilization of apparatus.
Ultraviolet germicidal irradiation (UVGI)	It is a mean of disinfection which breaks down microorganisms and can be used to prevent the spread of certain infectious diseases (*65*)

Methods

On 25 September 2018, we conducted a literature search in four databases: Medline (January 1946 to September 2018), PubMed (January 1950 to September 2018), EMBASE (1980 to September 2018), and CENTRAL (The Cochrane Library, 2018, Issue 5). Articles of all languages were included. Reference lists of retrieved articles were also reviewed for additional potential articles for this review. Studies were selected if they mentioned the use of UV light in community setting and reported laboratory-confirmed influenza virus infections as a study outcome. Two independent reviewers (ES and ZX) reviewed retrieved titles and subsequent relevant abstracts independently.

Results

A total of 1155 articles were retrieved from four electronic databases after removing duplicate publications. Titles, abstract content and full text were subsequently reviewed for inclusion; 67 abstracts were selected for subsequently screening and eventually 39 full texts were assessed for eligibility. No studies were identified in this review to quantify the efficacy of UV light with the laboratory-confirmed influenza outcome. The flow chart is shown in Fig. 12.

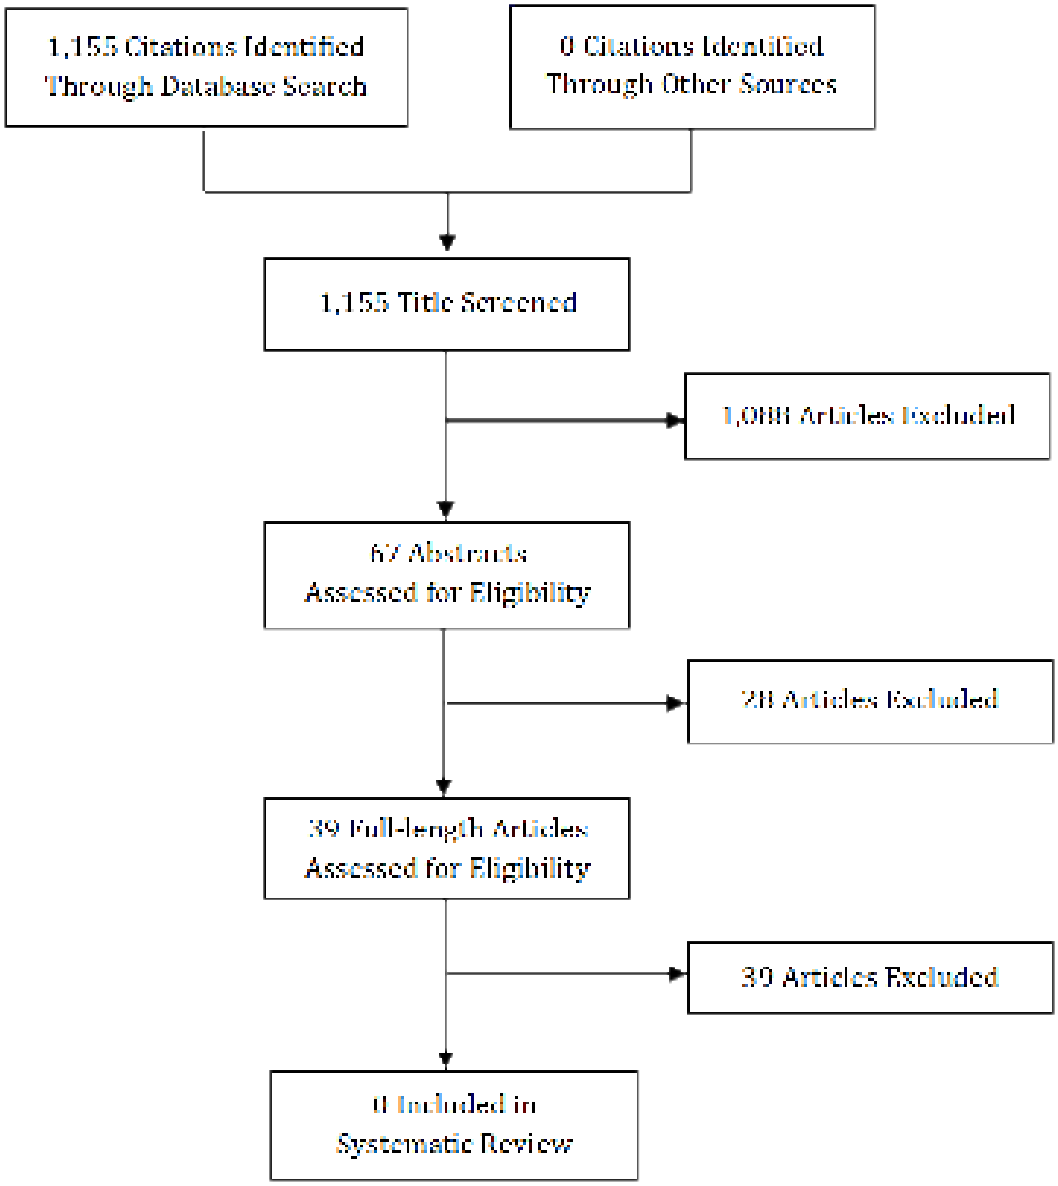

Fig. 12. The flow chart of the process and results of study selection

Ethical considerations

Exposure to UV light at certain wavelengths can increase the risk of skin cancer and cataracts; one study estimated that up to 20% of cataracts were due to UV overexposure (*64*). The use of UV light in occupied areas would need to be implemented carefully to control risks.

Knowledge gaps

The effectiveness of UV light in reducing the incidence of influenza virus infections still requires more evidence. Potential safety issues are also an important issue. Welch et al. reported that a low dose of far-UV-C light could inactivate aerosolized influenza H1N1 virus in a test chamber, and they reported an harmless effect on exposed mammalian skin (*66*), but more evidence is needed to confirm the impact of far-UV-C light in natural settings.

2.2. (*2*) Other environmental measures (ventilation)

Terminology
Definitions of ventilation are shown in Table 11 (*67*).

Table 11. Definition of ventilation terms

TERM	DEFINITION
Ventilation	Ventilation moves outdoor air into a building or a room, and distributes the air within the building.
Natural ventilation	Natural forces such as winds exchange the air in the building through windows, doors, solar chimneys, wind towers or trickle ventilators.
Mechanical ventilation	Mechanical ventilation uses mechanical fans to drive the outdoor air into the building at a designed flow rate.
	Mechanical ventilation can be integrated with air-conditioning system to control the indoor air temperature and humidity.
Hybrid (mixed-mode) ventilation	Combination of both mechanical and natural ventilation.
Air changes per hour (ACH)	The volume of air supplied to a room, in m3/hour, divided by the room volume, in m^3.

Methods
On 25 September 2018, we conducted a literature search in four databases: Medline (January 1946 to September 2018), PubMed (January 1950 to September 2018), EMBASE (1980 to September 2018), and CENTRAL (The Cochrane Library, 2018, Issue 5). Articles of all languages were included. Reference lists of retrieved articles were also reviewed for additional potential articles for this review. Studies that used modelling or simulation to describe the impact of ventilation on the rate of influenza virus infection in community settings were included. Two independent reviewers (ES and ZX) reviewed retrieved titles and subsequent relevant abstracts independently.

Results
A total of 630 articles were retrieved from four electronic databases after removing duplicate publications. Titles, abstract content and full text were subsequently reviewed for inclusion; 35 abstracts were selected for screening and then 18 full texts were assessed for eligibility. Three studies were identified for this review to evaluate the contribution of ventilation in influenza infection in community settings, both from the same author. The flow chart is shown in Fig. 13. and the description for each study is shown in Table 12.

A stimulation study modelled the transmission potential levels in an elementary school and predicted a reduction of R0 (from 11.38 to 3.97) with an increase in air changes per hour (ACH) from 0.5 to 2 (*68*).

Another stimulation study on an influenza outbreak, with consideration of possible airborne transmission in a community predicted a 40% reduction of peak daily-infected ratio by increasing the ventilation from 1 ACH to 9 ACH, and the peak would delay from Day 30 to Day 240 by increasing the ventilation from 1 ACH to 7 ACH (*69*). The authors further predicted that the overall attack rate during an epidemic would reduce from 100% to 3.3% if the ACH increased

from 1 to 7. They further studied the effectiveness of ventilation in another study, and predicted that doubling or tripling the ventilation rate could reduce the peak infection rate by over 60% under the assumption of equal contribution of airborne and close contact transmission; the authors concluded that an overall 30% reduction of peak infections was possible, even if airborne transmission only contributed to 20% of total infections (*70*).

Ethical considerations

No major ethical considerations.

Knowledge gaps

Mathematical models can only provide an indication of the potential spread of respiratory infections, and results can vary depending on the model assumptions. Experimental studies such as RCTs would provide more compelling evidence on the efficacy of increasing ventilation in reducing influenza transmission.

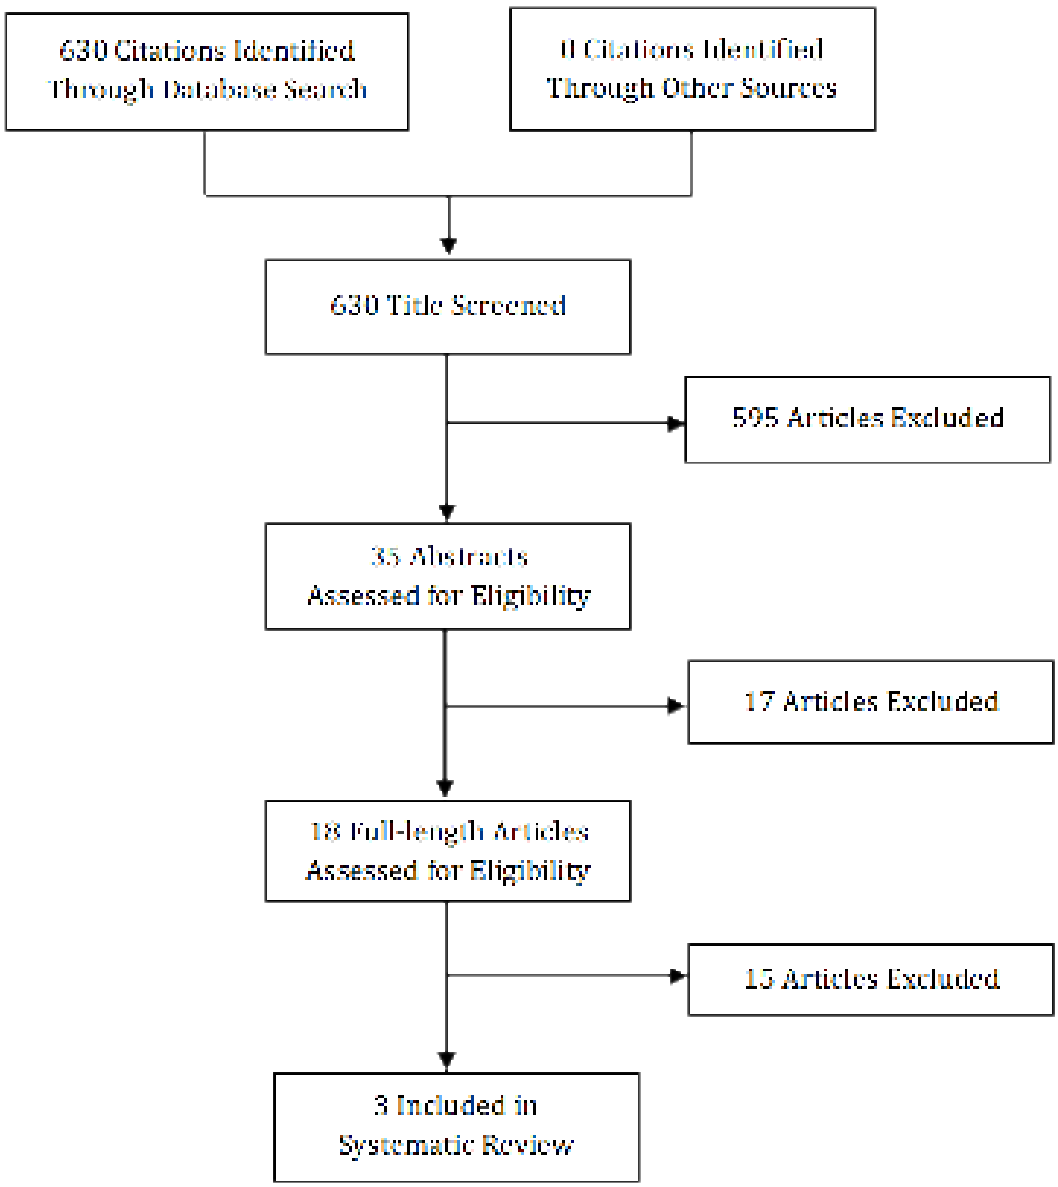

Fig. 13. The flow chart of the process and results of study selection

Table 12. Description of simulation studies included in the review of ventilation

STUDY	STUDY POPULATION	STUDY DESIGN	INTERVENTION	OUTCOME
Chen S, 2007 (*68*)	494 students (60 kindergarten and 434 elementary students) in an elementary school in Taipei City, Taiwan	Mathematical modelling	ACH, ACH + mask, 80% vaccination rate + 80% mask + 1.5 ACH	R0 is estimated to reduce from 11.38 to 3.97 for enhanced 0.5 and 2 ACH
Gao XL, 2009 (*69*)	Hong Kong SAR data in 2007	Mathematical modelling at community level	ACH, ACH + mask, ACH + UVGI, ACH + HEPA filter	Peak daily-infected ratio was reduced from 43% at 1 ACH to 21% at 3 ACH, 10% at 5 ACH, 3% at 7 ACH and 0.2% at 9 ACH; when ACH were increased from 1 to 5 ACH and 7 ACH, the disease attack rate was reduced from 100% to 69.8% and 3.3% respectively
Gao X, 2016 (*70*)	8 population groups (home stayers, office workers, classroom attendees, food service workers, shop workers, drivers, public space workers and other)	Mathematical modelling at 7 locations in communities	Ventilation, Ventilation + mask	Increasing ACH by doubling or tripling could reduce the peak infection rate by 65% and 83%; peak infection rate could reduce by about 34%, and outbreak could be delayed by over 50 days if applying a higher ventilation rate and masks for ill person

ACH: air changes per hour; HEPA: high-efficiency particulate air; R0: basic reproductive number; SAR: Special Administrative Region; UVGI: ultraviolet germicidal irradiation.

2.2. (*3*) Other environmental measures (humidity)

Terminology

Definitions of humidity are shown in Table 13.

Table 13. The definition of humidity terms

TERMS	TERMINOLOGY
Absolute humidity	A measure of actual amount of water vapour in the air, regardless of the air's temperature (expressed as grams of water per cubic metre volume of air) (*71*)
Relative humidity	A measure of amount of water vapour but relative to the temperature of air (expressed as a percentage) (*71*)

Methods
On 25 September 2018, we conducted a literature search in four databases: Medline (January 1946 to September 2018), PubMed (January 1950 to September 2018), EMBASE (1980 to September 2018), and Cochrane Library databases and the Cochrane Central Register of Controlled Trials (CENTRAL) (The Cochrane Library, 2018, Issue 5). Articles of all languages were included. Reference lists of retrieved articles were also reviewed for additional potential articles for this review. Studies that evaluated the impact of humidification in respect to the reduction of number of infected individuals in community settings were included.

Results
A total of 631 articles were retrieved from four electronic databases after removing duplicated publications. Titles, abstract content and full text were subsequently reviewed for inclusion; 16 abstracts were selected for subsequent screening, and eventually three full texts were assessed for eligibility. No studies were identified in Fig. 14.

Reiman et al. studied the effect of elevated humidification on influenza virus survival in preschool classrooms with the outcome measure being the detection of influenza virus in air and fomites *(72)*. They reported a significant reduction of influenza A virus in air and on fomite (markers and wooden toys) in humidified preschool classrooms compared to control rooms. Detection rate of influenza A virus in air and fomites were 20% at humidified rooms (humidification maintained at 9.89 millibar) compared to 14.5% at control rooms (at 6.33millibar); the differences in influenza detection were statistically significant in both air and fomites. Myatt et al. simulated the airborne survival of influenza virus with the impacts of home humidification with the CONTAM a multi-zone indoor air quality model, and described a 17.5% to 31.6% reduction of influenza virus survival in rooms with a humidifier operating (*73*). Noti et al. used a manikin to stimulate coughs containing influenza virus and assessed the viral infectivity under various levels of relative humidity in the examination room (*74*), and found that total virus during a 1-hour collection remained at about 70% infectivity at RH ≤ 23% but only about18% at RH ≥ 43% .

Ethical considerations
No major ethical considerations.

Knowledge gaps
The exact mechanism of how humidity affects the survival of the influenza virus is not clear (*72, 75*). Many studies have studied the effect under laboratory conditions, but very few have tested in natural settings.

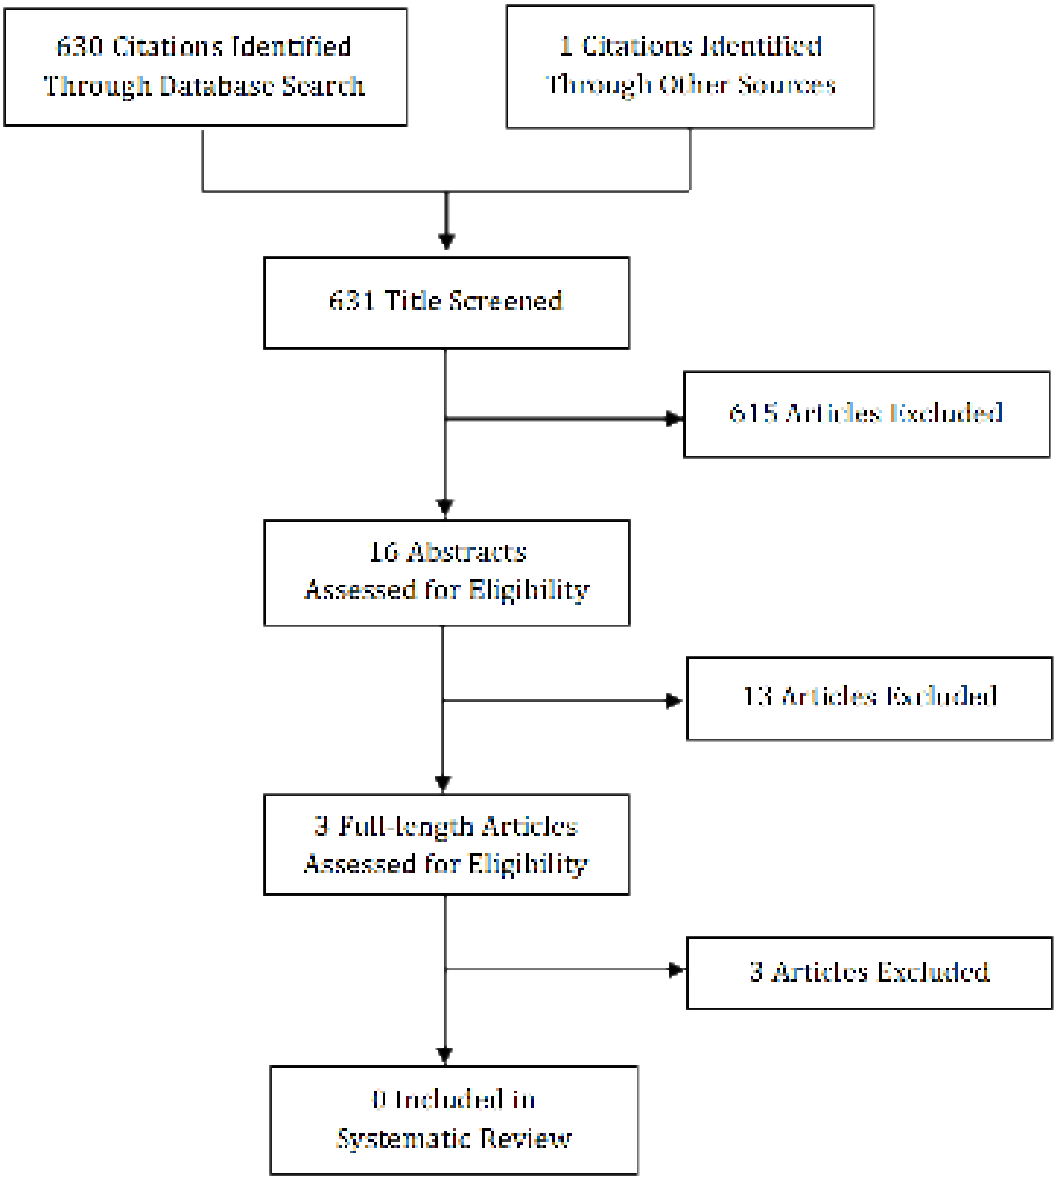

Fig. 14. The flow chart of the process and results of study selection

3. SOCIAL DISTANCING MEASURES

3.1. Contact tracing

Terminology

Contact tracing is the identification and follow-up of persons who may have come into contact with an infected person (76). Although contact tracing is often coupled with quarantine or provision of antiviral prophylaxis to exposed contacts, the term "contact tracing" does not involve these processes.

Methods

A literature search was conducted using PubMed, MEDLINE, EMBASE and CENTRAL (search date 12 November 2018). No language limit was applied for the literature search; however, literatures in languages other than English were excluded during full-text screening. The inclusion criteria were studies reporting the effectiveness of contact tracing on the control of influenza in non-health care settings. No limitation on study design was applied for study inclusion because preliminary works have identified no RCTs for this topic. Systematic reviews and meta-analyses, as well as studies involving clinical settings were excluded. Two reviewers independently (MF and SG) screened the titles, abstracts and full texts to identify articles for inclusion. Quality assessment of evidence was not conducted because no epidemiological study was included in this systematic review.

Results

The initial database search yielded 1188 articles, of which 75 were selected for full-text screening based on their title and abstract contents. Of these, 71 articles were excluded; the main reasons for exclusion of these articles include absence of discussion on effectiveness of contact tracing and irrelevance. The study selection process is detailed in Fig.15.

All four studies were simulation studies (*77-80*). None studied contact tracing as a single intervention; instead, this measure was studied in combination with other interventions, such as quarantine, isolation and provision of antiviral drugs (Table 14). Such combinations of interventions have been suggested to reduce transmission and delay the epidemic peak (*77, 79, 80*).

Reduction of impact

Wu et al. suggested in their simulation model of an influenza pandemic with a reproductive number (R_0) of 1.8 that the combination of contact tracing, quarantine, isolation and antivirals reduced the infection attack rate to 34% from the baseline of 74% (*77*). However, the addition of contact tracing on top of quarantine and isolation measures was suggested to provide only modest benefit, while at the same time greatly increasing the proportion of quarantined individuals. On the other hand, Fraser et al. found that it would be difficult to control influenza even with 90% contact tracing and quarantine, due to the presumed high level of presymptomatic or asymptomatic transmission in influenza (*79*).

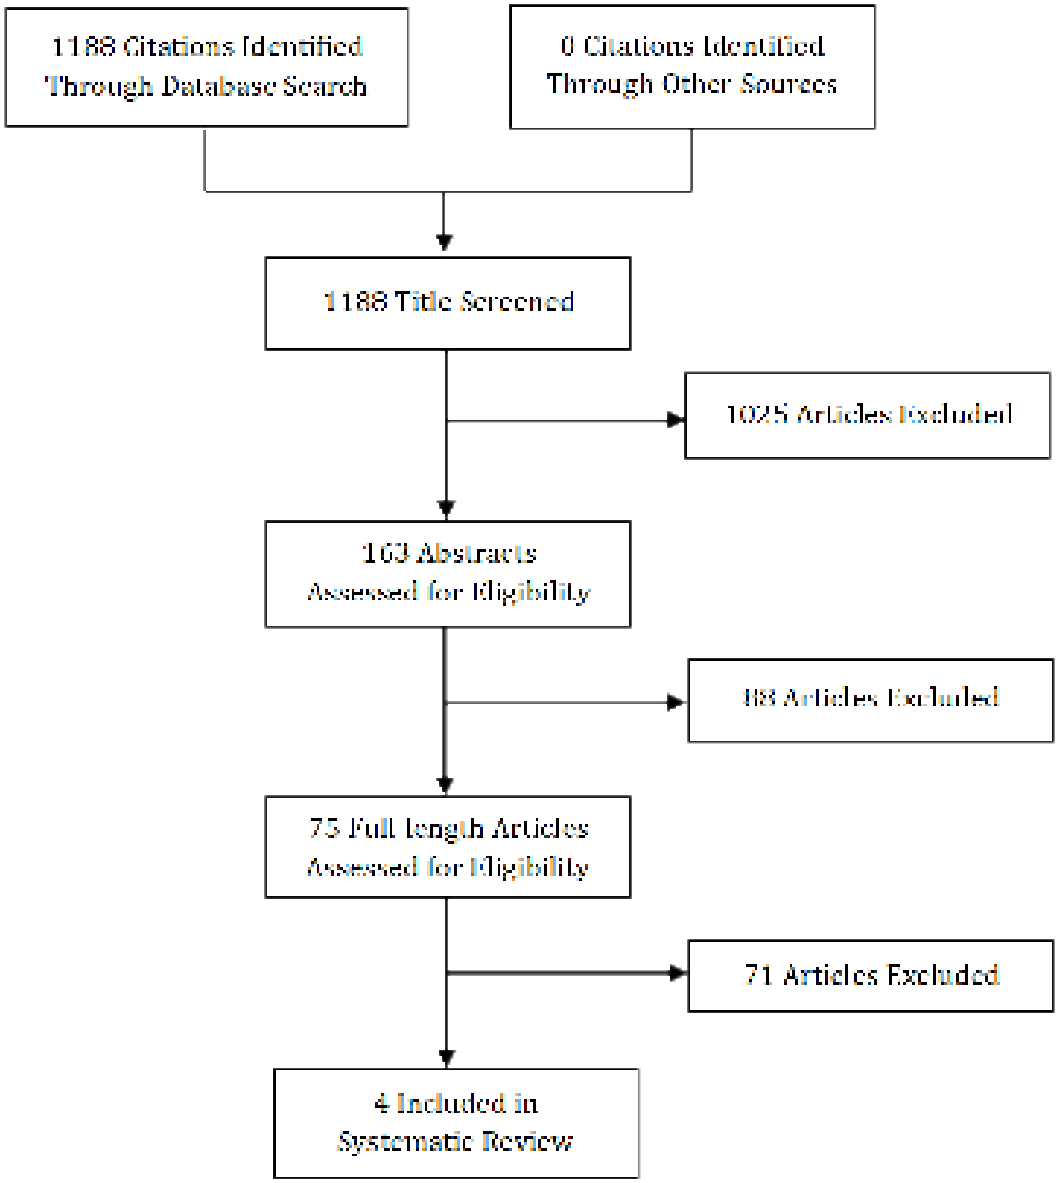

Fig. 15. The flow chart of contact tracing

Delay of epidemic peak

A combination of isolation, treatment of cases, contact tracing, quarantine and post-exposure prophylaxis for both community and household contacts, in addition to some household-focused measures, have been suggested to bring about delay in epidemic peak for up to 6 weeks, assuming a case detection rate of 10–30% (*80*). The study was set in the population structure of Germany in an epidemic with an R0 of 1.58. The authors assumed that the above combination of measures would be 75% effective in reducing secondary cases, while household-focused measures would be 50% effective.

Table 14. Summary of included studies

AUTHOR, YEAR PUBLISHED	TRANSMISSIBILITY OF THE INFLUENZA STRAIN (R_0)	STUDY SETTING & POPULATION SETTING	INTERVENTION	RESULTS & FINDINGS
Wu JT, 2006 (*77*)	1.80	(1) Model based on distribution of household sizes and average numbers of children in household of different sizes in Hong Kong SAR (2) Constant introduction of 1.5 infected individuals per day per 100 000 people for 365 days (3) 70% of transmission occur outside home (in schools and workplaces)	Combination of contact tracing with other interventions such as quarantine, isolation and antivirals. When contact tracing was in effect, each compliant adult member of a household named on average five members of their peer group. Contacts were traced with a mean delay of 1 day. Contacts were asked to take precautionary measures. Interventions were active before arrival of infected individuals in the city	Combination of quarantine, isolation and antivirals reduce the baseline infection attack rate of 74% to 40%. Addition of contact tracing further reduce infection attack rate to 34%, but increase proportion of population in quarantine considerably
Peak CM, 2017 (*78*)	1.54	Initial infected population of 1000 individuals in early epidemic phase, assuming no substantial depletion of susceptible within first few generations of transmission	Symptomatic contacts were isolated immediately, contacts who were asymptomatic when identified were placed under either quarantine or symptom monitoring (at high performance, delay in contact tracing was 0.5 ± 0.5 days, 90% of contacts were traced, 50% were truly infected among traced contacts)	Combination of contact tracing with quarantine is more effective in reducing reproduction number than combination of contact tracing with symptom monitoring
Fraser C, 2004 (*79*)	Upper bound of R0 was 21	(1) Disease outbreak in its early stages in a community of homogenous mixing (2) Proportion of presymptomatic transmission is 30–50%	Isolation of symptomatic individuals, contact tracing and quarantine of a proportion of contacts that are infected prior to isolation of symptomatic individual. Isolation and quarantine were implemented without delay. Efficacy of isolation of symptomatic individuals considered were 75%, 90%, and 100%; contact tracing and isolation of infected contacts were 100% effective	Control of influenza is very difficult even at 90% quarantine and contact tracing, due to the high level of presymptomatic transmission
an der Heiden M, 2009 (*80*)	1.34, 1.58, 2.04	(1) Model based on the age distribution and size of the population of Germany: 71 000 000 adult population and 11 000 000 children (< 15 years old), entire population is fully susceptible at onset of the epidemic (2) Children are 2.06 times as susceptible as adults, 86% of infected individuals become symptomatic	(1) Intensive case-based measures (CCM1; consisting of isolation and therapy of cases, contact tracing, quarantine and post-exposure prophylaxis of selected contacts in- and outside of the household) (2) Less-intensive measures (CCM2; isolation and therapy of cases, quarantine and post-exposure prophylaxis of household contacts); CCM1 and CCM2 were set to be 75% and 50% effective in reducing secondary cases	(1) When the first 500 cases are managed with CCM1 followed by 10 000 cases managed by CCM2, the peak of epidemic is delayed for up to 6 weeks (R0 1.58, 5 imported cases per day, case detection rate 10–30%). If only CCM1 was adopted without CCM2, delay was estimated to be 6–20 days (case detection rate 10–30%). (2) Effectiveness of these combination of interventions is affected by the R0 of the influenza strain and case detection rate, i.e. higher R0 causes interventions to be ineffective at an earlier time point

CCM: combination of case-based methods; R0: basic reproductive number; SAR: Special Administrative Region.

Reduction in transmissibility

Peak et al. compared the combination of contact tracing with quarantine or symptom monitoring in the early phase of an epidemic with an R0 of 1.54 (*78*). The study suggested that contact tracing combined with quarantine was more effective than a combination with symptom monitoring in reducing transmission.

Ethical considerations

There are no major ethical issues. Identification of contacts of infected individuals does bring about privacy concerns; however, this may be justified because contact tracing does allow identification of persons at-risk and timely provision of treatment and care (81, 82). There may be more ethical concerns when contact tracing is coupled with measures such as household quarantine, discussed further in Section 3.3. As discussed in the results section above, contact tracing is able to increase substantially the proportion of people quarantined, but may not offer much additional benefit to existing interventions (*77*). A considerable amount of resources is also needed for contact tracing is these circumstances. Wu et al. suggested addition of contact tracing to existing interventions is only justified when the R0 can be reduced below 1 (*77*).

Methods

A literature search was conducted using PubMed, MEDLINE, EMBASE and CENTRAL (search on 5 August 2018). No language limit was applied for the literature search; however, literatures in languages other than English were excluded during full-text screening. The inclusion criterion is studies reporting the effectiveness of isolation on control of influenza in non-health care settings. No limitation on study design was applied for study inclusion as preliminary works have identified no RCT for this topic. Systematic review and meta-analyses, as well as studies involving clinical settings were excluded. Two reviewers independently (MF and SG) screened the titles, abstracts and full texts to identify articles for inclusion. Quality assessment of evidence was conducted for epidemiological studies for effectiveness of isolation on mitigation of influenza.

Results

The initial database search yielded 588 articles, of which 70 were selected for full-text screening based on their title and abstract contents. Of these, 56 articles were excluded; the main reasons for exclusion of relevant articles included absence of discussion on effectiveness of isolation and focus on health care setting. One other study for inclusion was identified through snowball searches. The study selection process is detailed in Fig.16.

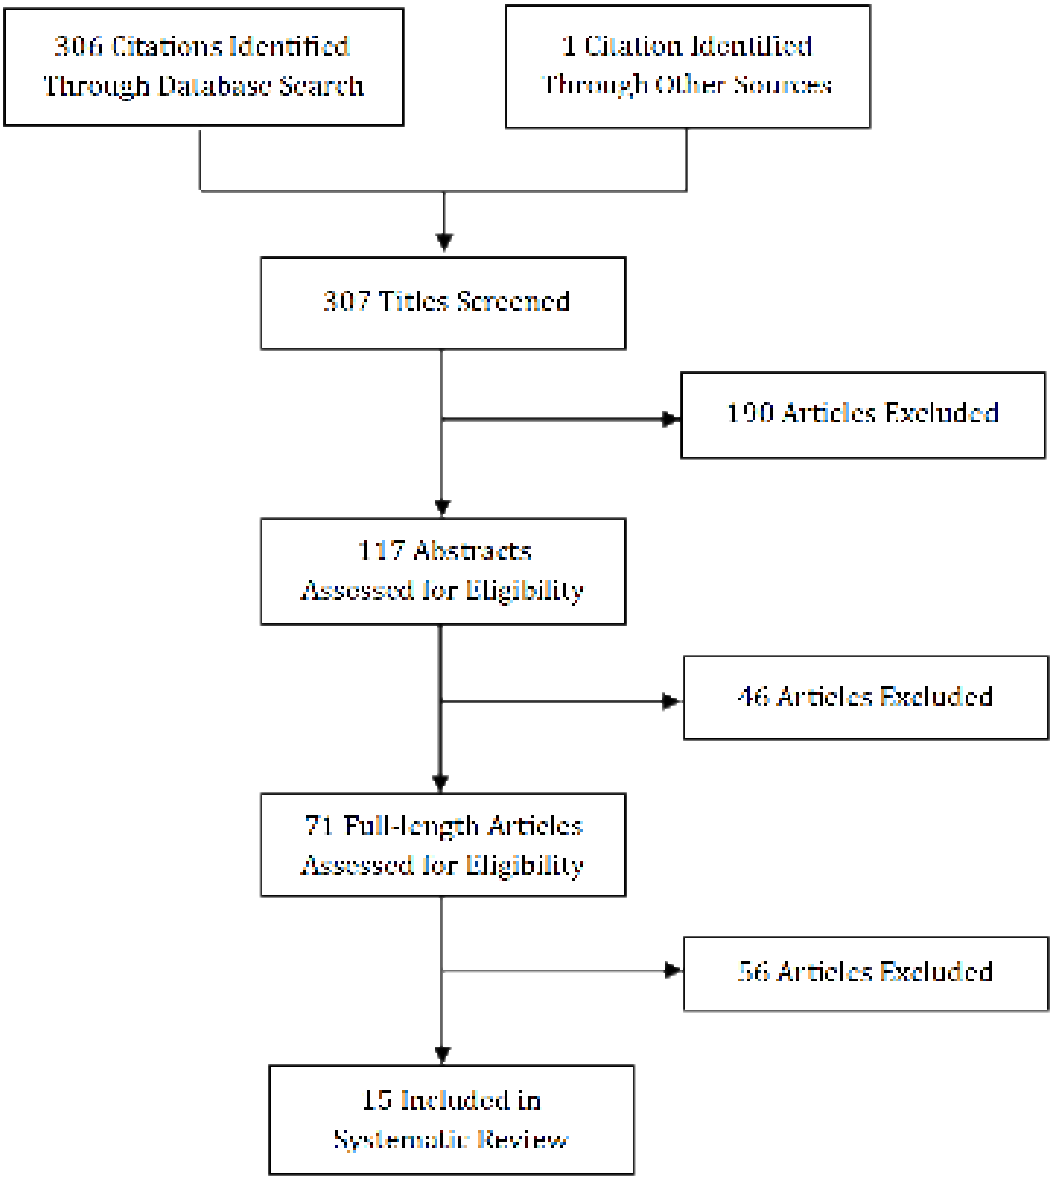

Fig. 16. The flow chart of isolation

Of the 15 included studies, four were epidemiological studies, of which one was an analysis of historical data from the 1918–1919 pandemic in 43 cities in the USA and three were outbreak investigations that occurred in a home for the elderly in France, a training camp in China and a Peruvian navy ship, respectively (Table 15) (*83-86*). The remaining 11 were simulation studies (Table 16) (*77, 79, 87-94*). Case isolation was implemented in the outbreaks as a combination with various other interventions, such as antiviral prophylaxis and use of face mask. Case isolation was also studied as a single intervention or combined with other interventions in the 11 simulation studies. It is of note that the simulation studies were conducted based on a wide range of assumptions; for example, asymptomatic fraction and contact rate reduction brought forth by isolation, hence providing wide-ranging insights on effectiveness of isolation in different scenarios. These included studies focused mostly on reduction of attack rate, epidemic size, transmissibility and delay in epidemic peak as outcomes of interest. All but one study suggested a favourable impact of isolation, or combination of isolation with other interventions in epidemics with R0 1.5–2.0.

Reduction of impact

Eight studies suggested a decrease in attack rate brought about by implementation of case isolation (*77, 83, 86-91*). An individual-based simulation model for the United Kingdom and the USA suggested rapid case isolation could reduce the cumulative clinical attack rate from 34% to 27% for a pandemic with R_0 2.0, assuming uniform reductions in contact rates in schools, workplaces and households (*87*). Kelso and colleagues reported similar findings, in which case isolation alone was able to prevent an epidemic (<10% infected) in a community of 30 000 persons with R_0 1.5, when 90% of cases are isolated and such a measure is implemented within 3 weeks from the introduction of an initial case (*90*). While isolation alone has been suggested to be more impactful than other interventions, combination with other interventions further improved the effectiveness (*77, 89-91*). In addition, the increase in isolation rate is quasi-linearly correlated with the decrease in attack rate of influenza (*88*).

A reduction in the cumulative incidence of infections due to an isolation policy was also recorded during an influenza A(H1N1)pdm09 outbreak on a navy ship (86). A combination of isolating ILI cases, and use of masks and hand sanitizers was implemented. The clinical attack rate of the outbreak was 23.9%, a significant reduction from the 97% projected in the absence of any intervention. This also corresponded to a reduction in the effective reproduction number (R) from 1.55 to 0.7 with the intervention. Chu et al. reported similar findings in an outbreak in a physical training camp, in which the final attack rate recorded was about one quarter of the projected attack rate of 81% in absence of previous exposure, immunity and any interventions (*83*). In the 1918–1919 pandemic, excess death rates due to pneumonia and influenza decreased in New York City and Denver after isolation and quarantine were implemented (*85*).

On the contrary, Fraser et al. discussed the difficulty in controlling influenza even with high level of case isolation combined with contact tracing and quarantine, due to high proportion of asymptomatic transmission of influenza (*79*). The probability of isolation without increased public health effort by individuals in the community have also been suggested to be high, at 50% and 90% for adult and children respectively (*90*).

Delay of epidemic peak

The study by Flauhault et al. suggested that case isolation would have the strongest impact on global spread of a pandemic involving 52 cities, as compared to air-travel restrictions and antiviral treatment, such that isolation of 40% of cases would delay the epidemic by 83 days as compared to absence of any intervention (*88*). A combination of isolation of 10% of symptomatic cases with 60% reduction in air traffic, on the other hand, would delay the start of epidemics in each city by an average of 19 days, with considerable case reduction (88). The study by Wang et al. showed a similar effect, albeit focusing on arrival time of influenza pandemic, in which isolation of a moderate proportion of cases delayed the arrival of the pandemic in a subpopulation for about a month, in the circumstance of high compliance and early implementation (*92*). Delay in response will reduce significantly the effectiveness. Combined intervention with quarantine, school closure (SC), community-contact reduction, and personal protective measures further augmented the effect (*91*).

Table 15. Summary of epidemiological studies

AUTHOR, YEAR PUBLISHED	INFLUENZA STRAIN OR TRANSMISSIBILITY (R_0)	TYPE OF STUDY	STUDY SETTING & POPULATION SETTING	INTERVENTION	RESULTS & FINDINGS	GRADE EVIDENCE
Chu C, 2012 (*83*)	A(H1N1)pdm09	Outbreak investigation	Outbreak in a physical training camp in China with 3256 persons	Combination of isolation with other interventions including oseltamivir treatment and prophylaxis, cancellation of training and group activities, face mask usage, ventilation and disinfection (implemented within a few days of surge in ILI)	(1) 72.7% clinical cases were reported before intervention, 27.3% after intervention. (2) The clinical attack rate recorded for the outbreak was 18.2%, while the projected attack rate in absence of previous exposure, immunity and any interventions was 80.9%	Very low
Gaillat J, 2008 (*84*)	Seasonal	Outbreak investigation	Outbreak in elderly home with 81 residents in summer (recorded attack rate of 39.5%)	Sick residents were immediately isolated and used face masks, oseltamivir treatment and post-exposure prophylaxis were given to residents and staffs	No new case was reported among residents and staffs within 2 days of implementation of intervention	Very low
Markel H, 2007 (*85*)	1918 pandemic H1N1	Analysis of historical data	43 large cities in the USA; utilized historical mortality data from the US Census Bureau and other historical archival documents	Combination of SC, public gathering bans, and isolation and quarantine (enforced and mandated respectively)	(1) All 43 cities implemented at least one intervention, and 15 cities implemented all three interventions. Cities that started implementation earlier had lower peak mortality and total mortality. (2) Excess death rate in New York decreased to baseline when isolation and quarantine were implemented, similarly in Denver when SC, isolation and quarantine were implemented	Very low
Vera DM, 2014 (*86*)	A(H1N1)pdm09	Outbreak investigation, stochastic model	Outbreak on a navy ship with 355 crews	Suspected ILI cases were placed in isolation, active case finding, face mask usage and hand hygiene, and antiviral provision	(1) Significant reduction in reproduction number during implementation of interventions (54.4%, from 1.55 to 0.7). The projected reproduction number without isolation was 4.5. (2) Clinical attack rate recorded was 23.9%, while the projected rate was 97%.	Very low

GRADE: Grading of Recommendations Assessment, Development and Evaluation; ILI: influenza-like illness; R0: basic reproductive number; SC: school closure; USA: United States of America.

