(h) government services including but not limited to policing and law enforcement, fire and emergency services, paramedics, coroner and pathology services, corrections and court services, licences and permits; and

(i) allotment gardens or community gardens.

Facilities for indoor or outdoor sports and recreational fitness activities

45. (1) Facilities for indoor or outdoor sports and recreational fitness activities that meet the conditions set out in subsection (2), (3), (4) or (7), as applicable.

(2) A facility for indoor or outdoor sports and recreational fitness activities may open if it meets the following conditions:

1. The facility is,

i. operated by, or for the sole use of, persons who are athletes, coaches or officials training or competing to be a part of Team Canada at the next summer or winter Olympic Games or Paralympic Games, if the persons are,

A. identified by a national sport organization that is either funded by Sport Canada or recognized by the Canadian Olympic Committee or the Canadian Paralympic Committee, and

B. permitted to train, compete, coach or officiate under the safety protocols put in place by a national sport organization mentioned in sub-subparagraph A, or

ii. REVOKED: O. Reg. 489/21, s. 2 (1).

2. REVOKED: O. Reg. 489/21, s. 2 (2).

If the facility is operated by a sports team, the team's league must have established a health and safety protocol for the use of training facilities, and the facility must be operated in compliance with the health and safety protocol.

3. The only persons permitted to enter and use the facility must be,

i. players, athletes, coaches or officials who are using the facility for the purposes of training or conditioning, and

ii. such staff as are strictly necessary to operate the facility and support the training or conditioning of the players.

(3) A facility for indoor or outdoor sports and recreational fitness activities may open if it meets the following conditions:

1. The facility must open solely for the purpose of providing space for any, some or all of the following:

i. A day camp for children described in section 24.

ii. A provider of child care within the meaning of the *Child Care and Early Years Act, 2014*.

iii. Mental health support services or addictions support services, so long as no more than ten people are permitted to occupy the space.

iv. The provision of social services.

2. The person responsible for the facility must,

i. record the name and contact information of every member of the public who attends the space described in paragraph 1,

ii. maintain the records for a period of at least one month, and

iii. only disclose the records to a medical officer of health or an inspector under the *Health Protection and Promotion Act* on request for a purpose specified in section 2 of that Act or as otherwise required by law.

(4) A facility for indoor or outdoor sports and recreational fitness activities may, but is not required to, open if it meets the following conditions:

1. The facility must be open solely for the purpose of allowing use of the facility by,

i. persons with a disability, within the meaning of the *Accessibility for Ontarians with Disabilities Act, 2005*, who,

A. have received a written instruction for physical therapy from a regulated health professional who is qualified to provide the instruction, and

B. are not able to engage in the physical therapy elsewhere,

ii. such staff as are strictly necessary to operate the facility and support the provision of the physical therapy, and

iii. such support persons or service animals as may be necessary for the person with a disability.

2. The facility must have established a health and safety protocol for the use of the facility that is consistent with sections 2, 3, 4, 5, 6 and 11 of Schedule 6, and the facility must be operated in compliance with the health and safety protocol.
3. The person responsible for the facility must,

i. record the name and contact information of every person described in paragraph 1 who enters and uses the facility,

ii. maintain the records for a period of at least one month, and

iii. only disclose the records to a medical officer of health or an inspector under the *Health Protection and Promotion Act* on request for a purpose specified in section 2 of that Act or as otherwise required by law.

(5) Despite paragraph 1 of subsection (3) and paragraph 1 of subsection (4), a facility may be open for both purposes described subsections (3) and (4) if the facility meets the conditions in both subsections.

(6) For greater certainty, no indoor or outdoor sports or recreational classes are permitted at any indoor or outdoor sport and recreational facilities, except as permitted under subsection (7).

(7) A facility for outdoor sports and recreational fitness activities, including a facility for indoor sports and recreational fitness activities that has such outdoor facilities, may be open if it complies with the following conditions:

1. The only activities permitted on the premises are outdoor fitness classes, personal training and training for team and individual sports.
2. No patrons are permitted to be in the indoor areas of the facility, except as may be necessary,

i. to access a washroom,

ii. to access an outdoor area that can only be accessed through an indoor route, or

iii. as may be necessary for the purposes of health and safety.

3. No more than 10 patrons may participate,

i. in an outdoor fitness class at any one time, or

ii. as a group in personal training or in training for team or individual sports.

4. No spectators are permitted to be at the facility. However, a person under the age of 18 years who is engaged in activities in the facility may be accompanied by one parent or guardian.
5. Any person who enters or uses the facility must maintain a physical distance of at least three metres from any other person who is using the facility.
6. For greater certainty, team sports must not be practised or played at the facility, with the exception of training sessions for members of a sports team that do not include games or scrimmage games.
7. Activities that are likely to result in individuals coming within three metres of each other must not be practised or played at the facility.
8. The person responsible for the facility must,

i. record the name and contact information of every member of the public who enters the facility,

ii. maintain the records for a period of at least one month, and

iii. only disclose the records to a medical officer of health or an inspector under the *Health Protection and Promotion Act* on request for a purpose specified in section 2 of that Act or as otherwise required by law.

9. The facility must actively screen individuals in accordance with the advice, recommendations and instructions of the Office of the Chief Medical Officer of Health before they enter the facility.

(8) Despite paragraph 1 of subsection (2) , paragraph 1 of subsection (3) and paragraph 1 of subsection (4), a facility may be open for both a purpose described in subsection (2), (3) or (4) as applicable and a purpose described in subsection (7) if the facility meets the conditions in both subsections.

(9) REVOKED: O. Reg. 440/21, s. 11 (21).

Personal physical fitness, etc.

45.1 Personal physical fitness and sports trainers that meet the following conditions:

1. Any services must be provided outside.
2. Services may not be provided to more than 10 patrons at one time.

3. No spectators are permitted. However, a person under the age of 18 years who is engaged in physical fitness or sports training activities may be accompanied by one parent or guardian.
4. Any person who is engaged in physical fitness or sports training activities must maintain a physical distance of at least three metres from any other person.
5. Training sessions for members of a sports team cannot include games or scrimmage games.
6. Activities that are likely to result in individuals coming within three metres of each other must not be practised or played.
7. The personal trainer or sports trainer must,

i. record the name and contact information of every member of the public who they are providing services to,

ii. maintain the records for a period of at least one month, and

iii. only disclose the records to a medical officer of health or an inspector under the *Health Protection and Promotion Act* on request for a purpose specified in section 2 of that Act or as otherwise required by law.

8. The personal trainer or sports trainer must actively screen individuals in accordance with the advice, recommendations and instructions of the Office of the Chief Medical Officer of Health before they engage in personal physical fitness or sports training activities.

Recreation

46. (1) Subject to subsection (2), businesses whose primary purpose is to operate an outdoor recreational amenity that is permitted to open under section 4 of Schedule 8.

(2) Amusement parks and water parks must be closed.

47. Outdoor horse racing tracks, car racing tracks and other similar venues may open for training and races if they comply with the following conditions:

1. No members of the public are permitted at the venue.
2. Only persons who are essential to the training, race or operation of the venue are permitted to be on the premises of the venue.

Research

48. Businesses and organizations that maintain research facilities and engage in research, including medical research and other research and development activities.

Health care and social services

49. Organizations and providers that deliver home care services or personal support services to seniors and persons with disabilities.

50. Regulated health professionals.

50.1 Osteopathic manual practitioners.

51. Professionals or organizations that provide in-person counselling services.

52. Organizations that provide health care including retirement homes, hospitals, clinics, long-term care facilities, independent health facilities and mental health and addictions counselling supports.

53. Laboratories and specimen collection centres.

54. Manufacturers, wholesalers, distributors and retailers of pharmaceutical products and medical supplies, including medications, medical isotopes, vaccines and antivirals, medical devices and medical supplies.

55. Manufacturers, distributors and businesses that provide logistical support of or for products and/or services that support the delivery of health care in all locations.

56. Organizations that provide critical personal support services in home or residential services for individuals with physical disabilities.

57. Organizations that support the provision of food, shelter, safety or protection, and/or social services and other necessities of life to economically disadvantaged and other vulnerable individuals.

Teaching and instruction

57.1 Businesses that open to provide in-person teaching and instruction and that meet the following conditions:

1. The instructional space for the in-person teaching and instruction must be outdoors.
2. The students must maintain a physical distance of at least two metres from every other person in the instructional space, except where necessary for teaching and instruction that cannot be effectively provided if physical distancing is maintained.
3. The total number of students permitted to be in each instructional space at any one time must be limited to 10 persons.

4. If the in-person teaching or instruction involves singing or the playing of brass or wind instruments,

i. every person who is singing or playing must be separated from every other person by plexiglass or some other impermeable barrier, or

ii. every person in the instructional space must remain at least three metres apart from every other person in the instructional space.

5. Students must be actively screened in accordance with the advice, recommendations and instructions of the Office of the Chief Medical Officer of Health before they enter the business.

6. The person responsible for the business shall,

i. record the name and contact information of every student who attends the in-person teaching and instruction,

ii. maintain the records for a period of at least one month, and

iii. only disclose the records to a medical officer of health or an inspector under the *Health Protection and Promotion Act* on request for a purpose specified in section 2 of that Act or as otherwise required by law.

58. Businesses that are primarily engaged in the provision of health and safety training and that meet the following conditions:

1. The instructional space for any in-person training must be operated to enable students to maintain a physical distance of at least two metres from every other person in the instructional space, except where necessary for teaching and instruction that cannot be effectively provided if physical distancing is maintained.
2. The total number of students permitted to be in each instructional space at any one time must be limited to the number that can maintain a physical distance of at least two metres from every other person in the business or place, and in any event cannot exceed 10 persons.

Media industries

59. Sound recording, production, publishing and distribution businesses.

60. (1) Commercial film and television production, including all supporting activities such as hair, makeup and wardrobe, that meet the following conditions:

1. No studio audiences may be permitted to be on the film or television set.

1.1 No more than 50 performers may be permitted to be on the film or television set.

2. The set must be configured and operated in such a way as to enable persons on the set to maintain a physical distance of at least two metres from other persons, except where necessary for the filming of the film or television production.
3. Persons who provide hair or makeup services must wear appropriate personal protective equipment.
4. REVOKED: O. Reg. 440/21, s. 11 (28).
5. The person responsible for the film or television production must ensure that the production operates in accordance with the guidance document titled "Film and television industry health and safety during COVID-19" issued by the Film and Television Health and Safety Advisory Committee of the Ministry of Labour, Training and Skills Development, as amended from time to time.

(2) For greater certainty, for the purposes of this section, the film or television set may be located in any business or place, including any business or place that is otherwise required to be closed under this Order.

61. Film and television post-production, visual effects and animation studios.

62. Book and periodical production, publishing and distribution businesses.

63. Commercial and industrial photography.

63.1 Photography studios and services that meet the following conditions:

1. Photography may only be provided by appointment.
2. Any in-person services provided to patrons, including the taking of photographs, must be provided outdoors.
3. Patrons must be actively screened in accordance with the advice, recommendations and instructions of the Office of the Chief Medical Officer of Health before photography is provided.

64. Interactive digital media businesses, including,

(a) computer system software or application developers and publishers; and

(b) video game developers and publishers.

Entertainment

65. (1) Concert venues, theatres and cinemas that meet the conditions set out in subsection (2) or (3).

(2) Concert venues, theatres and cinemas may open for the purpose of rehearsing or performing a recorded or broadcasted concert, artistic event, theatrical performance or other performance on outdoor premises if they comply with the following conditions:

1. No spectators may be permitted anywhere on the premises.
2. Only persons who are essential to the rehearsal or performance are permitted anywhere on the premises.
3. No more than 10 performers may be permitted to participate in the rehearsal or performance.
4. Every performer and other person who performs work for the concert venue, theatre or cinema must maintain a physical distance of at least three metres from every other person.
5. No performer or other person who performs work for the concert venue, theatre or cinema may be permitted in an indoor area of the concert venue, theatre or cinema, except,

i. where necessary to use a washroom,

ii. where necessary to access an outdoor area that can only be accessed through an indoor route, or

iii. as may otherwise be required for the purposes of health and safety.