Table 16. Summary of simulation studies

AUTHOR, YEAR PUBLISHED	TRANSMISSIBILITY OF THE INFLUENZA STRAIN (R_0)	STUDY SETTING & POPULATION SETTING	INTERVENTION	RESULTS & FINDINGS
Flahault A, 2006 (*88*)	Constant (3.1) in tropical zone, 0.3–3.24 elsewhere with seasonal differences	(1) Spread of influenza pandemic to 52 cities globally from Hong Kong SAR via air transport (2) 25% of the population has pre-existing immunity, 60% of cases are symptomatic	(1) Combination of isolation (exclusion of 10% of symptomatic individuals from simulation) and 60% air traffic reduction (implemented since day 1) (2) Combination of (1) with antiviral treatment and vaccination	(1) Isolation reduced case number by 9% (2) Combination of isolation and air traffic reduction delayed time to reach epidemic status (1/100 000) in each city by an average of 19 days (3) Increasing isolation proportion to 40% delayed epidemic by an average of 83 days; combination of isolation, air traffic reduction, antiviral, vaccination reduced case number by 65%
Fraser C, 2004 (*79*)	Upper bound of R_0 was 21	(1) Disease outbreak in its early stages in a community of homogenous mixing (2) Proportion of presymptomatic transmission is 30–50%	Isolation of symptomatic individuals, contact tracing and quarantine of a proportion of contacts that are infected prior to isolation of symptomatic individual. Isolation and quarantine were implemented without delay. Efficacy of isolation of symptomatic individuals considered were 75%, 90%, and 100%; contact tracing and isolation of infected contacts were 100% effective.	Control of influenza is very difficult even at 90% quarantine and contact tracing, due to the high level of presymptomatic transmission.
Halloran ME, 2008 (89)	1.9–2.1, 2.4 and 3.0	(1) Model based on population of Chicago (8.6 million people) (2) 67% of influenza infections are symptomatic, case ascertainment levels are 60–80%	Combination of home isolation of ascertained cases (compliance 60% or 90%; isolated in but not from household members) with quarantine and other social distancing measures, implemented at intervention threshold of 1, 0.1, and 0.01%	At R_0 of 1.9–2.1, 60% ascertainment and 90% compliance, intervention threshold of 0.1%, attack rate was 0.17–1.2%, as compared to baseline scenario of 42.4–46.8%
Kelso JK, 2009 (*90*)	1.5, 2.5, and 3.5	(1) Population of 30 000, grouped into hubs of schools, workplaces and other facilities. Other contacts were biased towards meetings between neighbouring individuals (2) Asymptomatic fraction matched seasonal influenza	(1) Isolation (assumed isolated individuals only made household contacts, 90% and 100% chance respectively for adults and children to be compliant) (2) Combination of isolation with SC, workplace non-attendance and community-contact reduction	(1) At R_0 of 1.5, case isolation implemented within 3 weeks was the only single intervention capable of preventing an epidemic (≥10% attack rate), daily attack rate reduced from 90/10,000 to < 35 if introduced within a month (2) Combination of all four measures reduced attack rate from baseline of 33% to 9%, influenza control is more difficult at higher R_0

AUTHOR, YEAR PUBLISHED	TRANSMISSIBILITY OF THE INFLUENZA STRAIN (R_0)	STUDY SETTING & POPULATION SETTING	INTERVENTION	RESULTS & FINDINGS
Saunders-Hastings P, 2017 (*91*)	1.5–2.5	(1) Model based on population of Ottawa–Gatineau census metropolitan area in 2011	Combination of isolation with other interventions including vaccination, antiviral treatment, prophylaxis, SC, community-contact reduction, personal protective measures and quarantine; best guess for adherence for voluntary isolation is 30%	(1) Combination of isolation and quarantine resulted in reduction of attack rate to 33.9%, from the baseline of 53.4%, lowest among all interventions studied. (2) Combination of isolation, quarantine, SC, community-contact reduction and personal protective measures reduced attack rate to 15.2% and delayed pandemic peak to more than 100 days
Zhang Q, 2015 (*94*)	2.5	(1) A community of households with distribution of household sizes based on Australian census data in 2001 (2) Chances of infection from community contacts is negligible as compared to infection from household member	Self-isolation or combination with antiviral prophylaxis (self-isolation assumed to have no impact on household contacts)	Self-isolation is able to overcome negative effect of delay in antiviral drug provision of 1 and 2 days by reducing household reproduction number, albeit compliance for self-isolation have to be significantly higher for 2-days delay
Zhang Q, 2014 (*93*)	1.5	(1) Stable population with homogenous mixing (2) Asymptomatic fraction is 0.5, and symptomatic cases are twice as infectious	Isolation or combination with antiviral prophylaxis	(1) Case isolation reduced reproduction number to below one (2) Combination of isolation and antiviral prophylaxis reduced substantially the cumulative number of infected individuals
Ferguson NM, 2006 (*87*)	1.4–2.0	(1) Model based on population density data and data on travel patterns of the USA and United Kingdom (2) 30% of transmission occurred in household, the rest in general community, workplaces and schools; asymptomatic fraction was 0.5	Rapid case isolation (assumed uniform reduction of contact including household contacts)	Rapid case isolation reduced cumulative attack rates from 34% to 27% for R0 2.0 if 90% of cases were isolated
Wu JT, 2006 (*77*)	1.80	(1) Model based on distribution of household sizes and average numbers of children in household of different sizes in Hong Kong SAR (2) Constant introduction of 1.5 infected individuals per day per 100 000 people for 365 days (3) 70% of transmission occur outside home (e.g. in schools and workplaces)	Combination of isolation and voluntary quarantine. Interventions were active before arrival of infected individuals in the city.	Combination of isolation and voluntary quarantine reduced the baseline attack rate of 74% to 43%.

AUTHOR, YEAR PUBLISHED	TRANSMISSIBILITY OF THE INFLUENZA STRAIN (R_0)	STUDY SETTING & POPULATION SETTING	INTERVENTION	RESULTS & FINDINGS
Wang L, 2012 (*92*)	1.75	International spread of influenza to cities at early stage of a pandemic outbreak	Isolation (implemented by removing some infectious individuals from the simulation model)	Isolation of a moderate proportion of cases delayed the arrival of the pandemic for about a month, in the circumstance where cases were fully compliant and intervention was started at the first instance of the pandemic
Yasuda H, 2009 (*95*)	A(H1N1)pdm09	Community of 8800 individuals, with family structures based on Japanese census data	Home isolation of one in three adults and 70–90% of school-aged children	Total number of infections reduced by 33% when one in three adults and all children were isolated at home compared to baseline situation

R_0: basic reproductive number; SC: school closure; United Kingdom: United Kingdom of Great Britain and Northern Ireland; USA: United States of America.

Reduction in transmissibility

Zhang et al. showed in their simulation studies that isolation of cases can reduce the household reproduction number to below one, and compensate for a delay in antiviral drug distribution by 1 to 2 days. Compliance for self-isolation has to be significantly higher to offset longer delays (*93, 94*). An outbreak in a home for the elderly in France reported an abrupt cessation of outbreak after case isolation, antiviral treatment and prophylaxis were implemented (*84*). Reduction in eproduction number was also recorded in the navy ship outbreak previously described, by 54% from 1.55 to 0.7 with a combination of interventions (*86*). The projected reproduction number without implementation of isolation was 4.5.

Ethical considerations

Home isolation is commonly done voluntarily by ill individuals who do not feel well enough to work or engage in other daily activities (*88, 90*). Some ethical concerns may arise when isolation interventions are mandated, of which the main concern is freedom of movement (*96*). Studies on acceptability of isolation as an intervention to control influenza have also suggested the potential of social stigma as a concern for some individuals (97). Home isolation may also bring about increased risks of infection among household members, in the circumstances in which the contact rate between the infected individual with household members increase due to home isolation. Such risks can be reduced by adopting good precautionary measures such as wearing a face mask or employing hand hygiene. Such concern is more significant when concurrent quarantine of household members is mandated.

Knowledge gaps

Most currently available studies on effectiveness of isolation are simulation studies, which have a low strength of evidence. Available epidemiological studies studied isolation together with other interventions, or did not use laboratory confirmation as the outcome of interest. Although it is difficult to study isolation in an RCT, robust findings from such studies would be very valuable. In addition, in some of the relevant simulation studies, assumptions have been used to predict the effect of isolation on social contact rate, which in turn affect the transmission dynamics and control of influenza. Limited information exists at present for this aspect, as well as other commonly used assumptions including asymptomatic fraction, and dynamicity due to the nature of compliance behaviour, resource planning and distribution capacity (*77*).

3.2. Quarantine of exposed individuals

Terminology

Terms relevant to quarantine are defined in Table 17.

Table 17. Definition of terms relevant to quarantine

TERM	DEFINITION
Quarantine	Imposed separation or restriction of movement of persons who are exposed, who may or may not be infected but are not ill, and may become infectious to others (*98*).
Household quarantine	Confinement (commonly at home) of non-ill household contacts of a person with proven or suspected influenza (*2, 98*).
Home quarantine	Home confinement of non-ill contacts of a person with proven or suspected influenza.
Self-quarantine	Voluntary confinement of non-ill contacts of a person with proven or suspected influenza.

TERM	DEFINITION
Work quarantine	1) Measures taken by workers who have been exposed and who work in a setting where the disease is especially liable to transmit (or where there are people at higher risk from infection), e.g. people working in elderly homes and nurses in high risk units (*98*). 2) Measures taken by health care workers who chose to stay away from their families when off-duty so as not to carry the infection home (*98*).
Maritime quarantine	Monitoring of all passengers and crew for a defined period before disembarking from a ship is permitted in a jurisdiction (*99*).
Onboard quarantine	Monitoring of all passengers and crew for a defined period before disembarking from a flight is permitted (100). Also known as 'airport quarantine' (*100*).

Methods

Literature search was conducted using PubMed, MEDLINE, EMBASE and CENTRAL (search date 24 July 2018). No language limit was applied for the literature search; however, literatures in languages other than English were excluded during full-text screening. Studies reporting the effectiveness of quarantine on the control of influenza in non-health care settings were included. No limitation on study design was applied for study inclusion as preliminary works identified no RCT for this topic. Systematic review and meta-analyses, as well as studies involving clinical settings, were excluded. Two reviewers (MF and SG) independently screened the titles, abstracts and full texts to identify articles for inclusion. Quality assessment of evidence was conducted for epidemiological studies for effectiveness of quarantine on mitigation of influenza.

Results

The initial database search yielded 1873 articles, of which 120 were selected for full-text screening based on their title and abstract contents. Of these, 104 articles were excluded; the main reasons for exclusion of relevant articles include absence of discussion on effectiveness of quarantine and focus on health care setting. The study selection process is detailed in Fig.17.

The included studies were comprised of 10 simulation studies (Table 19) (*77, 80, 87, 89, 91, 101-105*). The epidemiological studies included one modelling study based on pandemic influenza A(H1N1)pdm09 transmission in Beijing (106), two analyses of historical data (1918–19 influenza pandemic in the USA and South Pacific, respectively) (*85, 99*), two observational studies and one a quasi-cluster-RCT in Japan (Table 18) (*100, 107, 108*). Quarantine measures studied include home quarantine, household quarantine, border quarantine as well as maritime quarantine. Quarantine were studied as a single intervention or as combination with other interventions, commonly with isolation and antiviral prophylaxis. These included studies focused mostly on reduction of attack rate, transmissibility and delay in epidemic peak as outcomes of interest.

Reduction of impact

Five studies suggested reduction in attack rate with implementation of household quarantine measures (77, 87, 89, 91, 107). Miyaki and colleagues conducted a quasi-cluster RCT in Japan in 2009–2010, which involved two clusters of company workers; the intervention was voluntary waiting at home on full pay if a family member was experiencing ILI. The intervention reduced risk and number of infections for members of the cluster and in the workplace involved (107).

Ferguson et al. reported in their simulation study that household quarantine were effective in reducing attack rate at R0 1–4.2, especially at low values (87). Combination of quarantine with other interventions such as household isolation with prophylaxis, SC and workplace distancing were suggested to further reduce the cumulative incidence of infections (77, 87, 89).

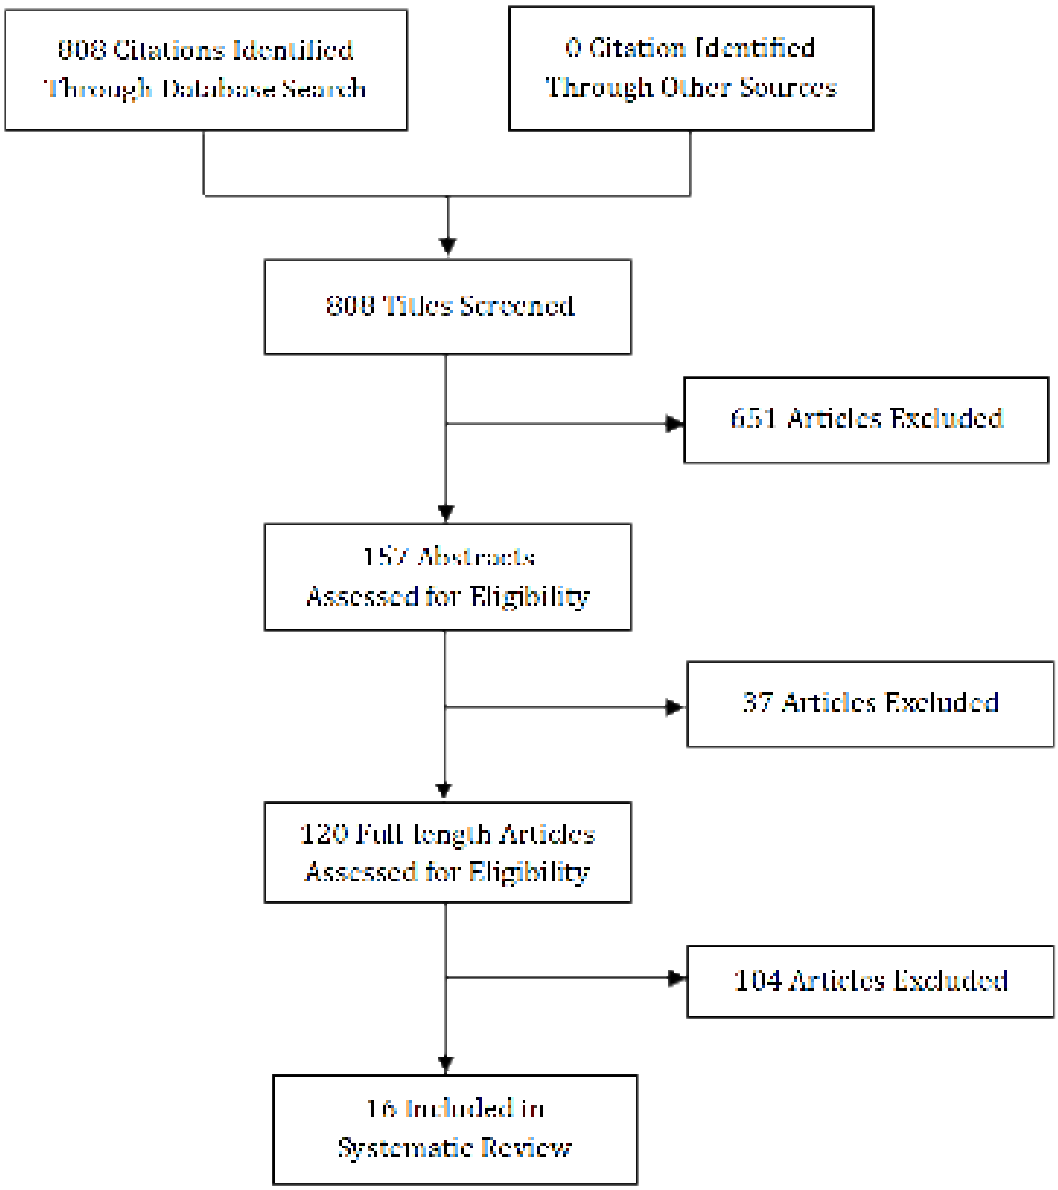

Fig. 17. The flow chart of quarantine

Household quarantine has also been suggested to be highly effective in reducing peak and total number of cases in a pandemic, provided that compliance is high (*105*). Longini et al. reported similar findings; that is, the effectiveness of household quarantine in reducing number of cases is conditioned by high compliance at 70% and relatively low R0, in addition to early implementation *(101)*. On the other hand, border quarantine has been suggested to cause minimal impact on reduction of number of cases (*104*).

Both analyses of historical data of the 1918–19 pandemic studied the effectiveness of interventions on mortality (*85, 99*). When a combination of isolation and quarantine was implemented, excess death rates due to pneumonia and influenza were shown to decrease in New York City and Denver (*85*). Maritime quarantine in the pacific islands have also delayed or prevented arrival of the epidemic, indirectly reducing mortality in the region (*99*).

Transmissibility

Both household quarantine and border quarantine have been suggested to reduce transmissibility, albeit with moderate effectiveness (*100, 102, 103*). Fujita et al. reported in their assessment of onboard quarantine inspection in Japan during the 2009 H1N1 pandemic, minimal impact in detecting and preventing entry of cases; however, following up with passengers thereafter was found to be effective in preventing secondary infection in the community from travellers (*100*). Nishiura and colleagues also suggested that border quarantine of 9 days would prevent 99% of entry of infectious travellers into small island nations (*102*).

Increased risk to household contacts

While reducing risk and number of infections in the intervention cluster, the quasi-cluster RCT of Miyaki et al. also reported that more individuals fell ill in the intervention group when there was an ill family member (*107*). The likelihood of a household contact (concurrently quarantined with an isolated individual) becoming a secondary case has been estimated to increase with each day of quarantine (*108*).

Table 18. Summary of epidemiological studies

AUTHOR, YEAR PUBLISHED	INFLUENZA STRAIN OR TRANSMISSIBILITY (R_0)	TYPE OF STUDY	STUDY SETTING & POPULATION SETTING	INTERVENTION	RESULTS & FINDINGS	GRADE EVIDENCE
Markel H, 2007 (*85*)	1918 pandemic H1N1	Analysis of historical data	43 large cities in the USA; utilized historical mortality data from the US Census Bureau and other historical archival documents	Combination of SC, public gathering bans, and isolation and quarantine (enforced and mandated respectively)	(1) All 43 cities implemented at least one intervention, and 15 cities implemented all 3 together. Cities that started implementation earlier have lower peak mortality and total mortality; (2) Excess death rate in New York decreased to baseline when isolation and quarantine were implemented, similarly in Denver when SC, isolation and quarantine were implemented	Very low
Fujita M, 2011 (*100*)	A(H1N1)pdm09	Observational	Japan (passengers at Narita International Airport for onboard quarantine and Japan at-large for the outbreak)	Onboard quarantine was conducted for 500 flights carrying 120 069 passengers in Narita International Airport over 25 days. Patients identified by positive rapid test, and persons seated around them were isolated. If patient was subsequently confirmed of their infection by PCR, patient was isolated while persons seated around them were quarantined	Onboard quarantine detected few cases and was not effective in preventing virus entry into the country, however onboard quarantine improved traceability of travellers. Upon monitoring after travellers are in town, onward transmission/ secondary infection is prevented	Very low
Li X, 2013 (*106*)	A(H1N1)pdm09	Model based on epidemiologic dynamics of influenza A(H1N1)pdm09	Beijing (N = 20 million); utilized data of daily confirmed cases reported by Beijing Municipal Bureau of Health (May-July 2009)	Mandatory quarantine for all close contacts	Reduced number of cases at peak of epidemic to 5 times less than the projected scenario in which mandatory quarantine was not conducted, and delayed epidemic peak. Pandemic size remained the same and authors discussed on high economic and social costs of quarantine	Very Low

CI: confidence interval; GRADE: Grading of Recommendations Assessment, Development and Evaluation; ILI: influenza-like illness; PCR: polymerase chain reaction; R0: basic reproductive number; RCT: randomized controlled trial; SC: school closure; USA: United States of America.

Table 18. Summary of epidemiological studies

AUTHOR, YEAR PUBLISHED	INFLUENZA STRAIN OR TRANSMISSIBILITY (R_0)	TYPE OF STUDY	STUDY SETTING & POPULATION SETTING	INTERVENTION	RESULTS & FINDINGS	GRADE EVIDENCE
McLeod MA, 2008 (*99*)	1918 pandemic H1N1	Analysis of historical data	South Pacific islands (including Australia); utilized archival data from national archives of relevant countries, government departments and international organizations	Maritime quarantine (monitoring all passengers and crew for on average 5–7 days before allowing disembarkation)	Strict maritime quarantine have delayed or prevented arrival of the pandemic in said jurisdictions, and associated with reduced mortality rate. Partial quarantine (routine release, without quarantine of asymptomatic passengers) in Fiji and Tahiti was unsuccessful, as in other jurisdictions that did not adopt any border control interventions	Very low
Miyaki K, 2011 (*107*)	A(H1N1)pdm09	Quasi-cluster-RCT	15 134 general employees (aged 19–72 years) of two sibling companies in Japan	Employees in intervention group were asked to stay home voluntarily if any co-habiting family members showed signs of ILI, until 5 days had passed since the resolution of ILI symptoms or 2 days after alleviation of fever, while on full pay. Employees in the control group reported to work as usual even if a household member developed ILI	Infection in workplace is significantly reduced among intervention group, however participants in this group are at higher risks of getting infected when there is an infected household member	Low
van Gemert C, 2011 (*108*)	A(H1N1)pdm09	Retrospective cross-sectional	Confirmed cases reported to the Victorian Department of Health, Australia from May-June 2009 (n = 36 index case-patients, 131 household contacts)	Antiviral drug usage (treatment and prophylaxis) and household quarantine	Odds of a household contact who was concurrently quarantined with the index case-patient becoming a secondary case-patient increased for each additional day (adjusted odds ratio 1.25, 95% CI 1.06–1.47)	Very low

CI: confidence interval; GRADE: Grading of Recommendations Assessment, Development and Evaluation; ILI: influenza-like illness; PCR: polymerase chain reaction; R0: basic reproductive number; RCT: randomized controlled trial; SC: school closure; USA: United States of America.

Table 19. Summary of simulation studies

AUTHOR, YEAR PUBLISHED	TRANSMISSIBILITY OF THE INFLUENZA STRAIN (R_0)	STUDY SETTING & POPULATION SETTING	INTERVENTION	RESULTS & FINDINGS
an der Heiden M, 2009 (*80*)	1.34, 1.58, 2.04	(1) Model based on the age distribution and size of the population of Germany: 71 000 000 adult population and 11 000 000 children (< 15 years old), entire population is fully susceptible at onset of the epidemic; (2) Children are 2.06 times as susceptible as adults, 86% of infected individuals become symptomatic	(1) Intensive case-based measures (CCM1; consisting of isolation and therapy of cases, contact tracing, quarantine and post-exposure prophylaxis of selected contacts in- and outside of the household); (2) Less-intensive measures (CCM2; isolation and therapy of cases, quarantine and post-exposure prophylaxis of household contacts); CCM1 and CCM2 were set to be 75% and 50% effective in reducing secondary cases	(1) When the first 500 cases are managed with CCM1 followed by 10 000 cases managed by CCM2, the peak of epidemic is delayed for up to 6 weeks (R0 1.58, 5 imported cases per day, case detection rate 10–30%). If only CCM1 was adopted without CCM2, delay was estimated to be 6–20 days (case detection rate 10–30%); (2) Effectiveness of these combination of interventions is affected by the R0 of the influenza strain and case detection rate (i.e. higher R0 causes interventions to be ineffective at an earlier time point).
Saunders-Hastings P, 2017 (*91*)	1.5–2.5	(1) Model based on population of Ottawa–Gatineau census metropolitan area in 2011	Combination of quarantine with other interventions including vaccination, antiviral treatment, prophylaxis, SC, community-contact reduction, personal protective measures and isolation; best guess for adherence for quarantine is 15%	(1) Combination of quarantine and isolation resulted in reduction of attack rate to 33.9%, from the baseline of 53.4%, lowest among all interventions studied. (2) Combination of quarantine, isolation SC, community-contact reduction and personal protective measures reduced attack rate to 15.2% and delayed pandemic peak to more than 100 days
Ferguson NM, 2006(*87*)	1.4–2.0	(1) Model based on population density data and data on travel patterns of the USA and United Kingdom; (2) 30% of transmission occurred in household, the rest in general community, workplaces and schools; asymptomatic fraction was 0.5	Voluntary household quarantine for 14 days (assumed 50% compliance, external contact rates reduced by 75% and intra-household contact rate increased by 100%)	Voluntary household quarantine was effective in reducing attack rates in the community and delaying epidemic peak, in the circumstance where compliance is high. A combination of household quarantine and antiviral prophylaxis provision will further strengthen the effect, at the same time alleviate the ethical dilemma of household quarantine

AUTHOR, YEAR PUBLISHED	TRANSMISSIBILITY OF THE INFLUENZA STRAIN (R_0)	STUDY SETTING & POPULATION SETTING	INTERVENTION	RESULTS & FINDINGS
Wu JT, 2006 (*77*)	1.80	(1) Model based on distribution of household sizes and average numbers of children in household of different sizes in Hong Kong SAR; (2) Constant introduction of 1.5 infected individuals per day per 100 000 people for 365 days; (3) 70% of transmission occur outside home (in schools and workplaces)	Combination isolation and voluntary quarantine (household quarantine of on average 7.5–8.2 days). Interventions were active before arrival of infected individuals in the city	Combination of isolation and voluntary quarantine reduced the baseline infection attack rate of 74% to 43%
Halloran ME, 2008 (89)	1.9–2.1, 2.4 and 3.0	(1) Model based on population of Chicago (8.6 million people); (2) 67% of influenza infections are symptomatic, case ascertainment levels are 60–80%	Combination of household quarantine (for 10 days with compliance of 30%, 60% or 90%) with isolation, and other social distancing measures, implemented at intervention threshold of 1, 0.1, and 0.01%	At R_0 1.9–2.1, 60% ascertainment and 90% compliance, intervention threshold of 0.1%, attack rate was 0.17–1.2%, as compared to baseline scenario of 42.4–44.7%
Sato H, 2010 (104)	2.3	(1) Population of 100 000 individuals (2) Transmission caused by cases undetected by onboard quarantine	Onboard quarantine combined with SC and home quarantine (with compliance of 10%, 30% and 50%; quarantined individuals were assumed to have no contact with infectious individuals for 3, 7 or 14 days)	The interventions were effective in reducing maximum number of daily asymptomatic cases and delaying the epidemic peak. Such effectiveness depends heavily on compliance; low compliance result in minimal impact. Home quarantine for 14 days with compliance of 50%, starting on day 6 was the most effective, which reduced number of cases by 44% and delayed the epidemic peak by 17 days
Longini IM Jr, 2005 (101)	1.4	Population of 500 000 individuals, with age and household sizes based on the Thai 2000 census (rural Thailand)	Household quarantine (contact probabilities within households and household clusters were doubled for quarantined individuals)	Household quarantine alone was effective in reducing number of cases. Early implementation and high compliance are needed for successful intervention

AUTHOR, YEAR PUBLISHED	TRANSMISSIBILITY OF THE INFLUENZA STRAIN (R_0)	STUDY SETTING & POPULATION SETTING	INTERVENTION	RESULTS & FINDINGS
Nishiura H, 2009 (*102*)	1.67	Disease-free small island nation, which permitted arrival of 20 aircraft with a total of 8000 incoming individuals before closing all airports	Border quarantine – all incoming individuals were placed into routine quarantine on arrival, and were monitored for onset of symptoms. All infected individuals who develop influenza symptoms were successfully detected. Quarantine security was assumed to be fully effective and that no secondary transmission would occur in the quarantine facility	Reduction of 99% of risks of introducing infectious individuals into small island nations with quarantine period of 9 days. Combination with rapid diagnostic testing can reduce the quarantine period to 6 days
Roberts MG, 2007 (*103*)	2.0	(1) Population of one million persons (2) Proportion of symptomatic infective 67%, asymptomatic individuals have 50% infectivity as compared to symptomatic individuals	(1) Home quarantine (70% compliance) for 6 days, hence 56% of all transmission from those infected within their household is prevented. (2) Home quarantine (50% compliance), hence 40% of transmission from household contacts is prevented (3) Combination of home quarantine with SC, and targeted antiviral prophylaxis	Home quarantine alone was successful in reducing the reproduction number, as well as proportion of population infected. At higher transmissibility, R0 3.0, only the combination of home quarantine with SC and targeted antiviral prophylaxis is effective in preventing an epidemic
Yang Y, 2011 (*105*)	1.79	(1) Population of 8382 persons, with population and social structure based on the city of Eemnes	(1) Household quarantine (stay at home at all times with compliance 25%, 50%, 75%, and 100%). (2) Combination of household quarantine with SC and refrain from social activities; Delay between interventions and out-break threshold was less than one day	At 50% compliance, household quarantine reduced 22.4% and 20.8% total number of cases and peak cases respectively, as well as delayed epidemic peak. A combination of all 3 interventions did not add much benefit in reducing the total number of cases, however reduced the peak cases by 56%, and delayed the epidemic peak

CCM: combination of case-based methods; R0: basic reproductive number; SAR: Special Administrative Region; SC: school closure; United Kingdom: United Kingdom of Great Britain and Northern Ireland; USA: United States of America.

Delay of epidemic peak

Five studies reported the effectiveness of household quarantine, border quarantine and maritime quarantine in delaying peak of epidemic (*80, 91, 99, 104, 106*). As previously described, analysis of historical data suggested maritime quarantine effectively delayed or prevented arrival of the 1918–1919 pandemic in the pacific islands. Similarly, a model based on the 2009 H1N1 pandemic in Beijing reported delay in epidemic peak as compared to a projected scenario without mandatory quarantine (*106*). Combination with other interventions may improve effectiveness of quarantine (80). Saunders-Hastings et al. reported in their simulation study that a combination of quarantine with seven other interventions including voluntary isolation, SC, and personal protective measures can delay peak of pandemic for more than 100 days (*91*). On the other hand, as for reduction of impact, Sato et al. suggested minimal impact of border quarantine in delaying epidemic peak, mainly due to the low detection rate of cases (*104*).

Ethical considerations

As with isolation, the main concern of quarantine is freedom of movement of individuals (*106*). However, such concern is more significant for quarantine, because currently available evidence on effectiveness of quarantine varies and it involves restriction of movement of some healthy or non-ill individuals. Mandatory quarantine considerably increases such ethical concern as compared to voluntary quarantine (*96*). In addition, household quarantine can increase the risks of household members becoming infected, and such risk increases with the duration of quarantine (*87, 107, 108*). A combined policy of household quarantine with household prophylaxis has been suggested to be able to alleviate such concerns (*87*). Maritime quarantine and border quarantine are subject to similar concerns. On the other hand, onboard quarantine involves a shorter duration of restriction of movement, but currently available evidence has suggested the intervention to have low cost–effectiveness and minimal impact on influenza control.

Knowledge gaps

Most of the currently available evidence on effectiveness of quarantine on influenza control was drawn from simulation studies, which have very low strength of evidence. Available epidemiological studies did not rely fully on laboratory-confirmed influenza as the outcome of interest. While acknowledging the difficulties of studying quarantine in an RCT, robust data from experimental studies would be valuable. In addition, as part of simulation studies, assumptions have been used in various aspects of model construction, of which many still require more robust evidence, such as the asymptomatic fraction among all infections, as well as the possibility of superspreaders and the nature of compliance behaviour (*77, 102*).

3.3. School closures

Terminology

Closure of schools include scenarios either when virus transmission is observed in the school, or an early planned closure of schools before influenza transmission initiates. Types of closure are shown in Table 20 (*109*).

Table 20. The definition of SC terms

TERM	DEFINITION
School closure	School is closed to all children and staff.
Class dismissal	School campus remains open with administrative staff, but most children stay home.
Reactive Closure/ Dismissal	School is closed after a substantial incidence of ILI is reported among children and/or staff in that school.
Proactive Closure/ Dismissal	School is closed before a substantial transmission among children and staff is reported.

ILI: influenza-like illness.

Methods

The latest systematic review to review the effects of SCs on influenza outbreaks was published in 2013 by Jackson et al. (*110*). We conducted an additional search to update the systematic in PubMed, Medline, EMBASE and CENTRAL from 1 January 2011 to 4 September 2018. Inclusion criteria included study designs of RCTs, epidemiological studies and modelling studies reporting the effectiveness of SC in non-health care settings. Studies that described one or more influenza outbreaks, as well as the combination of SC and other NPIs, were also included. Modelling studies were included only if they used influenza surveillance data to evaluate the effectiveness of SC. Modelling studies based on stimulated data and/or on avian influenza virus, studies without school-specific data and studies published other than full report were excluded. Articles published other than English were also excluded after full-text screening. Two reviewers (SG and MF) independently screened titles, abstracts and full texts to identify the eligible articles. The quality of evidence was evaluated based on GRADE to assess the overall effectiveness of SC in mitigating influenza pandemics or epidemics, with seven specific metrics: reducing the epidemic peak, reducing overall attack rate, reducing incidence, reducing duration of the epidemic, reducing transmission, delaying the epidemic peak and reducing school absenteeism.

Results

The most recent systematic review was published in 2013, Jackson et al. identified 79 epidemiological studies on SCs and summarized the evidence as demonstrating that this intervention could reduce the transmission of pandemic and seasonal influenza among schoolchildren, but owing to the heterogeneity in the available data, the optimum strategy (e.g. the length of closure, reactive or proactive closure) remained unclear (*110*). The flow chart of study selection is shown in Fig. 19.

In the additional search to update the systematic review that was published by Jackson et al. in 2013, 287 papers were identified from the four databases and 12 citations were found from other sources, resulting in total of 299 citations for screening. Of these, 101 full-length articles were assessed for eligibility and 22 additional articles were identified. In total, 101 articles were included in our systematic review. The flow chart of study selection is shown in Fig. 18. The quality of evidence was assessed to be very low according to the GRADE criteria.

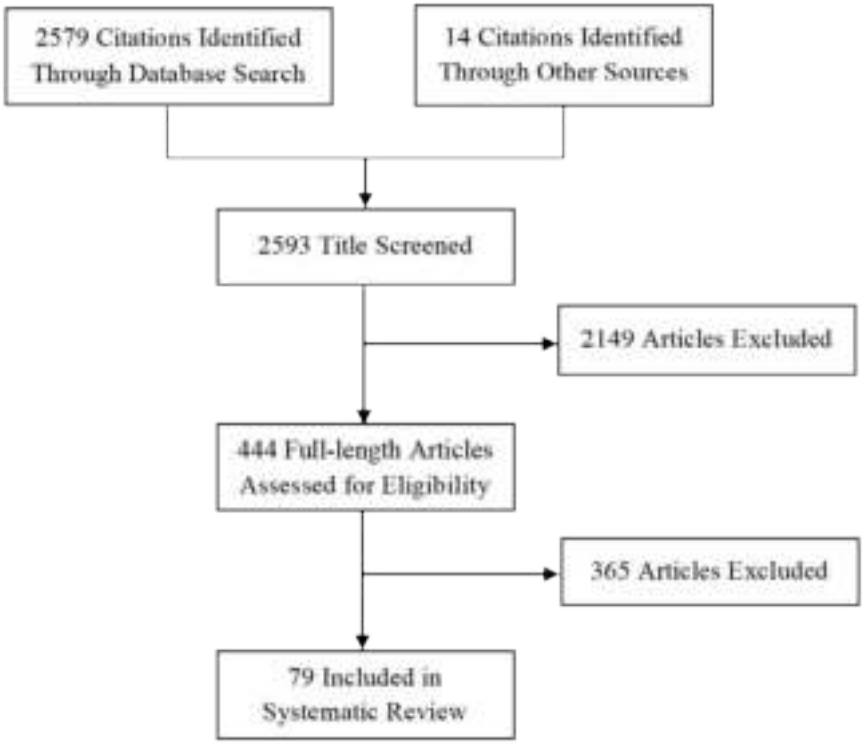

Fig. 18. The flow chart of systematic review by Jackson

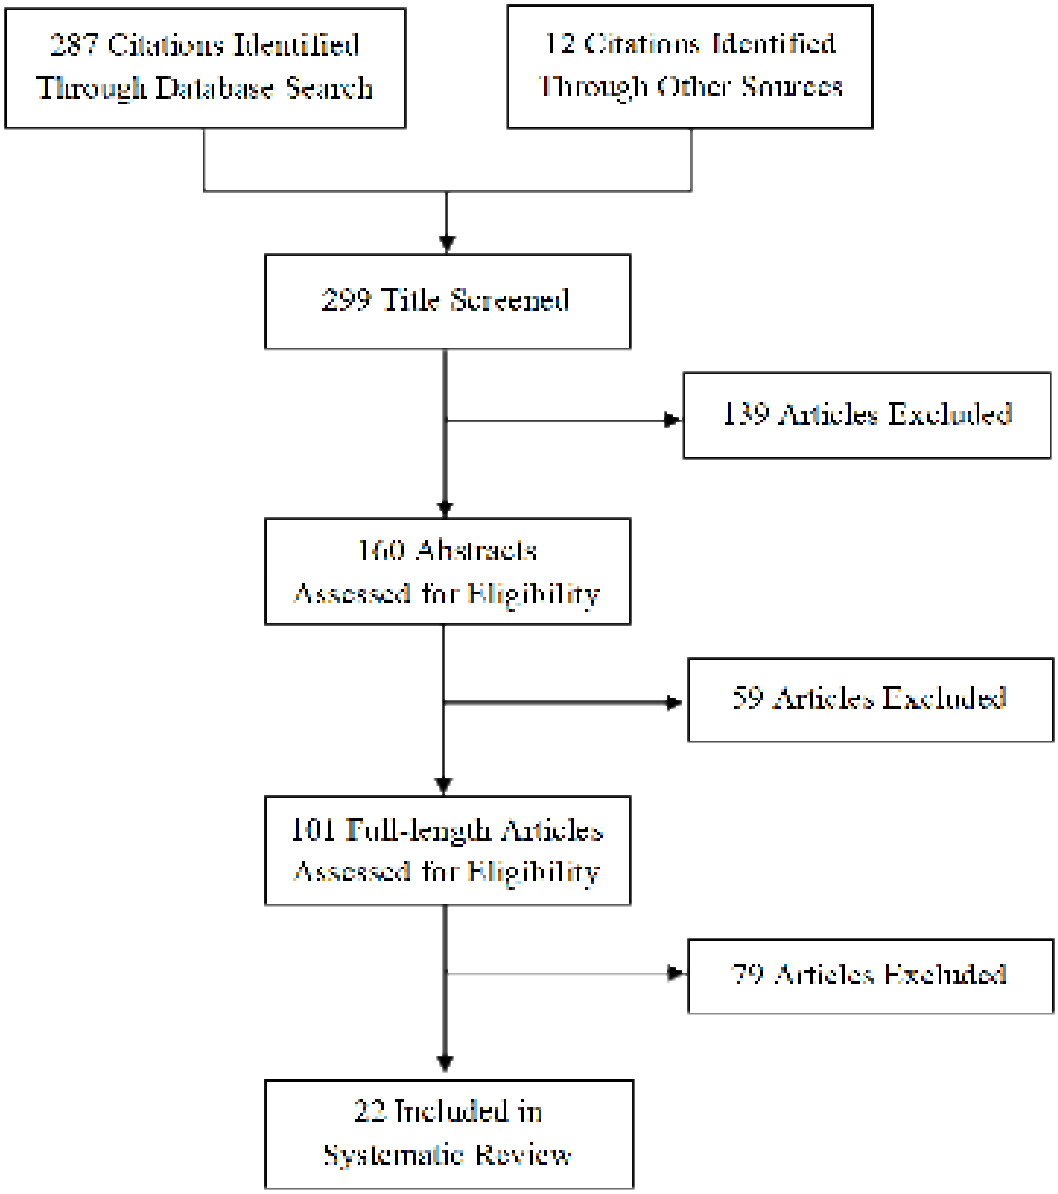

Fig. 19. The flow chart of updated studies in school closures

Among the included 101 articles, 16 articles presented data on reactive SCs (111-126), 13 articles examining proactive SCs (*85, 127-138*), 28 articles examined the impact of regular school holidays on transmission (*123, 125, 136, 139-163*), and 47 articles were related to outbreak reports or teachers' strike (*164-210*). The basic characteristic of the studies is shown in Table 21.

Table 21. Basic characteristic of the studies

	Number of studies (n=101)
Type of influenza strain	
Seasonal	30
1918 pandemic	7
1968 pandemic	1
2009 pandemic	62
Seasonal and 2009 pandemic	1
Study setting	
Asia	30
Europe	26
America	38
Africa	1
Australia	6
Nature of closure[a]	
Outbreak report or teachers' strike	47
Planned holiday	28
Reactive closure	16
Proactive closure	13
Duration of closure[b]	
7–13 days	40
14–20 days	24
≥ 21 days	22
< 7 days	13
Varied	8
Not clear	5

[a] A single article can contain different types of closure.

[b] Each study may present more than one dataset for which the durations of closure differed.

A total of 16 studies demonstrated that reactive SC could be a useful control measure during influenza epidemics or pandemics, with impacts that included reducing the incidence and reducing the peak size (Table 22). Several studies reported a reduction in number of confirmed or ILI cases (*114, 115, 117, 119, 123, 125, 126*). One study also showed a reduction in total infected cases by 32.7% (total reduced number of cases from 127.1 to 85.5) (*122*). Another observational study suggested a reduction in the peak of influenza epidemic curve by 24% during the 4-day closure, and also a reduction of the total number of infected students by 8% (*118*). However, two observational studies in China did not identify a significant difference on total attack rate between the control (SC not implemented) and intervention group (school closed) (*112, 113*). Two studies in the USA showed that absenteeism was lower after school reopening compared to before SC (*120, 121*).

Effectiveness of SCs can also be assessed by evaluating the transmission rate; that is, reproduction number. Hens el at. showed a reduction of the reproduction number from 1.33 (95% CI: 1.11–1.56) to 0.43 (95% CI: 0.35–0.52) after SC (116). An observational study from Japan reported that SC was more effective than class closure (dismissal of that particular class with substantial increase in influenza incidence) (126). In another study from Japan, a 2-day SC in the outbreak situation

(after a 10% of absentee occurrence in a school) was also shown to associate with the interruption of an outbreak within a week (124). One detailed study of transmission in a school in Pennsylvania identified no effect of the reactive closure that was implemented when 27% of students already had symptoms (*111*).

Effectiveness of proactive SC was studied in 13 articles (Table 23). A study showed that proactive SC had an advantage in delaying the epidemic peak for more than a week, affecting the modelled mean peak, and reducing the overall attack rate from 9.7% to 8.6% (*127*). Bootsma et al. estimated that early and sustained interventions, including SCs, reduced overall mortality by up to 25% in some cities (128). Hatchett et al. and Markel et al. also examined NPIs in the 1918–1919 pandemic, reporting that the combined use of NPIs including SCs were able to delay the time to peak mortality, and to reduce peak mortality and overall mortality (*85, 135*).