6. The person responsible for the concert venue, theatre or cinema must,

i. record the name and contact information of every performer or other person who is present at the rehearsal or performance,

ii. maintain the records for a period of at least one month, and

iii. only disclose the records to a medical officer of health or an inspector under the *Health Protection and Promotion Act* on request for a purpose specified in section 2 of that Act or as otherwise required by law.

7. The person responsible for the concert venue, theatre or cinema must ensure that individuals are actively screened in accordance with the advice, recommendations and instructions of the Office of the Chief Medical Officer of Health before they enter the premises.

(3) Concert venues, theatres and cinemas may open if they comply with the following conditions:

1. The movie, concert, artistic event, theatrical performance or other performance must be provided in a drive-in or drive-through format.
2. Each person in attendance at the drive-in cinema or the drive-in or drive-through concert, event or performance, other than persons who perform work for the drive-in cinema or the drive-in or drive-through concert, event or performance, must remain within a motor vehicle designed to be closed to the elements except,

i. where necessary to purchase admission,

ii. where necessary to use a washroom, or

iii. as may otherwise be required for the purposes of health and safety.

3. Every motor vehicle at the drive-in cinema or the drive-in or drive-through concert, event or performance may only contain members of a single household plus a maximum of one additional person from outside that household who lives alone.
4. The driver of a motor vehicle at the drive-in cinema or the drive-in or drive-through concert, event or performance must ensure that it is positioned at least two metres away from other motor vehicles.

66. Businesses that provide outdoor tour and guide services, including guided fishing and hunting trips, tastings and tours for wineries, breweries and distilleries, trail riding tours, walking tours and bicycle tours, but not motor vehicle tours or boat tours other than boat tours for guided fishing trips, may open if they comply with the following conditions:

1. The tour must be operated to enable every person on the tour, including tour guides, to maintain a physical distance of at least two metres from every other person, except where necessary,

i. to facilitate payment, or

ii. for the purposes of health and safety.

2. Every person on the tour must wear a mask or face covering in a manner that covers their mouth, nose and chin during any period in which they come within two metres of another person, unless they are entitled to any of the exceptions set out in subsection 2 (5) of Schedule 6.
3. The number of members of the public on the tour must not exceed the number of persons that would permit compliance with paragraph 1 while on the tour, and in any event cannot exceed 10 persons.

4. Every member of the public who intends to participate in the tour must be actively screened in accordance with the advice, recommendations and instructions of the Office of the Chief Medical Officer of Health before they participate in the tour.
5. The persons on the tour must remain outdoors at all times, except where necessary to use a washroom or as may otherwise be required for the purposes of health and safety.
6. The tour or guide service must,

i. record the name and contact information of every patron that participates in the tour,

ii. maintain the records for a period of at least one month, and

iii. only disclose the records to a medical officer of health or an inspector under the *Health Protection and Promotion Act* on request for a purpose specified in section 2 of that Act or as otherwise required by law.

SCHEDULE 8
PLACES THAT MUST CLOSE OR THAT ARE SUBJECT TO CONDITIONS AT STEP 1

Public libraries

1. (1) Public libraries may only open if they comply with the following conditions:

1. Circulating materials must be reserved over the telephone or online.
2. Circulating materials may only be exchanged with members of the public through contactless drop-off, pick-up or delivery.
3. Patrons must only be permitted to enter the premises to facilitate contactless drop-off and pick-up or to access computers, photocopiers or similar services.
4. Patrons must not be permitted to be in the book stacks, or to handle circulating materials that are shelved, or in other areas of library storage.
5. REVOKED: O. Reg. 440/21, s. 12 (2).
6. The person responsible for the public library must comply with subsection (3), if applicable.

(2) The conditions set out in paragraphs 3 and 4 of subsection (1) do not apply with respect to any space the library provides for,

(a) a day camp for children described in section 24 of Schedule 7;

(b) a provider of child care within the meaning of the *Child Care and Early Years Act, 2014*;

(c) mental health support services or addictions support services, so long as no more than ten people are permitted to occupy the space; or

(d) the provision of social services.

(3) The person responsible for a public library shall,

(a) record the name and contact information of every member of the public who attends the space described in subsection (2);

(b) maintain the records for a period of at least one month; and

(c) only disclose the records to a medical officer of health or an inspector under the *Health Protection and Promotion Act* on request for a purpose specified in section 2 of that Act or as otherwise required by law.

Post-secondary institutions

2. (1) Post-secondary institutions may only open if they meet the following conditions:

1. In-person teaching or instruction may only be provided if the following conditions are met:

i. The subject matter of the teaching or instruction requires that it be taught in-person, such as clinical training or training related to a trade.

ii. The instructional space must be operated to enable students to maintain a physical distance of at least two metres from every other person in the instructional space, except where necessary for teaching and instruction that cannot be effectively provided if physical distancing is maintained.

iii. The total number of students permitted to be in each instructional space at the institution at any one time must be limited to the number that can maintain a physical distance of at least two metres from every other person in the business or place, and in any event cannot exceed,

A. 50 persons, in the case of an instructional program described in subsection (2), and

B. 10 persons, in any other case.

2. If in-person teaching or instruction at the institution involves singing or the playing of brass or wind instruments,

i. every person who is singing or playing must be separated from every other person by plexiglass or some other impermeable barrier, or

ii. every person in the instructional space must remain at least three metres apart from every other person in the instructional space.

3. Any in-person examinations must be provided in accordance with the following rules:

i. Every person in the examination room must remain at least two metres apart from every other person in the examination room.

ii. The total number of persons who may take the examination in the same room at the same time cannot exceed,

A. 50 persons, in the case of an examination for an instructional program described in subsection (2), and

B. 10 persons, in any other case.

(2) An instructional program referred to in sub-subparagraphs 1 iii A and 3 ii A of subsection (1) is an instructional program in any of the following fields or an instructional program to train an individual for any of the following occupations, as the case may be:

0.1 Dental hygiene.

0.2 Dentistry.

1. Diagnostic cardiac sonography.
2. Diagnostic medical sonography.
3. Diagnostic ultrasound.
4. Medical imaging.
5. Medical laboratory assistant.
6. Medical laboratory technician.