One study estimated a 29–37% reduction in influenza transmission by the 18-day period of mandatory SCs and other social distancing measures including closure of restaurants and theatres, and cancellation events (130). A study in Mexico City estimated that effective reproduction ratio declined from 1.6 before closure to less than 1 during closure (134). Wu et al. estimated that the reproduction number was reduced from 1.7 to 1.5 during the proactive closures and to 1.1 during the rest of the summer holiday (*138*). One study in Mexico showed a 80% reduction of contact rate during closure period and a subsequent planned holiday (*136*). However, closing kindergartens and primary schools for 2 weeks in Hong Kong SAR did not show any significant effect on community transmission, although the incidence remained low after the peak during proactive closure (133).

A total of 28 studies monitored the change of influenza incidence across planned school holidays (e.g. the scheduled winter holiday each year), to estimate the impact of SC on influenza transmission (Table 24). Eight of these studies illustrated that planned holidays could reduce influenza transmission (*136, 139, 141, 147, 148, 150, 159, 163*). One study demonstrated that school holidays reduced the R0 of influenza A(H1N1)pdm09 by 14–27% in different regions of India compared with non-holiday period (139). One study also reported an association of school holiday with a reduction of 63% to 100% in transmission in Canada (148). Another study reported a reduction of R0 from 1.25 to 0.79 during the 8 days-national holidays in China, but reported that the 8-week summer school holiday had a limited effect on incidence of ILI (*163*). Two studies in the United Kingdom and Mexico showed that SCs could reduce contact rate by around 48–80% (*136, 141*). Two studies in Belgium and the Netherlands suggested that holidays delayed the epidemic peak by more than 1 week, and reduced the peak incidence by 4–27% (*155, 160*). A study from the USA showed that absenteeism in Adrian reduced by approximately 6% (*157*), whereas Rodriguez et al. reported no difference between closed schools and those that did not close (*158*).

Observational studies also reported a reduction in incidence of influenza associated with planned school holidays (*123, 125, 140, 142-146, 149, 150, 152-154, 156, 159, 161, 162*). Studies showed that summer or winter holidays were associated with the reduction of ILI incidences by showing significant changes of ILI incidence rate ratios of schoolchildren to adults during the breaks (*143, 145, 153*). A study based on national surveillance data in France showed that routine school holidays prevented 18% of seasonal influenza cases (18–21% in children) (*142*). Another study in Japan estimated a 38% reduction in number of medically attended clinical ILI cases (*152*). Wheeler et al. suggested that planned holidays could prevent or delay potential influenza cases among school-age children by around 42% (*161*). In comparison, a systematic of simulation studies that reviewed the effects of SCs on influenza outbreaks found that this intervention can be a useful control measure during an influenza pandemic (*211*).

A study conducted a review on social distancing interventions in schools other than SC (212). A total of 16 articles met the inclusion criteria, and 16 states in the USA mentioned school practices to promote social distancing in the published guideline documents. The most frequent categories of school measures included cancelling or postponing after-school activities, increasing space among students, cancelling classes or activities, and reducing mixing during transport.

A simulation study showed that classroom restrictions (the children must remain seated while in their classroom) were the best single intervention at lower infection probabilities. At higher transmission rates, staggered shifts (each classroom follows one of three different schedules put forth by the school: the current schedule, a shift of 45 minutes, and a shift of 90 minutes) is the best single intervention (*213*). A study by Cooley et al. reported that a 3-day weekend for schools could be effective at reducing peak attack rate, and would be less detrimental than sustained SC (*214*). Closing the playground and other common areas could significantly reduce the total number of infected students (*215*). However, the evidence is limited on the effectiveness of school measures.

Ethical considerations

Apart from a potential health impact, SCs can have a substantial social impact by requiring parents to make other arrangements for care or supervision of their children, which can be particularly challenging for some families and for prolonged closures. In addition there may be social equity concerns; for example, because of access to subsidized or free food at school for lower income families (*121*).

Knowledge gaps

More research is needed on the best trigger factors, timing and duration of SCs in order to maximize the impact of this disruptive intervention.

Table 22. Summary table of reactive closure

AUTHOR, YEAR	REDUCE PEAK	REDUCE OVERALL ATTACK RATE	REDUCE INCIDENCE	REDUCE DURATION	REDUCE TRANSMISSION	REDUCE ABSENTEEISM
Cauchemez S, 2011 (*111*)	–	–	–	–	Reproduction number remained unchanged during SC and after the reopening of school (R = 0.3)	–
Chen T, 2017 (*112*)	–	Total attack rate of 1–3 week of SC were close to that for no intervention	–	Duration of outbreak was prolonged	–	–
Chen T, 2018 (*113*)	–	Total attack rate of 1–3 week of SC were close to that for no intervention	–	Duration of outbreak was prolonged	–	–
Davis BM, 2015 (114) [a]	–	–	ILI rate ratio changed from 3.13 (3 weeks before peak), to 2.75 (at peak) and 1.79 (3 weeks after the peak)	–	–	–
Egger JR, 2012 (115)	–	–	7.1% reduction in ILI case over the outbreak period	–	–	–
Hens N, 2012 (116)	–	–	–	– –	Influenza case reproduction number decreased from 1.33 (during outbreak before SC) to 0.43 (after SC)	–
Janjua NZ, 2010 (117)	–	–	Daily number of ILI cases declined during SC	–	–	–

ILI: influenza-like illness (fever plus cough and/or sore throat); SC: school closure.

AUTHOR, YEAR	REDUCE PEAK	REDUCE OVERALL ATTACK RATE	REDUCE INCIDENCE	REDUCE DURATION	REDUCE TRANSMISSION	REDUCE ABSENTEEISM
Kawano S, 2015 (*118*)[b]	Number of infected students in a SC decreased by 24% at its peak	Cumulative number of infected students decreased by 8.0%	–	–	–	–
Loustalot F, 2011 (*119*)	–	–	Incidence remained low during closure	–	–	–
Miller JC, 2010 (*120*)	–	–	–	–	–	Absenteeism was lower after reopening compared to before closure
Russell ES, 2016 (*121*)	–	–	–	–	Closing schools after a widespread ILI activity did not reduce ILI transmission	Absenteeism changed from 1% (baseline), to 3.62% (during SC), and 0.68% (after school reopening)
Sato T, 2013 (*122*)	–	Total number of infected persons decreased from 127.1 to 85.5; the maximum number of infected cases decreased from 63.7 to 53.1	–	–	–	–
Sonoguchi T, 1985 (*123*)	–	–	Number of cases declined from 16 on the day before closure to almost 13, 5 and 0 on the three days of closure in high school	–	–	–
Sugisaki K, 2013 (*124*)	–	–	–	Outbreak duration decreased by 4.98 days if the class is closed for 2 days upon the observed 10% ILI-related absentee rate	–	–
Uchida M, 2011 (*125*)	–	–	Incidence declined during closure period	–	–	–
Uchida M, 2012 (*126*)[c]	–	–	At elementary school, subsequent peak of H1N1 case showed up despite school or class closure (Fig. 1); at junior high school, SC significant reduced the number of H1N1 case but not in class closure (Fig. 2)	–	–	–

ILI: influenza-like illness (fever plus cough and/or sore throat); SC: school closure.
[a] ILI rate ratio is compared at school district level, with 51–100% of schools being closed, compared with district level, with 1–50% of schools being closed.
[b] Author mentioned the recommended period of SC is > 4 days.
[c] Closure duration is significantly related with the number of cases within the 7-day of school opening.

Table 23. Summary table of proactive closure

AUTHOR, YEAR	REDUCE PEAK	REDUCE OVERALL ATTACK RATE	DELAY TIME TO PEAK	REDUCE INCIDENCE	REDUCE TRANSMISSION
Bolton, 2012 (*127*)	–	Overall attack rate decreased from 9.7% to 8.6%[a]	Epidemic peak would be delayed by over a week	–	–
Bootsma MC, 2007 (*128*)[b]	Earlier intervention may reduce peak mortality	Earlier intervention may reduce total mortality	–	–	–
Caley P, 2008 (*129*)[b]	–	–	–	–	Transmission reduced by 38% during period of social distancing
Chowell G, 2011 (*130*)[b]	–	–	–	–	Reproduction number decreased from 2.2 (before SC) to 1.0 (during SC); transmission rate is estimated to reduce by 29.6% during the intervention period
Copeland DL, 2013 (*131*)	–	–	–	Incidence rate of ARI increased from 0.6% (before closure), to 1.2% (during SC) and dropped to 0.4% (after school reopening)	–
Cowling BJ, 2008 (*133*)[c]	–	–	–	–	Not found a substantial effect on community transmission
Cowling BJ, 2010 (*216*)[c]	–	–	–	–	The estimated reproduction number changed from 1.5 (initial peak) to below 1 (during proactive closure), and fluctuated between 0.8 and 1.3 through the school vacations
Cruz-Pacheco G, 2009 (*134*)[b]	–	–	–	Incidence increased to peak then decreased gradually during closure period	Effective reproductive ratio R(t) declined from 1.6 before to < 1 during closure

ARI: acute respiratory infection (presence of at least 2 of the following symptoms: fever, cough, sore throat and runny nose);
ILI: influenza-like illness (fever plus cough and/or sore throat); SC: school closure.
[a] Assuming schools were closed for 4 weeks and the attack rate in children was threefold higher than in adults.
[b] SC combined with other interventions.
[c] Proactive closure followed by planned holidays.

AUTHOR, YEAR	REDUCE PEAK	REDUCE OVERALL ATTACK RATE	DELAY TIME TO PEAK	REDUCE INCIDENCE	REDUCE TRANSMISSION
Hatchett RJ, 2007 (135)[b]	Earlier intervention reduced peak weekly excess pneumonia and influenza death rate	–	–	–	–
Herrera-Valdez MA, 2011 (*136*) [b]	–	–	–	–	Reduced contact rates by around 80% during closure period
Markel H, 2007 (85) [b]	Earlier intervention reduced peak excess death rate	Earlier and increased duration of intervention reduced total excess death	Earlier interventions increased time to epidemic peak	–	–
Tinoco Y, 2009 (*137*)	–	–	–	Number of ILI cases decreased throughout closure period	–
Wu JT, 2010 (*138*) [c]					The reproduction number was reduced from 1.7 to 1.5 during the proactive closures and to 1.1 during the rest of the summer holiday

[a] Assuming schools were closed for 4 weeks and the attack rate in children was threefold higher than in adults.

[b] SC combined with other interventions.

[c] Proactive closure followed by planned holidays.

Table 24. Summary table of planned holidays

AUTHOR, YEAR	REDUCE PEAK	DELAY PEAK	REDUCE OVERALL ATTACK RATE	REDUCE INCIDENCE	REDUCE TRANSMISSION	REDUCE ABSENTEEISM
Ali ST, 2013 (*139*)	–	–	–	–	Reproduction number reduced by 14–27% in different regions of India	–
Baguelin M, 2010 (*140*)	–	–	–	Incidence declined throughout the closure period	–	–
Birrell PJ, 2011 (*141*)	–	–	–	–	Reduce contact rate among 5–14 years old by 72% (summer holiday) and 48% (half term holiday)	–
Cauchemez S, 2008 (*142*)	–	–	–	Routine school holidays prevented 18% of seasonal influenza cases (18–21% in children)	–	–
Chowell G, 2011 (*144*)	–	–	–	Number of confirmed cases declined throughout closure period	–	–
Chowell,G, 2014 (*143*)[a]	–	–	–	Schoolchildren-to-adult ratios decreased by 40–68% during the 2-week period immediately preceding the winter break	–	–
Chu Y, 2017 (*145*)	–	–	–	ILI incidence rate ratio of age 5–14 (schoolchildren) to adult (aged above 60) declined by 13.3% during summer break	–	–
Davies JR, 1988 (*146*)	–	–	–	Clinical influenza cases increased during closure period	–	–
Eames KT, 2012 (*147*)	–	–	–	–	The initial growth rate of the epidemic during holidays would be 35% lower than during term time (from 1.57 to 1.07)	–

AUTHOR, YEAR	REDUCE PEAK	DELAY PEAK	REDUCE OVERALL ATTACK RATE	REDUCE INCIDENCE	REDUCE TRANSMISSION	REDUCE ABSENTEEISM
Earn DJ, 2012 (*148*)	_	_	_	_	Reduction in transmission rate in school-age children was 63%, 100% and 86% as a result of schools closing for the summer in Calgary, Edmonton and the province of Alberta as a whole respectively	_
Evans B, 2011 (*149*)	_	_	_	Estimated number of ILI cases declined during school holiday	_	_
Ewing A, 2017 (*150*)[b]	_	Fig. 5A suggested a peak delay	_	Fig. 5B illustrated a reduction of influenza incidence	Influenza transmission decreased by approximately 15% (from 1.1 to 0.9) in most seasons and decreased to < 1 immediately following Christmas	_
Flasche S, 2011 (*151*)	_	_	_	_	No evidence found of a relationship between the effective reproduction number and the start of school holidays	_
Fujii H, 2002 (*152*)	_	_	_	Number of ILI cases declined by 38% during the first week of closure (from 191 to 118 cases), then increased to 173 cases during the second week of closure	_	_
Garza RC, 2013 (*153*)	_	_	_	ILI incidence rate ratio reduced by 37% among children 5–14 years of age during the week after the winter school break	_	_
Herrera-Valdez MA, 2011 (*136*)[c]	_	_	_	_	Reduced contact rates by around 80% during closure period	_

AUTHOR, YEAR	REDUCE PEAK	DELAY PEAK	REDUCE OVERALL ATTACK RATE	REDUCE INCIDENCE	REDUCE TRANSMISSION	REDUCE ABSENTEEISM
Louie JK, 2007 (*154*)	_	_	_	ILI incidence declined throughout closure; laboratory-confirmed declined slightly first, then increased	_	_
Luca G, 2018 (*155*)[d]	Peak incidence reduced by 4%	All holidays delay the peak time of 1.7 weeks	Epidemic size reduced by approximately 2%	_	_	_
Merler S, 2011 (*156*)[e]	_	_	_	Incidence declined during closure	_	_
Monto AS, 1970 (*157*)	_	_	_	_	_	Absenteeism reduced by approximately 6% in Adrin
Rodriguez CV, 2009 (*158*)	_	_	_	_	_	No difference in post-break absenteeism in schools on holidays compared with schools that remained open at the same times (relative rate = 1.07, 95% CI = 0.96–1.20)
Smith S, 2011 (*159*)	_	_	_	Consultation rates decreased in school-aged children	Transmission of influenza may be interrupted in that school-age group	_
Sonoguchi T, 1985 (*123*)	_	_	_	Case number remained low during closure period in middle school	_	_
Te Beest DE, 2015 (*160*)	Epidemic peak is lowered by 27%	Peak is delayed for approximately 1 week	_	_	_	_

AUTHOR, YEAR	REDUCE PEAK	DELAY PEAK	REDUCE OVERALL ATTACK RATE	REDUCE INCIDENCE	REDUCE TRANSMISSION	REDUCE ABSENTEEISM
Uchida M, 2011 (*125*)	_	_	_	Incidence declined during closure period	_	_
Wheeler CC, 2010 (*161*)	_	_	Daily number of ILI cases declined during SC	Prevent or delay around 42% of potential influenza cases among school-age children	_	_
Wu J, 2010 (*162*)	_	_	_	Cumulative incidence of confirmed cases increased during SC	_	_
Yu H, 2012 (*163*)	_	_	_	_	Reproduction number changed from 1.25 (before National Day holiday), to < 1 (during that holiday), and 1.23 (after that holiday); National day holiday reduced the reproduced number by 37%	_

CI: confidence interval; ILI: influenza-like illness; SC: school closure.

[a] Decline in ratio is caused by a decrease in ILI rates among schoolchildren and the average reduction in ILI incidence among schoolchildren in the 2 weeks during the winter break compared with the 2 weeks before.

[b] The holiday model combined the changes associated with both the SC and travel models.

[c] All holidays included Fall holiday, Christmas holiday, Winter holiday and Easter holiday.

[d] Mainly planned holidays, some reactive closures.

[e] SC combined with other interventions.

Table 25. Summary of outbreak reports and teachers' strike

AUTHOR,YEAR	OUTCOME
Armstrong C, 1921 (*164*)	Number of cases peaked on the day following closure and declined thereafter
Baker MG, 2009 (*165*)	Start of the school holidays in New Zealand reduced influenza transmission and that the return to school slightly accelerated the epidemic
Briscoe JH, 1977 (*166*)	Number of clinical cases declined during closure
Calatayud L, 2010 (*167*)	Cases decline after the half way of SC
Carrillo-Santisteve P, 2010 (*168*)	Number of confirmed and probable cases declined during closure
Cashman P, 2007 (*169*)	A planned SC may have contributed to controlling the outbreak without quantitative information
Chieochansin T, 2009 (*170*)	Laboratory-confirmed cases declined throughout period of closure
Cohen NJ, 2011 (*171*)	Number of respiratory illness cases were lower on the first day of closure compared to previous days, increased during closure and then declined
Danis K, 2004 (*172*)	Number of ILI cases declined during closure period
Echevarria-Zuno S, 2009 (*173*)	Epidemic continued while schools were closed and peaked around 1 week after closure
Effler PV, 2010 (*174*)	Number of confirmed cases declined during closure period
Engelhard D, 2011 (*175*)	ILI rate peaked and declined during closure
Farley TA, 1992 (*176*)	Absenteeism remained low after school reopening
Glass RI, 1978 (*177*)	School absenteeism was lower after the holiday than before
Gomez J, 2009 (*178*)	Number of pneumonia cases decreased from 130 cases at peak to around 40 during closure
Grilli EA, 1989 (*179*)	During the mid-term break there were a further 15 ILI cases (daily cases not provided)
Guinard A, 2009 (*180*)	No further cases during SC period, but epidemic appear to be over before the school was closed

AUTHOR, YEAR	OUTCOME
Health Protection Agency West Midlands H1N1v Investigation Team, 2009 (*181*)	Confirmed number of cases declined during closure period
Heymann A, 2004 (*182*)[a]	Significant decreases in the rate of diagnoses of respiratory infections (42%), visits to physician (28%) and emergency departments (28%) and medication purchases (35%)
Heymann AD, 2009 (*183*)[a]	Decease in ratio of 14.7% for 6–12 years old associated with teachers' strike
Hsueh PR, 2010 (*184*)	Number of class suspensions or SC generally associated with the number of hospitalizations
Huai Y, 2010 (*185*)	Number of confirmed cases peak at 30 cases on the first day of closure, then declined during closure period
Janusz KB, 2011 (*186*)	Absenteeism changed from 8% (baseline), to 15% (2-days before school outbreak), and 13% (post-school outbreak)
Johnson AJ, 2008 (*187*)	Number of parentally-reported ILI cases decline because of SC
Jordan EO, 1919 (*188*)	Incidence declined from 19 cases to 15 cases the following week in elementary school, and declined from 16 to 5 cases in high school
Kawaguchi R, 2009 (*189*)	Number of confirmed cases declined throughout closure period
Lajous M, 2010 (*190*)	Planned holiday was followed by a slight decrease in ILI case numbers
Leonida DDJ, 1970 (*191*)	Absenteeism continued decline during second SC
Lessler J, 2009 (*192*)	Both confirmed H1N1 influenza and self-reported ILI declined through closure period
Leung YH, 2011 (*193*)	Number of laboratory-confirmed cases increased during first two days of closure and then declined
Lo JY, 2003 (*204*)	Change in proportion of positive specimens were 50–100% lower in April-June than the average because of community control measures
Marchbanks TL, 2011 (*194*)	Number of ILI cases increased during first two days of closure and then declined
Miller DL, 1969 (*195*)	In children aged 5–14 years, rates of influenza declined during the Christmas holidays

[a] Articles related to teachers' strike.

AUTHOR,YEAR	OUTCOME
Nishiura H, 2009 (*196*)	Number of laboratory-confirmed cases declined throughout the closure
Olson JG, 1980 (*197*)	School absenteeism (all-cause) declined in Girls Teachers' Colleges Primary School; absenteeism very similar before and after closure in Taipei American School
Paine S, 2010 (*198*)	Case numbers peaked and declined during holiday, effective reproduction number declined before holiday and continued to decrease during the holiday
Petrovic V, 2011 (*199*)	Weekly incidence rate of ILI and the number of hospitalized cases decreased after the SC
Poggensee G, 2010 (*200*)	Practice index was associated with vacation density
Rajatonirina S, 2011 (*201*)	Only few cases continued to occur during closure period
Shaw C, 2006 (*202*)	Absenteeism was lower after closure than before closure in both reactive closure and planned holiday
Shimada T, 2009 (*203*)	Number of new confirmed cases decreased after SCs
Smith A, 2009 (*206*)	Number of ILI cases declined during closure period
Strong M, 2010 (*207*)	Number of self-reported ILI cases declined during closure period
van Gageldonk-Lafeber AB, 2011 (*208*)	Possible reduced incidence, or slowed epidemic growth
Wallensten A, 2009 (*209*)	Absenteeism almost not changed before and after closure
WHO, 2009 (*205*)	School absenteeism in the following weeks did not increase after school reopening
Winslow CEA, 1920 (*210*)	Cities with SCs had higher deaths rates; timing and duration of closure were not stated

ILI: influenza-like illness; SC: school closure.

3.4. Workplace closures

Methods

PubMed, Medline, EMBASE and CENTRAL were searched until 18 September 2018. No language limits were applied but papers in languages other than English were excluded in screening. The inclusion criteria included RCTs, epidemiological studies and simulation studies reporting the effectiveness of workplace closure (WC) in non-health care settings, as well as the combination of WC and other NPIs. The exclusion criteria included the following: studies in health care settings; studies do not have specific data related to WC; review, letter, news or summary articles; studies related to avian influenza; and the language of articles not in English. Two reviewers (SG and ES) independently screened titles, abstracts and full texts to identify eligible articles.

Results

A total of 475 citations were identified through database search and other sources, of which 18 full-length articles assessed for eligibility and six articles were selected for this systematic review. The flow chart of study selection is shown in Fig. 20.

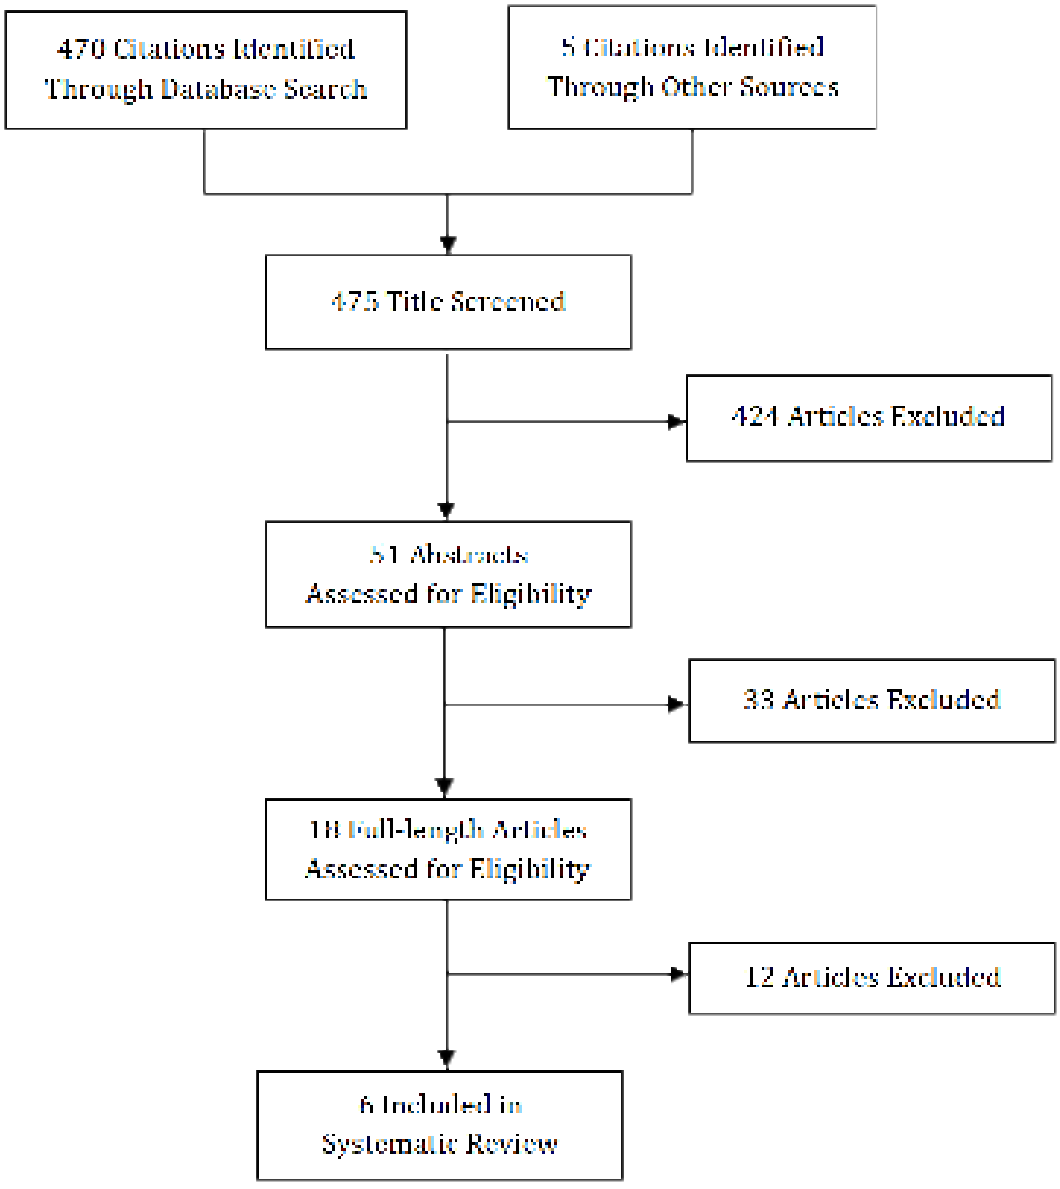

Fig. 20. The flow chart of workplace closure

Among these six studies, four were measured with SC, one targeted different single and multiple strategies, and another evaluated the effectiveness of WC alone (Table 26). All six studies represented simulation studies that met the inclusion criteria and the main outcome include the reduction of attack rate, peak number and delay of epidemic peak.

Predicted effects reduction

Five studies suggested the reduction in attack rate, infected duration or peak number. In the studies by Ferguson et al. (*87*) and Xia et al. (*217*), WC resulted in a small reduction in cumulative attack rate, while Carrat et al. (218) and Mao et al. (*219*) suggested an obvious decrease when assessing the effect of combining intervention. The study by Carrat et al. simulated individual and community level model in France, which suggested a decline of the cumulative attack rate from 46.8% to 1.1%, assuming the R0 of 2.07 (*218*). Mao et al. used an agent-based stochastic simulation model with R0 = 1.3–1.4 in the USA, and predicted a decline of overall attack rates from 18.6% to 11.9% with 100% SC and 10% WC, and from 18.6% to 4.9% with 100% SC and 33% WC (*219*).

A heuristic model using R0 of 1.7 and 2.0 suggested a small reduction in cumulative attack rate but a more substantial reduction in peak attack rates (up to 40%) when 100% SC and 10% WC was implemented. It also suggested that effectiveness could increase if 50% of workplaces were closed, but this would have a higher economic cost (*87*). A simulation model for the control of influenza in an isolated geographical region by Roberts et al. suggested the single WC strategy could not prevent the epidemic (with R0 = 2.0).

Delay the time of peak occurrence

Delaying the epidemic peak is another factor to consider the effectiveness of this intervention. A simulation study using individual-based model suggested that nationwide closure of schools and workplaces for weeks would delay the time of peak occurrence by 5–8 days, depending on the R0 = 1.4, 1.7 and 2.0 (*220*). However, the study by Mao et al. suggested that 100% SC and 33% WC could advance the peak by approximately 1 week (*219*).

Ethical considerations

Apart from a potential health impact, WC can have a substantial impact on the economy and productivity of the society (*221*).

Knowledge gaps

As with SCs, more research is needed on the best trigger factors, timing and duration of WCs in order to maximize the impact of this disruptive intervention.

Table 26. Description of studies included in the review of WCs

STUDY	INFLUENZA STRAIN & TRANSMISSIBILITY (R_0)	STUDY SETTING AND POPULATION	STUDY DESIGN	CLOSURE DURATION	CLOSURE PROPORTION	CLOSURE THRESHOLD	INTERVENTION	OUTCOME
Carrat F, 2006 (*218*)	Future pandemic strain; R_0 = 2.07	General population in France (n = 10 000)	Simulation both individual and community level	N/A	N/A	5 infections per 1000 subjects	SC + WC	Mean accumulation infection rate reduced from 46.8% (42.3–50.5%) to 1.1% (0.6–2.1%)
Ciofi degli Atti ML, 2008 (*220*)	Future pandemic strain; R_0 = 1.4, 1.7, 2	General population in Italy (n = 56 995 744)	Global SEIR model for importation of cases with an individual-based model	4 weeks	N/A	N/A	SC + WC	Nationwide closure could delay the time of peak occurrence by 5–8 days, based on various scenarios
Ferguson NM, 2006 (*87*)	Future pandemic strain; R_0 = 1.7, 2.0	300 million in USA, 58.1 million in United Kingdom	Heuristic model	N/A	Varied: 10%, 50%	N/A	100% SC + varied WC (10%, 50%)	100% SC + 10% WC could slightly reduce the cumulative attack rate, and might reduce the peak attack rate of up to 40%; 50% of WC could further improve the effectiveness with a higher economic cost
Mao L, 2011 (*219*)	Future pandemic strain; R_0 = 1.3–1.4	Urbanized area of Buffalo, NY, USA (n = 985 001)	Agent-based stochastic simulations	N/A	Varied: 10%, 33%	N/A	1) 100% SC + varied (10%, 33%) WC; 2) 100% SC + varied (10%, 33%) WC + preventive behaviour	1) Overall attack rates declined from 18.6% to 11.9% (10% WC) and 4.9% (33% WC), respectively 2); overall attack rate reduced to 3.99% (10% WC) and 1.83% (33% WC), respectively
Roberts MG, 2007 (*103*)	Future pandemic strain; R_0 = 1.1, 2.0 and 3.0	Isolated geographical region (n = 1 000 000)	A model based on published parameters	N/A	70%	N/A	1) WC; 2) WC + SC; 3) WC + SC + antiviral treat + 70% home quarantine	The single strategy of WC is not successful, the combination of four strategies would prevent the epidemic
Xia H, 2015 (*217*)	Simulate H1N1; R_0 = 1.35, 1.40, 1.45, 1.60 (all similar to R_0 = 1.35)	Delhi, India (over 13 million)	Realistic individual-based social contact network and agent-based modelling	3 weeks	60%	Over 0.1% population are infected	Single: WC	Intervention could reduce the attack rate and peak number, and delay the time of peak occurrence; single WC is the most ineffective method among vaccination, antiviral drugs, SC and WC

N/A: not applicable; NY: New York; R0: basic reproductive number; SC: school closure; SD: standard deviation; SEIR: susceptible–exposed–infectious–recovered; United Kingdom: United Kingdom of Great Britain and Northern Ireland; USA: United States of America; WC: workplace closure.

3.5. Workplace measures

Methods

The latest systematic review to review the effects of workplace measures in reducing influenza virus transmission was published by Ahmed et al. in 2018 (*222*). We conducted an additional search in PubMed, Medline, EMBASE and CENTRAL from 1 January 2017 to 28 September 2018. Workplace measures includes teleworking, flexible leave policies, working from home, weekend extension, segregation into smaller groups and social distancing at workplaces. All RCTs, epidemiological studies or simulation studies in non-health care workplaces were included in this review. Review, commentary, editorial articles, studies on WC and studies on generic social distancing not in workplace were excluded from our review. The following outcomes were extracted from the studies: cumulative attack rate, peak attack rate, occurrence of peak and other effects. Two reviewers (SG and ZX) worked independently. The GRADE method was used to evaluate the quality of evidence for the effectiveness of workplace measures in reducing influenza transmission.

Results

The most recent systematic review was published in 2018; Ahmed et al. identified 15 epidemiological or simulation studies (from 14 articles) on workplace measures. In the additional search to update the systematic review that was published by Ahmed et al., 81 articles were identified from the databases and one paper from other sources, resulting in total of 82 for title screening. Ten full-length articles were assessed for eligibility and four additional articles were identified. In total, 19 studies (18 articles) were included in our systematic review. The flow charts of study selection are shown in Fig. 21 and Fig. 22.

Among the included 19 studies, there were six epidemiological studies (Table 27) (*107, 223-227*). A cross-sectional study that randomly selected US adults from the Knowledge Networks online research panel showed that those who could not work from home from 7 to 10 days were more likely to have ILI symptoms compared to those who could (*223*). Another cohort study suggested that respondents who could work from home had a 30% lower rate of attending work with severe ILI symptoms compared to employees without such ability, which may be able to reduce employee-to-employee transmission (*225*). A cohort study in Singapore estimated that the intervention of enhanced surveillance and segregation of units into smaller working subgroups had significant lower serologically confirmed infections compared to those with standard pandemic plan (17% versus 44%) (*224*). A RCT study evaluated the effectiveness of voluntary waiting at home on full pay measure against influenza A(H1N1)pdm09 transmission in workplaces showed an overall risk reduction by 20% (*107*). Piper et al. (*227*) and Asfaw et al. (*226*) used the resources data from nationally representative survey in the USA, and illustrated that adults with paid sick days had a higher probability of staying at home and hence reduced the face-to-face transmission in workplace.

The remaining 13 studies were simulation studies (*89-91, 228-236*). The 12 simulation studies from the review by Ahmed et al. suggested that the workplace measure alone reduced the cumulative attack rate by 23%, as well as delaying and reducing the peak influenza attack rate (*89, 90, 228-236*). A study in Ottawa suggested that working from home measure combined with other interventions could reduce the illness attack rate from 55% to 8% (*91*).

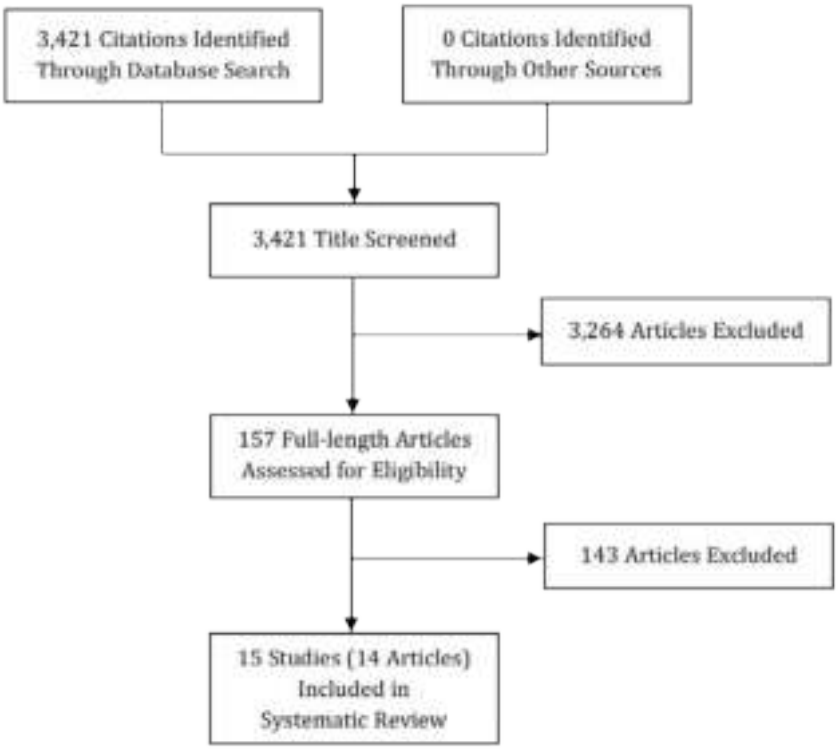

Fig. 21. The flow chart of systematic review by Ahmed

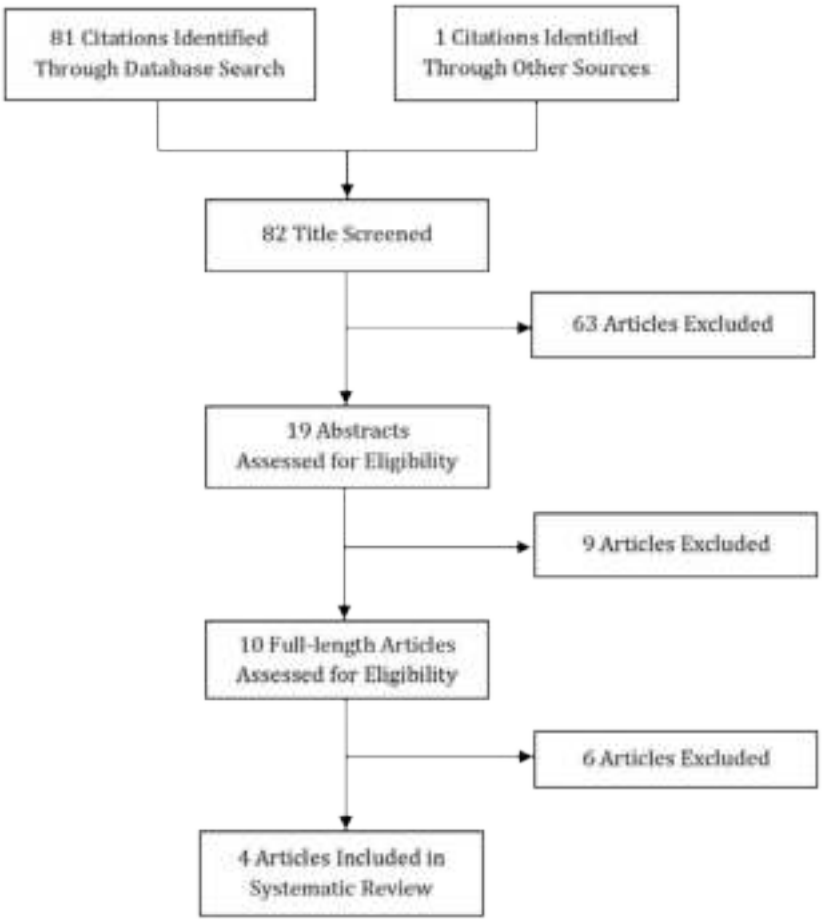

Fig. 22. The flow chart of updated studies in workplace measures

Ethical considerations
Similar to WC, workplace measures could affect the economy and productivity of the society.

Knowledge gaps
A comprehensive review of the ethical issues of workplace measures is lacking, as is a comparison of the benefits and costs of implementing the measures. Other workplace measures have not been studied in depth, such as providing separate studios for people with ILI. In addition, the studies on feasibility and scope of implementation of workplace measures, and the potential impact on families and society transmission are limited.

Table 27. Description of epidemiological studies included in the review of workplace measures

STUDY	STUDY DESIGN	INFLUENZA STRAIN	POPULATION AND SETTING	INTERVENTION	OUTCOME	QUALITY OF EVIDENCE
Asfaw A, 2017 (*226*)	National representative survey	Influenza A(H1N1)pdm09	71 200 people in the USA	Single: paid sick leave	Employees with paid sick leave have a 32% higher probability of staying at home than workers without paid sick leave, which might reduce the transmission of influenza	Very low
Kumar S, 2012 (*223*)	Cross-sectional study	Influenza A(H1N1)pdm09	Nationally representative sample (n = 2079) of USA	Single: can work from home	The people who unable to work at home were more likely to have had ILI (P< 0.05)	Very low
Lee V, 2010 (*224*)	Cohort study	Influenza A(H1N1)pdm09	Singapore military personnel (n = 437 in control group and n = 470 in intervention group)	Multiple: enhanced surveillance and segregation of units into smaller working subgroups	Confirmed infections were significantly (p< 0.001) lower in intervention group (17%) than in the control group (44%)	Very low
Miyaki K, 2011 (*107*)	Quasi-cluster-RCT	Influenza A(H1N1)pdm09	Two sibling companies (Cohort 1 n = 6634, Cohort 2 n = 8500) in Kanagawa Prefecture, Japan	Single: Voluntary waiting at home on full pay if the family became ILI	The intervention reduced around 20% of overall infection risk in the workplace	Low
Rousculp M, 2010 (*225*)	Cohort study	2007–2008 seasonal influenza	793 employees with ILI in three large US companies	Single: can work from home	Employees who could telework had a 29.7% lower rate of attending work with severe ILI symptoms, which indicated that implement teleworking policies may be able to reduce employee-to-employee transmission	Very low
Piper K, 2017 (*227*)	National representative survey (3 rounds interviews in 2009)	Influenza A(H1N1)pdm09	12 044 employees over 16 years old in the USA	Single: paid sick days	Individuals with paid sick leave are more likely to stay at home in order to reduce the influenza transmission in workplace	Very low

ILI: influenza-like illness; RCT: randomized controlled trial; USA: United States of America.

3.6. Avoiding crowding

Methods

The citations were identified from PubMed, Medline, EMBASE and CENTRAL until 18 October 2018. Two reviewers (SG and ES) screened each title, abstract and article that met the criteria in full. Both epidemiological and simulation studies relative to the effectiveness of avoiding crowding (e.g. cancellation or postpone of events and limitation of attendance) in public area are included. Studies that only report an outbreak event in a crowded area or perceptions on mass gathering but without specific data related to the effectiveness of avoid crowding and studies published in review, letter, news or summary articles were excluded. The effectiveness of cancelling, postponing or limiting attendance in reducing influenza transmission was used when examined the quality of evidence by GRADE.

Results

We identified three studies for the systematic review after reviewing 815 titles and 121 abstracts identified from databases and other sources. The flow chart is shown as Fig. 23. Among these three articles, two of them were based on the 1918 influenza pandemic and one focused on World Youth Day gathering in 2008 (details shown in Table 28).

Hachett et al. and Markel et al. reported a strong association between the early implementation of interventions and the mitigation of pandemic influenza. The study by Markel et al. showed three major categories for NPI: SC, cancellation of public gatherings, and isolation or quarantine in 43 cities in the USA. SC combined with a ban on public gatherings was the most common intervention with a median duration of 4 weeks, which can significantly reduce weekly excess death rate (EDR). Also, early implementation led to greater delays in reaching peak mortality (Spearman $\rho = -0.74$, $P < 0.001$), lower peak mortality rates (Spearman $\rho = 0.31$, $P = 0.02$) and lower total mortality (Spearman $\rho = 0.37$, $P = 0.008$) (*85*). There was a statistically significant association between increased duration of interventions and a reduction in total mortality burden (Spearman $\rho = -0.39$, $P = 0.005$) (*85*). Another study by Hatchett et al. also emphasized the early bans on public gathering, closure public places implementation in reducing the EDR (135). In addition, the basic group accommodation for 1 week during World Youth Day was described by Staff el at. (*237*). People accommodated in a single large place (17.2%) had a significantly higher attack rate compared with people who lived in small classrooms (9.2%) in the context of mass gatherings ($p < 0.01$) (*237*).