6.1 Medical laboratory technologist.

7. Medical radiation technology.
8. Medicine.
9. Mental health and addictions services, including psychology services, social work services and counselling services.

9.1 Midwifery.

10. Nursing.

10.1 Optometry.

11. Paramedic.

12. Personal support worker, supportive care worker, home care worker or a similar occupation.

13. Pharmacy/pharmacy technician.

13.1 Physician assistant.

14. Public health inspector, if the program is accredited by the Canadian Institute of Public Health Inspectors.

15. Rehabilitation sciences (nutrition, speech language pathology, occupational science, and physiotherapy).

16. Respiratory therapy.

17. Veterinary medicine.

(3) In this section,

"post-secondary institution" means,

(a) a university,

(b) a college of applied arts and technology,

(c) a private career college,

(d) an Indigenous Institute prescribed for the purposes of section 6 of the *Indigenous Institutes Act, 2017*,

(e) an institution that is authorized to grant a degree by an act of the Legislature,

(f) a person who is delivering in-person teaching or instruction in accordance with a consent given under section 4 of the *Post-secondary Education Choice and Excellence Act, 2000*,

(g) a person approved to provide training for apprenticeship programs under paragraph 5 of section 64 of the *Ontario College of Trades and Apprenticeship Act, 2009*, or

(h) any other institution that is a designated learning institution within the meaning of section 211.1 of the *Immigration and Refugee Protection Regulations* (Canada), other than a school or private school within the meaning of the *Education Act*.

Schools and private schools

3. (1) Schools and private schools within the meaning of the *Education Act* shall not provide in-person teaching or instruction.

(2) Despite subsection (1), schools and private schools within the meaning of the *Education Act* may open,

(a) to the extent necessary to facilitate the operation of a child care centre within the meaning of the *Child Care and Early Years Act, 2014*;

(b) if approved by the Minister of Education, to the extent necessary to facilitate the operation of an extended day program, as defined in the *Education Act*, for the provision of emergency child care for the children of individuals listed in Schedule 10 during the period when schools are not permitted to provide in-person teaching or instruction;

(c) to allow staff of the school or private school to provide remote teaching, instruction or support to pupils, so long as the school or private school operates in accordance with a return to school direction issued by the Ministry of Education and approved by the Office of the Chief Medical Officer of Health;

(d) to the extent necessary to provide in-person instruction to pupils with special education needs who cannot be accommodated through remote learning and who wish to attend a school or their private school for in-person instruction, so long as the school or private school operates in accordance with a return to school direction issued by the Ministry of Education and approved by the Office of the Chief Medical Officer of Health; or

(e) to facilitate the operation of a day camp for children described in section 24 of Schedule 7.

(3) Subsections (1) and (2) do not apply to schools that meet the condition set out in subsection (4) and that are operated by,

(a) a band, a council of a band or the Crown in right of Canada;

(b) an education authority that is authorized by a band, a council of a band or the Crown in right of Canada; or

(c) an entity that participates in the Anishinabek Education System.

(4) A school described in subsection (3) may open if it meets the following condition:

1. If a person who holds a study permit issued under the *Immigration and Refugee Protection Act* (Canada) and who entered Canada on or after November 17, 2020 attends the school, in-person teaching or instruction may only be provided to that person if the school or private school,

i. has a plan respecting COVID-19 that has been approved by the Minister of Education, and

ii. operates in accordance with the approved plan.

(5) A school or private school may allow persons, other than persons allowed to be at the school or private school under subsection (2), to enter the school or private school temporarily, as necessary,

(a) to prepare for an end-of-school-year celebration ceremony described in subsection 1 (5) of Schedule 9, if the person is a staff member or student at the school or private school and is required to be indoors for such preparation;

(b) to use a washroom or as may otherwise be required for the purposes of health and safety while attending the end-of-school-year celebration; or

(c) to return goods or supplies or retrieve personal belongings.

Recreational amenities

4. (1) Each person responsible for an indoor or outdoor recreational amenity that is not in compliance with this section, and that is not a facility for indoor or outdoor sports and recreational fitness activities that is permitted to open under section 45 of Schedule 7, must ensure that it is closed.

(2) The following outdoor recreational amenities may open if they are in compliance with subsection (3):

1. Parks and recreational areas.
2. Baseball diamonds.
3. Batting cages.
4. Soccer, football and sports fields.
5. Tennis, platform tennis, table tennis and pickleball courts.
6. Basketball courts.
7. BMX parks.
8. Skate parks.
9. Golf courses and driving ranges.
10. Frisbee golf locations.
11. Cycling tracks.
12. Trails.
13. Horse riding facilities.
14. Shooting ranges, including those operated by rod and gun clubs.
15. Playgrounds.
16. Portions of parks or recreational areas containing outdoor fitness equipment.

17. Archery ranges.
18. Boat and watercraft launches.
19. Lawn game courts, including lawn bowling, bocce and croquet courts.
20. Horseshoe pits.
21. Outdoor pools, splash pads, spray pads, whirlpools, wading pools and water slides.

(3) An outdoor recreational amenity described in subsection (2) may only open if the following conditions are met:

1. Subject to paragraph 2, any person who enters or uses the amenity must maintain a physical distance of at least two metres from any other person who is using the amenity.
2. Any person who engages in physical exercise in the amenity, including by engaging in a training session, sport or game, must maintain a physical distance of at least three metres from any other person who is using the amenity.
3. Team sports must not be practised or played within the amenity, with the exception of training sessions for members of a sports team that do not include games or scrimmage games.
4. Other sports or games that are likely to result in individuals coming within three metres of each other must not be played within the amenity.
5. Clubhouses on the premises must be closed, except to the extent that they,

i. are used in conjunction with an outdoor pool, splash pad, spray pad, whirlpool, wading pool or water slide, or

ii. provide access to equipment storage, a washroom or a portion of the amenity that is used to provide first aid.