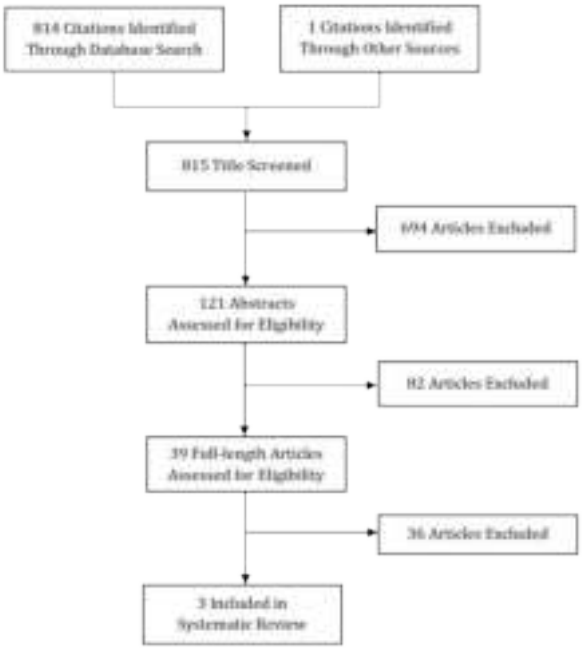

Fig. 23. The flow chart of avoiding crowding

Table 28. Description of studies included in the review of avoiding crowding

STUDY	INFLUENZA	INTERVENTION	OUTCOME	QUALITY OF EVIDENCE
Hatchett RJ, 2007 (*135*)	1918 Pandemic	Early church closure, theatre closure and bans on public gathering	Associated with lower peak excess death rates (Spearman $\rho = 0.56$, $\rho = 0.56$, $\rho = 0.46$ separately)	Very low
Markel H, 2007 (*85*)	1918 Pandemic	Multiple: SC + cancellation of public gatherings + isolation and quarantine.	Implemented earlier and longer duration are significantly associated with the reduction of influenza transmission	Very low
Staff M, 2011 (*237*)	World Youth Day 2008 pilgrims	1 group of pilgrims was accommodated as a large group in a gymnasium and another group was sub-divided into smaller groups and accommodated in classrooms for 1 week.	The attack rate was significantly ($p< 0.01$) higher among pilgrims accommodated in the gymnasium (17.2%) than those staying in the classrooms (9.2%)	Very low

SC: school closure.

Ethical considerations

In urban locations it can be difficult to avoid crowding without considerable social costs. Modification, postponement or cancellation of mass gatherings may have cultural or religious considerations, in addition to public health aspects.

Knowledge gaps

There are still major gaps in our understanding of person-to-person transmission dynamics. Reducing mass gatherings is likely to reduce transmission in the community, but the potential effects are difficult to predict with accuracy. Large-scale RCTs are unlikely to be feasible.

4. TRAVEL-RELATED MEASURES

4.1. Travel advice

Terminology
Travel advice refers to advice from official government to help members of the public to make informed decisions when they are planning to travel, and offer them an objective assessment of risk (*238*). Travel bans are more extreme, and discussed separately. Travel advice can increase travellers' awareness of the travel risk in pandemic countries or areas and may affect decisions to travel.

Methods
The databases including PubMed, Medline, EMBASE and Cochrane Library were searched until September 2018. Inclusion criteria were primary research evaluating travel advice for influenza in the community setting. Studies had to demonstrate any effectiveness following travel advice to the public. We excluded studies conducting at the health care settings, animal-related studies, systematic reviews and/or meta-analysis without updated evidences, not measuring effectiveness of travel advice to the community, and article type of letter, commentary or news. Two reviewers (SR and SG) contributed to the title, abstract and full-text screening.

Results
A total of 168 records were identified and included in the title and abstract screening, and 146 of the records were excluded. Twelve full-text records were evaluated for eligibility and all were excluded. No full-length articles were included in this systematic review. The flow chart of study selection is shown in Fig. 24.

Ethical considerations
Policy decisions and justification should be open to the public, so that the public awareness of influenza can be increased, and public trust to follow travel advice can be maintained (239).

Regarding the impact for the global economy through the public avoidance of travel or trade, travel advice may develop financial loss of the public (*239*).

Knowledge gaps
There is still no evidence measuring the quantitative effect of travel advice on influenza pandemic, which may hamper the development of policy in this area. Because the outcomes of effectiveness may vary by reproduction number, study of the level of infectivity and travel restriction, influenza strain-specific travel advice can be considered.

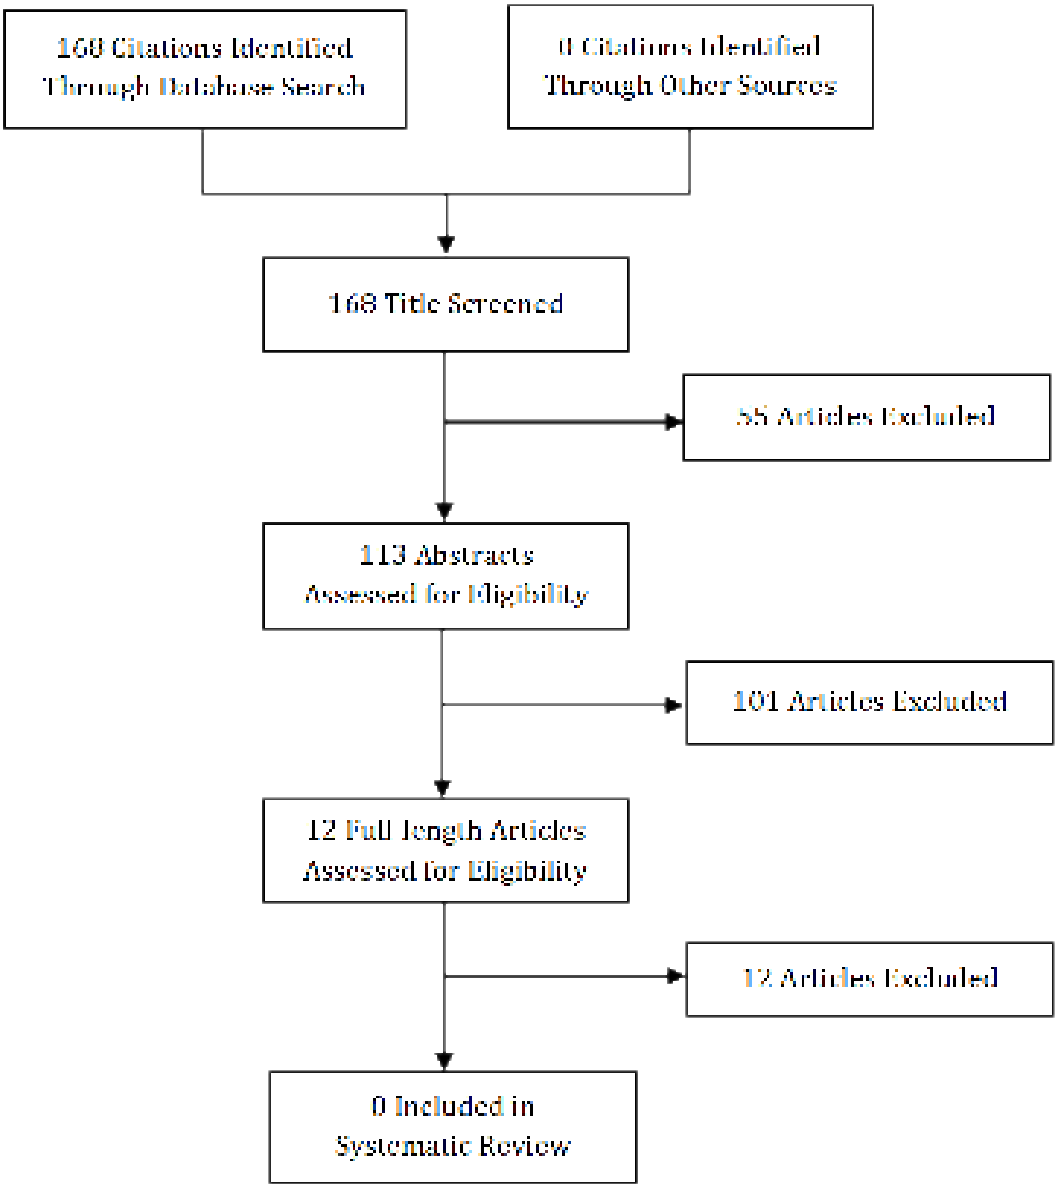

Fig. 24. The flow chart of travel advice

4.2. Entry and exit screening

Terminology

The aim of screening travellers for influenza is to reduce the number of infectious individuals entering or leaving a country. Screening measures include health declarations, visual inspection, and thermography to detect individuals with influenza-related symptoms (*240*). These measures can be conducted at arrival terminal (entry screening) or at departure terminal departure (exit screening) (*241*).

Methods

The databases PubMed, Medline, EMBASE and Cochrane Library were searched until September 2018. Inclusion criteria were primary research evaluating entry and/or exit screening for influenza in the community setting. Studies had to demonstrate any effectiveness following entry and/or exit screening in the community. We excluded studies conducting at health care settings, animal-related studies, systematic reviews and/or meta-analysis without updated evidence, not

measuring effectiveness of travel advice to the community, and article type of letter, commentary or news. Two reviewers (SR and SG) contributed to the title, abstract and full-text screening. The quality of evidence was measured using the GRADE approach. The rating was made for the overall effectiveness of entry and exit screening by two independent reviewers.

Results

A total of 297 records were identified and included in the title and abstract screening, and 230 were excluded; 31 full texts were evaluated for eligibility and 19 full texts were excluded. Ten full-length articles were included in this systematic review. A flow chart of study selection shown in Fig. 25. Study details are shown in Table 29, Table 30, Table 31 and Table 32.

A simulation study in the USA estimated that entry screening can detect 50% of infected travellers and is likely to lower the predicted pandemic influenza attack rate by less than 1% (*242*). Furthermore, several simulation studies showed that screening international travellers may help to delay the epidemic by a few days (0–12 days) (*163, 242-244*). However, several observational studies that were conducted at international airports demonstrated that the sensitivity of entry screening was low (5.8% at New Zealand, 6.6% at Japan and 1.1% at USA) (*245-247*), and half of international travel-related case-patients were identified more than a day after arrival by passive case finding and contact tracing in the community, although 37% of international travel-related cases of influenza were screened at the border entry site (*163*). Simulation studies predicted that screening of travellers may not prevent case import and local epidemics (*243*, *244*).

Fig. 25. The flow chart of entry and exit screening

Sensitivity of screening can affect the effectiveness of travellers' screening. One of the major criteria for screening influenza infected travellers is fever, because it is a relatively specific sign of influenza compared with other signs or symptoms. Infrared thermometers have been used for border screening in many locations due to the instantaneous and non-invasive nature. One study showed that the sensitivity and specificity of infrared thermometer were 50.8–70.4% and 63.6–81.7% respectively during influenza A(H1N1)pdm09 in Japan (*248*). An infrared thermal image scanner (ITIS) is another screening tool for the massive number of travellers. A study conducted in New Zealand demonstrated that the sensitivity and specificity of ITIS ranged from 84–86% and 31–71%, respectively (*249*).

Molecular diagnostics can be used, but will be expensive and resource intensive if used in a large population (*250*). Point-of-care antigen detection tests might be more feasible but would still be costly (*250*).

Considering the incubation period of influenza virus infection of 1–2 days (*163*), the variation of symptom presentation and imperfect screening methods (*251*), screening travellers to prevent the introduction of influenza still has limitations. Furthermore, the public health resources including trained staff, screening devices and laboratory resources are limited (247); thus, screening targeted travellers from and to high risk area should be carefully considered.

Although exit screening has been recommended in the past, we did not identify any reports of the actual implementation of exit screening in the literature.

Ethical considerations

Screening should be conducted voluntarily as much as possible, and compulsory screening should be considered very carefully (*239*). Informed consent from the traveller for the screening of specimen-collection including nasal swabs should be obtained in accordance with the International Health Regulations (*252*).

Knowledge gaps

There were no high-quality studies on the effectiveness of entry and exit screening. Quantitative study for the implementation of screening programmes at different times, different combinations, and different pathogens are required to understand the potential advantage of screening (*251*).

Table 29. Summary of epidemiological studies included in the review

STUDY	INFLUENZA STRAIN INVOLVED AND STRAIN TRANSMISSIBILITY (R_0)	STUDY DESIGN, SETTING AND POPULATION	INTERVENTION AND MEASURE OF INTERVENTION	NO. OF TRAVELLERS HAD MEDICAL ASSESSMENT	CASE DEFINITION FOR SCREENING AND NO. OF TRAVELLERS MET	LABORATORY TEST FOR THE CASE AND NO. OF SPECIMENS ANALYSED	OUTCOME	COMMENTS AND LIMITATIONS	QUALITY OF EVIDENCE
Hale MJ, et al. 2012 (*245*)	• Influenza A(H1N1)pdm09 • R_0 = N/A	• Cross-sectional study • Auckland international airport, New Zealand. • 456 518 international travellers including flight passenger and crew member arriving between 27 April and 22 June 2009	• Entry screening - In-flight announcement - Locator card completion - Travel advisory information - Self presentation	• 409 (0.09%)	• ILI • 109 (27% of medical assessment)	• RT-PCR from 109 respiratory swab	• 4 were positive. • 69 travellers were confirmed as cases passed through airport. • Sensitivity of screening: 5.8% (95% CI: 2.3–14.0%)	• Low sensitivity of entry screening • Mild illness might not see a doctor or did not diagnosed. • The number of cases who passed through the airport was based on estimated fraction of data from the first 100 cases	Very low
Priest PC, et al. 2013 (*247*)	Seasonal influenza	• Cross-sectional study • Christchurch airport, New Zealand. • 23 513 international travellers including flight passenger and crew member arriving between 23 June and 12 September 2008	• Entry screening - In-flight questionnaire (symptoms)	• 1358 (17%)	• Traveller who reported 1 or more of: cough, sore throat, sneezing, fever or chill, runny or blocked nose, muscle aches or pains, feeling generally unwell, chest discomfort or breathing difficulties	• Commercial EasyPlex multiplexed tandem PCR kit from respiratory swab No. of Case and non-case:1331 and 2438	• 60 were positive (51, type B; 8, type A; 1 type A&B) • Estimated prevalence: 1.13% (95% CI: 0.77–1.48)	• Either resource intensive or ineffective • Symptom based screening • Not report symptom	Very low
Sakaguchi H, et al. 2009 (*246*)	• Influenza A(H1N1) pdm09; • R_0 = N/A	• Cross-sectional study • Narita airport, Japan • 471 933 international travellers including flight passenger and crew member visited affected countries arriving between 28 April and 18 June 2008	• Entry screening – Screening surface body temperature using infrared thermal scanners	N/A	• Traveller who visited influenza affected countries with 2 symptoms or more of 4 symptoms (1. Nasal discharge or nasal obstruction; 2. Sore throat; 3. Cough; 4. Fever or feeling feverish and chills) or travellers with body temperature > 38°c	• Rapid influenza diagnostic test and RT-PCR from 805 respiratory specimens	• 9 were positive. • 141 travellers were found during the community containment measures. • Sensitivity of screening: 6.6%	• Require large amount of human resources • Mild illness travellers were not examined • Not report symptom	Very low
Yu H, et al. 2012 (*163*)	• Influenza A(H1N1)pdm09; • R_0 = N/A	• Retrospective cohort study • China (193 sentinel hospital, 30 provinces) • 7 1 665 persons with confirmed A (H1N1) pdm09 virus between 7 May and 30 November 2009.	• Entry screening – active surveillance at the border and medical monitoring	N/A	• Confirmed case: ARI with laboratory evidence of influenza A(H1N1) pdm09 • ARI: fever (≥ 37.3), and/or recent onset of 1 or more of the following: rhinorrhea, nasal congestion, sore throat or cough	• RT-PCR	• 932 were related to international travel. • 37% of int'l travel-related cases identified at the border. • Half (468/932) were identified 1 or more days after their arrival. • Detection rate of case identified at the entry screening: fever + before arrival: 76%, fever- before arrival 63%	• Epidemic likely delayed by 4 days (100% of screening sensitivity) • Mild illness or subclinical infection might not be examined • Case-based surveillance	Very low

ARI: acute respiratory infection; CI: confidence interval; ILI: influenza-like illness; N/A: not applicable; PCR: polymerase chain reaction; R0: basic reproductive number; RT: reverse transcription.

Table 30. Summary of simulation studies included in the review

STUDY	INFLUENZA STRAIN INVOLVED AND STRAIN TRANSMISSIBILITY (R_0)	STUDY DESIGN, SETTING AND POPULATION	INTERVENTION AND MEASURE OF INTERVENTION	NO. OF TRAVELLERS HAD MEDICAL ASSESSMENT	SCENARIO	OUTCOME	COMMENTS AND LIMITATIONS	QUALITY OF EVIDENCE
Malone JD, 2009 (*242*)	• Pandemic influenza • R0 = 2.4 (Europe), 2.1 (Latin America), and 2.0 (Canada and USA)	• Stochastic discrete event simulation model • 18 US international airport	• Entry screening	• 409 (0.09%)	• 50% of passengers predicted to be infected and high detection rate of 80% for symptomatic travellers for the screening • 100% of passengers infected and 80% of detection rate from screening • 50% of passengers infected and < 50% of detection rate from the screening	• Lowest number of arriving infected passengers (peak day 45–980); attack rate of without and with screening: 30.7% and 30.4% • Peak days 24 and 45 arrive; attack rate of without and with screening: 30.8% and 30.5% • Highest number of arriving Peak day 45–1600 arrive; attack rate of without and with screening: 30.9% and 30.6%	• Entry screening lower the attack rate by less than 1% • Possible variation by airline patterns, screening effectiveness and test accuracy of RT-PCR.	Very low
Cowling BJ, 2010 (*244*)	•R0 = influenza H1N1 N/A	• Bootstrapping • 35 countries had reported to WHO by 6 July 2009 • 100 confirmed cases	• Entry screening - Temperature check prior to disembarkation - Health declaration forms - Observation of symptoms by staffs - Body temperature scan by thermal scanners	N/A	• No screening • a) Medical check before disembarkation • b) Health declaration forms • c) Symptom screening • d) Thermal scanning • e) b) OR c) OR d) • f) b) AND c) AND d)	• Median interval with inter quartile range between first imported case and first local case: 22 days (0, 22days) • a) 21 days (14, 28) • b) 22 days (13, 34) • c) 33 days (7, 41) • d) 22 days (7, 33) • e) 22 days (7, 35) • f) 23 days (9, 35)	• Entry screening did not delay significantly in local transmission • Mild illness or self-limiting nature may affect the result • Did not consider the size of local epidemics.	Very low
Caley P, 2007 (*243*)	• New pandemic influenza •R0 = 1.5, 2.5, and 3.5	• Simulation study • 100% sensitivity for detecting symptomatic infection, • 12 hours of travel	• Exit screening • Entry screening – Screening surface body temperature using infrared thermal scanners	N/A	• Traveller who visited influenza affected countries with 2 symptoms or more of 4 symptoms (1. Nasal discharge or nasal obstruction; 2. Sore throat; 3. Cough; 4. Fever or feeling feverish and chills) or travellers with body temperature > 38°c	• Rate of evading screening: 0.26 (R0 = 1.5), 0.45(R0 = 2.5), 0.59 (R0 = 3.5) • Median delay from 57 to 60 days by screening (R0 = 1.5, 400 travellers / day); natural median delay 57 days * Time delay: the start of an influenza pandemic and its subsequent initiation in other countries	• Delay effect by implementing screening is small compare with natural delay • In-flight transmission not fully considered.	Very low

N/A: not applicable; PCR: polymerase chain reaction; R0: basic reproductive number; RT: reverse transcription; USA: United States of America; WHO: World Health Organization.

Table 29. Summary of epidemiological studies included in the review

STUDY	INFLUENZA STRAIN INVOLVED AND STRAIN TRANSMISSIBILITY (R_0)	STUDY DESIGN, SETTING AND POPULATION	INTERVENTION AND MEASURE OF INTERVENTION	NO. OF TRAVELLERS HAD MEDICAL ASSESSMENT	CASE DEFINITION FOR SCREENING AND NO. OF TRAVELLERS MET	LABORATORY TEST FOR THE CASE AND NO. OF SPECIMENS ANALYSED	OUTCOME	COMMENTS AND LIMITATIONS	QUALITY OF EVIDENCE
Nishiura H, 2011 (*248*)	• Influenza including A(H1N1)pdm09 and other • R_0 = N/A	• Observational study • A) 471 733 travellers including flight passengers and crew members from 28 April 2009 to 18 June 2009 • B) 9 140 435 flight passengers from 1 September 2009 to 31 January 2010	• Entry screening	• a) 805 • b) 1049	• a) (1) contract in Canada, Mexico or USA, or (2) fever ≥ 38°C or 2≥ acute upper respiratory symptoms • b) (a) self-reported symptoms, (2) relatives or friends of (1) or identified by an infrared thermal scanner	• a) RT-PCR from 805 respiratory swab	• a) sensitivity of entry screening: 22% (18/805) • b) sensitivity and specificity of infrared thermal scanners in detecting hyperthermia: 50.8–70.4% and 63.6–81.7%. PPV: 37.3–68.0%	• Fever screening as a sole measure of entry screening is insufficient • Used non-randomized dataset • Confounding factors including age and outdoor temperature should be considered for the performance of infrared thermal scanners	Very low
Priest PC, 2011 (*249*)	Seasonal influenza	• Observational study • Christchurch airport, New Zealand. • 8020 travellers including flight passengers and crew members from 2008	• Entry screening - In-flight questionnaire (symptoms)	• 5274 questionnaires returned • 823 were symptomatic • 1281 were measured temperature using tympanic and ITIS.	• Traveller who reported 1 or more of: cough, sore throat, sneezing, fever or chill, runny or blocked nose, muscle aches or pains, feeling generally unwell, chest discomfort or breathing difficulties.	• MT-PCR	• Sensitivity and specificity of ITIS (84–86% and 42–72%)	• Fever screening using ITIS is insufficient to detect influenza infection • Majority of travellers in this population was afebrile. • Some of infected travellers had anti-pyretic before arrival	Very low

ITIS: infrared thermal image scanner; MT: multiplexed tandem; N/A: not applicable; PCR: polymerase chain reaction; PPV: positive predictive value; R0: basic reproductive number; RT: reverse transcription; USA: United States of America.

Chen J, 2018 (*250*)	• Seasonal influenza • R_0 = N/A	• Observational study • Xiamen international airport China • 1 540 076 incoming travellers between May 2015 and May 2016	• Entry screening	• 1224	• ILI (fever≥ 37.5°C, either cough, rhinorrhea, sore throat and/or gastrointestinal discomfort)	• Flu Dot-ELISA • Viral culture	• Sensitivity of Flu Dot-ELISA: 96.6% (95% CI: 92.7–98.7)	• suitable to use rapid influenza test (Flu Dot-ELSIA) • Missed detection of asymptomatic travellers • Sensitivity of viral culture is less than 100%	Very low

ILI: influenza-like illness; PCR: polymerase chain reaction; R0: basic reproductive number.

4.3. Internal travel restrictions

Terminology

Because airports and land transportation are associated with long-distance spread of influenza (*253*), travel restrictions are considered as a measure to reduce regional and international spread (*254*). Although a previous quantitative expert survey study suggests that this travel restriction is likely to be ineffective due to its limited evidence (1), internal travel restriction to prevent domestic travel of persons to influenza is still considered as an NPI.

Methods

The most recent systematic review of travel restriction was published in 2014 by Mateus et al. (*255*). They identified eight studies, which found that internal travel restriction has limited effectiveness and remained unclear. This review included few simulation studies and several reviews of simulation studies, and was intended to measure the overall travel restriction including internal and international restriction. Instead of using this previous review, we conducted a new search in the databases PubMed, Medline, EMBASE and Cochrane Library, until September 2018. Inclusion criteria were primary research evaluating internal travel restriction for influenza pandemic in the community setting. Studies had to demonstrate any effectiveness following internal travel restriction to the public. We excluded studies conducting at the health care settings, animal-related studies, systematic reviews and/or meta-analysis without updated evidence, not measuring effectiveness of travel advice to the community, and article type of letter, commentary or news. Two reviewers (SR and SG) contributed to the title, abstract and full-text screening. The quality of evidence was measured using the GRADE approach. The rating was made for the overall effectiveness of internal travel restrictions by two independent reviewers. The flow chart of study selection is shown in Fig. 26.

Results

At total of 67 records were identified and included in the title and abstract screening, and 56 were excluded; 11 full-text articles were evaluated for eligibility and six of these were excluded; thus, five full-length articles were included in this systematic review. The summary is shown in Table 33.

A time series analysis study conducted in the USA showed that frequency of domestic airline travel is temporally associated with the rate of influenza spread and following September 11 2001, had markedly delayed the epidemic peak 13 days later than the average for other years (*256*). A simulation study predicted that implementation of strict travel restriction (95% travel restriction and enforced for 4 weeks) could reduce the ILI peak by 12% and moderate restriction (50% travel restriction and enforced for 2–4 weeks) could delay the pandemic peak between 1 and 1.5 weeks (127). Another simulation study predicted that more than 80% of internal travel restriction is beneficial (R0 = 1.5; 80% and 99% restriction delayed median days of 22–32 and 52, respectively, until 20 infectious persons arrivals in the designated city) (254). One simulation study estimated that strict internal travel restrictions (90%) could have some impact in delaying the epidemic peak by 2 weeks in the United Kingdom and by less than 1 week in the USA; however, 75% travel restriction would be ineffective (*87*).

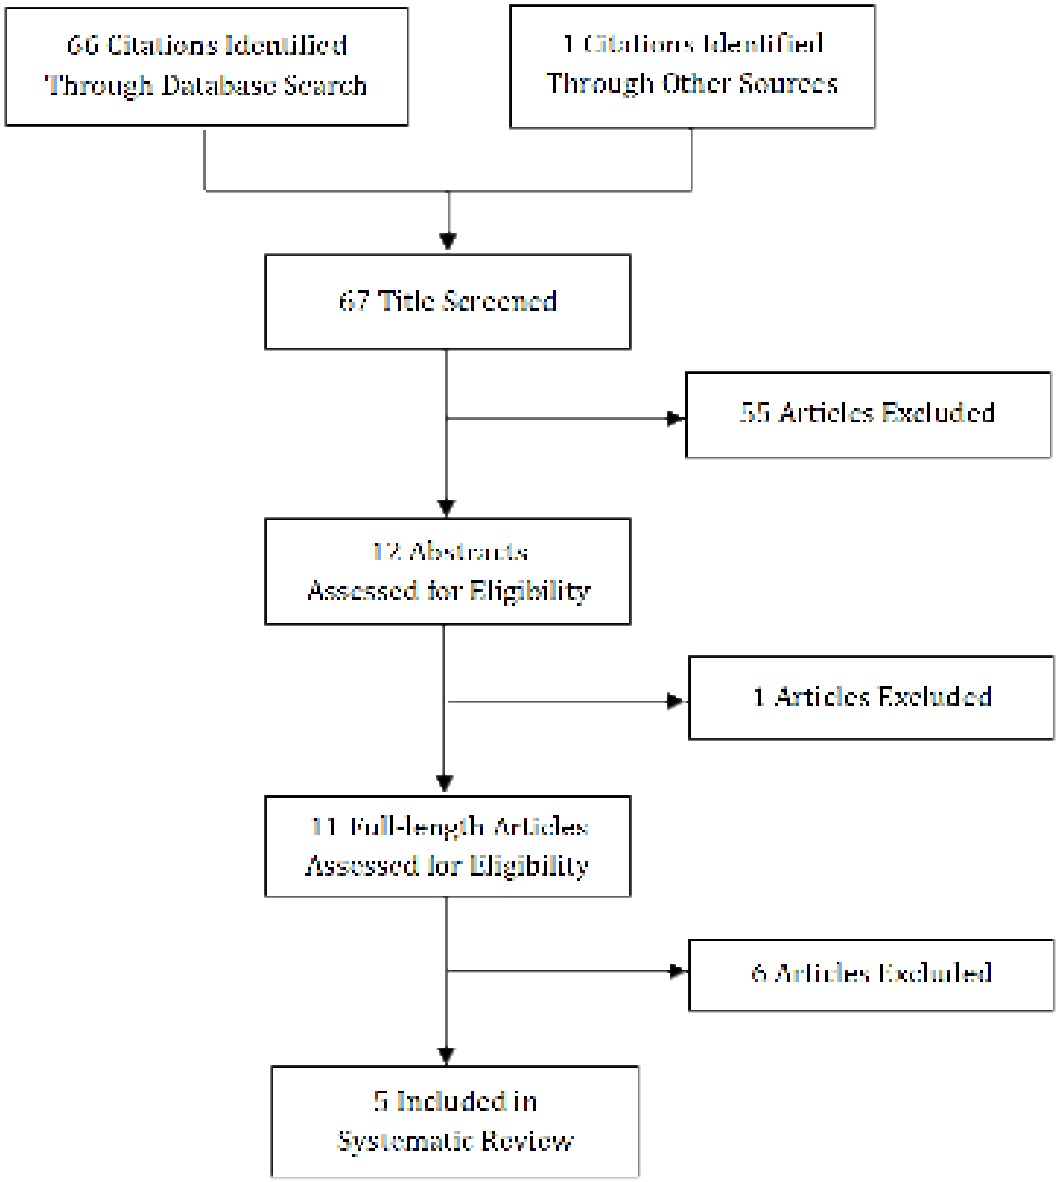

Fig. 26. The flow chart of internal travel restriction

Ethical considerations

Travel restriction should be voluntarily applied as much as possible, and compulsory intervention should be involved as a last resort (*239*). Furthermore, governments should pay close attention to adverse economic consequences, particularly on vulnerable populations including workers who have frequent travel and individuals who need to have immediate medical treatment (*239*).

Knowledge gaps

Although most of the literature on this topic results from simulation studies and natural experiments, it is unlikely that large trials will ever be done. Improved understanding of transmission dynamics of influenza would be advantageous; for example, on how environmental or other factors can affect influenza transmission and seasonality (*256*).

Table 33. Summary of studies included in the review

STUDY	STUDY DESIGN INFLUENZA STRAIN INVOLVED AND STRAIN TRANSMISSIBILITY (R_0)	STUDY DESIGN, SETTING AND POPULATION	INTERVENTION AND MEASURE OF INTERVENTION	OUTCOME	COMMENTS AND IMITATIONS	EVIDENCE QUALITY RATING
Brownstein JS, 2006 (*256*)	• Seasonal influenza • R_0 = N/A	• Time series analysis • USA • Weekly mortality from pneumonia and influenza for 9 influenza seasons (from 1996–1997 to 2004–2005)	• N/A	• Following September 11 2001, had markedly delayed peak 13 day later than average	• Domestic air travel affects the influenza spread in USA • Study used the data from voluntarily reporting system • Study used influenza mortality time series data which may not correspond to influenza activity	Very low
Bolton KJ, 2012 (*127*)	• Seasonal influenza • R_0 = around 2	• Stochastic, compartmental patch model of SEIR • Mongolia	• Travel restriction - 50% reduction in mean travel volume in early epidemic	• Delayed the pandemic peak by about 1.5 weeks if maintained for 4 weeks of restriction and by about 1 week if maintained for 2 weeks of restriction • Reduced the attack rates by less than 0.1% when travel volume was reduced by 95%	• Benefit of travel restriction may be limited • Not considered the transmission at the level of household	Very low
Wood JG, 2007 (*254*)	• Seasonal influenza • R_0 = 1.5–3.5	• Stochastic SIR model • Australia • Average daily volumes of domestic air travel between Sydney, Melbourne and Darwin	• 80%, 90% and 99% of travel restriction • Median time between the day when the no. infected person first reached 20	• Scenario (Sydney to Melbourne) Beginning of epidemic was delayed in 22–32 days (80% restriction), and 52 days (99% restriction)	• Strict travel restriction required to delay the time • Seasonal variation and further importation of influenza was not considered	Very low
Ferguson NM, 2006 (87)	• Seasonal influenza • R_0 = 1.4–2.0	• Stochastic mathematical individual-based model • United Kingdom and USA	• Reactive movement restrictions in a 20 km exclusion zone around every case – 75 and 90% restriction • Peak time delay	• Delaying the peak of the epidemic by less than 1 week in USA (without int'l travel restriction) – 90% restriction have some effect on the delaying the peak, but 75% restriction have almost none effect	• Internal travel restriction must be highly strict to have impact • Not considered the effect of personal protective measures on transmission	Very low
Germann TC, 2006 (*257*)	• Seasonal influenza H5N1 • R_0 = 1.6, 1.9, 2.1, and 2.4	• Stochastic agent-based discrete-time simulation model • USA	• 90% of travel restriction	• Epidemic peak delayed few days • 0.2% of increase of cumulative incidence (R_0 = 1.6) • 0.5% of increase of cumulative incidence (R_0 = 1.9)	• The combination of intervention such as social distancing and vaccination may increase the effectiveness of travel restriction	Very low

N/A: not applicable; R0: basic reproductive number; SEIR: susceptible–exposed–infectious–recovered; SIR: susceptible–infectious–recovered; United Kingdom: United Kingdom of Great Britain and Northern Ireland; USA: United States of America.

4.4. Border closures

Terminology
International travel can cause infectious disease cross-border transmission; thus, border closure, one of the measures that can be rapidly implemented, may reduce the epidemic spread of influenza. The transportation of international travel includes ship, bus, train and aeroplane.

Methods
The databases (PubMed, Medline, EMBASE and Cochrane Library) were searched until September 2018. Inclusion criteria were primary research evaluating border closure for influenza pandemics in the community setting. Studies had to demonstrate any effectiveness following border closure in the community. We excluded studies conducted in health care settings, animal-related studies, systematic reviews and/or meta-analysis without updated evidence, not measuring effectiveness of travel advice to the community, and article type of letter, commentary or news. Two reviewers (SR and SG) contributed to the title, abstract and full-text screening. The quality of evidence was measured using the GRADE approach. The rating is made for the overall effectiveness of border closure by two independent reviewers.

Results
A total of 327 records were identified and included in the title and abstract screening, and 314 were excluded; 13 full texts were assessed for eligibility and 11 full-length articles were identified for inclusion in the systematic review. The flow chart of study selection is shown in Fig. 27.
The description of the studies shown in Table 34.

An epidemiological study demonstrated that international airline travel could significantly reduce the mortality impact of a pandemic (*256*). Another simulation study estimated that a 99% restriction of border travel between Hong Kong SAR and mainland China may delay the epidemic peak compare with non-travel restriction (sole air restriction, 2 week–delay; both air and land, 3.5 week–delay; all air, land and sea, 12 weeks) (*258*). However, international travel restrictions of other modes of transportation such as land and sea would have less impact (2–3 day delay of the epidemic peak) (*258*). Implementing border crossing travel restrictions within three months of identification of first global case could reduce the seven–month cumulative attack rate by around 2% (*258*). However, implementing travel restrictions after the 5 months of arrival of the first global case would not be expected to be effective (*258*).

Another simulation study reported that international air-travel restriction could delay the peak of epidemic by about 1–3 weeks depending on the transmission rate (1.4, 1.7, or 2) and the level of restriction (90% or 99%), although the attack rate was not significantly affected (*220*). Furthermore, global-scale simulation study reported that travel restrictions could delay the epidemics by about 2 to 3 weeks (*259*) and significantly delay global spread by 5–133 days (*260*).

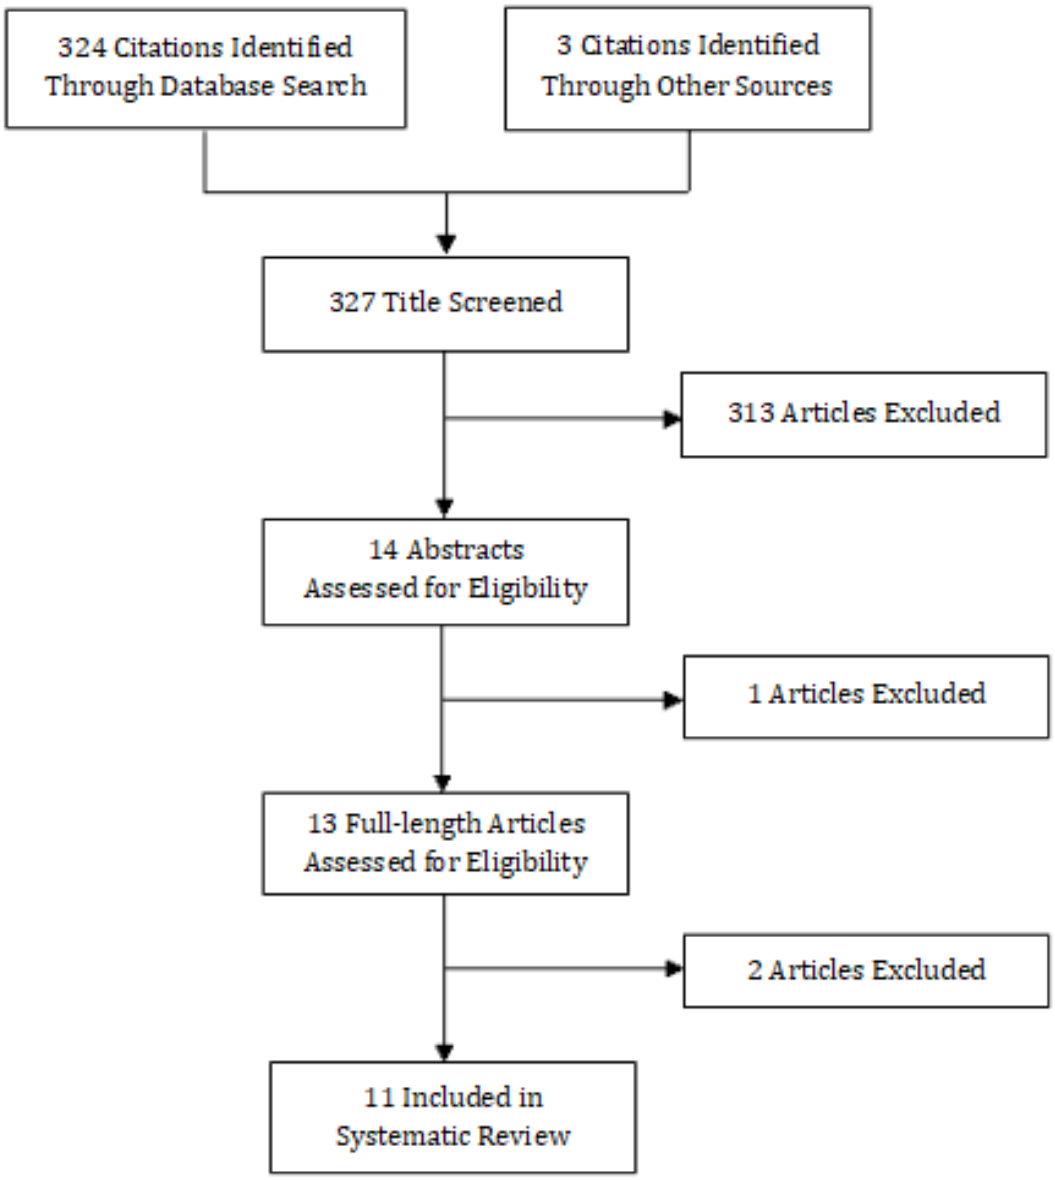

Fig. 27. The flow chart of border closures

A simulation study predicted that 99.9% border control could delay the epidemic peak by 6 weeks (90% and 99% of border control would delay 1.5 and 3 weeks, respectively) (87). Another study estimated that international travel restrictions would slow the importation of cases, and an 80–99% travel restriction would delay of the exportation of cases range 6.6–133 days; however, it did not reduce the magnitude of spread (*261*). Another simulation study predicted that children-selective restriction could be helpful to delay epidemic for a few weeks (*262*).

A simulation study based on travel data from Pacific Island Countries and Territories (PICTs), only six PICTs would be likely to prevent importation of influenza pandemic by 99% of travel restriction through border control. In PICTs, critical necessity such as food and medical supplies are largely dependent on importation, so that strict border closure was carefully considered in PICTs (*263*). Although 99% of travel restriction of all mode of transportation has delayed the epidemic peak, the magnitude of the epidemic was reduced less than 10% in this study. Another observational study in South Pacific Island jurisdictions, during the influenza pandemic which began in 1918,

reported that strict maritime quarantine reduced attributable mortality rate from pandemic influenza between 0 and 840 (crude mortality rate per 1000 population) (*99*).

Border closure such as travel restriction is a measure that can be rapidly implemented and it may decelerate the epidemic growth; however, this may not be effective at limiting the magnitude of influenza epidemics (*258*).

Ethical considerations

The human rights of mobility should be considered (*239*). Therefore, as with internal travel restriction, border controls should be voluntarily applied as much as possible, and compulsory intervention should be involved as a last resort (*239*). Furthermore, the stigmatization and discrimination of individuals from influenza affected areas, and economic consequences by implementing border closures should also be considered (*239*, *264*).

Knowledge gaps

Although most of the literature on this topic results from simulation studies and natural experiments, it is unlikely that large trials will ever be done. Improved understanding of transmission dynamics of influenza would be advantageous; for example, on how environmental or other factors can affect influenza transmission and seasonality (*256*).