(4) Paragraphs 1 and 2 of subsection (3) do not apply in respect of the following persons who enter or use an outdoor recreational amenity:

1. Parasport participants and their attendants or guides.
2. Members of a single household.

(5) Paragraphs 1 to 4 of subsection (3) do not apply with respect to an amenity, or a particular area of an amenity, during periods when the amenity or the particular area is exclusively being used by persons who are athletes, coaches and officials training or competing to be a part of Team Canada at the next summer or winter Olympic Games or Paralympic Games if the persons are,

(a) identified by a national sport organization that is either funded by Sport Canada or recognized by the Canadian Olympic Committee or the Canadian Paralympic Committee; and

(b) permitted to train, compete, coach or officiate under the safety protocols put in place by a national sport organization mentioned in clause (a).

(6) Each person responsible for a boat or watercraft shall ensure that if a group of persons uses that boat or watercraft together for recreational purposes, the members of the group are all members of the same household or one other person from outside that household who lives alone or a caregiver for any member of the household.

Museums, etc.

5. (1) Subject to subsections (2) and (3), museums, galleries, aquariums, zoos, science centres, landmarks, historic sites, botanical gardens and similar attractions must be closed to members of the public.

(2) An attraction described in subsection (1) may open to provide drive-in or drive-through access to the public if it complies with the conditions set out in section 65 of Schedule 7, subject to any necessary modifications.

(3) An outdoor attraction described in subsection (1) may open if it complies with the following conditions:

1. The number of members of the public in the attraction must be limited so that the total number of members of the public in the outdoor ticketed area of the attraction at any one time does not exceed 15 per cent capacity, determined by taking the total square metres of outdoor ticketed area accessible to the public in the attraction, dividing that number by 26.67 and rounding the result down to the nearest whole number.
2. The person responsible for the attraction must post a sign in a conspicuous location visible to the public that states the maximum capacity they are permitted to operate under.
3. No member of the public may enter a ticketed area of the attraction unless they have made a reservation to do so.
4. No member of the public may be permitted access to interactive exhibits or exhibits that would create a high risk of personal contact.
5. No member of the public may be permitted to enter any indoor area of the premises, except,

i. to access a washroom,

ii. to access an outdoor area that can only be accessed through an indoor route, or

iii. as may be necessary for the purposes of health and safety.

6. No amusement rides or tour vehicles may be operated by the attraction.

O. Reg. 96/21, s. 10; O. Reg. 348/21, s. 2; O. Reg. 440/21, s. 12.

SCHEDULE 9
ORGANIZED PUBLIC EVENTS, CERTAIN GATHERINGS AT STEP 1

Gatherings

1. (1) Subject to sections 2 to 4, no person shall attend,

(a) an organized public event that is held indoors;

(b) a social gathering that is held indoors, including a social gathering associated with a gathering described in clause (d);

(c) an organized public event or social gathering of more than 10 people that is held outdoors, including a social gathering associated with a wedding, funeral or a religious service, rite or ceremony, but not including the wedding, funeral or a religious service, rite or ceremony itself;

(d) an indoor gathering for the purposes of a wedding, a funeral or a religious service, rite or ceremony where the number of persons occupying any particular room in a building or structure while attending the gathering exceeds 15 per cent of the capacity of the room; or

(e) an outdoor gathering for the purposes of a wedding, a funeral or a religious service, rite or ceremony where the number of persons attending the gathering exceeds the number that can maintain a physical distance of at least two metres from every other person in the space where the gathering is held.

(2) A person attending an organized public event, social gathering or a gathering for the purposes of a wedding, a funeral or a religious service, rite or ceremony shall comply with public health guidance on physical distancing.

(3) For greater certainty, subsections (1) and (2) apply with respect to an organized public event, social gathering or a gathering for the purposes of a wedding, a funeral or a religious service, rite or ceremony, even if it is held at a private dwelling.

(4) For greater certainty, the limits in clauses (1) (b) and (c) apply to a social gathering associated with a wedding, a funeral or a religious service, rite or ceremony, such as a wedding reception, while the limits that apply to the wedding, funeral or religious service, rite or ceremony itself are set out in clauses (1) (d) and (e).

(5) Clause (1) (c) does not apply with respect to an outdoor end-of-school-year celebration ceremony held by a school or private school within the meaning of

the *Education Act* that is in compliance with a direction issued by the Ministry of Education and approved by the Office of the Chief Medical Officer of Health.

(6) All persons participating in an end-of-school-year celebration ceremony described in subsection (5) must remain outdoors at all times, except as permitted under subsection 3 (5) of Schedule 8.

(7) Clauses 1 (a) and (c) do not apply with respect to day camps for children that are in compliance with section 24 of Schedule 7.

Exception, single household, etc.

2. Section 1 does not apply with respect to,

(a) a gathering of members of a single household;

(b) a gathering that includes members of a household and one other person from another household who lives alone; or

(c) a gathering that includes persons described in clause (a) or (b), and a caregiver for any of those persons.

Exception, retirement homes

2.1 Section 1 does not apply with respect to a gathering in a retirement home within the meaning of the *Retirement Homes Act, 2010* if it is in compliance with the policies or guidance, if any, issued by the Retirement Homes Regulatory Authority.

Exception, attendance at business

3. The prohibitions on attendance at an organized public event in subsection 1 (1) do not apply with respect to attendance at a business for a purpose related to providing or receiving the goods or services provided by the business if the business is not required to close under this Order.

Gathering in motor vehicles for religious service, rite or ceremony

4. (1) This section applies with respect to gatherings for the purposes of a wedding, funeral, religious service, rite or ceremony if the persons attending the gathering, other than those conducting the service, rite or ceremony, do so in a motor vehicle.

(2) Clause 1 (1) (e) does not apply to a person who attends a gathering to which this section applies if the person follows all of the following precautions that apply to the person:

1. Each person attending the gathering, other than the persons conducting the service, rite or ceremony, must remain within a motor vehicle that is designed to be closed to the elements, except,

i. where necessary to use a washroom, or

ii. as may otherwise be necessary for the purposes of health and safety.

2. The driver of a motor vehicle must ensure that it is positioned at least two metres away from other motor vehicles.

3. A person who ordinarily uses a non-motorized vehicle because of their religious belief and who attends the gathering must remain within their non-motorized vehicle except where necessary to use a washroom or as may otherwise be required for the purposes of health and safety, and paragraph 2 applies with necessary modifications.

COVID-19 Routes of Transmission – What We Know So Far

Introduction

Public Health Ontario (PHO) is actively monitoring, reviewing and assessing relevant information related to Coronavirus Disease 2019 (COVID-19). "What We Know So Far" documents provide a rapid review of the evidence related to a specific aspect or emerging issue related to COVID-19.

The development of these documents includes a systematic search of the published literature as well as scientific grey literature (e.g., ProMED, CIDRAP, Johns Hopkins Situation Reports) and media reports, where appropriate. Relevant results are reviewed and data extracted for synthesis. All "What We Know So Far" documents are reviewed by PHO subject matter experts before posting.

As the COVID-19 outbreak continues to evolve and the scientific evidence rapidly expands, the information provided in these documents is only current as of the date of posting.

See Appendix A for Glossary of Terms for COVID-19 Routes of Transmission.

Updates in Latest Version

Since the last version (July 16, 2020), multiple new studies and systematic reviews have been published with evidence on the potential for transmission via several routes including respiratory droplet and close-contact, vertical, conjunctival and fomite transmission. There was more evidence against several modes of transmission, including sexual and transmission through breast milk.

Importantly, there are now experimental studies and outbreak case studies that support severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) transmission through small particle respiratory droplets or aerosols during prolonged exposure in a poorly ventilated space. The primary mode of SARS-CoV-2 transmission; however, remains through respiratory droplets and unprotected close contact.

New modes of transmission addressed in this update include potential transmission from wastewater, food, urine and zoonotic transmission (through animals).

Key Points

- Overall, the evidence for various transmission routes relies heavily on the detection of viral RNA in clinical and environmental samples, rather than the detection of viable, infectious virus. Further, the quantity of viral RNA that is representative of an infectious dose is unclear.

- Transmission of SARS-CoV-2 occurs predominantly through close (<2 m), unprotected contact with an infected individual(s). Based on the epidemiology of COVID-19, transmission predominantly occurs via respiratory droplets from symptomatic, presymptomatic or less commonly, asymptomatic individuals.
- Transmission over longer distances (>2 m) is less common, but possible under certain conditions such as prolonged exposure in a poorly ventilated space. Under these conditions, inhalation of small particle respiratory droplets and aerosols can occur. SARS-CoV-2 is likely an *opportunistic* airborne pathogen, as non-airborne transmission is most common, but aerosols may result in transmission under favourable conditions.
- Relatively uncommon routes of transmission of SARS-CoV-2 include conjunctival, vertical (intrauterine), fecal-oral, fomite and zoonotic. While these routes of transmission are possible, their contribution to the epidemiology of COVID-19 is unclear.
- Routes of transmission that are theoretically possible due to the detection of viral RNA, but that are very unlikely, are sexual transmission (via semen and vaginal secretions); bloodborne transmission (blood products, organ transplant); transmission through breast milk; transmission through urine; food-borne transmission; and transmission through contaminated wastewater.

Background

The purpose of this document is to outline the evidence for various SARS-CoV-2 transmission routes, based on a review of the scientific literature. SARS-CoV-2 is genetically similar to other coronaviruses and shares a high degree of genetic similarity (79%) with the coronavirus (SARS-CoV-1) responsible for Severe Acute Respiratory Syndrome (SARS).[1] Therefore, in instances of limited evidence for COVID-19, we have extrapolated existing data from other coronaviruses, in particular SARS-CoV-1.

During the COVID-19 pandemic, evidence for and against potential routes of transmission has evolved. In some instances, there is no consensus on the contribution from certain modes of transmission. A number of reports postulate transmission routes; however, in many it is challenging to determine the precise mode of transmission where there are multiple opportunities for transmission to occur (i.e. through direct contact, fomites, or inhalation). In addition, the strength of evidence by transmission route has changed. In contrast to the July 16, 2020 version of this document, there have been several systematic reviews published on the subject that are included. The systematic reviews contribute to bringing the evidence base closer to a consensus. Within this document, we underpin our findings with systematic reviews and meta-analyses where available, supporting findings with case series and cohort studies.

Methods

In considering feasibility, scope and the need for responsiveness, a rapid review was chosen as an appropriate approach to determining the routes of transmission for SARS-CoV-2. A rapid review is a type of knowledge synthesis wherein certain steps of the systematic review process are compromised in order to be timely.[2]

PHO is actively monitoring, reviewing and assessing relevant information related to COVID-19. This document provides a rapid review of the evidence related to transmission routes of SARS-CoV-2.

On October 14, 2020, PHO Library Services developed and conducted a search in MEDLINE (Appendix B). English language peer-reviewed and grey literature records that describe transmission of SARS-CoV-2

were included. We did not restrict year of publication. We reviewed references of included studies for additional articles.

Two reviewers screened titles and abstracts, and the senior author reviewed the application of the eligibility criteria. The senior author synthesized relevant data. We did not perform a critical appraisal of the methodological quality of studies due to time constraints. PHO subject matter experts reviewed this rapid review before posting.

Results

Droplet and Contact Transmission

Current evidence suggests that the primary mode of transmission of COVID-19 is through direct contact from respiratory droplets that have the potential to be propelled for varying distances.[3-5]

Household secondary attack rates are indicative of predominantly droplet and close-contact transmission:

In household settings, people are in close proximity to one another, thereby increasing the risk of infection. The consensus among systematic reviews is that most infections are occurring in household settings where physical distancing is not feasible and household secondary attack rates are higher than in casual-contact settings (e.g., shopping).