Table 33. Summary of studies included in the review

STUDY	STUDY DESIGN INFLUENZA STRAIN INVOLVED AND STRAIN TRANSMISSIBILITY (R_0)	STUDY DESIGN, SETTING AND POPULATION	INTERVENTION AND MEASURE OF INTERVENTION	OUTCOME	COMMENTS AND IMITATIONS	EVIDENCE QUALITY RATING
Brownstein JS, 2006 (*256*)	• Seasonal influenza • R_0 = N/A	• Time series analysis • USA • Weekly mortality from pneumonia and influenza for 9 influenza seasons (from 1996–1997 to 2004–2005)	• N/A	• September 11 2001 affected international flight volume decreased by 27%, and the peak of influenza mortality was delayed by 2 weeks	• Decrease in travel volume was associated with a delayed and prolonged influenza season. • Study used the data from voluntarily reporting system • Study used influenza mortality time series data which may not correspond to influenza activity	Very Low
Chong KC, 2012 (*258*)	• Influenza H1N1 pandemic • R_0 = 1.4	• Stochastic SEIR model • Hong Kong SAR and mainland China	• Travel restriction – 90%, and 99% travel restriction on different mode transportation (air, land, sea) • Measure the first passage time (first global case onset ~ first local case report)	• 99% of international air-travel restriction delayed the interval between the first imported case and one hundred infected case passed the border by a week and the epidemic peak delayed by two weeks • 99% of restriction of both air and land travel delayed the interval (passage time) by an additional one to two weeks and the epidemic peak delayed about 3.5 weeks • 99% restriction of all mode of transportation delayed the interval by additional 2 months, and delayed the epidemic peak time for about 12 weeks • Travel restriction 3 month after the arrival of first global case reduce the 7-months cumulative attack rate around 2%	• Travel restriction may not be effective • Not considered the infection risk for the out bound susceptible travellers • No adjustment of multi-step journey	Very Low
Ciofi degli Atti ML, 2008 (*220*)	• Pandemic influenza • R_0 = 1.4, 1.7, 2.0	• Global deterministic SEIR model • Italy	• Incoming international flight restriction (90% or 99%)	• Int'l air-travel restriction delayed the interval between first global case report and the importation of the first cases by 7–37 days. Furthermore, the pandemic peak delayed by 6–39 days. The attack rate was reduced less than 0.1%	• Air-travel restrictions can delay 1 to 3 weeks in delaying the epidemic.	Very Low

Table 34. Summary table of studies included in the review

STUDY	STUDY DESIGN INFLUENZA STRAIN INVOLVED AND STRAIN TRANSMISSIBILITY (R_0)	STUDY DESIGN, SETTING AND POPULATION	INTERVENTION AND MEASURE OF INTERVENTION	OUTCOME	COMMENTS AND IMITATIONS	EVIDENCE QUALITY RATING
Epstein JM, 2007 (*259*)	• Pandemic influenza • R_0 = 1.4, 1.7, 2.0	• Global influenza transmission model • Global (Hong Kong SAR, London and Sydney)	• Travel restriction (90%, 95%, and 99%) • The interval between the outbreaks occurred in Hong Kong SAR or London and the case-passage time to USA	• First passage time is delayed from 18 days to 31 days (outbreak originated from Hong Kong SAR), and from 7 days to 27 days (from London) with R_0 = 1.7 The delays are larger for smaller R_0	• Air-travel restrictions can delay 2 to 3 weeks in delaying the epidemic. • Model is based on the largest metropolitan areas	Very Low
Cooper BS, 2006 (*260*)	• Pandemic influenza • R_0 = 1.8–5	• Metapopulation model • Global (Hong Kong SAR, London, Sydney)	• Air-travel restriction from affected cities (50, 90, 99 and 99.9%) • Susceptibility (10%, 60%, and 100%)	• Median epidemic peak delay can be ranged between 7–102 days	• Banning flight from affected region would be effective delaying global spread	Very Low
Ferguson NM, 2006 (*87*)	• Seasonal influenza • R_0 = 1.4–2.0	• Stochastic spatially structured mathematical model • USA	• 90, 99% or 99.9% border control in USA	• Imported infections might delay the epidemic peak of USA by 1.5 weeks (90% border control), 3 weeks (99%), and 6 weeks (99.9%)	• Combing travel restriction measure including internal and international have more impact delaying epidemic peak	Very Low
Hollingsworth TD, 2006 (*261*)	• Pandemic influenza • R_0 = N/A • Pandemic influenza	• Simple mathematical SEIR model of an epidemic in a source country with cases exported to other countries	• 80, 99, or 99% of travel restriction • Peak time delay	• The mean time delay exporting the infected case is 5.3 days (80% of restriction), 11.7 days (90%), and 131.7 days (99%)	• Restriction on travel may have limited benefit of global spread of pandemic influenza	Very Low

Table 34. Summary table of studies included in the review

STUDY	STUDY DESIGN INFLUENZA STRAIN INVOLVED AND STRAIN TRANSMISSIBILITY (R_0)	STUDY DESIGN, SETTING AND POPULATION	INTERVENTION AND MEASURE OF INTERVENTION	OUTCOME	COMMENTS AND IMITATIONS	EVIDENCE QUALITY RATING
Eichner M, 2009 (*263*)	• R_0 = 1.5, 2.25, and 3.0	• Probalistic model • PICTs	• 79% or 99% of travel restriction • Assess the probability that an island either occur epidemics or escape the pandemic	• Among 17 PICTs, with 99% travel restriction, six countries (with R_0 = 1.5) and four to five countries (with $R_0 \geq$ 2.25) would be likely escaped the pandemic influenza with more than 50% probability. However, with 79% of travel restriction, only one country (with R_0 = 1.5) and no country (with R0≥ 2.25) was likely escaped the pandemic	• Border control can benefit only a few PICTs for avoiding pandemic influenza • Some of data used in this analysis was missing and suboptimal	Very Low
McLeod MA, 2008 (*99*)	• Pandemic influenza • R_0 = N/A	• Epidemiological study • 11 South Pacific Island jurisdictions	• 5–7 days' maritime quarantine • Death rate	• Arrival of pandemic and death rates attributed to influenza per 1000 population was significantly delayed and reduced compare with the other Pacific Island Jurisdiction - American Samoa (1920, no death reported) - Australia (early January 1919, death rate = 2.4) - Tasmania (August 1919, death rate = 0.81) - New Caledonia (1921, death rate less than 11)	• Strict border control in the island can be advantage to delay the pandemic and reduce the mortality • Confounding factors including pre-existing immunity may affect this result	Very Low
Lam ET, 2011 (*262*)	• Pandemic influenza • R_0 = 1.2, 1.6, 2.0	• Simple stochastic model • Hong Kong SAR	• 100% border crossing travel restriction among children	• Children-selective travel restriction delayed the epidemic for a 19–35 days (R_0 = 1.2), and less than 15 days (R_0 = 1.6 and 2.0)	• The intervention was assumed to implemented after pandemic declared	Very low
Bajardi P, 2011 (*265*)	• Pandemic influenza • R_0 = 1.7 with generation interval 3.6 days	• SEIR-like Global Epidemic and Mobility model	• 40% and 90% of int'l travel restriction to and from Mexico	• Mean delay of the arrival of infection from other countries was less than 3 days (40% of restriction), and about 2 weeks (90% of restriction)	• The intervention was assumed to implemented at the early stage of the outbreak (by 3 months)	Very low

N/A: not applicable; PICTs: Pacific Island Countries and Territories; R0: basic reproductive number; SAR: Special Administrative Region; SEIR: susceptible–exposed–infectious–recovered; USA: United States of America.

SUMMARY OF EVIDENCE

Personal protective measures

Personal hygiene measures such as hand hygiene, respiratory etiquette and face masks are widely used as non-pharmaceutical intervention measures to reduce the risk of acquiring or spreading respiratory infections, and for mitigating pandemic influenza. However, our review identified a lack of compelling evidence for the effectiveness of hand hygiene, respiratory etiquette and face masks against influenza transmission in the community. There are still gaps in the evidence base which further research would help to fill.

Environmental measures

Environmental measures including surface and object cleaning are generally conducted to limit the risk of acquiring or spreading respiratory infections within an area. The evidence for the effect of surface and object cleaning on influenza prevention is limited, and no significant reductions in influenza infections were observed by surface and object cleaning intervention; studies provided very low to low quality evidence. Other environmental measures including UV light as air disinfection, ventilation as increasing air change and humidity as amount of water vapour in the air were limited. Therefore, additional research is required to confirm whether these measures could be of value in mitigating pandemic influenza.

Social distancing measures

Social distancing measures including contact tracing, isolation and quarantine of influenza affected individuals, closures of school and workplace, and avoiding crowding reduce the risk of influenza transmission in community settings. Evidence for the overall effectiveness of contact tracing is very limited. Only one study discussed the benefit of adding contact tracing to isolation and quarantine. The addition of contact tracing is estimated to provide at most modest benefit; however, it will increase considerably the proportion of individuals in quarantine. For isolation, currently available evidence showed that even as a single intervention isolation is effective. Compliance of individuals and timeliness of intervention do affect the effectiveness of isolation in mitigation of influenza. Quality of evidence based on GRADE assessment is, however, very low. More robust evidence drawn from epidemiological studies is needed. The effectiveness of quarantine in mitigation of influenza varies. Household quarantine is suggested to be effective in reducing the impact and transmissibility, and in delaying the epidemic peak; the combination of quarantine with other interventions such as case isolation and SC will further strengthen the effectiveness. There is also an increased risk of infection in individuals quarantined concurrently with an isolated individual. Hence, ethical concerns arise for mandated quarantine. Onboard quarantine, on the other hand, has a minimal impact, based on a very low quality of evidence. More robust evidence drawn from epidemiological studies is needed.

SC can reduce the spread of the influenza; however, the threshold for closing time and duration are uncertain. The combination of SC with other interventions is more effective in reducing the spread of infection. Unlike the evidence of effectiveness of SC, evidence on WCs is limited and all six studies for this effectiveness measure were simulation models (i.e. the quality of evidence is very low). Five of these studies suggested that reductions in attack rate, duration of infection or peak numbers occurred because of the WC. The combination with other interventions may enhance the effectiveness of the individual measures. Workplace measures are effective and feasible during a pandemic. Avoiding crowding, which includes separating people into small groups or cancellation of public gatherings, is effective as an intervention in preventing transmission of influenza as well. However, the quality of evidence is very low based on the GRADE approach.

Travel-related measures

Travel-related measures including travel advice, traveller screening, travel restriction and border closures have been used in previous pandemics to limit international spread. The evidence of travel advice against influenza transmission is still uncertain. The effectiveness of screening incoming and/or outbound travellers against influenza spread is also controversial. However, travel restriction and border closure may slow the spread of influenza at the community level, although all the evidence available was of very low quality.

Table 35. Quality of evidence and summary of results for each NPI

MEASURES	QUALITY OF EVIDENCE		RESULTS
1. Hand hygiene	Moderate (lack of effectiveness in reducing influenza transmission)		Eleven RCTs were included in this review. While hand hygiene was not effective against laboratory-confirmed influenza in meta-analysis in community settings and university halls, it was effective in one of two trials conducted in schools.
2. Respiratory etiquette	**None**		No scientific studies were identified for inclusion in this review.
3. Face masks	Moderate (lack of effectiveness in reducing influenza transmission)		Ten RCTs were included in meta-analysis, and there was no evidence that face masks are effective in reducing transmission of laboratory-confirmed influenza.
4. Surface and object cleaning	Low (lack of effectiveness in reducing influenza transmission)		Two RCTs and one cross-sectional study were included in the systematic review. There was evidence that surface and object cleaning could reduce detections of virus in the environment, but there was no evidence of effectiveness against laboratory-confirmed influenza virus infection.
5. Other environmental measures	**UV light**	**None**	No scientific studies were identified for inclusion in this review.
	Ventilation	Very low (effective)	In simulation studies, increasing the ventilation rate reduced influenza transmission.
	Humidity	**None**	No scientific studies were identified for inclusion in this review.
6. Contact tracing	Very low (unknown)		Evidence for overall effectiveness of contact tracing was limited. All included studies were simulation models. Only one study suggested the benefit of adding contact tracing on top of isolation and quarantine. Such addition was estimated to provide at most modest benefit, at the same time this would considerably increase the number of quarantined individuals.

MEASURES	QUALITY OF EVIDENCE	RESULTS
7. Isolation of sick individuals	Very low (effective)	Simulation studies suggested that isolation of sick individuals can reduce transmission in epidemics and pandemics. The overall effectiveness of the measure is moderate and combination with other interventions may improve the effectiveness.
8. Quarantine of exposed individuals	Very low (variable effectiveness)	We identified 6 epidemiological studies and 10 simulation studies eligible for inclusion in our review. Quarantine is generally effective in reducing burden of disease, transmissibility and delaying epidemic peak.
9. SCs	Very low (variable effectiveness)	The effect of reactive SC in reducing influenza transmission varied but was generally limited. Proactive closures and planned school holidays had a moderate impact on transmission. While SCs alone might have an impact, combination with other interventions further improved the effectiveness.
10. WCs	Very low (effective)	The strength of evidence on WC is very low since the identified studies are all simulation studies. Large-scale WCs could delay the epidemic peak for more than one week, and small-scale closures may have a modest impact on attack rate or peak number.
11. Workplace measures	Very low (effective)	The included studies indicated that workplace measures could reduce overall and the peak number of influenza cases, as well as delaying the peak occurrence. While the overall effectiveness and feasibility of workplace measures is modest, combination with other interventions can further improve its effectiveness.
12. Avoiding crowding	Very low (unknown)	Avoiding crowding including separating people into small groups or cancelling public gatherings is an effective intervention to prevent the spread of influenza. However, the effects of measures to avoid crowding in reducing transmission is uncertain.

Table 35. Quality of evidence and summary of results for each NPI

MEASURES	QUALITY OF EVIDENCE	RESULTS
13. Travel advice	**None**	No scientific studies were identified for inclusion in this review.
14. Entry and exit screening	Very low (lack of effectiveness in reducing influenza transmission)	Ten studies were included in this review. Considering the asymptomatic period of infected patients and the sensitivity of screening devices, the effectiveness of screening travellers is likely to be very limited.
15. Internal travel restrictions	Very low (effective)	The effectiveness of internal travel restriction is dependent on the level of restriction, and only very strict restrictions would be expected to have an impact on influenza transmission.
16. Border closures	Very low (variable effectiveness)	Eleven studies were included in this review. Generally, only strict border closures are expected to be effective within small island nations. For island nations, border closure should be carefully considered because it may affect the supply of essential items to the population.

NPI: non-pharmaceutical intervention; RCT: randomized controlled trial; SC: school closure; UV: ultraviolet; WC: workplace closure.

DOI: https://doi.org/10.3201/eid2608.201498

To the Editor: We read with interest the meta-analysis conducted by Xiao et al. (*1*) that found no significant reduction in influenza transmission with the use of surgical masks in the community, based on 10 randomized controlled trials. Nevertheless, mechanistic studies found that surgical masks could prevent transmission of human coronavirus and influenza virus infections if worn by infected persons (*2*). The authors pointed out the limitations of their study: small sample size and suboptimal adherence in the mask-wearer group (*1*). Recommendations on masks in the community vary across countries during the coronavirus disease (COVID-19) pandemic (*3*); studies have reported mixed results (*2*,*4*,*5*).

Epidemiologic data may provide an alternative insight. As of April 3, 2020, Taiwan recorded 348 COVID-19 cases (1.46/100,000 population), of which 48 (13.8%) were local cases. Singapore recorded 1,114 cases (19.07/100,000 population), of which 572 (51.3%) were local cases. Taiwan and Singapore both employed stringent measures. Taiwan recommended the use of masks early in the pandemic. In contrast, Singapore did not recommend the use of masks until April 3 and initiated its Stay Home policy on April 7.

Before the 2003 severe acute respiratory syndrome coronavirus epidemic in Taiwan, only persons with open tuberculosis wore masks in public. During the epidemic, wearing a mask in public was stigmatized. Thereafter, we educated the public to wear masks as a practice of respiratory hygiene. Although evidence is limited for their effectiveness in preventing transmission of severe acute respiratory syndrome coronavirus 2, either for source control or to reduce exposure, the wearing of masks by healthy persons may prevent potential asymptomatic or presymptomatic transmission (*3*). This marginal reduction in transmission may produce substantial results, particularly when it is implemented early. Taiwan had the foresight to create a large stockpile of medical and surgical masks; other countries or regions might now consider doing so as part of future pandemic plans (*3*).

About the Author

Mr. Chiang is a medical student at National Taiwan University. His primary research interests are epidemiology and prevention of communicable diseases.

SUMMARY

Background: Face mask usage by the healthy population in the community to reduce risk of transmission of respiratory viruses remains controversial. We assessed the effect of community-wide mask usage to control coronavirus disease 2019 (COVID-19) in Hong Kong Special Administrative Region (HKSAR).

Methods: Patients presenting with respiratory symptoms at outpatient clinics or hospital wards were screened for COVID-19 per protocol. Epidemiological analysis was performed for confirmed cases, especially persons acquiring COVID-19 during mask-off and mask-on settings. The incidence of COVID-19 per million population in HKSAR with community-wide masking was compared to that of non-mask-wearing countries which are comparable with HKSAR in terms of population density, healthcare system, BCG vaccination and social distancing measures but not community-wide masking. Compliance of face mask usage in the HKSAR community was monitored.

Findings: Within first 100 days (31 December 2019 to 8 April 2020), 961 COVID-19 patients were diagnosed in HKSAR. The COVID-19 incidence in HKSAR (129.0 per million population) was significantly lower ($p<0.001$) than that of Spain (2983.2), Italy (2250.8), Germany (1241.5), France (1151.6), U.S. (1102.8), U.K. (831.5), Singapore (259.8), and South Korea (200.5). The compliance of face mask usage by HKSAR general public was 96.6% (range: 95.7% to 97.2%). We observed 11 COVID-19 clusters in recreational 'mask-off' settings compared to only 3 in workplace 'mask-on' settings ($p=0.036$ by Chi square test of goodness-of-fit).

Conclusion: Community-wide mask wearing may contribute to the control of COVID-19 by reducing the amount of emission of infected saliva and respiratory droplets from individuals with subclinical or mild COVID-19.

Introduction

Coronavirus disease 2019 (COVID-19) due to severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), which is closely related to bat SARS related coronaviruses,[1] is the second pandemic of the 21st century following the influenza A H1N1 pandemic of 2009. With the rapidly galloping epidemic due to globalization and international travel, World Health Organization (WHO) declared COVID-19 to be a pandemic on 11 March 2020,[2] which is 72 days after the first official announcement of clusters of patients with community-acquired pneumonia in Wuhan, Hubei Province of China on 31 December 2019 (day 1).[3] As of 8 April 2020 (day 100), over 1.35 million people have been infected worldwide with nearly 80,000 deaths.[4] In response, proactive infection control measures have been implemented in hospital settings.[5,6] In addition, non-pharmaceutical public health interventions including border control or closure, quarantine and testing of all incoming travelers or returnees, massive reverse-transcription polymerase chain reaction (RT-PCR) testing for case detection, rapid contact tracing and quarantine, frequent hand hygiene, and later social distancing measures

including school closure, home office, cancelation of all mass gatherings, later stay-at-home order, and cessation of all socioeconomic activities except essential services, were also adopted to various degrees and at different time points in different geographical areas to reduce the risk of community transmission. Many of these measures had been used for the control of community transmission of severe acute respiratory syndrome (SARS) in 2003 and pandemic influenza A H1N1 in 2009 in Hong Kong Special Administrative Region of China (HKSAR) and other parts of the world.[7,8] However, the efficacy of community-wide masking of the population during these past epidemics or the present COVID-19 pandemic has not been clearly investigated. Unlike 2003 SARS which was generally manifested with high fever and progressive pneumonia with a mortality of about 10%, COVID-19 can be associated with very mild symptoms and a mortality of less than 4%. Thus subclinical or asymptomatic SARS-CoV-2 shedders may play an important role in perpetuating the pandemic.[9,10] We hypothesized that community-wide masking in HKSAR may break the chain of transmission of SARS-CoV-2 by reducing the infectiousness of the subclinical virus shedders while also offering some protection to the susceptible population.

In HKSAR, community-wide masking was practiced by the general population at an early stage of the local COVID-19 epidemic. Here, we described the comparative epidemiology of COVID-19 during the first 100 days. We also analyzed the incidence of COVID-19 in geographical areas with or without community-wide masking for most individuals, and also the number of COVID-19 clusters of COVID-19 in relation to workplace (mask-on setting) or non-workplace recreational settings (mask-off setting) of HKSAR.

Methods

Community control measures against COVID-19 in HKSAR

HKSAR is a cosmopolitan city of 7.45 million people in Southern China. Occupying only 1104 square-kilometers, it is the third most densely populated area in the world with around 6700 people per square-kilometer. Soon after the official announcement of a cluster of patients with community-acquired pneumonia in Wuhan by the National Health Commission of the People's Republic of China, on 31 December 2019 (day 1), the center for Health Protection (CHP) of the Department of Health, the HKSAR government alerted members of the public to maintain good personal and environmental hygiene, with specific emphasis on hand hygiene, refraining from work or attending class at school, avoiding crowded places, seek medical advice promptly and wear a surgical mask if they develop respiratory symptoms.[3] Step-wise introduction of other community interventions later to control the spread of COVID-19 was described. As an objective parameter of community-wide preparedness, compliance of face mask usage by the general public monitored by staff working in Infection Control Unit, and Department of Microbiology, Queen Mary Hospital for three consecutive days from 6 April to 8 April 2020 (day 98 to day 100). Each staff member would count the number of persons not wearing a mask among the first 50 persons encountered in the street during their morning commute. The residential district of the staff was recorded.

Epidemiology of COVID-19 in HKSAR

A multi-pronged screening strategy to identify patients infected with SARS-CoV-2 was implemented.[5,6] The epidemiology of newly confirmed cases was announced in the daily press conference jointly held by CHP and Hospital Authority. Major clusters arising from mask-on (workplace) and mask-off (recreational) settings were analyzed to evaluate the efficacy of wearing face masks.

Comparing the epidemiology of COVID-19 in HKSAR and other parts of the world

The epidemiology of COVID-19 of HKSAR was compared to that of the representative countries in North America, Europe, and Asia using publicly accessible information from the website of WHO to understand the overall effect of our control measures used in HKSAR. Countries with well-established healthcare system, where face mask usage was not universally adopted in the community, and having over 100 confirmed cases at day 72 when WHO declared a pandemic were selected for comparison.

Laboratory diagnosis of SARS-CoV-2

Clinical specimens including nasopharyngeal aspirates, nasopharyngeal swabs, throat swab, saliva, sputum, endotracheal aspirates, or bronchoalveolar lavage were subjected to nucleic acid extraction by the eMAG extraction system (bioMérieux, Marcy-l'Étoile France) as we previously described.[5,6] The presence of SARS-CoV-2 RNA in specimens was first determined by the Light-Mix Modular SebeccoV E-gene commercial kit (TIB Molbiol, Berlin, Germany) at all public hospitals under the Hospital Authority and the Public Health Laboratory Service of the Department of Health, and further confirmed by in-house real-time RT-PCR assay targeting the SARS-CoV-2 RNA-dependent RNA polymerase/helicase gene as described.[11]

Statistical analysis

Incidence rates were compared using the exact Poisson test using R software. Proportions were compared using the chi-squared test. A p value of <0.05 was considered statistically significant.

Results

Community response to COVID-19 in HKSAR

Due to the prior experience of the SARS outbreak in 2003, the general public of HKSAR was on high alert after the official announcement of a cluster of pneumonia cases of unknown etiology in Wuhan on 31 December 2019 (day 1), because a total of 1755 infected persons with 299 (17.0%) deaths over 133 days (11 February 2003 to 23 June 2003) was recorded during this past SARS epidemic. When the causative agent of COVID-19 was identified on 9 January 2020 (day 10), and named as SARS-CoV-2 on 12 February 2020 (day 44), this emerging pathogen was perceived to be as detrimental as 2003 SARS-CoV by the HKSAR general public. Even though initially HKSAR government only advocated people with respiratory symptoms to wear a surgical mask according to the recommendations of WHO and Centers for Disease Control and Prevention (CDC) of the United States, the general public volunteered to wear face mask quite compliantly from the pre-pandemic to pandemic phase of COVID-19.

Sixty-seven staff members (9 from Infection Control Unit, and 58 from Department of Microbiology), residing in all 18 administrative districts in HKSAR, recorded the number of persons not wearing face mask among the first 50 people they encountered during their morning commute to Queen Mary Hospital (located in Southern district) between 7:00am to 9:00am over three consecutive days from 6 April to 8 April 2020 (day 98 to day 100). A total of 10,050 persons were observed. Only 337 (3.4%) persons did not wear face mask. The daily compliance of face mask usage was 97.2%, 97.1%, and 95.7% over three consecutive days in all 18 administrative districts in HKSAR.

Besides proactive infection control measures implemented by public hospitals under the governance of Hospital Authority,[5,6]

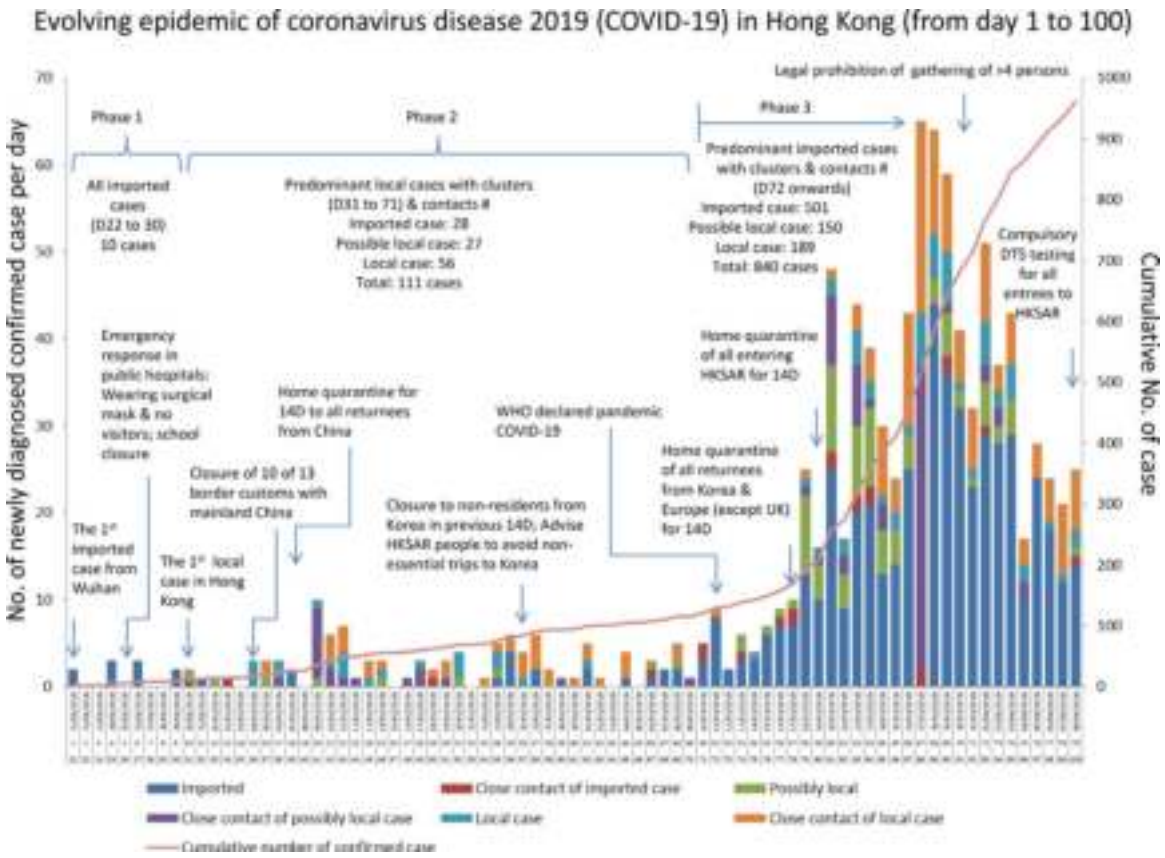

Fig. 1. Evolving epidemic of coronavirus disease 2019 (COVID-19) in Hong Kong (from day 1 to 100).
Note. #including their close contacts
COVID-19, coronavirus disease 2019; DTS, deep throat saliva; WHO, World Health Organization.

step-wise introduction of epidemiological measures by the HKSAR government were enforced. They included border controls to reduce imported SARS-CoV-2 cases from mainland China on 4 February 2020 (day 36). This was followed by imposing home quarantine order for 14 days to all entrees from mainland China on 8 February 2020 (day 40). Subsequently, the quarantine order was progressively imposed to all entrees into HKSAR on and after 19 March 2020 (day 80) (Fig. 1). All entrees were compulsorily tested for SARS-CoV-2 by collecting their posterior oropharyngeal saliva with effect from 8 April 2020 (day 100). As in other localities, isolation of confirmed case, contact tracing and quarantine, closure of affected or high risk premises, and social distancing measures such as home-office and school closure were instituted.

Epidemiology of COVID-19 in HKSAR

Up to day 100 of the epidemic, a total of 961 cases of COVID-19 were confirmed in HKSAR. Transmission of COVID-19 was divisible into four phases: phase 0 (from day 1 to 21) with no confirmed cases of COVID-19 in HKSAR; phase 1 (from day 22 to 30) with 10 imported cases; phase 2 (from day 31 to 71) with 111 cases (predominantly local cases) and; phase 3 (from day 72, WHO declared COVID-19 pandemic, onwards) with 840 cases (predominantly imported cases with local clusters of cases) (Fig. 1). Among the 961 confirmed cases, there were 11 clusters of 113 persons that were directly engaged in mask-off activities such as dining and drinking in restaurant or bar, singing at karaoke, and exercise in fitness clubs. There were only three clusters involving 11 persons engaged in mask-on settings at the workplace. Using the chi-square test of goodness-of-fit with Williams' continuity correction, there were significantly more COVID-19 clusters involving mask-off settings than might be expected assuming that the null hypothesis of equal number of clusters involving mask-on and mask-off settings was true ($p = 0.036$).

Comparing the epidemic progression of COVID-19 in HKSAR with other parts of the world

The incidence and cumulative number of COVID-19 cases in HKSAR and the representative countries or areas since the first laboratory-confirmed case of SARS-CoV-2 are illustrated in Fig. 2a& 2b. The incidence of COVID-19 in HKSAR was significantly less than that of the selected countries (with well-established healthcare system and having over 100 confirmed cases at day 72 when WHO declared a pandemic) in Asia, Europe, and North America, where face mask usage was not universally adopted in the community (Table 1). Singapore's land area and population density are comparable to HKSAR.[4] On day 100 (8 April 2020), the incidence of COVID-19 per million population in Singapore was significantly higher than that in HKSAR (259.8 per million population vs 129.0 per million population, $p < 0.001$) (Table 2). In South Korea, the number of molecular diagnostic tests per million population was comparable to HKSAR. The proportion of local cases in South Korea related to mask-off settings was significantly higher than that in HKSAR [5150/10,384 (49.6%) vs 113 / 961 (11.8%), $p < 0.001$] because of super-spreading events at a church which was also a mask-off setting (Table 2).

Discussion

Evidence for using face masks to prevent transmission of respiratory viruses in the community remains limited to a few stud-

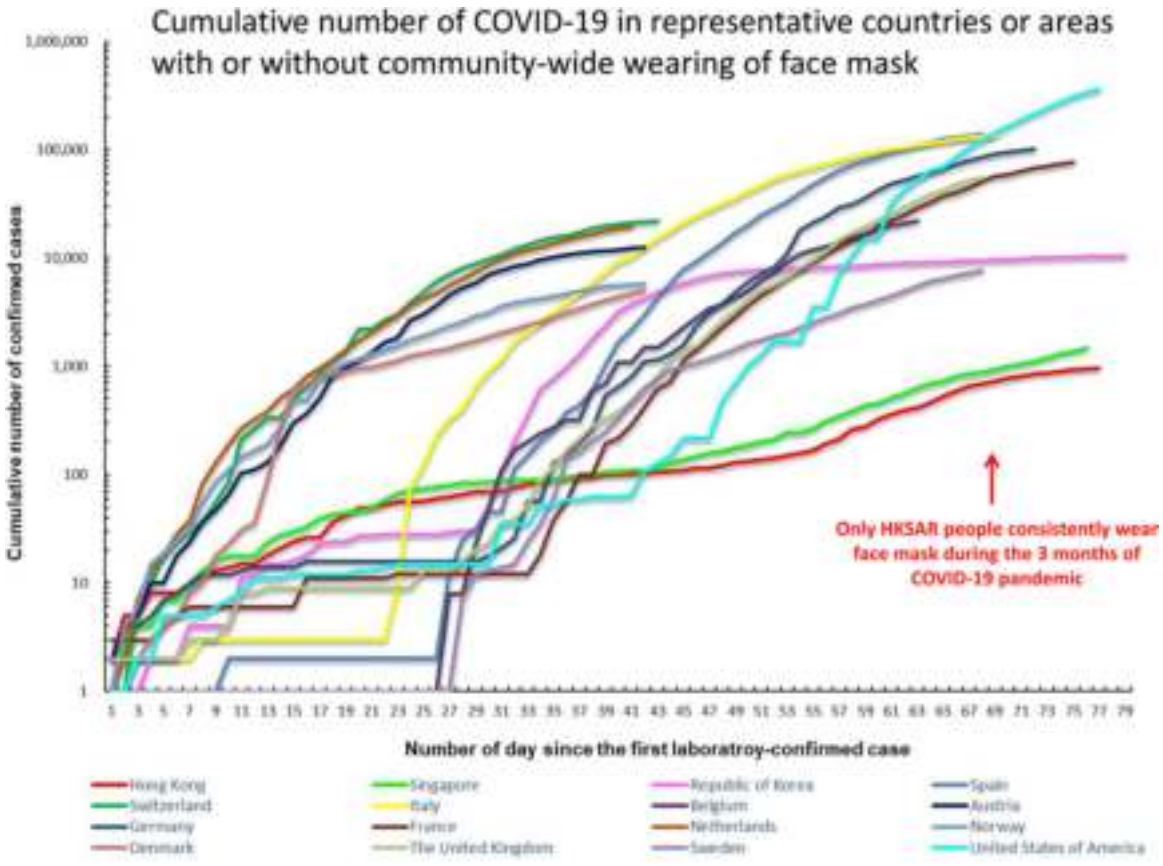

Fig. 2a. Cumulative number of COVID-19 in representative countries or areas with or without community-wide wearing of face mask
Note. The x-axis denotes the number of days since the first laboratory-confirmed case in the representative countries or areas.
The date of first laboratory-confirmed case in Hong Kong (21 January 2020), Singapore (24 January 2020), South Korea (21 January 2020), Spain (1 February 2020), Switzerland (26 February 2020), Italy (31 January 2020), Belgium (06 February 2020), Austria (27 February 2020), Germany (28 January 2020), France (25 January 2020), Netherlands (28 February 2020), Norway (27 February 2020), Denmark (27 February 2020), The United Kingdom (1 February 2020), Sweden (01 February 2020) and United States of America (23 January 2020).

ies conducted in the household setting.[12,13] Although there is no expert consensus on this issue, universal masking is voluntarily adopted by people in our HKSAR community soon after the first imported case of COVID-19 was reported. This public action was linked to the painful experience of the 2003 SARS outbreak (1755 cases with 299 deaths in 6.73 million population) when HKSAR people adopted universal masking in addition to other non-pharmaceutical interventions such as hand hygiene, social distancing and school closure.[7] These community hygienic measures during the SARS outbreak resulted in a significant reduction of positive specimens of all circulating respiratory viruses including influenza viruses in 2003 compared with preceding periods.[14] In a case-control study conducted in Beijing during 2003 SARS, consistent wearing of a face mask outdoors was associated with a 70% risk reduction, compared to those not wearing a face mask.[15]

HKSAR is the only area practicing universal masking despite the recommendation of WHO and CDC that mask should be reserved for those with symptoms and in healthcare settings. We therefore compared the number of COVID-19 clusters in mask-on settings at workplace with that of the mask-off settings such as dining and drinking in restaurant or bar, singing at karaoke, and exercising in gymnasium, where there was a large gathering of people sharing food, drinks, and instruments. In effect, these mask-off settings allowed the sharing of their saliva and respiratory droplets, which may contain a viral load of 100 million per ml, directly or indirectly.[16,17] In HKSAR hospitals, wearing face masks is mandatory during the pandemic. It is also the practice among many community service providers and those who are working indoors. Since the supply of face mask was tight in the community as well as in the healthcare setting, it is the practice of our general public not to use more than one face mask per person per day. We observed that the overall compliance of face mask usage was 97% in all administrative districts in the morning. Thus we have the reason to believe that their compliance to face mask usage would remain high throughout the day at the workplace. It is therefore not surprising that the number of COVID-19 clusters was significantly higher in the mask-off recreational settings in HKSAR.

Universal masking in the community may mitigate the extent of transmission of COVID-19 and may be a necessary adjunctive public health measure in a densely populated city like HKSAR, with an average of 170,000 people entering HKSAR from Mainland and overseas per day.[18] Our incidence of COVID-19 was also lower than that of other areas with local transmission, vindicating this approach. In particular, our incidence of COVID-19 was significantly lower than that of Singapore, a city comparable with HKSAR in terms of area, population density, healthcare infrastructure, BCG vaccination,[19] as well as adopting social distancing strategies and SARS-CoV-2 testing infrastructure.[20] Besides a lower ambient temperature and a higher risk of importation of COVID-19 cases from the mainland which are factors promoting COVID-19 transmission in HKSAR, the most important difference between the two cities is the community-wide usage of face masks in HKSAR but not in Singapore. Moreover, 50% of local transmission of COVID-19 in South Korea was attributed to religious activities where face mask usage

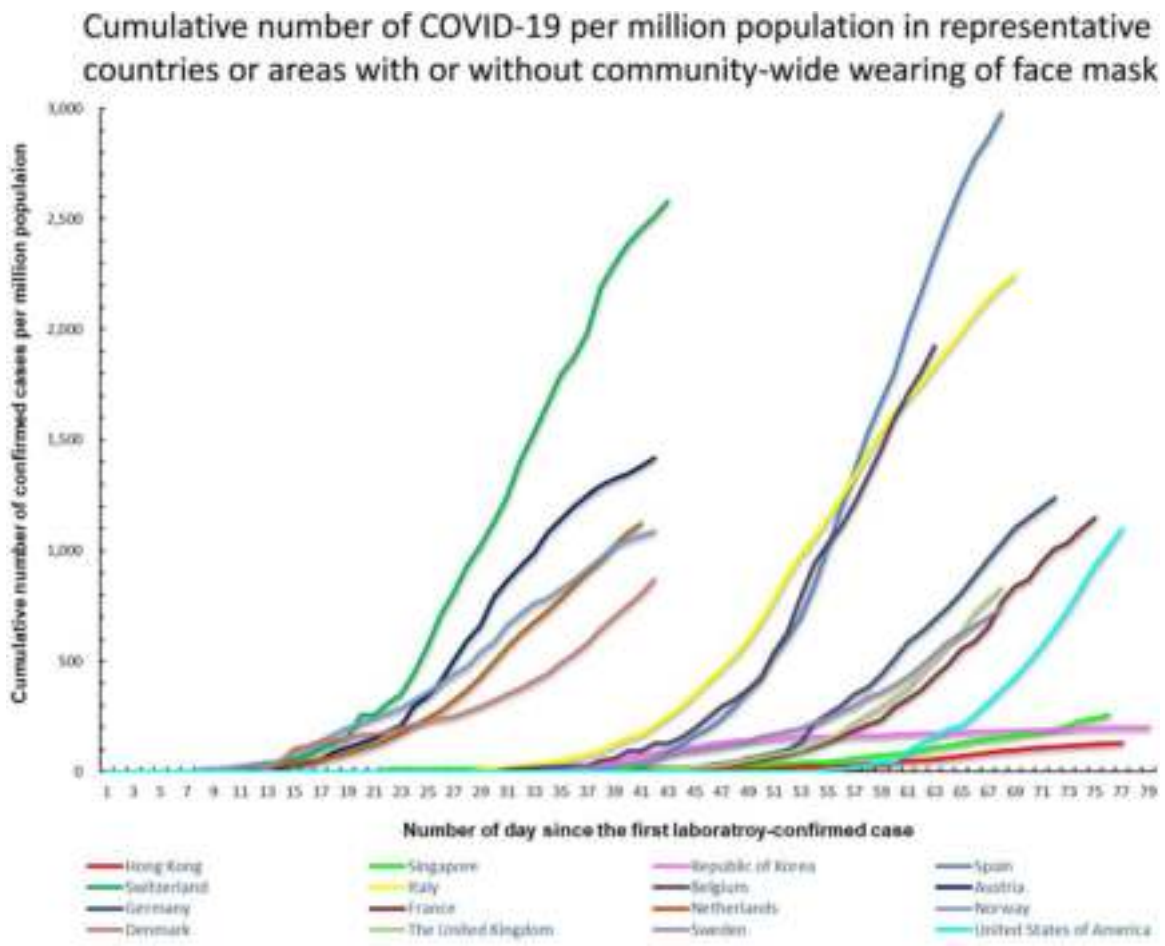

Fig. 2b. Cumulative number of COVID-19 per million population in representative countries or areas with or without community-wide wearing of face mask
Note. The x-axis denotes the number of day since the first laboratory-confirmed case in the representative countries or areas.
The date of first laboratory-confirmed case in Hong Kong (21 January 2020), Singapore (24 January 2020), South Korea (21 January 2020), Spain (1 February 2020), Switzerland (26 February 2020), Italy (31 January 2020), Belgium (06 February 2020), Austria (27 February 2020), Germany (28 January 2020), France (25 January 2020), Netherlands (28 February 2020), Norway (27 February 2020), Denmark (27 February 2020), The United Kingdom (1 February 2020), Sweden (01 February 2020) and United States of America (23 January 2020).

was discouraged. Mask-off activities clearly have potential implications for COVID-19 transmission in the community.

However, the use of face mask in the community remains controversial.[21,22] WHO issued an interim guideline regarding the use of masks in the context of COVID-19 on 6 April 2020, stating no evidence that wearing a mask by healthy persons in the wider community setting can prevent acquisition of COVID-19.[23] European Centre for Disease Prevention and Control issued a technical report on 8 April 2020 that the use of face masks in the community could be considered, especially when visiting busy, closed spaces, despite not knowing how much the use of masks in the community can contribute to a decrease in transmission in addition to the other counter measures.[24] On 3 April 2020, CDC recommended the use of cloth face coverings, especially in areas of significant community-based transmission.[25] The shift of paradigm from not recommending to promoting the use of face masks was based on the rationale of pre-symptomatic shedding of SARS-Cov-2 and presence of asymptomatic patients with high viral load in the community.[9,26] The use of face mask may serve as source control by preventing dispersal of droplets during talking, sneezing, and coughing,[27] and also reduce the risk of environmental contamination by SARS-CoV-2. Despite some supporters of WHO recommendation speaking against universal masking in our local medical community, most opinion leaders in the clinical microbiology and infectious disease specialties of HKSAR openly championed this measure for the control of community transmission of COVID-19.[28] Masking is a continuous form of protection to stop the spreading of saliva and respiratory droplets to others or from others, and to the environment or from the environment to the susceptible by hands through touching of nose, mouth and eye. Touching nose and mouth is a subconscious behavior.[29] Hand hygiene is always the cornerstone to prevent transmission of COVID-19 but it is a one-off discontinuous process where hand contamination may occur easily between each alcoholic handrubbing or hand washing. Although we have successfully implemented directly observed hand hygiene (DOHH) by regular delivery of alcohol-based hand rub to conscious hospitalized patients and persons in residential care homes for the elderly before meal and medication rounds,[30–32] it may be difficult to practice DOHH in the community. Studies have also shown that wearing a mask with frequent hand hygiene significantly reduced transmission of seasonal influenza virus in the community setting. But once the effect of the use of surgical mask was removed, the effect of hand hygiene became insignificant.[33] With the understanding that the supply of face masks should primarily be reserved for usage in healthcare settings, we believe that it is still advisable to encourage people to wear face masks in the public based on the precautionary principles.[34] Moreover, wearing a cloth mask with less filtration efficiency may still be better than no mask at all in communities of high transmission.

Table 1
Incidence of coronavirus disease 2019 (COVID-19) infection in Hong Kong Special Administrative Region (HKSAR) as compared with that of selected countries as of 8 April 2020 (at day 100 after official announcement of pneumonia outbreak in Wuhan, Hubei Province, China)[a].

Countries or city	Population (million)[b]	Cumulative number of confirmed case[c]	Number (percentage) of death	Incidence per million population[d]	P value (incidence compared with HKSAR)	Population density: population per km^2 (rank in the world)[e]
Hong Kong SAR[f]	7.45	961	4 (0.4%)	129.0	Not applicable	6782 (3rd)

[k] There is postulation of countries with BCG vaccination program tends to have lower incidence and death due to COVID-19[19].

SARS-CoV-2 is a highly transmissible respiratory virus which causes upper and lower respiratory tract infection leading to a high viral load in respiratory secretions and saliva as shown in clinical studies and transmission studies by close contact in animal models.[35] Moreover, SARS-CoV-2 can suppress the host innate immune response in terms of interferon and cytokine response which in turn leads to a higher level of viral replication than that by the 2003 SARS-CoV in an *ex vivo* lung tissue explant model.[10] These *ex vivo* findings supported the suggestion that an important proportion of COVID-19 patients may be pre-symptomatic or mildly symptomatic virus shedders. These groups of patients are unlikely to be tested or isolated and may contribute to the perpetuation of

the pandemic. Therefore community-wide mask usage irrespective of symptoms may reduce the infectivity of these silent COVID-19 cases to the susceptible individuals.

There are several limitations in our study. First, we did not analyze the mask-off settings in the family because the modes of transmission among close household contacts can be more diverse. If the 15 family clusters were also counted within the mask-off settings, the difference would be even more significant ($p<0.001$). Second, the type of mask used in the community cannot be controlled. The compliance of wearing face mask in terms of not touching the external surface of mask or face, and hand hygiene before or after touching the mask cannot be assessed. Third, we cannot count the mask compliance directly for every community settings. Nevertheless, in the absence of effective antiviral and vaccines, the pandemic spread COVID-19 to many countries provide an unique opportunity to study the effectiveness of this non-pharmaceutical control measures. As of 27 February 2020 (day 38 since the first reported case in South Korea), South Korea government has started to distribute face masks to the public amid the outbreak of the COVID-19,[36] which was associated with a flattening of the epidemic curve. As of 14 April 2020 (day 82 since the first reported case in Singapore), Singapore government has started to enforce a penalty of 300 Singapore dollar for anyone going out from home without a mask.[37] Further studies on this important non-pharmaceutical control measure are warranted. In order to live with emerging infectious diseases and seasonal influenza epidemics, every individual should have personalized reusable mask, gown, and gloves made of self-disinfecting fabrics, and even reusable anti-fog face shield within their own set of Epidemic Combat Kit for their personal protection.

Non-pharmaceutical interventions
COVID-19
Time-Varying effective reproduction number (Rt)

ABSTRACT

Background: To evaluate and compare the effectiveness of four types of non-pharmaceutical interventions (NPIs) to contain the time-varying effective reproduction number (Rt) of coronavirus disease-2019 (COVID-19).

Methods: This study included 1,908,197 confirmed COVID-19 cases from 190 countries between 23 January and 13 April 2020. The implemented NPIs were categorised into four types: mandatory face mask in public, isolation or quarantine, social distancing and traffic restriction (referred to as mandatory mask, quarantine, distancing and traffic hereafter, respectively).

Results: The implementations of mandatory mask, quarantine, distancing and traffic were associated with changes (95% confidence interval, CI) of −15.14% (from −21.79% to −7.93%), −11.40% (from −13.66% to −9.07%), −42.94% (from −44.24% to −41.60%) and −9.26% (from −11.46% to −7.01%) in the Rt of COVID-19 when compared with those without the implementation of the corresponding measures. Distancing and the simultaneous implementation of two or more types of NPIs seemed to be associated with a greater decrease in the Rt of COVID-19.

Conclusion: Our study indicates that NPIs can significantly contain the COVID-19 pandemic. Distancing and the simultaneous implementation of two or more NPIs should be the strategic priorities for containing COVID-19.

Introduction

The coronavirus disease-2019 (COVID-19), caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), was first reported in Wuhan, China, in December 2019. The World Health Organization (WHO) declared it as a pandemic on 12 March 2020. As of 28 May 2020, there are more than 5.5 million confirmed cases of COVID-19 and 353,373 related deaths worldwide (World Health Organization, 2020). Many countries have implemented a series of non-pharmaceutical interventions (NPIs), such as traffic restriction and social distancing, to contain the outbreak of this disease (Jon Cohen, 2020; Lewnard and Lo, 2020).

Owing to the rapid transmission of COVID-19 worldwide and the lack of an efficient vaccine or treatment for this novel infectious disease, NPIs are among the few approaches to cope with the resulting pandemic. There is an urgent need to understand whether these NPIs are effective and which of these NPIs are more efficient. However, the information on this topic is limited.

Most previous studies have focused on evaluating a single NPI within a single city or country using a modelling method, and the results of these studies are inconsistent. Few studies have investigated the simultaneous implementation of multiple NPIs and compared the effectiveness of different NPIs (Lai et al., 2020; Min et al., 2020). To the best of our knowledge, no study has examined the association between various NPIs and the time-varying effective reproduction number (Rt) of COVID-19 on the global scale. Therefore, we investigated and compared the effectiveness of four types of NPIs, namely mandatory face mask in public, isolation or quarantine, social distancing and traffic restriction, on the transmission of COVID-19 in 190 countries between 23 January and 13 April 2020.

Method

Study design and setting

This ecological study included a total of 415 sites (comprising 235 cities from 10 countries and 180 countries) between 23 January and 13 April 2020. Information on the daily number of confirmed COVID-19 cases was extracted from a data repository sourced from Johns Hopkins University Center for Systems Science and Engineering and the Wind Financial database, which archive data from the official websites of health ministries worldwide (Dong et al., 2020; Wind, 2020).

Data pertaining to the implementation of NPIs during the study period were obtained from official webpages of high-circulation newspapers published in the 415 cities/countries. In brief, we first recorded any legal NPIs announced by the government of each site and its implementation date [i.e., start date and end date (if applicable before the study end date)]. Then, we categorised the NPIs into the following four types: 'mandatory face mask in public' (referred to as mandatory mask hereinafter), 'isolation or quarantine' (referred to as quarantine hereinafter), 'social distancing' (referred to as distancing hereinafter) and 'traffic restriction' (referred to as traffic hereinafter). Details pertaining to the process of categorising the NPIs are summarised in Table S1. If any NPI of a type was deemed officially announced as being in force at a site on any day of the study period, then that NPI type was treated as 'on' for that site on that day in our data analysis. In contrast, if no NPI of a type was found to be effective at a site on any day of the study period, the NPI type was treated as 'off' in our data analysis.

Moreover, we collected demographic and socioeconomic status data for each site. Data on population size (number of persons), population density (persons per square km) and median age (years) were obtained from United Nations, Department of Economic and Social Affairs, Population Division (Elaboration of data by United Nations, 2019) and/or statistics bureau of the countries studied. Data on the percentage of populations aged 65 years or older were obtained from the World Bank data portal (2019 revision). Information about the Global Health Security Index (GHSI) was collected from the GHSI report (Johns Hopkins, 2019). Because only country-level GHSI data were available, we applied them to all cities within a given country.

Calculation of time-varying effective reproduction number (Rt)

We used Rt, which represents the average number of secondary infected cases generated by a primary infected individual at time t, to estimate the changes in COVID-19 transmissibility. Rt >1 indicates an expansionary trend of the epidemic, whereas Rt <1 indicates a contractionary trend of the epidemic. We calculated the Rt and its 95% credible interval for each day by applying the method developed by Cori et al. (2013) through a 7-day moving average. We assumed that the serial interval distribution of COVID-19 followed a gamma distribution with a mean of 3.96 days and a standard deviation (SD) of 4.75 days (Du et al., 2020).

Data analysis

First, we used the generalised linear mixed model (GLMM) to assess the effectiveness of the four types of NPIs on the transmission of COVID-19 separately. The implementation status (on/off) of each type of NPI (i.e., mandatory mask, quarantine, distancing and traffic) at each site on each day was included in the model as an independent variable. The dependent variable was Rt, which was log-transformed to normalise before data analysis and then retransformed to the original scale for presentation. Effect estimations were reported as percentage differences in the Rt between sites with a given type of NPI and sites without the corresponding type of NPI as the reference. A city/country-level random intercept was included in the model to control for clustering effects within the same city/country. Two models were developed. Model 1 included the following covariates: calendar time to control seasonal and long-term trends over the study period; Rt of the previous day to account for temporal autocorrelation; public health response time, which was defined as the number of days between the date of activation of the first NPI and the date on which the first case was reported; an indicator for the day of the week and public holidays to account for weekly or periodic variations in the number of people who underwent the SARS-CoV-2 test; duration for which a type of NPI was implemented to control for the potential effects of implementation duration; population density to account for a higher transmission rate in regions with high population density; median age to account for higher incidence rates among the elderly; and GHSI to account for countries' capacity to prevent and mitigate epidemics and pandemics. Model 2 was further mutually adjusted for the other three types of NPIs, for example, adjusted for quarantine, distancing and traffic to determine the association between the 'mandatory mask' type of NPI and Rt.

Second, we compared the effectiveness of the different types of NPIs implemented. We classified the 415 sites into the following 16 mutually exclusive groups: no implementation of NPIs; implementation of any one type of NPIs, namely mandatory mask only, quarantine only, distancing only or traffic only; implementation of any two types of NPIs, namely 'distancing + mandatory mask', 'distancing + quarantine', 'traffic + mandatory mask', 'traffic + quarantine', 'traffic + distancing' or 'quarantine + mandatory mask'; implementation of any three types of NPIs, namely 'distancing + quarantine + mandatory mask', 'traffic + quarantine + mandatory mask', 'traffic + distancing + mandatory mask' or 'traffic + distancing + quarantine'; and implementation of all four types of NPIs, that is, 'traffic + distancing + quarantine + mandatory mask'. We applied the GLMM mentioned above with the same covariates as those used in Model 1. The reference group was 'no implementation of NPIs'.

Third, stratified analyses were performed to investigate whether these associations were modified by WHO regions, population density and GHSI.

Finally, we performed three sensitivity analyses to examine the robustness of the estimated associations and the lag effects: (1) We used the Rt on the third day (Lag 3), the seventh day (Lag 7) and the 14th day (Lag 14) as the dependent variable to examine the lag effect; (2) we investigated the associations by excluding Hubei province in China, which was a significant outlier in the model; and (3) we investigated the associations by adjusting for percentages of populations aged 65 years or older instead of median age to consider the effects of age structure.

All data analyses were performed using R 3.6.1 (R Core Team, Vienna, Austria). A two-tailed P value of <0.05 was considered statistically significant.

Result

A total of 415 sites (i.e., 235 cities from 10 countries and 180 countries) were included in this study. Table S2 summarises the relevant information on COVID-19 and the NPIs implemented in the 190 countries during the study period. As of 13 April 2020, 1,908,197 cases of COVID-19 infection were reported. The highest number of cases was reported in the United States of America [577,165 (30.25% of the total number of cases reported worldwide)], followed by Spain, Italy, France, Germany, the United Kingdom, China, Iran, Turkey and Belgium.

Table 1 shows the data pertaining to the implementation of NPIs at the study sites over the study period. No official NPIs were ever implemented in 382 sites. In many sites, two or more types of NPIs were implemented simultaneously during the study period. The common types of NPIs or combinations of NPI types that were implemented across the sites were 'traffic only' (138 sites), 'traffic + quarantine' (130 sites), 'traffic + distancing' (177 sites) and 'traffic + distancing + quarantine' (218 sites). The implementation durations of each type of NPI or each combination of NPI types ranged from 4 to 38 days. Relatively long median durations of implementation were observed for 'traffic only' (12.5 days), 'distancing + mandatory mask' (16 days), 'traffic + quarantine' (33 days), 'traffic + distancing' (19 days), 'traffic + quarantine + mandatory mask' (38 days), 'traffic + distancing + quarantine' (24 days) and 'traffic + distancing + quarantine + mandatory mask' (37 days).

Table 2 presents the associations between each type of NPI and the Rt of COVID-19. The implementations of any type of NPI were significantly associated with a decrease in the Rt of COVID-19. Mutual adjustments substantially diluted these associations. The implementations of mandatory mask, quarantine, distancing and traffic were associated with changes of −15.14% (from −21.79% to −7.93%), −11.40% (from −13.66% to −9.07%), −42.94% (from −44.24% to −41.60%) and −9.26% (from −11.46% to −7.01%) in the Rt of COVID-19, respectively, when compared with the Rt in the sites without the implementation of the corresponding measures.

Table 3 shows the comparisons of the effectiveness of different NPIs on the Rt of COVID-19. 'Distancing only' led to a greater decrease in the Rt of COVID-19 than 'traffic only' and 'quarantine only'. The combinations of other types of NPIs with distancing were generally associated with a greater decrease in the Rt when compared with the combinations without distancing. The combinations with more types of NPIs were generally associated with a greater decrease in the Rt. No significant associations were observed for 'mandatory mask only', 'distancing + mandatory mask', 'traffic + mandatory mask' and 'traffic + distancing + mandatory mask'.

As shown in Table 4, subgroup data analysis generally yielded similar results. The association strengths differed slightly for some subgroups, that is, greater decreases in the Rt were observed for the subgroups of 'higher population density' and 'lower GHSI'. No significant associations were observed for some subgroups.

Tables S3-S5 summarise the results of our sensitivity analyses. The decreased magnitudes in the Rts were generally smaller on days Lag 3, Lag 7 and Lag 14 when compared with those on the current day (Table S3). Similar results were obtained by excluding the outlier province (Hubei, China) (Table S4) and by adjusting for percentages of subjects aged ≥65 years instead of median age (Table S5).

Discussion

This comprehensive ecological study covering 190 countries indicated that the implementation of any type of NPI, namely traffic, distancing, mandatory mask or quarantine was significantly associated with a decrease in the Rt of COVID-19. All NPI implementations involving distancing were associated with a greater decrease in the Rt of COVID-19 than those not involving distancing. Accordingly, combinations with more types of NPIs seemed to be associated with a greater decrease in the Rt of COVID-19.

Most previous studies have investigated the effectiveness of a single NPI rather than a group of NPIs despite the fact that two or more NPIs are commonly implemented simultaneously (Auger et al., 2020; Chinazzi et al., 2020; Hernandez et al., 2020; Milne and Xie, 2020). The results of our study were consistent with those of the studies, which concluded that the implementation of NPIs was

Table 1
Non-pharmaceutical interventions implemented in the 190 countries between 23 January 2020 and 13 April 2020 (N = 415).

Type of NPIs	No. of sites that implemented the NPIs (%)	Median duration (range) of NPI implementation (days)
0 NPIs	382 (92.05%)	N/A
Any one type of NPI		
Mandatory mask only	1 (0.24%)	4 (N/A)
Quarantine only	48 (11.57%)	7 (1–53)
Distancing only	40 (9.64%)	4 (1–31)
Traffic only	138 (33.25%)	12.5 (1–75)
Any two types of NPIs		
Distancing + mandatory mask	1 (0.24%)	16 (N/A)
Distancing + quarantine	21 (5.06%)	6 (1–35)
Traffic + mandatory mask	1 (0.24%)	4 (N/A)
Traffic + quarantine	130 (31.33%)	33 (1–72)
Traffic + distancing	177 (42.65%)	19 (1–38)
Quarantine + mandatory mask	0 (0.00%)	N/A
Any three types of NPIs		
Distancing + quarantine + mandatory mask	2 (0.48%)	8.5 (1–16)
Traffic + quarantine + mandatory mask	36 (8.67%)	38 (2–42)
Traffic + distancing + mandatory mask	1 (0.24%)	7 (N/A)
Traffic + distancing + quarantine	218 (52.53%)	24 (2–49)
All four types of NPIs		
Traffic + distancing + quarantine + mandatory mask	60 (14.46%)	37 (1–75)

NPIs: Non-pharmaceutical interventions.
%: Percentage of sites implementing corresponding types of NPI among the 415 included sites.
N/A: not applicable.

Table 2
Associations of individual type of non-pharmaceutical intervention with the Rt of COVID-19.

Type of NPI	Model 1		Model 2	
	Difference (95% CI)	*P*	Difference (95% CI)	*P*
Mandatory mask (Yes vs. No)	−33.35% (-39.07 to -27.09)	<0.001	−15.14% (-21.79 to -7.93)	<0.001
Quarantine (Yes vs. No)	−32.98% (-34.59 to -31.33)	<0.001	−11.40% (-13.66 to -9.07)	<0.001
Distancing (Yes vs. No)	−46.46% (-47.63 to -45.27)	<0.001	−42.94% (-44.24 to -41.60)	<0.001
Traffic (Yes vs. No)	−29.09% (-30.73 to -27.42)	<0.001	−9.26% (-11.46 to -7.01)	<0.001

NPIs: Non-pharmaceutical interventions.
Sites without the corresponding type of NPI as the reference.
Results are presented as percentage differences in the Rt with [95% Confidence Interval (CI)].
Model 1: Adjusted for the calendar time, Rt on the previous day, public health response time defined as the time in days between the activation of the first NPI and the date of reporting of the first case, an indicator of the day of the week and public holidays, implementation duration of NPIs, population density, median age and GHSI.
Model 2: Further mutually adjusted for the other three types of NPIs, for example, adjusted for quarantine, distancing and traffic in the model for the association between 'mandatory mask' type of NPI and Rt.

Table 3
Comparison of effectiveness of different NPI types or combinations on the Rt of COVID-19.

Type of NPIs	Difference (95% CI)	*P*
Any one type of NPIs		
Mandatory mask only	−34.06% (-60.78 to 10.87)	0.116
Quarantine only	−10.6% (-15.31 to -5.64)	<0.001
Distancing only	−23.03% (-28.43 to -17.22)	<0.001
Traffic only	−9.64% (-12.21 to -7.00)	<0.001
Any two types of NPIs		
Distancing + mandatory mask	53.30% (-2.50–141.03)	0.064
Distancing + quarantine	−38.58% (-44.23 to -32.37)	<0.001
Traffic + mandatory mask	−66.58% (-92.67 to 52.41)	0.157
Traffic + quarantine	−17.83% (-20.07 to -15.53)	<0.001
Traffic + distancing	−44.11% (-46.37 to -41.76)	<0.001
Any three types of NPIs		
Distancing + quarantine + mandatory mask	−69.73% (-82.48 to -47.69)	<0.001
Traffic + quarantine + mandatory mask	−17.06% (-24.99 to -8.29)	<0.001
Traffic + distancing + mandatory mask	−54.32% (-79.59 to 2.24)	0.057
Traffic + distancing + quarantine	−54.12% (-55.63 to -52.56)	<0.001
All four types of NPIs		
Traffic + distancing + quarantine + mandatory mask	−62.81% (-66.27 to -58.98)	<0.001

NPIs: Non-pharmaceutical interventions.
Sites with No NPI implementation are the reference.
Results are presented as percentage differences in the Rt with [95% Confidence Interval (CI)].
Adjusted for calendar time, Rt on the previous day, public health response time defined as the number of days between the date of activation of the first NPI and the date of reporting of the first case, an indicator of the day of the week and public holidays, implementation duration of a type of NPI, population density, median age and GHSI.

associated with a decrease in transmissibility, such as the studies in mainland China showing that travel restrictions might delay the progression of the COVID-19 epidemic by 3–5 days (Chinazzi et al., 2020; Tian et al., 2020), and the study in New York showing that wearing a mask could reduce daily deaths by 17%–45% over 2 months (Eikenberry et al., 2020). Moreover, two studies reported social distancing to be an effective NPI (Hernandez et al., 2020; Zhang et al., 2020). A study conducted in China showed that social distancing and epicentre lockdown might reduce the number of new infection cases by up to 98.9% (Zhang et al., 2020), while another study indicated that social distancing reduced the growth rate of confirmed cases in five countries (Austria, Belgium, Italy, Malaysia and South Korea) by 52.37% on average (SD 13.37%) (Hernandez et al., 2020). A few studies investigated the effectiveness of multiple NPIs in China (Cowling et al., 2020; Lai et al., 2020; Milne and Xie, 2020; Pan et al., 2020), European countries (Flaxman et al., 2020), the United Kingdom (Davies et al., 2020) and Singapore (Koo et al., 2020). Their results showed that the implementation of multiple NPIs was associated with a reduction in the transmission of COVID-19. In contrast, a study conducted in 20 European countries revealed that stay-at-home orders, closure of all non-essential businesses and wearing of face masks in public were not significantly associated with the incidence rate of confirmed cases (Hunter et al., 2020). It is difficult to directly compare the results of our study with those of previous studies owing to multiple reasons, such as differences in study design and period, targeted populations and transmissibility parameters. Moreover, most previous studies used modelling methods to simulate the epidemic with the implementation of NPIs. In contrast, we used the data published on the official webpages of the governments of 190 countries to provide direct evidence about the effectiveness of NPI implementation on COVID-19 transmission. Nevertheless, our study and most previous studies support the implementation of NPIs as a measure for containing the global pandemic of COVID-19.

Few studies have compared the effectiveness of different NPIs and their combinations for containing COVID-19. Our results showed that the NPI of distancing and its combinations with other NPI types are associated with a greater decrease in the Rt of COVID-19, suggesting that distancing should be adopted as a priority NPI for COVID-19 containment. This is in line with a modelling study in China, which also suggested that social distancing seemed to have a greater impact on the containment of COVID-19 outbreak than travel restrictions (Lai et al., 2020). Moreover, our study indicated

Table 4
Subgroup analysis of association between non-pharmaceutical interventions and the Rt of COVID-19 transmission.

Types of NPIs	Subgroup analysis			
	Stratified by continents			
	European	American	Asia	African
Comparison of individual types of NPIs[a]				
Mandatory mask (Yes vs. No)	−1.33% (-13.02–11.94)	−23.68% (-41.5 to -0.45)	−0.26% (-6.15 to 6.01)	−28.56% (-48.8 to -0.31)
Quarantine (Yes vs. No)	−18.27% (-22.14 to -14.21)	−4.23% (-10.07 to 1.99)	−4.55% (-8.47 to -0.46)	−10.72% (-16.04 to -5.07)
Distancing (Yes vs. No)	−39.4% (-42.07 to -36.59)	−42.87% (-45.37 to -40.27)	−17.76% (-20.56 to -14.85)	−16.05% (-21.33 to -10.41)
Traffic (Yes vs. No)	−11.26% (-15.18 to -7.17)	−8.34% (-13.75 to -2.58)	−8.62% (-11.95 to -5.17)	−30.86% (-34.83 to -26.66)
Comparison of combinations of NPI types[b]				
Any one type of NPI				
Mandatory mask only	−41.49% (-65.82 to 0.16)	N/A	N/A	N/A
Quarantine only	−20.21% (-27.00 to -12.79)	0.84 % (-10.00–12.98)	−11.62% (-18.83 to -3.76)	−4.01% (-15.45 to 8.97)
Distancing only	−38.35% (-45.64 to -30.09)	−33.33% (-42.93 to -22.12)	−18.8% (-30.30 to -5.41)	11.55 % (-3.32 to 28.71)
Traffic only	−9.21% (-13.65 to -4.54)	−15.12% (-22.68 to -6.81)	−12.58% (-16.2 to -8.81)	−24.60% (-30.13 to -18.62)
Any two types of NPIs

All four types of NPIs				
Traffic + distancing + quarantine + mandatory mask	−54.29% (-59.07 to -48.96)	−71.21% (-75.22 to -66.54)	−72.36% (-74.83 to -69.65)	−56.94% (-70.12 to -37.95)

N/A: not applicable due to no sites implemented the corresponding type of NPIs.
Results are presented as percentage differences in the Rt with [95% Confidence Interval (CI)].

[a] Sites without the corresponding type of NPI as the reference. Adjusted for calendar time, Rt on the previous day, public health response time defined as the number of days between the date of activation of the first NPI and the date of reporting of the first case, an indicator of day of the week and public holidays, implementation duration of a type of NPI, population density, median age and GHSI and mutually adjusted for the other three types of NPIs, for example, adjusted for quarantine, distancing, and traffic in the model for the association between the 'mandatory mask' type of NPI and Rt.

[b] Sites with No NPI implementation are the reference. Adjusted for calendar time, Rt on the previous day, public health response time defined as the number of days between the date of activation of the first NPI and the date of reporting of the first case, an indicator of the day of the week and public holidays, implementation duration of a type of NPI, population density, median age and GHSI

that the simultaneous implementation of two or more NPI types seems to be associated with a greater decrease in the Rt of COVID-19.

In the comparisons of the effectiveness of different NPIs and their combinations, we found non-significant associations for 'mandatory mask only' and the combinations 'distancing + mandatory mask', 'traffic + mandatory mask' and 'traffic + distancing + mandatory mask' (Table 3). Non-significant associations were also found in some subgroup analyses (Table 4), which were inconsistent with previous studies reporting that the face mask was associated with reduced risk of COVID-19 infection (Cheng et al., 2020; Chu et al., 2020; Eikenberry et al., 2020). The lack of statistical significance for these associations in our study may be ascribed to the small number of cities or countries that implemented the above NPI types and combinations.

Our study has several important strengths. First, we captured the available data on confirmed cases of COVID-19 infection and legal NPIs implemented from 190 countries, which suggests that our findings are applicable in most countries worldwide. The large sample size allowed us to obtain more stable estimates and conduct a series of subgroup and sensitivity analyses, which generally yielded similar results, indicating that the associations observed in our study are robust. Second, we adjusted for a series of important confounders in the model, including socio-demographics and health security capacities. Finally, this study is the first to present a comprehensive and quantitative comparison of the effectiveness of various NPIs and their combinations at a global scale, which may provide timely evidence for policymakers to adopt appropriate NPIs in different countries to control the outbreak of COVID-19.

Several limitations should be noted. First, we treated an NPI as 'on' in the data analysis if the NPI was officially announced as being in force by a government. We were unable to account for the intensity of enforcement and people's compliance, which might have varied across countries and cities. Also, contents of each NPI at different sties might be somewhat different. However, we included a city-level random intercept that may control the between-city variations in intensity and compliance. Second, we considered four types of NPIs that were legally and officially announced by the governments of countries and cities considered in this study. A few NPIs, such as knowledge promotion, voluntary isolation and voluntarily wearing a mask were not considered. Moreover, some cultural factors such as personal hygiene, social habits and family size may influence the spread of COVID-19. Further investigations are warranted to assess the effects of these factors. Third, the information of testing capacities in each site was not available. However, we already adjusted for GHSI, which is an important indicator reflecting testing capacity. Fourth, although our results show non-significant associations of Rt with 'mandatory mask only' and the combinations 'distancing + mandatory mask', 'traffic + mandatory mask' and 'traffic + distancing + mandatory mask', we should interpret with caution because these estimates came from only a few sites. Fifth, because all the cities or countries took action to separate infected persons from uninfected persons at the outset, the effects of not separating infected persons remain unknown. Additionally, the effects of different NPIs may be highly correlated because they commonly, synchronously occurred and were jointly implemented, which may contradict the assumption of independent covariates in GLMM model. However, the results could also be affected by other NPIs if only one type of NPIs was considered. Thus, we gradually introduced two models and presented them separately in Table 2. The two models will allow us to compare the potential influences of additional three other NPIs on the effect of an individual NPI. Furthermore, mutually adjusted for the other three types of NPIs did not materially affect the conclusion.

In conclusion, we found that any type of NPI, namely mandatory face mask in public, isolation or quarantine, social distancing and traffic restriction, may reduce the spread of COVID-19. Social distancing seems more effective than the other three types of NPIs. The simultaneous implementation of two or more types of NPIs may be more effective for containing the spread of COVID-19.

ABSTRACT State policies mandating public or community use of face masks or covers in mitigating the spread of coronavirus disease 2019 (COVID-19) are hotly contested. This study provides evidence from a natural experiment on the effects of state government mandates for face mask use in public issued by fifteen states plus Washington, D.C., between April 8 and May 15, 2020. The research design is an event study examining changes in the daily county-level COVID-19 growth rates between March 31 and May 22, 2020. Mandating face mask use in public is associated with a decline in the daily COVID-19 growth rate by 0.9, 1.1, 1.4, 1.7, and 2.0 percentage points in 1–5, 6–10, 11–15, 16–20, and 21 or more days after state face mask orders were signed, respectively. Estimates suggest that as a result of the implementation of these mandates, more than 200,000 COVID-19 cases were averted by May 22, 2020. The findings suggest that requiring face mask use in public could help in mitigating the spread of COVID-19.

One of the most contentious issues being debated worldwide in the response to the coronavirus disease 2019 (COVID-19) pandemic is the value of wearing masks or face coverings in public settings.[1] A key factor fueling the debate is the limited direct evidence thus far on how much widespread community use would affect COVID-19 spread. However, there is now substantial evidence of asymptomatic transmission of COVID-19.[2,3] For example, a recent study of antibodies in a sample of customers in grocery stores in New York State reported an infection rate of 14.0 percent by March 29 (projected to represent more than 2.1 million cases), which substantially exceeds the number of confirmed COVID-19 cases.[4] Moreover, all public health authorities call on symptomatic people to wear masks to reduce transmission risk. Even organizations that at the time of our study had not yet recommended widespread community use of face masks for COVID-19 mitigation (that is, everyone without symptoms should use a face mask outside of their home), such as the World Health Organization, strongly recommend that symptomatic individuals wear them.[5] Because mask wearing by infected people can reduce transmission risk, and because of the high proportion of asymptomatic infected individuals and transmissions, there appears to be a strong case for the effectiveness of widespread use of face masks in reducing the spread of COVID-19. However, there is no direct evidence thus far on the magnitude of such effects, especially at a population level.

Researchers have been reviewing evidence from previous randomized controlled trials for other respiratory illnesses, examining mask use and types among people at higher risk of contracting infections (such as health care workers or people in infected households). Systematic reviews and meta-analyses of such studies have provided suggestive, although generally weak, evidence.[6] The estimates from the meta-analyses

based on randomized controlled trials suggest declines in transmission risk for influenza or influenza-like illnesses to mask wearers, although estimates are mostly statistically insignificant possibly because of small sample sizes or design limitations, especially those related to assessing compliance.[7–9] There is also a relationship between increased adherence to mask use, specifically, and effectiveness of reducing transmission to mask wearers: In one randomized study of influenza transmission in infected households in Australia, transmission risk for mask wearers was lower with greater adherence.[10] Further, the evidence is mixed from randomized studies on types of masks and risk for influenza-like illness transmission to mask wearers; for example, a recent systematic review and meta-analysis comparing N-95 respirators versus surgical masks found a statistically insignificant decline in influenza risk with N-95 respirators.[11]

Positions on widespread face mask use have differed worldwide but are changing over time. In the US, public health authorities did not recommend widespread face mask use in public at the start of the pandemic. The initially limited evidence on asymptomatic transmission and concern about mask shortages for the health care workforce and people caring for patients contributed to that initial decision. On April 3, 2020, the Centers for Disease Control and Prevention (CDC) issued new guidance advising everyone to wear cloth face covers in public areas where close contact with others is unavoidable, citing new evidence on virus transmission from asymptomatic or presymptomatic people.[12] Guidelines differ between countries, and some, including Germany, France, Italy, Spain, China, and South Korea, have mandated the use of face masks in public.[13–16]

This study adds complementary evidence to the literature on the impacts of widespread community use of face masks on COVID-19 spread from a natural experiment based on whether or not US states had mandated the use of face masks in public for COVID-19 mitigation as of May 2020. Fifteen states plus Washington, D.C., issued mandates for face mask use in public between April 8 and May 15.

We identified the effects of state mandates for the use of face masks in public on the daily COVID-19 growth rate, using an event study that examined the effects over different periods. We considered the impact of mandates for mask use targeted only to employees in some work settings, as opposed to communitywide mandates. This evidence is critical, as states and countries worldwide begin to shift to "reopening" their economies and as foot traffic increases. Mandating the public use of masks has become a socially and politically contentious issue, with multiple protests and even acts of violence directed against masked employees and those asking customers to wear face masks.[17] Face cover recommendations and mandates are part of the current set of measures, following earlier social distancing measures such as school and nonessential business closures, bans on large gatherings, and shelter-in-place orders being considered by states and local governments, especially as regions of the country reopen. For example, during Virginia's phase one reopening, begun May 22, 2020, everyone in the state was required to wear a face mask in public where people congregate.[18] Even though more states have issued such orders since the study was completed, it is critical to provide direct evidence on this question not only for public health authorities and governments but also for educating the public.

Study Data And Methods

DATA We collected information on statewide face cover mandate orders from public data sets on such policies and from searching and reviewing all state orders issued between April 1 and May 21, 2020. Our study focused on state executive orders or directives signed by governors that mandate use. Recommendations or guidelines from state departments of public health were not included, as these largely follow the CDC guidelines and might not necessarily add further information or impact. See online appendix A for a more detailed description of the data sources and measuring of the mandates.[19]

States differ in whether or not they require their citizens to wear face masks (covers) to limit COVID-19 spread. Between April 8 and May 15, governors of fifteen states and the mayor of Washington, D.C., signed orders mandating all individuals who can medically tolerate the wearing of a face mask do so in public settings (for example, public transportation, grocery stores, pharmacies, or other retail stores) where maintaining six feet of "social distance" might not always be practicable. These sixteen jurisdictions also have specific mandates requiring employees in certain professions to wear masks at all times while working.

In addition to these sixteen jurisdictions, twenty additional states have employee-only mandates (but no community mandate) requiring that some employees (for example, close-contact service providers such as in barber shops and nail salons) wear a face mask at all times while providing services. The face mask defined in these orders primarily refers to cloth face coverings or nonmedical masks. The state orders

strongly discourage the use of any medical or surgical masks and N-95 respirators, which should be reserved for health care workers and first responders. The orders also clearly specify that the face masks are not a replacement for any other social distancing protocols. More information on dates and links to these state orders are in appendix exhibit A1 and appendices D and E.[19] Fifteen states had not yet issued community or employee mandates when we performed the study.

The main model used publicly available daily county-level data of confirmed COVID-19 cases from March 25 through May 21.[20] The data covered all states plus Washington, D.C., and the analytical sample included 2,930 unique counties plus New York City (five boroughs combined). See appendix A for a more detailed description of COVID-19 data.[19]

STATISTICAL ANALYSIS We employed an event study, which is generally similar to a difference-in-differences design, to examine whether statewide mandates to wear face masks in public affect the spread of COVID-19 based on the state variations noted earlier. This design allowed us to estimate the effects in the context of a natural experiment, comparing the pre-post mandate changes in COVID-19 spread in the states with mandates versus changes in COVID-19 spread in the states that did not pass these mandates, over time. The model also tested whether states issuing these mandates had differential pre-event trends in COVID-19 rates before they were issued. This is a critical assumption of the validity of an event study that must be upheld under testing. In addition, the model allowed us to control for a wide range of time-invariant differences between states and counties, such as population density and socioeconomic and demographic factors, plus time-variant differences between states and counties, such as other mitigation and social distancing policies, in addition to state-level COVID-19 testing rates.

We estimated the effects of face cover mandates on the daily county-level COVID-19 growth rate, which is the difference in the natural log of cumulative COVID-19 cases on a given day minus the natural log of cumulative cases in the prior day, multiplied by 100.[21] This measure gives the daily growth rate in percentage points.

The reference period for estimating the face cover mandate effects was 1–5 days before signing the order. We examined how effects change over five post-event periods: 1–5, 6–10, 11–15, 16–20, and 21 or more days. The model also tested for pre-event trends over the course of 6–10, 11–15, and 16 or more days before signing the mandate. For all counties in the analytical sample, the main model included daily data from March 31 (seven days before the first state signed a face cover mandate) through May 22. The models were estimated by least squares weighted by the county's 2019 population with heteroscedasticity-robust and state-clustered standard errors.

As noted earlier, all of the fifteen states plus Washington, D.C., that mandated face cover use in public also mandated employee mask use. To assess the effects of employee face cover mandates, we employed another event study model that focused solely on the employee face cover mandate as the policy intervention. In this analysis, we excluded the sixteen jurisdictions that enacted both public and employee face cover mandates and focused on the twenty states that enacted an employee-only mandate and the fifteen states with neither a public nor an employee mandate.

LIMITATIONS We were unable to measure face cover use in the community (that is, compliance with the mandate). As such, the estimates represent the intent-to-treat effects of these mandates—that is, their effects as passed and not the individual-level effect of wearing a face mask in public on one's own COVID-19 risk. Related, we did not measure enforcement of the mandates, which might affect compliance. We also did not have data on county-level mandates for wearing face masks in public. In some states without state-level mandates at the time of our study, such as California,[22] Texas,[23] and Colorado,[24] multiple counties had enacted such mandates. These county-level mandates did not bias the intent-to-treat estimates of effects of state-level mandates as actually passed, but they added local-level heterogeneity not directly accounted for in the model. We did examine the robustness of estimates to the exclusion of some of these states. Finally, we were able to examine only confirmed COVID-19 cases. However, there is evidence of a higher infection rate in the community than is reflected in the number of confirmed cases.[25]

Study Results

EFFECTS OF MANDATES FOR FACE COVERING IN PUBLIC Exhibit 1 plots the event study estimates of effects of state mandates for community face covering in public on the county-level daily growth rate of COVID-19 cases, with 95 percent confidence intervals, obtained from the main regression model (in appendix B),[19] using county-level daily data from March 31 through May22; appendix exhibit C1 (column 1) reports the exact estimates. The effects are shown over the course of five periods after signing the orders, relative to the five days before signing (which is the reference period). Also shown

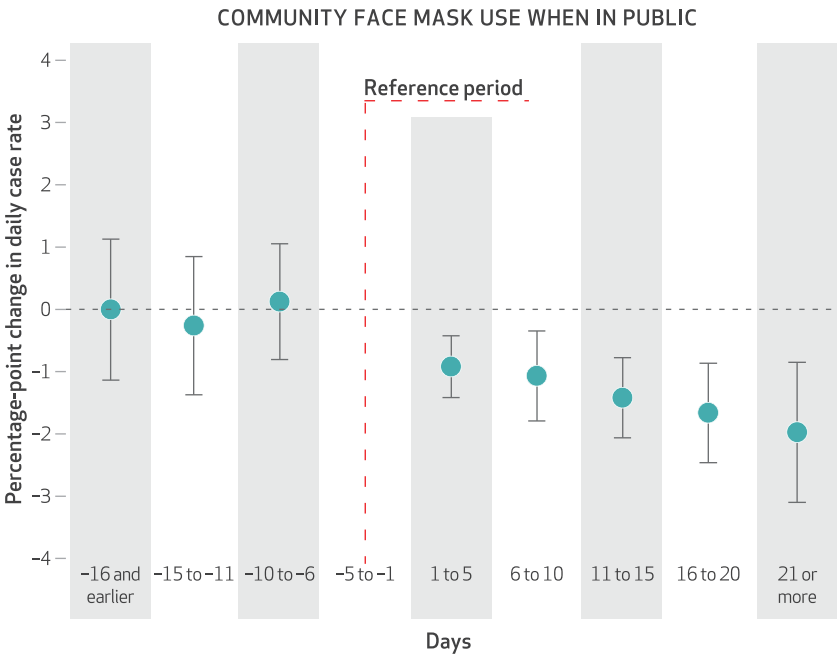
EXHIBIT 1

Event study estimates of the effects of states mandating community face mask use in public on the daily county-level growth rate of COVID-19 cases, 2020



SOURCE Authors' analysis of US county-level COVID-19 case data between March 31 and May 22, 2020. **NOTES** Event study estimates (dots) and 95% confidence intervals (bars) of the effects of states mandating community use of face covers or masks when people are in public on the county-level daily growth rate of COVID-19 cases over different periods before and after the mandate order was signed. The reference period was the first five days before the mandate order was signed. The model controlled for major COVID-19 mitigation policies as time-varying (closure of K–12 schools, county-level or statewide shelter-in-place orders, nonessential business closure, closure of restaurants for dining in, closure of gyms or movie theaters), COVID-19 tests per 100,000 people, county fixed effects, and day fixed effects. The model was estimated by least squares weighted by the county 2019 population, and the standard errors were robust to heteroscedasticity and clustered at the state level.

are estimated differences in daily COVID-19 growth rates between states with and without the mandates over the course of three periods before the reference period.

There was a significant decline in daily COVID-19 growth rate after the mandating of face covers in public, with the effect increasing over time after the orders were signed. Specifically, the daily case rate declined by 0.9, 1.1, 1.4, 1.7, and 2.0 percentage points within 1–5, 6–10, 11–15, 16–20, and 21 or more days after signing, respectively. All of these declines were statistically significant ($p < 0.05$ or less). In contrast, the pre-event trends in COVID-19 case growth rates were small and statistically insignificant.

We also projected the number of averted COVID-19 cases with the mandates for face mask use in public by comparing actual cumulative daily cases with daily cases predicted by the model if none of the states had enacted the public face cover mandate at the time they did (see details in appendix B).[19] The main model estimates suggested that because of these mandates, 230,000–450,000 cases may have been averted by May 22. Estimates of averted cases should be viewed cautiously and only as general approximations.

ROBUSTNESS CHECKS We estimated multiple extensions of the main event study model to assess the robustness of estimates to different model specifications and sample choices. These checks started the event study on March 26; added flexible controls for social distancing measures, state reopening measures, employee face mask use mandates, and county-specific time trends; and allowed time trends to vary by sociodemographic indicators. Other checks used the mandate effective date instead of the signing date, used hyperbolic sine transformation to account for zero cases, included states as the unit instead of counties, included only urban counties, and excluded some states without state-level mandates but with multiple counties having local mandates. The detailed description and results of these robustness checks are in appendix C.[19] The results were robust across these checks; effects were smaller when we used the effective dates instead of the signing dates, which differ by about two to three days, on average, suggesting earlier compliance, and when we used states as the unit of analysis. But the estimates remained meaningful and statistically significant in all checks.

EFFECTS OF EMPLOYEE-ONLY FACE COVER MANDATES As noted earlier, we also directly assessed the effects of states mandating only that certain employees wear face masks. Twenty states issued employee use mandates but not community use mandates. We reestimated the event study model described earlier for an employee-only mandate including those twenty states (issued between April 17 and May 9) and the fifteen states without mandates, and excluding the sixteen jurisdictions that issued both public and employee use mandates. Exhibit 2 plots the event study estimates of changes in county-level daily COVID-19 growth rates with the employee-only face cover mandates and their 95 percent confidence intervals. All pre- and postmandate estimates were small and insignificant. Overall, these results indicate no evidence of declines in daily COVID-19 growth rates with employee-only mandates.