In a systematic review and meta-analysis, Lei et al. reported the secondary attack rate in households was 27% (95% confidence interval [CI]: 21−32); the risk of secondary infection was 10 times higher in households compared to non-household settings (odds ration [OR]: 10.72; 95% CI: 5.70–20.17; p<0.001).[7] In another systematic review and meta-analysis by Madewell et al., the household secondary attack rate was 18.8% (95% CI: 15.4–22.2).[8] Koh et al, in a meta-analysis, reported that the household secondary attack rate was 18.1% (95% CI: 15.7–20.6), much higher than the secondary attack rate in health care settings (0.7%; 95% CI: 0.4–1.0).[9] Further, these findings do not support predominant airborne transmission. If SARS-CoV-2 was predominantly and efficiently spread through an airborne route (i.e., through aerosols), household secondary attack rates would be expected to be substantially higher (e.g., >90% in measles).[6]

Contact tracing studies also show higher secondary attack rates in households, compared to other settings. The limited transmission to contacts outside the household setting suggests that the mode of SARS-CoV-2 transmission is predominantly from close contact. Luo et al. studied 3,410 close contacts of 391 index cases in Guangzhou, China and found that the secondary attack rate was lower when people were exposed in health care settings (1.0%; OR: 0.09; 95% CI: 0.04–0.20) and on public transportation (0.1%; OR: 0.01; 95% CI: 0.00–0.08), compared to the household secondary attack rate (10.3%).[10] In a retrospective cohort study in Guangzhou, China, Jing et al. reported the household secondary attack rate (among close relatives) was 12.4% (95% CI: 9.8–15.4).[11] In most studies, non-household close contacts have secondary attack rates less than 1% (Bi et al., Chaw et al., Cheng et al., Li et al.).[12-15]

Evidence for SARS-CoV-2 droplet and contact transmission:

The majority of COVID-19 cases have been linked to person-to-person transmission through close, direct contact with symptomatic patients,[16-18] or through close contact with a pre-symptomatic patient.[19-21] In addition, high viral loads have been identified in individuals who were asymptomatic or pre-

symptomatic .[22-24] In a case-control study of patients 18 years old and older in the United States (US), Fisher et al. reported that close contact with a person with COVID-19 was reported more often among cases (42%) than controls (14%).[25] A study modelling the transmission risk from epidemiological data among train passengers revealed that travellers directly adjacent to the index patient had a much higher infection risk (relative risk [RR]: 18.0; 95% CI: 13.9–23.4), and the attack rate decreased with increasing distance.[26] Furthermore, the attack rate increased by 0.15% (p=0.005) per hour of co-travel time.

Using whole-genome sequencing of SARS-CoV-2 clinical samples during a nosocomial outbreak of COVID-19 in Dublin, Ireland, Lucey et al. reported that the majority of infections were among patients who required extensive and prolonged care by health care providers.[27] The authors concluded that the likely mode of transmission from health care workers to patients was through respiratory droplets and close contact, rather than airborne transmission.

The reproductive number (R_0) is less suggestive of airborne spread, as airborne infections tend to have a higher R_0. For example, in a systematic review by Guerra et al., the R_0 for measles in the pre-vaccine era was 6.1–27.0;[28] compared to the range of R_0 (2–3) reported for COVID-19.[29]

Evidence for distance travelled by respiratory droplets:

Researchers have demonstrated the propulsion of respiratory droplets up to 2 m, and in a study by Guo et al., respiratory droplets were found on the floor up to 4 m away from a patient.[30] A systematic review of studies assessing the horizontal distance travelled by respiratory droplets found that droplets could travel up to 8 m.[31]

Airborne Transmission

Respiratory virus transmission occurs on a spectrum from larger droplets that spread at close range to smaller droplets (or aerosols) that have the potential to be infectious over longer distances (i.e. >2 m) and may be suspended for longer periods of time (typically hours). As summarized above, current evidence supports that SARS-CoV-2 transmission is predominantly through close, unprotected contact, which supports larger droplet spread. However, under conditions of poor ventilation or with recirculation of unfiltered and untreated air, aerosols may accumulate in sufficient quantities to become infectious and transmission via inhalation is plausible based on the emerging literature.[32] Further evidence regarding the quantity of viral particles required to cause infection is needed. There is no evidence at this time of transmission over long distances through the air (such as through air ducts). The term “airborne transmission” has special meaning in public health, for infection prevention and control purposes, and in health care settings. This term is typically reserved to describe infections efficiently transmitted by small droplets and particles suspended in the air over long distances and persisting in the air for long periods (see Appendix for size designations). Airborne pathogens typically require specialized engineering controls to prevent spread (e.g. negative-pressure isolation rooms and specific personal protective equipment (PPE) such as respirators). However, the historical dichotomy of airborne vs non-airborne pathogens used in health care settings is likely imprecise. Infectious pathogens can be considered on a spectrum of efficiency for airborne transmission classified as *obligate* (infection only occurs via aerosols), *preferential* (aerosols predominate), or *opportunistic* (non-airborne transmission is most common but aerosols may transmit under favorable conditions). Current evidence supports SARS-CoV-2 as an *opportunistic* airborne pathogen.[33]

A commentary by Morawska and Milton appealed to the medical community to recognize the potential for airborne transmission, based on experimental evidence that small respiratory droplets (or aerosols)

could be inhaled.[34] Another commentary by Klompas et al. discussed how the balance of currently available evidence does not support long-range aerosol transmission as the dominant mode of COVID-19 transmission. While aerosols are reported by Stadnytskyi et al. to be produced during activities such as speaking, breathing and coughing,[35] it is not clear what role aerosols have in transmission for distances greater than 2 m, as viable SARS-CoV-2 has only once been detected during air sampling. The role of these aerosols has been suggested in a modelling study by Chen et al. to be most important for transmission in close proximity (<2 m).[36]

As discussed in the Droplet and Contact Transmission section, household secondary attack rates are more consistent with primary transmission through respiratory droplets when people are in close contact with one another, rather than airborne transmission. There is emerging evidence that *opportunistic* aerosol transmission occurs under the right combination of conditions (i.e. poorly ventilated space with sufficient quantity of infectious virus produced). However, as discussed above, this appears to be less frequent, and less efficient, when compared with direct close contact.

Environmental exposures, such as sunlight, may have significant effects on viability of SARS-CoV-2. Using a rotating drum experiment similar to other studies for viability of SARS-CoV-2, simulated sunlight (UVA/UVB) was applied to aerosolized virus through a window on the drum.[37] Results indicated 90% inactivation of virus within 20 minutes.