Discussion

Around the world, governments have been fighting COVID-19 spread through a mix of policies and mitigation measures such as school and nonessential business closures and shelter-in-place orders. Some countries have also recommended or mandated widespread community use of face

Downloaded from HealthAffairs.org on January 23, 2021.

masks as a mitigation measure. However, the effectiveness of this measure is highly debated. The debate and uncertainty are fueled by the limited direct empirical evidence available on the magnitude of the effects of widespread face mask use in public on COVID-19 mitigation. There is a critical need for empirical evidence on the magnitude of these effects from natural experiments.[8] This evidence is especially relevant as governments reopen their economies and loosen social distancing restrictions while new infections continue to occur and while there is no vaccine or widely accessible or effective treatments in sight.

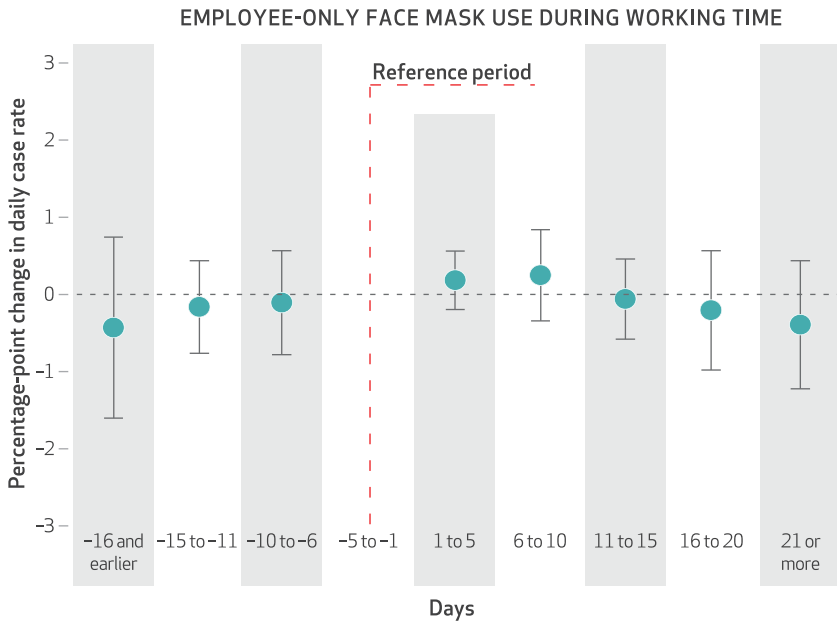
The study provides direct evidence on the effectiveness of widespread community use of face masks from a natural experiment that evaluated the effects of state government mandates in the US for face mask use in public on COVID-19 spread. Fifteen states plus Washington, D.C., mandated face mask use between April 8 and May 15. Using an event study that examined daily changes in county-level COVID-19 growth rates, the study found that mandating public use of face masks was associated with a reduction in the COVID-19 daily growth rate. Specifically, we found that the average daily county-level growth rate decreases by 0.9, 1.1, 1.4, 1.7, and 2.0 percentage points in 1–5, 6–10, 11–15, 16–20, and 21 or more days after signing, respectively.

These estimates are not small; they represent nearly 16 percent to 19 percent of the effects of other social distancing measures (school closures; bans on large gatherings; shelter-in-place orders; and closures of restaurants, bars, and entertainment venues) after similar periods from their enactment.[21] The estimates suggest that the effectiveness of and benefits from these mandates increase over time. By May 22, 2020, the estimates suggest that 230,000–450,000 COVID-19 cases may have been averted on the basis of when states passed these mandates. Again, the estimates of averted cases should be viewed cautiously, as they are sensitive to assumptions and different approaches to transforming the changes in the daily growth rate estimates to cases.

The early declines in the daily growth rate over the course of five days after signing the order are broadly consistent with the timing of the effects of other social distancing measures such as business closures.[21] Although the median incubation period is estimated to be around five days,[26] there is a wide range from 2.2 days (2.5th percentile) to 11.5 days (97.5th percentile), which suggests that for many people, symptoms may appear relatively early. Further, people may become aware of the mandates early through governors' briefings and related media reports, or they may be anticipating them.

EXHIBIT 2

Event study estimates of effects of states mandating only employee use of face masks during working time on daily county-level growth rate of COVID-19 cases



SOURCE Authors' analysis of US county-level COVID-19 case data between March 31 and May 22, 2020. **NOTES** Event study estimates (dots) and 95% confidence intervals (bars) of the effects of states mandating employee use of face covers or masks on the county-level daily growth rate of COVID-19 cases over different periods before and after the mandate order was signed. This model excluded fifteen states plus Washington, D.C., that made the use of face covering mandatory for both the general public and employees. The reference period was the first five days before the mandate order was signed. The model controlled for major COVID-19 mitigation policies as time-varying (closure of K–12 schools, county-level or statewide shelter-in-place orders, nonessential business closure, closure of restaurants for dining in, and closure of gyms or movie theaters), COVID-19 tests per 100,000 people, county fixed effects, and day fixed effects. The model was estimated by least squares weighted by the county 2019 population, and the standard errors were robust to heteroscedasticity and clustered at state level.

There is no evidence of differential pre-mandate COVID-19 trends with respect to issuing these mandates. The estimates represent the intent-to-treat effects of the statewide face cover mandates as passed, conditional on other national and local measures. In that way, the effects are independent of the CDC national guidance to wear face masks that was issued April 3, 2020.[12] These effects were robust to several model checks. The study provides evidence from a natural experiment on the effectiveness of mandating public use of face masks in mitigating the spread of COVID-19. We found no evidence for effects of states mandating employee face mask use, perhaps because many businesses themselves already required their employees to wear masks.[27,28] In that case, mandating employee mask use reinforce what many businesses already choose to do on their own.

Although the intent-to-treat estimates are of interest for understanding the effectiveness of

these policies in limiting COVID-19 spread at the community and population levels, understanding how their effects change with compliance and enforcement strategies is important for designing effective policies. Our study has built the first step in estimating the overall effect of these policies as enacted. However, these policies vary in their strictness and the consequences of noncompliance. The mandates generally require wearing a face mask in public whenever the social distance cannot be maintained. States such as Delaware, Maryland, Massachusetts, and Maine clarify what "public" areas are (for example, indoor space in retail establishments, outdoor space in busy parking lots and waiting areas for take-out services, semi-enclosed areas such as at public transportation stops, and enclosed spaces such as in taxis and other public transportation). The language on enforcement and penalties for noncompliance also vary. In states such as Delaware, Hawaii, Maryland, and Massachusetts, the face mask orders state that they have the force and effect of law, with a willful violation subject to a criminal offense with penalties. For example, the order in Maryland states that "a person who knowingly and willfully violates this order is guilty of a misdemeanor and on conviction is subject to imprisonment not exceeding one year or a fine not exceeding $5,000 or both."[29] In contrast, the orders of other states such as Connecticut, Maine, and Pennsylvania, although clearly mandating the wearing of a face mask in public, do not appear to clearly specify that violations of the order are subject to criminal offense or penalties. Future work should examine whether and how differences in strictness and enforcement modify the effects of these mandates.

Compliance and enforcement may also differ across contextual factors (such as other social distancing measures, workforce distribution, population demographics, and socioeconomic and cultural factors). In that regard, it is important to clarify that the suggested benefits from mandating face mask use are not substitutes for other social distancing measures; the effects are conditional on the other enacted social distancing measures and how communities are complying with them. It is also important to extend the evidence into additional measures of exposure to the virus in the community as data become available, such as from serological testing for antibodies. Finally, future work can examine effects on deaths, which lag cases and change not only with the number of cases but also with case severity.

Conclusion

The study provides evidence that US states mandating the use of face masks in public had a greater decline in daily COVID-19 growth rates after issuing these mandates compared with states that did not issue mandates. These effects were observed conditional on other existing social distancing measures and were independent of the CDC recommendation to wear face covers issued April 3, 2020. As international and state governments begin to relax social distancing restrictions, and considering the high likelihood of a second COVID-19 wave in the fall and winter of 2020,[30] requiring the use of face masks in public could help in reducing COVID-19 spread. ■

Trends in COVID-19 Incidence After Implementation of Mitigation Measures — Arizona, January 22–August 7, 2020

M. Shayne Gallaway, PhD[1,2]; Jessica Rigler, MPH[1]; Susan Robinson, MPH[1]; Kristen Herrick, MPH[1]; Eugene Livar, MD[1]; Kenneth K. Komatsu, MPH[1]; Shane Brady, MPH[1]; Jennifer Cunico[1]; Cara M. Christ, MD[1]

On October 6, 2020, this report was posted as an MMWR *Early Release on the* MMWR *website (https://www.cdc.gov/mmwr).*

Mitigating the spread of SARS-CoV-2, the virus that causes coronavirus disease 2019 (COVID-19), requires individual, community, and state public health actions to prevent person-to-person transmission. Community mitigation measures can help slow the spread of COVID-19; these measures include wearing masks, social distancing, reducing the number and size of large gatherings, pausing operation of businesses where maintaining social distancing is challenging, working from or staying at home, and implementing certain workplace and educational institution controls (*1*–*4*). The Arizona Department of Health Services' (ADHS) recommendations for mitigating exposure to SARS-CoV-2 were informed by continual monitoring of patient demographics, SARS-CoV-2 community spread, and the pandemic's impacts on hospitals. To assess the effect of mitigation strategies in Arizona, the numbers of daily COVID-19 cases and 7-day moving averages during January 22–August 7, 2020, relative to implementation of enhanced community mitigation measures, were examined. The average number of daily cases increased approximately 151%, from 808 on June 1, 2020 to 2,026 on June 15, 2020 (after stay-at-home order lifted), necessitating increased preventive measures. On June 17, local officials began implementing and enforcing mask wearing (via county and city mandates),* affecting approximately 85% of the state population. Statewide mitigation measures included limitation of public events; closures of bars, gyms, movie theaters, and water parks; reduced restaurant dine-in capacity; and voluntary resident action to stay at home and wear masks (when and where not mandated). The number of COVID-19 cases in Arizona peaked during June 29–July 2, stabilized during July 3–July 12, and further declined by approximately 75% during July 13–August 7. Widespread implementation and enforcement of sustained community mitigation measures informed by state and local officials' continual data monitoring and collaboration can help prevent transmission of SARS-CoV-2 and decrease the numbers of COVID-19 cases.

ADHS supports surveillance and investigation efforts of local public health departments, compiles surveillance and investigation information across counties, and provides infrastructure statewide to support infectious disease surveillance. Data on laboratory-confirmed and probable (*5*) COVID-19 cases (based on the Council of State and Territorial Epidemiologists case definitions)† were collected in the centralized Medical Electronic Disease Surveillance Intelligence System (MEDSIS),§ which is used by state, tribal, and county public health agencies to report human-based diseases in Arizona. Information was submitted to or entered into MEDSIS by health care providers, laboratories, local health departments, tribal entities, and ADHS. Multiple laboratory tests submitted for a single patient were combined into a single record. Specimen collection date was used for confirmed cases, and symptom onset date was used for probable cases.

Temporal trends were examined by comparing the number of daily COVID-19 cases (as of September 1)¶ and 7-day moving averages before, during, and after implementation of enhanced community mitigation measures, defined as the following: limitations on persons' time away from their place of residence except for essential activities; certain business closures and service limitations (e.g., occupancy limitations, curbside pickup, and delivery of goods); enhanced sanitation practices**; social distancing, employee mask wearing, and symptom screenings for all businesses operating a physical location; limitations on the occurrence and size of public events; and local mandates enforcing mask use. The 7-day moving average was calculated after the cumulative case count exceeded 20 cases and is presented to describe COVID-19 trends.

On March 11, 2020, Arizona declared a public health state of emergency to prepare for, prevent, respond to, and mitigate the spread of SARS-CoV-2. Additional guidance was provided to local officials, businesses, communities, and individual persons to implement social distancing and close schools statewide

* Mandates and ordinances varied and were county- and city-specific. Enforcement types included educating persons on the dangers of COVID-19 spread, issuing fines to persons and businesses who refused to comply with mandates, and loss of licenses for businesses not enforcing rules or mandates.

† https://cdn.ymaws.com/www.cste.org/resource/resmgr/ps/positionstatement2020/Interim-20-ID-02_COVID-19.pdf.

§ https://azdhs.gov/preparedness/epidemiology-disease-control/infectious-disease-services/index.php#medsis-faqs.

¶ https://www.azdhs.gov/preparedness/epidemiology-disease-control/infectious-disease-epidemiology/covid-19/dashboards/index.php.

** Based on guidance from ADHS, CDC, and the Department of Labor, and Occupational Safety and Health Administration to limit and mitigate the spread of COVID-19, including promoting healthy hygiene practices; and intensifying cleaning, disinfection and ventilation practices.

(March 15); postpone and limit large gatherings to fewer than 50 persons; recommend telework options; restrict access to congregate settings; require restaurants to provide dine-out options only; and close all bars, gyms, and movie theaters in counties with confirmed COVID-19 cases (March 19) (Table). Based on Arizona data and CDC guidance (*1*,*2*), ADHS also recommended limiting persons' time away from their place of residence except for essential activities (i.e., stay-at-home order, "Stay Home, Stay Healthy, Stay Connected")†† (March 31).

During April 1–May 15, the 7-day moving average of daily cases ranged from 154 to 443 (Figure). During April 29–May 11, Arizona initiated a phased approach for retail shops and stores, cosmetologists, and barbers to reopen and operate, and for restaurants to resume dine-in services; the stay-at-home order ended May 15.

Average daily cases increased 151% from June 1 (808) to June 15 (2,026), necessitating an increased focus on preventive measures by businesses, communities, and individual persons. Updated guidance from state officials provided local governments the authority to implement mask policies (June 17) and enforcement measures tailored to local public health needs (local policies were applicable to approximately 85% of the total Arizona population). Before June 17, mask wearing had not been widely mandated or enforced. Arizona limited organized public events to fewer than 50 persons (with some exceptions); closed bars, gyms, movie theaters, and water parks and recreational tubing facilities (June 29); and limited restaurants' indoor dining to <50% capacity, with at least 6 feet of separation between patrons (July 9). The 7-day moving average of daily cases peaked during June 29–July 2 (range = 4,148–4,377), stabilized during July 3–12 (range = 3,609–4,160), and subsequently decreased 75% from July 13 (3,506) to August 7 (867). Mitigation measures put in place in June were extended through August to further limit transmission.

Discussion

Quantitative data on the effectiveness of community mitigation measures at suppressing the spread of COVID-19 are limited. The primary goal of implementing widespread enhanced mitigation measures in Arizona was to protect and save lives and maintain capacity in the health care system. A combination of voluntary and enforceable measures is more effective than any single measure (*6*). Mitigation measures mandated through public policy can effectively increase social distancing (*7*), and wearing masks has prevented transmission of SARS-CoV-2 (*8*). In Arizona, decreases in daily COVID-19

†† https://www.azdhs.gov/preparedness/epidemiology-disease-control/infectious-disease-epidemiology/index.php#novel-coronavirus-admin-orders; https://azgovernor.gov/executive-orders.

TABLE. Public policies to implement and enforce COVID-19 community mitigation measures and dates of issue/reissue* — Arizona, March 11–August 7, 2020

Mitigation measure	Date of issue/reissue
Declaration of emergency	Mar 11
School closure (on-site learning)	Mar 15
Limits on senior living facilities visitation	Mar 19
Expanded availability and coverage for telemedicine for persons, pets, and animals	Mar 25, Apr 1
Deferred requirements to renew driver license	Mar 20
Stay-at-home order	Mar 30–May 15
Business/Service closures	
Bars	Mar 19, Jun 29, Jul 23
Movie theaters	Mar 19, Jun 29, Jul 23
Indoor gyms and fitness clubs	Mar 19, Jun 29, Jul 23
Restaurants, on-site dining	Mar 19
Pools	Mar 19
Water parks and recreational tubing facilities	Jun 29, Jul 23
Business/Service limits (requirements)	
All businesses operating a physical location (enhanced sanitation,† social distancing, employee mask wearing, symptom screenings)	Jun 17
Retail (limited capacity, social distancing, enhanced sanitation)	Apr 29
Barbers and cosmetologists (employee mask wearing, spaced appointments, enhanced sanitation)	May 4
Restaurants (social distancing, limited capacity, employee mask wearing, patron mask wearing [when not eating or drinking], employee screening, enhanced sanitation)	May 4, Jul 9
Public pools (e.g., at hotels; limited capacity)	Jun 29, Jul 23
Private pools in public areas (e.g., multihousing complexes; limited capacity)	Jun 29, Jul 23
Public events (<50 persons)	Mar 15, Jun 29, Jul 23
Wearing masks (mandatory)	
Local officials able to mandate and enforce wearing masks	Jun 17
Yuma County	Jun 18
Maricopa County	Jun 19
Pima County	Jun 19

Abbreviation: COVID-19 = coronavirus disease 2019.

* Issue dates are the dates the issuing official signed the order implementing the mandatory mitigation measure. In some instances, mitigation measures were effective either immediately or within 1 to 3 days of issue. https://www.azdhs.gov/preparedness/epidemiology-disease-control/infectious-disease-epidemiology/index.php#novel-coronavirus-admin-orders; https://azgovernor.gov/executive-orders.

† As of September 1, 2020. Specimen collection date was used for confirmed cases, and symptom onset date was used for probable cases.

§ Plotting of 7-day moving average began when cumulative case count exceeded 20 cases.

cases were observed after widespread sustained community mitigation measures that promoted social distancing, limited large gatherings, paused operations of businesses where mask use and social distancing were difficult to maintain, mandated and enforced mask wearing, and promoted voluntary resident actions to stay at home and wear masks (when and where not mandated). The number of COVID-19 cases stabilized and began to decrease approximately 2 weeks after local officials began mandating mask wearing (throughout several counties and cities) and enhanced sanitation practices. Additional declines in case counts were associated with implementation of statewide limitations and closures sustained throughout July and extended into August.

The findings in this report are subject to at least four limitations. First, the relationship between mitigation measures and changes in case counts are temporal correlations and should not be interpreted to infer causality. Other factors that might have influenced the rate of change (e.g., travel restrictions, neighboring state mitigation measures, and individual choices to reduce movement before implementation of mandates) cannot be ruled out. Second, health centers run by tribal entities and federal health facilities (i.e., Indian Health Service, Veteran's Administration, and Department of Defense) in the state are requested but not required to comply with state reporting rules. Many of these health centers and federal health facilities complied with reporting, but the completeness of reporting by these entities is unknown. Third, adherence to

Summary

What is already known about this topic?

Community mitigation measures can help slow the spread of COVID-19.

What is added by this report?

The number of COVID-19 cases in Arizona stabilized and then decreased after sustained implementation and enforcement of statewide and locally enhanced mitigation measures, beginning approximately 2 weeks after implementation and enforcement of mask mandates and enhanced sanitations practices began on June 17; further decreases were observed during July 13–August 7, after statewide limitations and closures of certain services and businesses.

What are the implications for public health practice?

Widespread implementation and enforcement of sustained community mitigation measures, including mask wearing, informed by state and local officials' continual data monitoring and collaboration can help prevent transmission of SARS-CoV-2 and decrease the numbers of COVID-19 cases.

mitigation measures was not assessed, nor could the extent to which each individual measure affected the number of incident COVID-19 cases be established. Finally, Arizona might not be representative of other U.S. states, and community mitigation measures might have a different impact in more populous or densely populated states; thus, these findings are not necessarily generalizable to other settings.

Enhanced mitigation measures should be implemented by communities and persons to slow COVID-19 spread, particularly before a vaccine or therapeutic treatment becomes widely available. State, local, and tribal officials are best positioned to continually monitor data and collaborate to determine the level and types of enhanced mitigation required. Mitigation measures, including mask mandates, that are implemented and enforced statewide appear to have been effective in decreasing the spread of COVID-19 in Arizona.

Introduction: Cloth face coverings and surgical masks have become commonplace across the United States in response to the SARS-CoV-2 epidemic. While evidence suggests masks help curb the spread of respiratory pathogens, research is limited. Face masks have quickly become a topic of public debate as government mandates have started requiring their use. Here we investigate the association between self-reported mask wearing, social distancing and community SARS-CoV-2 transmission in the United States, as well as the effect of statewide mandates on mask uptake. **Methods:** Serial cross-sectional surveys were administered June 3 through July 27, 2020 via web platform. Surveys queried individuals' likelihood to wear a face mask to the grocery store or with family and friends. Responses (N=378,207) were aggregated by week and state and combined with measures of the instantaneous reproductive number (R_t), social distancing proxies, respondent demographics and other potential sources of confounding. We fit multivariate logistic regression models to estimate the association between mask wearing and community transmission control (R_t<1) for each state and week. Multiple sensitivity analyses were considered to corroborate findings across mask wearing definitions, R_t estimators and data sources. Additionally, mask wearing in 12 states was evaluated two weeks before and after statewide mandates. **Results:** We find an upward trend in mask usage across the U.S., although uptake varies by geography and demographic groups. A multivariate logistic model controlling for social distancing and other variables found a 10% increase in mask wearing was associated with a 3.53 (95% CI: 2.03, 6.43) odds of transmission control (R_t<1). We also find that communities with high mask wearing and social distancing have the highest predicted probability of a controlled epidemic. These positive associations were maintained across sensitivity analyses. Segmented regression analysis of mask wearing found no statistical change following mandates, however the positive trend of increased mask wearing over time was preserved. **Conclusion:** Widespread utilization of face masks combined with social distancing increases the odds of SARS-CoV-2 transmission control. Mask wearing rose separately from government mask mandates, suggesting supplemental public health interventions are needed to maximize mask adoption and disrupt the spread of SARS-CoV-2, especially as social distancing measures are relaxed.

Introduction

In December 2019, SARS-CoV-2 and the resulting COVID-19 disease were first identified in Wuhan, China[1]. The disease has spread globally since its identification, causing widespread morbidity and mortality[2,3]. In the absence of a vaccine or curative therapy, governments in the United States and worldwide have adopted numerous approaches to curb the virus's continued transmission[4,5]. Despite widespread implementation, the efficacy of various nonpharmaceutical interventions has been intensely debated[6], resulting in significant individual and community heterogeneity in the acceptance of these interventions[7], including the use of face masks and respirators[8].

Evidence strongly supports N95 respirators as an effective method to prevent viral respiratory transmission, but supply chain shortages necessitate their preferential allocation to high-risk, front-line medical personnel[9,10]. Consequently, cloth face coverings and surgical masks (henceforth collectively, "face masks") are recommended as an alternative for the general public[11]. Following the initial spread of the virus in the United States, many local and state jurisdictions have mandated the use of face masks in public settings[5]. These masks are intended to serve as a mechanical barrier that absorbs virus-laden droplets expelled by the user[12]. Therefore, their purpose is to reduce transmission events by the user, rather than protect the individual from infection. Accordingly, face masks are advocated as a source of collective benefit, akin to herd immunity with vaccination, which is most successful with high levels of adoption[13].

Real-world evidence on the effectiveness of face masks at preventing respiratory transmission of SARS-CoV-2 is limited but growing[11,14]. While work on other respiratory infections[15] and two recent case reports[16,17] suggest mask usage may be effective, a recent global analysis found a limited marginal effect of mask mandates in the presence of other interventions[18]. Here, we use an ecological approach to assess mask compliance directly, irrespective of mandates. We combine survey data on personal mask wearing habits across the United States with a time varying measure of transmission control, as quantified by the effective reproductive number (R_t) in each state. We then evaluate the association of a change in mask wearing with the timing of mask mandates to better understand the conflicting evidence.

Materials and Methods

Survey Description

A web survey hosted on SurveyMonkey.com was deployed and promoted in conjunction with COVIDNearYou (a Boston Children's Hospital based digital surveillance platform), as part of an effort to increase participatory syndromic surveillance for COVD-19[19–21]. The survey data were collected through SurveyMonkey's "end page river sampling" [www.surveymonkey.com/mp/survey-methodology]. Briefly, over 2 million people around the world complete surveys designed by individuals, community groups, and businesses using the SurveyMonkey online survey platform every day. At the completion of these surveys, respondents in the United States are randomly offered to participate in the COVIDNearYou web survey. The river sample is not a stochastic probability sample of the entire population; however, it reaches respondents with diverse geographic and demographic backgrounds to ensure broad representativeness. Responses to this questionnaire were collected between June 3, 2020 and July 27, 2020 in all 50 states and the District of Columbia. Respondents were not provided incentives to complete the questionnaire. This study was approved by the Boston Children's Hospital Institutional Review Board.

Survey responses were analyzed using crude data (unweighted) and survey weights that reflect the demographic composition of the United States. Survey weights standardize for age, race,

medRxiv preprint doi: https://doi.org/10.1101/2020.08.23.20078964.this version posted August 28, 2020. sex, education, and geography using the Census Bureau's American Community Survey. Also included was an additional smoothing parameter for political party identification based on aggregates of SurveyMonkey research surveys, refreshed weekly with rolling two-week aggregated data. Weights are generated daily for weekday surveys and once after weekend surveys.

Mask Wearing Exposure

Survey respondents were asked a range of questions (full survey: www.surveymonkey.com/r/COVIDNearYouSurveyMonkey) including how likely they were to wear a mask while "grocery shopping" or "visiting family and friends" on a 4-point scale, from "very likely" to "not likely at all". A composite exposure of consistent self-reported face mask wearing (referred to as *mask wearing*) is defined as the percentage of respondents who replied "very likely" to both questions. The percentage of respondents who replied "very likely" to each question, separately, was also evaluated in sensitivity analyses. Surveys without responses to either question (N=4,186) were excluded. For validation, the exposure was aggregated by county (limited to those with over 50 observations, N = 324) between July 2 and July 14, 2020 and compared against cross-sectional New York Times and Dynata interviews on mask wearing[8] completed during this time period.

Social Distancing Exposure

Population-level social distancing by state and by week was quantified as the duration of time spent at home compared to baseline (defined as January 3, 2020 - February 6, 2020)[22]. Duration of time spent at home was estimated with the Google community "residential time" mobility measure[23], which was estimated using anonymized and aggregated data from individual Google users who opted into location history on their mobile devices[24]. A measure of social distancing from Facebook's COVID-19 symptom survey[25] was included in a sensitivity analysis. Individuals were asked "In the past 24 hours, with how many people have you had direct contact, outside of your household," in a variety of settings. The number of self-reported contacts at "social gatherings" (censored outlier responses) was aggregated over each week and state utilizing Facebook's weighted sampling scheme[25].

Community Transmission Control Outcome

The daily estimated instantaneous reproductive number (R_t) – the number of secondary cases arising from a single case for a given day – was used to measure state-specific community transmission control. R_t was aggregated to the week and dichotomized as epidemic slowing (1 if $R_t < 1$) or maintenance/growth (0 if $R_t \geq 1$). R_t estimates were extracted from rt.live, which was fit to case data from The COVID Tracking Project (method and adaptation previously described[26–28]). Sensitivity analyses were performed with R_t values extracted from epiforecasts.io[29,30] (available through July 19, 2020) and with R_t dichotomized at different cutoffs.

Modelling Mask Effectiveness on Transmission Control

We fit multivariate logistic regression models using *R* (version 3.6.2) to predict the community transmission control outcome (dichotomized R_t) using state- and week-specific estimates of mask wearing (crude and survey-weighted) and social distancing (relative residential time). State population density was included as a potential confounder given the association between population structure and SARS-CoV-2 transmission[31,32] as well as the association between urban versus rural regions and face mask usage[8]. Percent non-white was included as a confounder due to the relationship with epidemiological indicators of SARS-CoV-2[33] and uptake of non-pharmaceutical interventions[34]. A linear weekly time trend was also modeled.

medRxiv preprint doi: https://doi.org/10.1101/2020.08.23.20078964.this version posted August 28, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. It is made available under a CC-BY 4.0 International license .

To address the potential of reverse causation, where high previous transmission induced elevated mask wearing as well as lower potential R_t (due to reduced effective contact availability), we included each state's peak R_t from March-May 2020 as a confounder in a sensitivity analysis. We also evaluated an interaction between the exposures of mask wearing and social distancing.

For each model, influential observations (up to n = 24) with a Cook's distance over 4/N were excluded[35]. The influential observations removed varied between models, except for observations from New Jersey (characterized by high mask wearing, very high social distancing, and high community transmission control) which were repeatedly excluded for influence. Serial correlation was assessed in the final models but was abated following the aggregation of data.

Two additional modeling frameworks were utilized in sensitivity analyses. While each survey consisted of an independent sample of respondents, a mixed model with a random intercept for state and the same fixed effects as reported in the crude logistic model (model 1) was fit to account for the potential hierarchical structure of the observations. Additionally, an ordinal logistic regression was fit to measure the association of mask wearing with multiple, ordered categories of R_t.

Mask Mandates

The date for each statewide mask mandate was extracted from the masks4all.org database[36]. To assess the effect of mask mandates on mask wearing, segmented regression[37] was run comparing the 2 weeks preceding and 2 weeks following each state's intervention.

Results

Self-reported mask wearing was evaluated using N=378,207 survey responses recorded between June 3, 2020 and July 27, 2020. Most (84.6%) reported "very likely" to wearing a face mask to the grocery store, while just under half (40.2%) did so to visit friends and family. A similar number (39.8%) reported they were very likely to wear a mask to the grocery store and with family and friends. Very few (4.7%) reported they were "not likely [to wear a mask] at all" in either situation. The percentage of individuals in each county who reported "always" wearing a mask in the New York Times interviews was correlated with those who reported they were "very likely" to wear a mask to the grocery store (Spearman's ρ = .80, p<0.0001), with family and friends (Spearman's ρ = .57, p<0.0001), and the composite score (Spearman's ρ = .57, p<0.0001).

Mask wearing was higher among women, elderly, non-white or Hispanic, and lower income respondents (p<0.0001, **Table 1**). There was substantial geographic heterogeneity in survey responses (**Figure 1**, **A.**), with the highest percentage of mask wearers along the coasts and southern border, as well as in large urban areas. There was a general trend of increased mask use across U.S. Census Divisions throughout the survey period (**Figure 1**, **B.**) and the West North Central Census Division reported the lowest mask usage across the entire period surveyed.

We find a negative relationship between the mean percentage of people that report wearing a mask and the instantaneous reproductive number (**Figure 2)**. In a multivariate logistic regression model adjusting for confounders, social distancing and a time trend, there is a significant association between percent reporting mask wearing and community transmission control (i.e. R_t<1) with an OR = 1.14 [95% CI: 1.07,1.20] (**Table 2, Model 1**). A 10% increase in mask wearing was associated with an over three-fold increase in odds of transmission control [OR = 3.53, 95% CI: 2.03, 6.43]. The association between mask wearing and community

medRxiv preprint doi: https://doi.org/10.1101/2020.08.23.20078964.this version posted August 28, 2020. The copyright holder for this preprint

It is made available under a CC-BY 4.0 International license .

transmission control was robust to changes in definitions of mask wearing, R_t estimated from epiforecasts.io, control for peak R_t, and survey-weight standardization (**Table 2, Models 2-6**). When adjusting for community self-reported contacts instead of mobility, the association between one percent change in mask wearing and community transmission control was attenuated [OR = 1.09, 95% CI: 1.02, 1.16], but remained significant (**Figure S1**). Mask wearing was also significantly associated with reduced transmission across multiple R_t dichotomization thresholds (**Figure S2**) and when categorized as an ordinal variable (**Figure S3**). A mixed model with a random intercept for state found a stronger association of mask wearing on community transmission control [OR = 1.18, 95% CI: 1.07, 1.30].

Communities with high levels of mask wearing and social distancing are predicted by the model to have the highest probability of community transmission control (**Figure 3**). States with the highest percentage of reported mask wearing but lowest levels of social distancing have less than a 35% probability of community transmission control, though there are wide confidence intervals. The interaction between social distancing and mask wearing was not statistically significant (**Table 2, Model 7**).

We evaluated the change in mask wearing in the 2 weeks before and after statewide mask mandates for 12 states (**Figure 4**). While there was a general trend of increased mask usage across these states over time, the linear segmented regression models resulted in no significant change in slope in crude, β = .04 [95% CI: -.47, .54], or weighted, β = .31 [95% CI: -.28, .91], mask usage following the interventions. There was a non-significant 2.2% [95% CI: -2.1%,6.5%] change in average mask usage following the mandate in the unweighted model and a 2.31% [95% CI: -2.76%,7.38%] change in the weighted model.

Discussion

The effect of mask wearing on community transmission of SARS-CoV-2 has been the subject of substantial debate, despite evidence from detailed transmission studies and population-wide data from other respiratory pathogens. Here we present findings from over 300,000 serial cross-sectional surveys administered daily in June and July 2020 that confirm a high percentage of reported face mask wearing is associated with a higher probability of transmission control in U.S. states. Face mask wearing was more commonly reported among certain socio-economic groups (especially non-white and lower-income respondents). However, the impact of face mask wearing on lowering the instantaneous reproductive number below one – the threshold required for transmission control – remained despite adjusting for demographics, social distancing and prior peak transmissibility.

Mask wearing is shown to increase the odds of transmission control across all levels of social distancing, suggesting that any intervention to improve this community-based behavior may be worthwhile. The absence of a statistical change in mask wearing the two weeks following state-wide mandates highlights the point that regulation alone may not drive increased masking behavior. However, we found that there is a general increase in mask wearing prior to the implementation of these policies and mask mandates may be important tools in maintaining this trend. Masking behavior assessed from anonymous surveys may provide insight into where education or other interventions should be directed. These results are consistent with case studies of mask wearing in the United States[16,17], and potentially provide some insight into why one report found no substantial effect of mask mandates in conjunction with other interventions[18]. The data presented here may highlight a gap between governmental policy and actual user behavior, but more research is needed.

medRxiv preprint doi: https://doi.org/10.1101/2020.08.23.20078964.this version posted August 28, 2020. Our evidence supports the role of mask wearing in controlling SARS-CoV-2 transmission; however, this ecological study cannot inform questions of causality. It is difficult to disentangle individuals' engagement in mask wearing from their adoption of other preventative hygiene practices, and mask wearing may be serving as a proxy for other risk avoidance behaviors not queried (e.g. avoiding indoor spaces) – especially considering the magnitude of the reported effects. While our findings remained despite controlling for individual-level contacts from the Facebook survey, a proxy that likely includes other aspects of risk reduction, the possibility of residual confounding is likely. Additionally, observations from smaller states are overrepresented when results are aggregated at the state-level and further observations from survey respondents may not reflect the general population. However, our findings were consistent even with application of US census-based survey-weights.

A state that demonstrates social distancing may also be subject to additional non-modeled but impactful interventions including gathering size reductions, travel limitations, and the closing of businesses[38]. While the social distancing proxy used here captures the broad activity level that would result from the implementation of these policies, future research should focus on incorporating data from disaggregated interventions with empirical assessments of mask wearing. Additionally, potential R_t and mask wearing within a state may be the result of prior transmission. While we showed the effect of mask wearing was robust to peak R_t in the first wave of the epidemic, our methods do not control for time-dependent confounding or variations in mask usage by susceptibility status.

The validity of epidemiologic parameters of transmission are only as accurate as the incidence data to which the models are fit. If states reporting low mask wearing also underreport incidence (e.g. limited testing), we may be underestimating the true effect of mask wearing. Conversely, instantaneous R_t estimations of transmission are subject to uncertainty, especially towards the end of the time-series before reports are complete[27]. While our results were robust to different estimators, our model does not account for estimation error. Additionally, mask wearing measures, social distancing and R_t all exhibit significant temporal autocorrelation. To combat this, we dichotomized R_t and aggregated our exposures by week, but further analyses may consider complex time-series models, mechanistic and quasi-experimental methods to estimate the effect of face masks.

We find a community benefit for "face masks" which collectively include masks of various hypothesized efficacies[39]. We did not query specific mask type or the use of face shields in conjunction with masks. The reported association may understate the maximum potential for face masks to curb respiratory transmission, which can only be realized through increasing the utilization of superior mask materials (i.e. choosing surgical masks over fleece gaiters). Additional study of effect modification by mask type is necessary to estimate true causal effects.

When considering the various challenges the US population has faced in slowing the spread of SARS-CoV-2, evidence on the impact of nonpharmaceutical interventions is paramount. Our data suggest widespread use of face masks by the general public may aid in limiting the SARS-CoV-2 epidemic as social distancing restrictions are rolled back around the United States. Given mixed evidence on the effect of mask mandates, but a strengthening body of evidence on the effect of masks, policy makers should consider innovative strategies for evaluating and increasing mask usage to help control the epidemic.

BMR, LFW and JSB conceived of the study. BMR, LFW, CMA and JSB wrote the first draft of the manuscript. BMR, LFW, MRB, and CMA contributed to the data analysis. JC, JB and JC oversaw and implemented data collection. All authors contributed to the interpretation of the data and editing of the final manuscript. All authors have seen and approved the manuscript.

Declaration of Interests

LB sits on the board of Ending Pandemics and the Skoll Foundation.

Table 1. Characteristics of Unweighted Survey Respondents by Mask Wearing Status

Characteristics of Unweighted Survey Respondents by response to the question, “how likely are you to wear a face mask to visit family and friends.” For each response, N (row %) and p-value from χ^2 test is presented. Overall N (column %) also included for each category.

How Likely Are You To Wear a Face Mask To Visit Family and Friends?

Table 2. Regression Results

Estimated odds ratios [95% confidence intervals] from multivariable logistic regression models. Model 1 reports the association of the outcome of community transmission control (R_t<1) with the percentage of surveys reporting “very likely” to wear a mask to the grocery store and to visit family and friends, aggregated by state and week. Model 1 controls for a weekly time trend, social distancing (relative Google mobility “residential time”), percentage non-white and population density. We evaluated the association using survey weights (Model 2), alternative estimators of R_t (Model 3), and alternative definitions of mask usage (Models 4 and 5). Model 6 accounts for each states peak R_t prior to the start of the study and model 7 includes an interaction of mask wearing with social distancing.

Figure 1. Mask wearing across three-digit zip code and time

The percentage of individuals who responded they were very likely to wear a mask to the grocery store and with family and friends was averaged across the entire study period and each 3-digit ZCTA prefix (fuzzy matched with reported zip code) in the United States (Panel A). ZCTA clusters with less than 50 responses are shown in gray. Observations of mask wearing were also aggregated at the daily level across each Census division for the study period (Panel B).

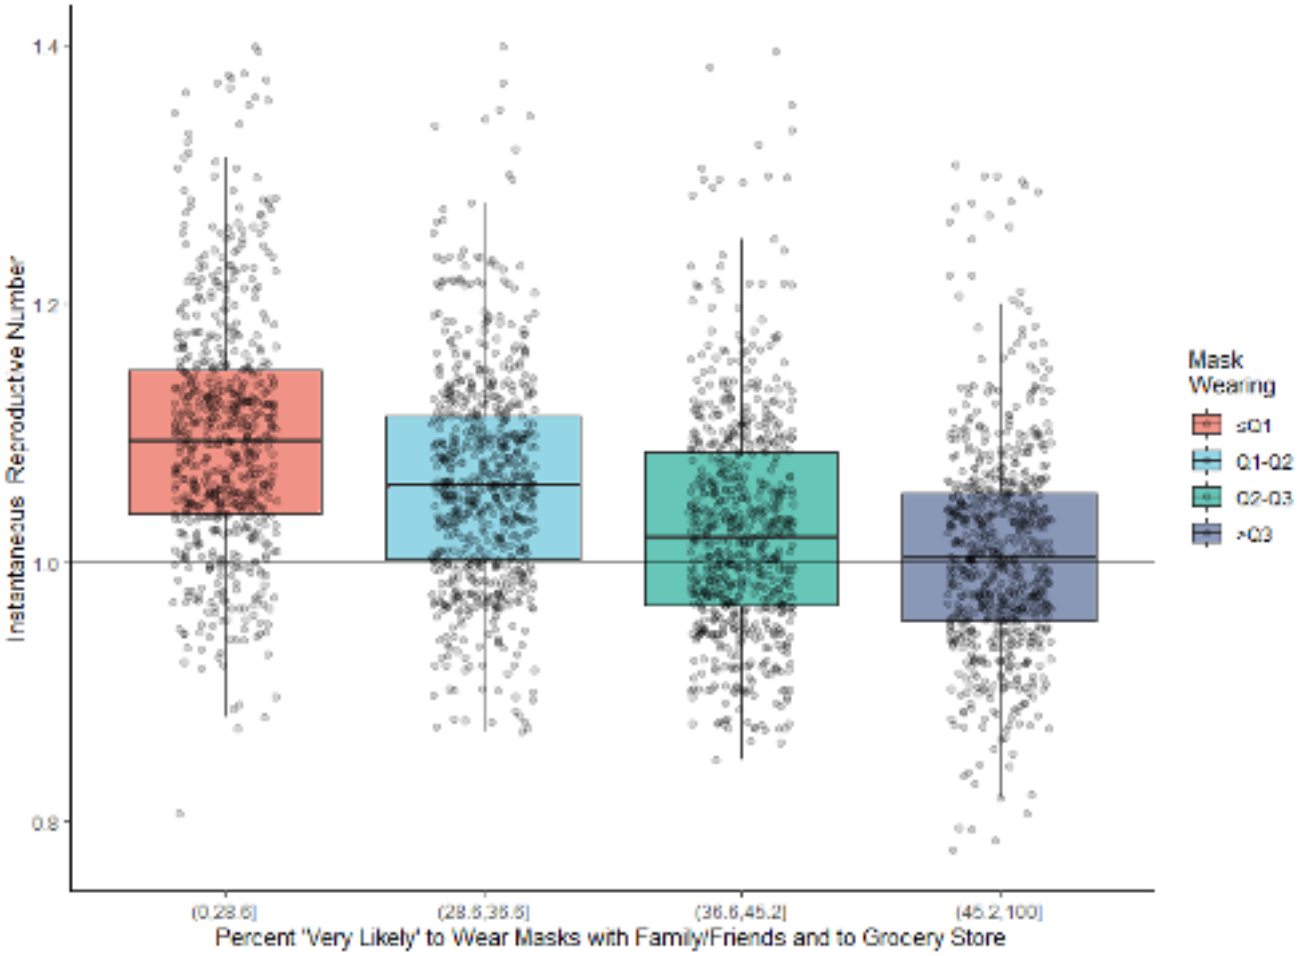
Figure 2. Mask Wearing and the Effective Reproductive Number

Box (median and IQR) and whiskers (minimum and maximum excluding outliers) of R_t estimates (rt.live) for each week and state (grey circles). Plot is stratified by quartiles (Q1: 28.8%, Q2: 36.6%, and Q3: 45.2%) of the percentage of individuals that report they are very likely to wear a mask with family/friends and to the grocery store.



medRxiv preprint doi: https://doi.org/10.1101/2020.08.23.20078964.this version posted August 28, 2020. The copyright holder for this preprint

Figure 3. Mask Wearing, Social Distancing and the Predicted Probability of R_t below 1

Projected values from a logistic regression model measuring the association of community transmission control (R_t <1) with mask-wearing and social distancing in US states adjusting for population density, percent non-white and a time trend (Model 1). Values of social distancing are from the Google Community reports of relative residential time and represent no change from baseline, the national median during the study period (June 3 – July 31, 2020), and 97.5th percentile observed during the study period. Observed mask wearing was between 8.1%-73.7%, so estimates outside this range are model-based extrapolations. Horizontal line placed at 80% probability of community transmission control, though the desired % may be higher.

Figure 4. Mask Wearing in 14 Days Preceding and Following Statewide Mask Mandates

Daily measure of the percentage of individuals that report they are very likely to wear a mask with family/friends and to the grocery store in 12 states. Values are for the 14 days preceding and following each state's institution of a statewide mask mandate. The mean daily value across all states is presented for the same timeframe.

Supplementary Materials

Figure S1. Mask Wearing, Social Contacts and the Predicted Probability of *Rt* below 1

Projected values from a logistic regression model measuring the association of community transmission control (R_t <1) with mask-wearing and social contacts in US states adjusting for population density, percent non-white and a time trend (Model 1). The number of self-reported contacts at "social gatherings" from Facebooks' COVID-19 symptom survey was aggregated over each week and state utilizing a weighted sampling scheme.

Figure S2. Association of mask wearing with R_t at different dichotomization cutoffs

Results from a logistic regression model measuring the association of community transmission control ($R_t < x$) with mask-wearing adjusting for social distancing, population density, percent non-white and a time trend. Model was repeated as cutoff for R_t dichotomization (x) was varied. The odds ratio (point) and 95% confidence interval (-) for mask wearing that resulted from each iteration is shown.

Abstract: Many complex mathematical and epidemiological methods have been used to model the Covid-19 pandemic. We took a different approach. Making no assumptions, we simply plotted cases, hospitalizations and deaths, on a $\log_2$ Y axis and a linear date-based X axis, and analyzed them using segmented regression. The data fit straight lines with correlation coefficients ranging from 92% - 99%, and these lines broke at interesting intervals, revealing that school closings dropped infection rates in half, lockdowns dropped the rates 3 to 4 fold, and other actions (such as closing bars and mandating masks) brought the rates even further down. Hospitalizations and deaths lagged, but paralleled cases. The graphs, which are easy to read, have several implications for modeling and policy development during this and future pandemics. Overall three interventions had the most impact: closing schools, closing bars and wearing masks: a message easily understood by the public.

One Sentence Summary: Regression analysis showed that closing schools, closing bars, and wearing masks had major effects on infections, hospitalizations and death rates in the US during the Covid-19 pandemic.

NOTE: This preprint reports new research that has not been certified by peer review and should not be used to guide clinical practice.

Main Text: As of August 1st, 2020, the Covid-19 pandemic has been in effect for about six months in the US. Infection rates have climbed, fallen and climbed again, as different state governments ordered interventions to fight the pandemic, rescinded them to open their economies, and then (in some cases) reinstituted them as infections resurged. In this study, we analyzed the effects of those interventions using a simple approach. We started by asking if a pandemic in its earliest stages, when the population is completely naïve, might be described by simple kinetics similar to those that model chemical reactions in their earliest stages, before the increasing concentrations of reaction products begin to impinge on the reaction rate. Making no assumptions, we simply plotted the data for Covid-19 cases in several states in the USA as the pandemic evolved. We confined our analysis to the USA for several reasons. First, we did not think it wise to compare countries with different types of health systems. Second, in the absence of a coordinated federal response, different states made different policy decisions, on different dates; allowing for detailed local comparisons of states with strict and early lockdowns, states with no restrictions at all, and states with similar policies implemented at different times. Because of these state-to-state differences, we thought that an analysis done at the granular state level might be able to distinguish the results of different interventions from one another, and show which were most effective.

Our earliest plots indicated that the daily increases in cases during the initial days of the pandemic follow a purely exponential trajectory, regardless of country, state or county. We therefore plotted the data on a $\log_2$ Y axis, choosing $\log_2$, rather than the more standard $\log_{10}$, because it makes the doubling time easy to calculate (e.g. if a plot of new cases per day is a straight line and passes through three horizontal lines [2^3] in a period of 15 days, then the doubling time is 5 days. We also saw that the curves could be rendered as a series of straight lines that visually seemed to "break" into new straight lines with new slopes that seemed to correlate with changing government policies. To add rigor to our visual results, we used segmented regression analysis, a statistical method for determining discontinuous changes in slope. We found, for the first few months of the pandemic, that the data fit straight lines with R values usually greater than 92% - 99%, and that the breaks (slope changes) occurred at interesting and revealing intervals. For example, school closings reduced the rate of infections by half or more, with a 6-14 day delay. Lockdowns reduced the rates of infections by 2 to 4 fold, with a similar delay. Further actions (such as mandating masks or closing bars) similarly brought the rates further down with somewhat more variable lag times. Deaths, as expected, were a lagging indicator, but closely paralleled the other two main parameters (cases and hospitalizations) about one week later. This method remained useful even in later stages of the pandemic, as the country began to open up, as it enabled visualization of the effects of relaxing restrictions, and showed the mitigating effects of late interventions. The graphs, which are easy to read, show how various individual policy decisions reduced or increased the rates of new Covid cases, hospitalizations and deaths; and can potentially serve as the groundwork for future policy decisions during this and future pandemics.

Results:

Outlining the process for one state

We begin here with data from a single state, Maryland (MD), the home of the NIH, where we assumed we would have access to precise data (an issue with some states). We graphed cases, hospitalizations and deaths on a $\log_2$ Y axis, and applied segmented regression analysis to evaluate the accuracy of the visually estimated slopes and breakpoints.

Figure 1 displays a progression of graphs for the state from March 6, 2020, when the first three cases were reported, to April 15th. This simple method appeared to be adequate to model the data during this initial stage of the pandemic, and revealed some features that were not obvious from

other, more commonly used plots, most of which are plotted on linear Y axes[1-2] or, at best, on axes of Log_{10} (ref 3).

Because the total number of Covid-19 cases (Figure 1A, solid green line) tended to increase exponentially, resulting in a fairly straight line on the log_2 scale, we were able to determine from the slope (dashed green line) that the initial doubling time was 2.5 days. This rapid rate lasted until March 29, at which time it slowed to a doubling time of 4.7 days. This change occurred 15 days after schools closed, 12 days after bars and restaurants closed, and one day before the state lockdown, suggesting that the effect of one or both of the first two policy decisions was to reduce the doubling rate of cases to slightly more half of the original rate. Figure 1B shows that the slopes for hospitalizations and deaths followed the same pattern, with lag times of about three and eight days longer respectively than the lag times of positive cases. Figure 1C shows the effect of the lockdown in MD, which was followed twelve days later by an additional threefold change in doubling time, from 4.7 to 12.8 days, and similar rate reductions in hospitalizations and deaths with additional lags of 2 and 6 days respectively. Segmented regression analysis showed that the combined broken lines fit the data remarkably well, with R values well over 99 for total cases (99.89), for total hospitalizations (99.85) and total deaths (99.42). Figure 1D shows the data for daily new cases, whose slopes tend to change within a day of those for total cases, and undergo greater changes.

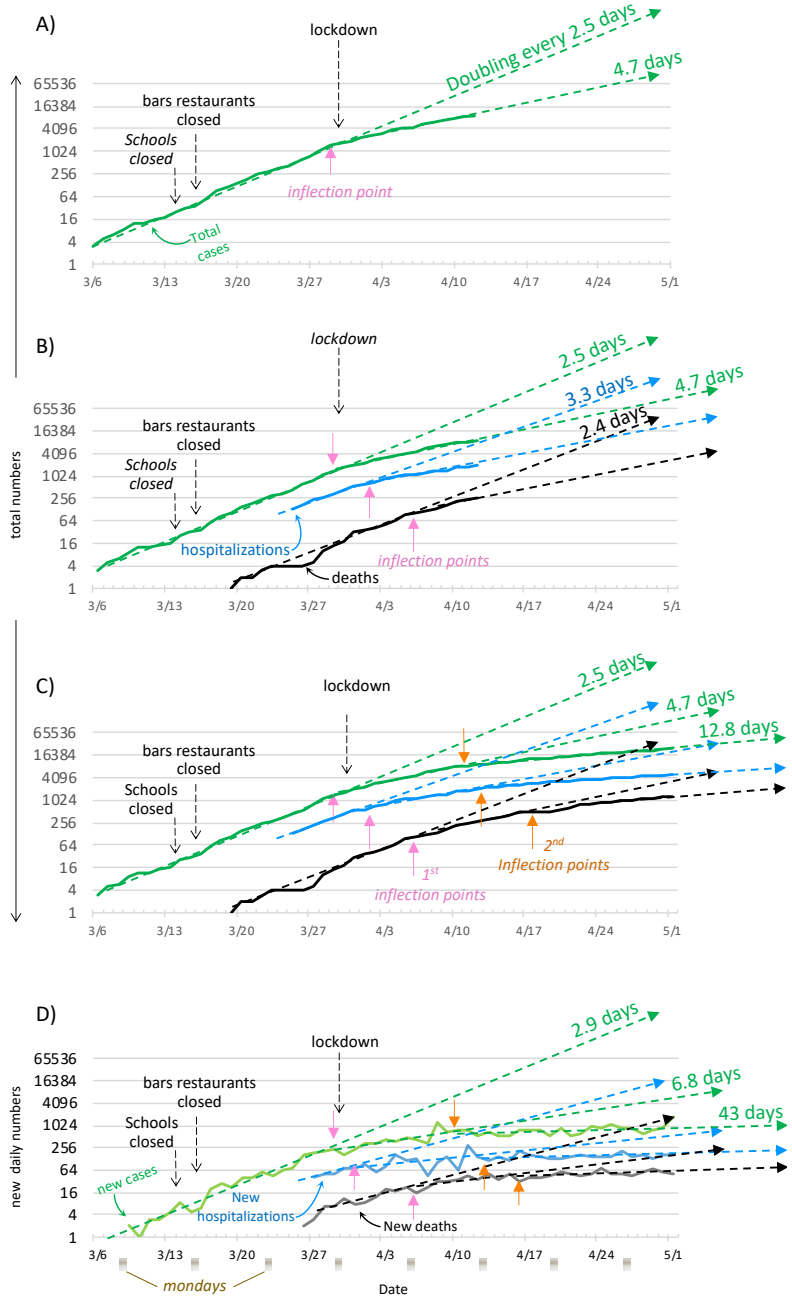

Figure 1) Laying out the process for one state (Maryland). (A-C) Graphs for total accumulating cases, hospitalizations and deaths. **(D)** graph of new daily cases, hospitalizations and deaths. Pink and Orange arrows =1st and 2nd inflection points respectively.
A) First rate drop: Initially Covid-19 cases double every 2.5 days. Then, 15 days after schools, bars & restaurants are closed (and one day before lockdown), the doubling rate slows to every 4.7 days.
B) Other parameters also drop. Hospitalization and death rates drop, 3 and 8 days respectively after the decline in cases.
C) 2nd rate drop: the lockdown is followed by a second rate decline to a doubling time of 12.8 days, for cases, hospitalizations and deaths at 12, 14 and 18 days later respectively
D) New daily cases: new cases, new hospitalizations and new deaths follow similar patterns. The data are less smooth, partly due to the smaller numbers and partly because reporting is lower on Sundays and Mondays (brown arrows) and rebound later in the week.

The fact that the inflection points for daily new cases often occur one day before those for total cases, rather than on the same day, and that the correlation coefficient value (96.99) is slightly lower than that for total cases, is likely due to the fact that daily new cases have a periodic dip on Sundays and Mondays, and then rebound slightly as the reporting catches up during the week. This variability results in a greater "fuzziness" that creates an uncertainty in the break points and a somewhat lower accuracy in the slopes. Nevertheless, the high correlation coefficients suggest that these slopes are good representations of the trends in the data.

Effects of School Closings and of Lockdowns

Because Maryland closed bars and restaurants just three days after closing schools, it was impossible to separate the effects of those two actions from each other. A recent study on closing schools[4] ran into the same problem. In fact, the near simultaneous execution of several different interventions by many states and countries has made it difficult to assess the value of any one particular intervention. We therefore asked if any state had witnessed changes in slopes after closing schools but before taking any other major action, such as closing bars and restaurants, closing essential businesses, or giving "stay at home" orders. We found three states with no mask mandates (Georgia, Tennessee, Mississippi), that had spaced their other interventions far enough apart to enable us to examine the effects of each by itself. (Fig2)

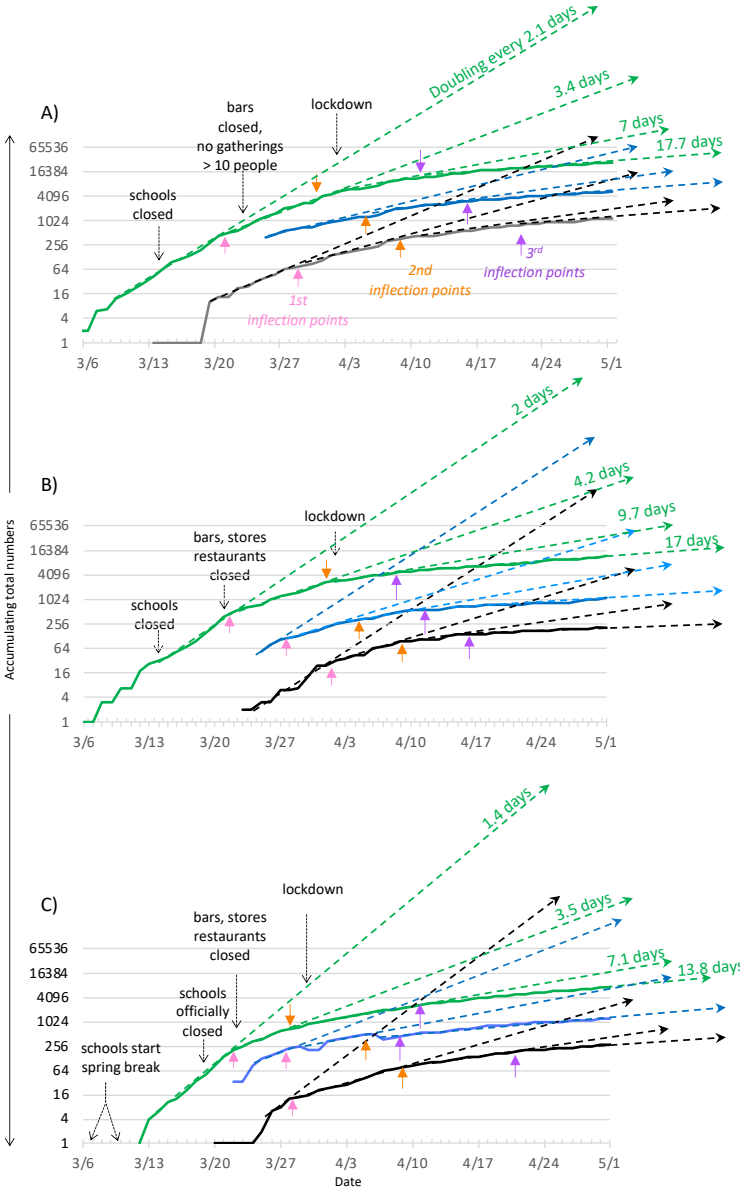

Figure 2: the effect of closing schools: graphs cover three states from 3/6/2020 to 5/1/2020. Colored arrows point to inflection points. Pink = 1st, orange = 2nd and purple = 3rd inflection point.
A) **Georgia:** Total cases and death rates decline 8 and 14 days, respectively, after school closings. Cases, hospitalizations and deaths drop again 11, 14 and 17 days, respectively, after closing bars, and again, with similar lag times, after lockdown. **B) Tennessee:** Total cases decline 8 days after school closings, again 11 days after non-essential businesses close, and again 7 days after lockdown. Hospitalizations and deaths follow with typical lag times. **C) Mississippi:** Case rates drop about 2 days after official school closings (10-12 days after the start of spring break), again 10 days after non-essential businesses close, and again 14 days after the lockdown. Hospitalizations and deaths follow with variable lag times.

Georgia (Figure 2A) officially closed schools on March 16[9]. However, the 16th was a Monday, and we therefore chose to specify Saturday, March 14th, as the school closing date, as this was the first day that children did not attend school. Seven days later, on March 21st, Georgia's initial doubling rate of 2.2 days for total positive cases dropped to a doubling time of 3.5 days. Two days after that, Georgia closed bars and restaurants, and this was followed eight days later

medRxiv preprint doi: https://doi.org/10.1101/2020.09.26.20202457; this version posted September 28, 2020. by a second change to a doubling time of 7.6 days. Two days after this second rate drop, the governor ordered a lockdown[11], which was followed by a third decline in the slopes after a lag of nine days. The observation that each change in doubling times occurred before the next government intervention suggests that each intervention is followed by its own rate change and that additional interventions have additional effects.

Two days after this second rate drop, the governor ordered a lockdown[11], which was followed by a third decline in the slopes, after a lag of nine days, to a doubling time of 17.7 days. The observation that each change in doubling times occurred before the next government intervention suggests that each intervention is followed by its own rate change and that additional interventions have additional effects.

Tennessee (Figure 2B) also closed schools on March 14th and saw a twofold drop 8 days later, the same day that bars, restaurants and non-essential business were closed. This second intervention was followed eleven days later by another twofold drop in rate. One day after this second drop, the governor issued a "stay at home" order[14], which correlated with a third drop 7 days later.

Mississippi (Figure 2C) was a puzzle at first, because the first rate drop occurred only two days after the official order to close schools[5]. Rather than dismiss this as a simple outlier - it was the only state among the 50 that had such a short lag time - we delved into other possible explanations, thinking that perhaps we were simply wrong, and some aspect of human behavior other than school closings was responsible for the first sets of rate reductions. Perhaps, Americans had simply started going out less, as suggested by the phone mobility data from Apple, Google and Cuebiq[6-8].

However, an analysis of the mobility data for Mississippi in comparison with other states (Supplemental Figure 1), showed no change in mobility that could underlie Mississippi's early rate change. We therefore looked for other factors, and discovered that spring breaks for Mississippi colleges[9] and K-12 schools[10] had almost all begun earlier than other states, with slightly variable start dates from March 6 to March 10. Although the K-12 breaks normally last only one week, the governor asked schools to extend their spring breaks because of the virus[11], and nearly all of the schools did not go back into session before he officially closed them on the 18th of March[5,12]. Consequently, the drop in the rate of cases that occurred on March 20th most likely resulted from the fact that children had stopped attending school 10-14 days earlier, rather than from the March 20th executive order to close schools.

Thus, for states that separated their government actions by a week or more, we were able to assess the effects of those actions individually. Closing schools appeared to cut the rate of infections in half, beginning 8-14 days post-closure, and similarly reduced hospitalizations, but with lag times 2-4 days longer than for positive infections. Deaths followed suit, lagging an additional 7-11 days.

Closing bars and restaurants and ordering lockdowns similarly reduced the rates of infections, with similar lag times. Cumulatively, these interventions resulted in 7-10 fold drops in the rates of infections, hospitalizations and deaths. Nevertheless, even when combined, these effects were frequently insufficient to result in a steady decrease in the daily tallies of new infections. For that we needed masks.

Mask Mandates

Although the federal government never mandated masks, and many government officials continued to eschew them, a few state governors wrote orders for their constituents to wear

medRxiv preprint doi: https://doi.org/10.1101/2020.09.26.20202457; this version posted September 28, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

masks. Unlike school closings, which occurred all over the US in the space of about two weeks, from March 6 (Mississippi) to March 23rd (Idaho), mask mandates were put in place over a longer time period, from March to July. This gave us an opportunity to evaluate both early and late mandates. We found that they were about equally effective (Figures 3 and 4).

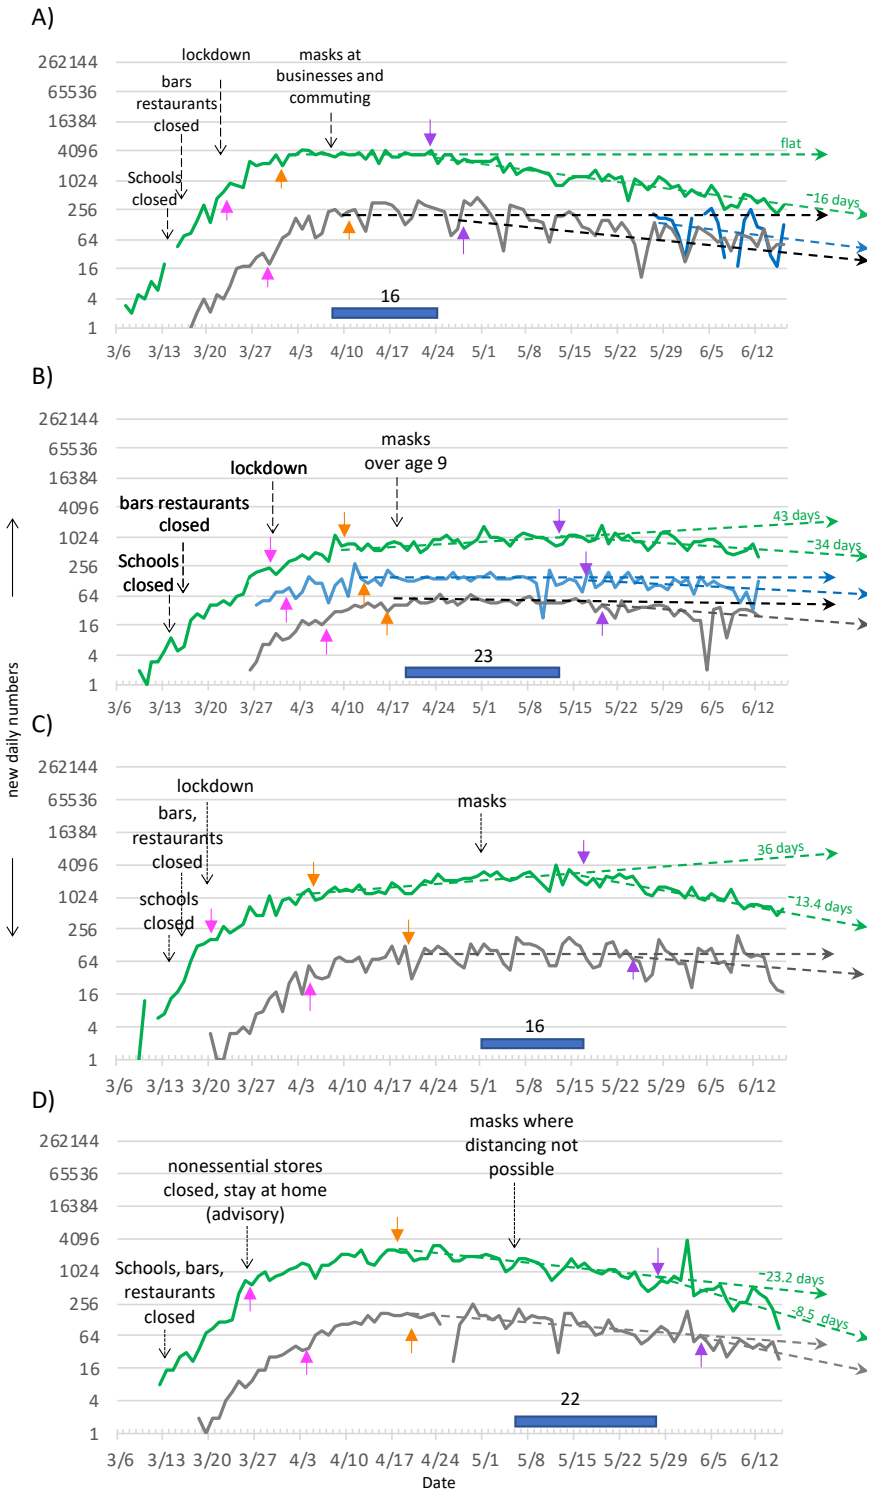

Figure 3 shows the effects of early mask mandates from four states that ordered the use of masks at times spanning a month, from April 8th to May 6th. We depict new daily numbers, as total numbers were high enough by this time to be slow to show intervention effects. Each state's mandate was followed by a drop in the rates of infections, and then by drops in the rates of hospitalizations (where reported) and deaths, showing that the effect of mandating masks is to drop the slopes about 2 fold. As the mandates stepped through time, the rate reductions followed in concert, with later mandates correlating with later inflection points. This supports the view that these rate reductions were due to wearing masks, rather than other potential changes in mobility[6-8] or behavior.

Figure 3: the effect of wearing masks: graphs depict new daily numbers for four states that mandated masks at different times from April 8 to May 6, 2020. Pink, orange and purple arrows point respectively to 1st, 2nd, 3rd inflections points. **A) New Jersey:** 16 days after mask mandate on 4/8 the slope drops about 2 fold. After this point, daily new cases drop by half every 16 days**. B) Maryland:** 23 days after mask mandate, on 4/18 the slope drops 1.5 fold to a halving rate of 34 days**. C) Illinois:** 18 days after mask mandate on 5/1 the slope declines about 2 fold, to a halving rate of 13.4 days**. D) Massachusetts:**18 days after mask mandate on 5/6, an already declining slope drops about 2 fold further, to a halving rate of 8.5 days.

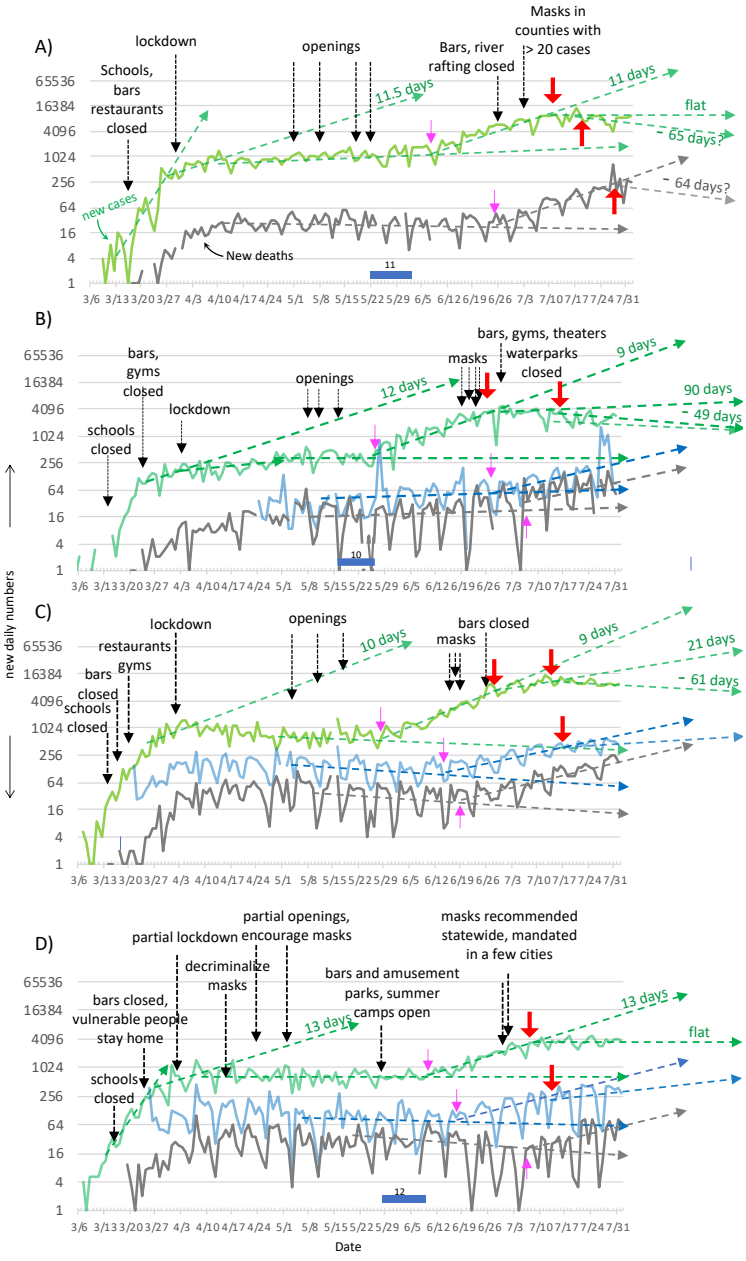
The lag times for the effect of masks (16-23 days, as indicated by dark blue bars near the X axis) seemed somewhat longer than those that followed closing schools, bars and restaurants, or ordering lockdowns, perhaps because it takes time for people to obtain masks and get into the habit of wearing them, whereas a school or a business can be closed in a day.

An exception to the effectiveness of mask wearing was seen in New York, which implemented a mask mandate during its lockdown, when new daily cases were already being cut in half every

Openings

As states reopened their economies, and experienced surges in new infections, we found that the new infection rates showed the effects of previous interventions that remained operational, as well as clear effects of interventions that were implemented later. For example, figure 4 shows data for four states (Texas, Arizona, Florida and Georgia) that opened in the middle of May. We chose these four because they had not previously mandated masks, in order to determine the effect of late mask mandates. These states had flattened or even reversed their slopes by closing schools, bars and restaurants, and non-essential businesses. All but Georgia had also implemented strict stay-at-home orders (Figure 4A - C)



The first effect we observed was the lasting impact of school closings. As infection rates surged following reopening of state economies, the benefit from having closed the schools persisted. In all four states, as schools remained shuttered for the summer, the rates of new infections never recouped the initial doubling times of 2-3 days, instead returning to the slower doubling times of 9-11 days that had followed the school closings, despite the fact that all other restrictions had been lifted. This suggests that the effect of each intervention endures as long as that intervention remains place, regardless of other actions that may be implemented or rescinded.

Figure 4: infection rates after opening mimic post-school-closing rates, and are flattened by wearing masks and closing bars. Small pink and large red arrows point respectively to beginnings of surges and reductions in infections. **A) Texas:** May1: opening almost everything (but not bars). May 8: personal care services open. May 18: gyms open. May 22: bars. On 6/16 Texas suddenly added 14 open. **B) Arizona openings**: May 8: many businesses open. May 11: restaurants open. May 16: everything else opens (including bars). **C) Florida openings**: May1: some counties open. May 11: Palm beach opens. May 18: Miami-Dade and Broward counties open. **D) Georgia openings**: April 24: personal services, gyms open. May 1: opening just about everything except bars and amusement parks. May 28: Bars, amusement parks, overnight camping open.

medRxiv preprint doi: https://doi.org/10.1101/2020.09.26.20202457; this version posted September 28, 2020. This article is a US Government work. It is not subject to copyright under 17 USC 105 and is also made available for use under a CC0 license.

The second thing we noticed was that the post-opening surges seemed to be strongly correlated with the opening of bars. Regardless of the timing or sequence of other relaxations, opening bars was followed 11-12 days later by surging infection rates. Texas, for example (Figure 4A), opened many businesses, including restaurants from May 1st to May 18th, with little repercussions on infection rates. On May 22nd, bars were opened (along with aquariums, zoos, rodeos, bowling alleys, bingo halls and skating rinks) and 11 days later, infection rates surged.

Arizona (Figure 4B) opened everything over an 8 day period, with bars opening only on the last day (May 18th). As with Texas, Arizona's surge of new cases also began 11 days later. Georgia (Figure 4D) carefully opened its economy over a period of more than a month, with no ill effects until it opened bars on the last day, along with amusement parks and overnight camping. It saw a surge starting 12 days later. In Florida each county decided individually when to open, making it impossible to determine the effect of opening bars in the Sunshine State, but for the other three states, the lag from opening bars to surges in infection rates was remarkably consistent (11-12 days), with only 1 day's difference among the three.

Thirdly, the data suggested that the simple combination of closing bars and wearing masks was a highly effective way to clamp down on surging infection rates. Each of these measures brought the infection rates down by twofold, for a cumulative reduction of fourfold in new infection rates. States that implemented both interventions, put surging infection rates into decline. Texas, Arizona and Florida (Figure 4 A-C) all carried out both interventions, though in different orders. In all three states, surging doubling times of 9-11 days sank to halving times ranging from 49 (Arizona) to 65 (Texas) days.

In contrast to the other three surging states, Georgia's governor neither closed bars nor mandated masks (Figure 4 D). However, he did encourage mask wearing, and several mayors mandated them for their cities, covering about 20% of the state's population. This mask mandate was followed about ten days later by a twofold reduction in the rate of new cases. Nonetheless, new cases did not go into decline, but instead flatlined. The major difference between Georgia and the three states that dropped their post-opening surge rates to declining ones is that the more successful states not only mandated mask wearing, they also closed their bars.

Together the data from these four states suggest that bringing cases down to manageable levels might not require shutting down an entire economy. The combination of closing schools, closing bars, and wearing masks may be enough.

Discussion

As countries and states debate the best way to prevent Covid-19 infections, and as they contemplate re-opening schools in the fall, the analysis of the information thus far gleaned about this new pandemic is vital to those decisions. There have been several previous attempts to correlate various government interventions with rates of SARS-Cov-2 infections, and predict which might be most effective[13-18]. These studies, however, have mostly taken a global view, and this is not necessarily the most productive for the US. Although a global view has the advantage of large numbers, it has the disadvantage of combining disparate interventions, done at different times in different places, into one global soup, in an attempt to find common themes.

We honed down instead to the granular data at the state - and sometimes city - level, painstakingly combing governors' executive orders and press releases (and those of mayors when necessary) to find examples of states that had implemented each of their interventions sufficiently far apart to enable us to distinguish the effect(s) of each individual intervention.

medRxiv preprint doi: https://doi.org/10.1101/2020.09.26.20202457; this version posted September 28, 2020. A second difference between this and previous studies is the method we used. A maxim among scientists is to use the simplest method that explains the data. Our decision to plot the data, as they came, without any assumptions, on a Log_2 Y axis, allowed us to see the straight lines in the data, find the slopes of those lines, and the inflection or "break" points where those slopes changed. The human eye, coupled with human intuition is a powerful tool, and can guide a simple mathematical approach. We therefore used segmented regression analysis to test our visually-based hypotheses about breakpoints, slopes and doubling times. The high R values for the segmented slopes highlight the accuracy of the visually based breakpoints, despite the variability of the data of new daily cases known to occur because of the "weekend effect" of low reporting, and of low initial numbers.

The results, demonstrate that, other than full lockdowns, three government interventions had the most impact on the rates of Covid-19 infections: closing schools, closing bars and wearing masks.

Schools: Closing schools not only flattened the early curves of rapidly rising numbers of infections in March (Figure 2), it prevented a return to those initial rates after states opened up their economies in mid-summer - a time when schools remained closed (figure 4). This demonstrates that the effect of a particular intervention lasts as long as that intervention is in place, regardless of other interventions that might be mandated and/or rescinded.

Although it could be argued that the mid-summer surging rates of infections were lower than the initial rates in March because of increased resistance in the US population, this is unlikely. At the time (early to mid-June), the number of confirmed cases in the US – just under 2 million - constituted a mere 0.6 percent of the population[19]. Even if the true infection rate were 8-10 times higher, as underscored by a recent study[20], the increase to 6% would still be too small to account for the reduced rates of post-opening infections, which closely mimicked the early post-school-closing rates.

These findings help to resolve the conflicting conclusions of two previous reports. In contrast to two early predictive models suggesting that closing schools would bring down Covid-19 infection rates, a study covering the effects of government interventions in six countries[21] concluded that closing schools had no effect in the US. However, the authors analyzed each of those countries as a whole, which is not useful in the case of the US, which had no national policy on the matter. The second study[22] analyzed individual states, and concluded that closing schools had a major impact. However, in evaluating all the states together, the authors noted that they were unable to discount the potential effects of other interventions. Our study, like theirs, shows that closing schools had a major effect, and supports this idea with the results from the small set of states (Figure 3), where the effect could not be explained by other interventions.

Bars: The effect of closing and opening bars became evident in those states that opened their economies in stages (Figure 4). Although most states closed bars and restaurants simultaneously during their early shutdowns, some opened them at different times during the re-openings. We found that, regardless of other relaxations, new infections surged beginning 11-12 days after bars were opened, and fell once again about 8 days after bars were re-shuttered. This suggests that closing (and re-opening) settings that might not be conducive to social distancing has more impact on new infection rates than would opening other types of businesses (dog groomers, markets, hardware stores; even restaurants).

Masks. Akin to school closings, the beneficial effect of wearing masks was evident during the early period when states were closing down (Figure 3), and also later during post-opening surges. Under

medRxiv preprint doi: https://doi.org/10.1101/2020.09.26.20202457; this version posted September 28, 2020. both conditions, those states that mandated masks[23] saw about a twofold reduction in the rate of new cases. Although political controversy reduced the proportion of the population that wears masks, those states that combined masks with bar closures saw their post-opening surge rates drop to declining ones (Figure 4). We surmise that better adherence to the mask mandates would likely have generated even larger decreases in infection rates.

One exception to the effect of early mask mandates was evident in the data from New York (Supplemental figure 2), which mandated masks after it had already turned its rapidly rising infection numbers into declining ones. The mask mandate had no further suppressive effect on infections. However, when New York later opened its economy, and infections began to rise, that increase was remarkably lower than those of states that opened without mask mandates in place (figure 3), suggesting that the early mask mandate had a long lasting effect.

Several studies suggested that early interventions have more effect than later ones. However, our data show that late interventions can be just as effective as early ones. Compare, for example, the twofold reductions in infection rates that follow early mask mandates in Figure 3, with the similar reductions seen in figure 4 - with mandates made months later. Although the numbers of cases at the time of a late intervention may be larger, setting a higher baseline, the proportional rate reductions are about the same. Whether flattening a curve at 10 or1000 new cases per day, these interventions have a major effect that can lead, with time, to lowering infections to the same level.

Finally, Figures 1-4 show that rates of new daily hospitalizations and new deaths seem to parallel those of new cases, with lag times of about three days to a week for hospitalizations, and a further lag of 3 - 10 days for deaths. Although improvements in medical care may start to change this picture[24-26], it currently appears that a fairly constant proportion of infected people will become ill and die. To counter this, we need a global set of effective policies to reduce new infections, as reductions in hospitalizations and deaths will follow. In the absence of a uniform US federal policy, we have been able to use the different state policies to determine the value of different interventions. Our analysis shows that, when combined, the three most powerful interventions - closing schools, closing bars and wearing masks - successfully flattened initial infection rates, and turned post-opening surges into declining ones, suggesting that the country could perhaps open up its economy safely if it kept bars and schools closed, and required the strict wearing of masks in public

Coda: If, in a future pandemic with a new infectious agent, governing bodies decide to base decisions on analyses of rates of infections, hospitalizations and deaths, we will need to eliminate the weekend effect, which results in underreporting on weekends and Mondays, and over-reporting later in the week, in every state examined. This can delay the determination of a rate change for a week or more, because many data points must accumulate to reliably assign a breakpoint and new slope. As there is already a biological delay from infection to the onset of symptoms, and a further delay before testing, any additional delay prevents the timely implementation of needed interventions. In a rapidly evolving pandemic, reliable data are crucial to the outcome, and every day counts.

We thank Tim D. Blood of the Maryland Department of Health for pulling and cleaning data, Gabrielle Bains and Yvonne Rosenberg for scientific and editing suggestions, the science writer, David C. Holzmann for improving flow and clarity, Mihalis Lionakis and Robert Munford for critical review, and Steve Holland for support, insightful questions and occasional butt kicks.

Funding: this work was entirely funded by the Division of Internal Research, National Institute of Infectious Diseases, NIH. **Author contributions:** Polly Matzinger conceived the graphing model, researched all the state interventions, wrote the paper and created the figures. Jeff Skinner wrote the programs to compute the statistical analysis and wrote the statistical analysis methods section. **Competing interests:** Authors declare no competing interests. **Data and materials availability:** All data are available in the main text and the supplementary materials. Code used for segmented regression analysis freely available on request.

Supplementary Materials:

Materials and Methods

Data acquisition: Data for different US states were taken from those published online by the individual State Health Departments, from "the Covid Tracking Project"[27] at the Atlantic under a Creative Commons CC BY-NC-4.0 license, from Statista[28] and from the IHME[29]. For school closings, mobility data, and other government actions, we also relied on GitHub[30] and then verified the dates with the various governors' orders. If the date of official school closing was a Monday, we used the Saturday before as the first date that students were not in school. For Mississippi, we found that Colleges and Universities, and most K-12 districts had gone on spring break about a week and a half before the official Governor's order to close the schools. We contacted the Mississippi department of Education, and most of the individual school districts, to find which, if any, had gone back to school in the interim between spring break and the official closing order, covering 97.2% of students in the state, and discovered that >87% of those students had not gone back to school, mostly because of local decisions by their mayors, school boards or boards of health. We consequently used the first day of spring break as the date of school closing in Mississippi.
For deaths, we report the combined "confirmed plus probable" when available.

Data analysis:

Data were analyzed in two ways. First by visualization on a plot using a Log2 Y axis to find the approximate dates of breakpoints in the lines. Second, using segmented linear regression to find and estimate the breakpoints, and to compute regression slopes and confidence intervals. To this end, trends in the number of new cases, total cases and total deaths were estimated by segmented regression using the "segmented" package library in R following its authors instructions[31]. The independent variable (X) was always "number of days" starting from March 3rd as Day 1. March 3rd was chosen because none of the states examined had any COVID-19 cases, hospitalizations or deaths reported prior to March 3rd. Initial values for either 2 or 3 segment breakpoints were provided using the 33rd, 50th, and 66th percentiles of date numbers spanning the range of the total deaths reported from that particular state. Total deaths were chosen because they typically had the smallest range of dates, so initial values chosen from the range of total deaths would usually work for the positive cases and the hospitalizations. If only 2 breakpoints were needed, then only 33rd and 66th percentiles were used. In rare cases where these initial values would not work to fit a particular variable (e.g. hospitalization or new cases), initial values would be chosen manually based on the date range of that variable. Estimated breakpoints were generally robust to the initial values chosen, and would typically yield the same estimated breakpoints even when substantially different initial values were provided. Estimated breakpoints were reported in number of days with their standard errors and their predicted date. Slopes for the resulting 3 or 4 regression segments were also reported with their adjusted 95% confidence intervals and their doubling times, calculated as 1/slope. The 95% confidence intervals can be compared against zero, to determine if slopes are increasing or decreasing, and they can be compared against each other to determine if one slope has significantly flattened or significantly increased relative to the previous slope.

Visualizations: Graphs follow the principles of Edward Tufte[32] as closely as possible.

Supplemental data

Supplemental Figure 1) Apple Mobility data for Georgia, Tennessee and Mississippi: Graphs show how much cell phones moved by driving each day. Different colors represent different counties in each state. Overall, phones in all 50 states started moving less in mid march. (the small spike in mid February is Valentine's day weekend). There is no obvious difference im the mobility data for the three states.

Supplemental Figure 2) New York new daily cases and deaths: pink, orange and purple arrows point respectively to 1st, 2nd, 3rd inflection points found during early stages of pandemic. Larger red arrows point to inflection points during the state's economic openings. Question marks indicate slope and inflection point where the estimate is questionable because of lack of sufficient data points.