Experimental evidence of aerosol generation of SARS-CoV-2:

In a study comparing SARS-CoV-2 and SARS-CoV-1, van Doremalen et al. reported that SARS-CoV-2 could be artificially aerosolized with a jet nebulizer and detectable for up to 3 h in a rotating metal drum.[38] The half-lives of SARS-CoV-2 and SARS-CoV-1 were similar in aerosols with median estimates of the half-life of 1.1–1.2 h. While the van Doremalen et al. study concluded that aerosol transmission was possible, they did not demonstrate that it occurred (refer to the PHO Synopsis on this study for further details). Fears et al. drew similar conclusions through conducting a similar experiment.[39]

Lee modelled the minimum sizes of aerosols emitted from an infected individual that could be expected to contain viral particles.[40] Under certain assumptions, Lee estimated that the minimum sizes theoretically ranged from 0.4–42 μm; by using experimental data of virus in oral fluid, they estimated a range of 4.7–32 μm. Studies discussed by Lee detected virus by polymerase chain reaction (PCR) in much smaller aerosol sizes (<0.25–4 μm). The author reconciled differences in the modelled sizes and air-sampled sizes by acknowledging that aerosols evaporate to smaller sizes (which may take only seconds) and/or the possible range of virus in oral fluid can be higher than reported by the previous experiment used to inform this model. Lee also noted that the virus particles captured in those experiments may not be viable.

Studies have not consistently detected viable SARS-CoV-2 in air samples:

Multiple air sampling studies performed in proximity to confirmed COVID-19 cases were unable to detect any virus by PCR.[41-47] Santarpia et al. was unable to culture virus from air samples collected outside of patient rooms.[48] Similarly, Binder et al. reported that 3 PCR-positive air samples, collected at distances of 1–3.2 m from patients, were culture negative.[49] Cheng V et al. sampled air at a high flow rate 10 cm from the chin of symptomatic and asymptomatic patients (n=6), with no viable virus detected by culture from collected air samples.[44] One PCR-positive air sample was obtained during an endotracheal intubation within 10 cm of the patient's head in a naturally ventilated room (window open

with fan attached); eleven other air samples near patients and 17 samples outside patient rooms and at nursing stations were PCR-negative.[50]

Lednicky et al. used a prototype and commercial version of an air sampler and custom PCR probes for detection of SARS-CoV-2 in a patient room with two patients. One patient was discharged soon after sampling periods began and after receiving a negative PCR test.[51] The remaining patient began experiencing respiratory illness two days prior to admission to the room. The results of the study include PCR-positive air samples following 3 h of sampling as well attempting viral cultures. Researchers positioned samplers 2–4.8 m from the recently symptomatic patient's head. The ventilation unit provided 6 air changes/h, filtering air and treating air with UV irradiation before recycling the air. Estimates of virus per volume of air ranged from 6–74 tissue culture infective dose $(TCID)_{50}$ units/L of air. More studies quantifying viable virus, with details of the type of ventilation and patient characteristics as reported in this study, are needed to inform the gaps in understanding aerosol transmission.

Another study detected SARS-CoV-2 by PCR in 38.7% (14/31) of air samples from a London hospital in the United Kingdom (UK) during the first peak of their epidemic. However, Zhou et al. did not detect virus by culture, suggesting there may not be adequate virus present in air samples to cause transmission.[52] Another study by Guo et al. detected SARS-CoV-2 by PCR in 35% (14/40) of air samples in an intensive care unit (ICU) and 12.5% (2/16) of air samples in the general ward that manages patients with COVID-19. 15 of 16 PCR-positive air samples were from within 2 m of patients, with 1/8 samples positive at 4 m away.[30] Ben-Shmuel et al. conducted limited sampling (generally one air sample per area) in rooms with ventilated and non-ventilated patients, at a nursing station, and in private and public areas of a quarantine hotel.[53] Positive air samples were detected in a room with a ventilated patient (n=1/1), at a nursing station (n=1/1), and in a quarantine hotel room (n=1/1). However, there were no positive air samples in rooms of non-ventilated patients (n=0/3), a doffing area (n=0/1), and a public area of a quarantine hotel (n=0/1).

Kenarkoohi et al. detected SARS-CoV-2 in 1/5 samples from a ward containing intubated, severely ill patients, but did not find any positive air samples in other areas of the hospital such as wards with suspected, confirmed and mild patients.[54] In a series of distinct room types (two airborne infection isolation rooms [AIIR] with 15+ air changes per hour, an isolation room without negative pressure, and a shared cohort room) for patients admitted within 7 days of symptom onset, Kim et al. reported that 32 air samples were negative and 20 air samples from anterooms were also negative.[55]

Chia et al., in an extended study of Ong et al., detected SARS-CoV-2 RNA by PCR in air samples collected within 1 m of patients in two of three AIIRs.[56] Lei et al. reported limited detection of SARS-CoV-2 virus by air sampling in open wards, private isolation rooms and bathrooms.[57]

Further research is needed to reconcile differences in viral RNA detection and viral viability in air samples, despite positive samples found on the surfaces of ventilation units. Differences may be due to several factors, including: 1) air sampling devices were potentially not capable of maintaining viability of captured virus; 2) timing of air sampling varies by time since onset of symptoms, severity of disease, or viral load; and, 3) the conditions of ventilation (engineering controls) reducing concentrations of viral aerosols to undetectable levels.[49,51,53]

Evidence for long distance spread of SARS-CoV-2 is uncommon:

There were few reports that have identified long distance transmission of SARS-CoV-2. The minimal transmission to fellow passengers seated near individuals with COVID-19 on airplanes does not support an airborne transmission route.[58-60] The airflows in an airplane cabin were modelled in a study

demonstrating how risk of infection may be restricted to certain areas in front and behind an infected passenger.[61]

In one case study, worshippers who were not wearing masks were exposed to a presymptomatic index patient for 100 minutes while on a bus.[62] Twenty-four of 67 worshippers became infected, including several passengers seated beyond 2 m distance. Seven of 172 other worshippers attending the same event were positive for SARS-CoV-2. The bus containing the index patient was heated and air was recirculated without filtration. Infections occurred in individuals at either end of the bus and the index case was located roughly in the middle. Risk of infection was only moderately higher for individuals sitting closer to the index patient. The authors of this study postulate that the poor ventilation in the bus supports aerosols in this large transmission cluster; however, other routes of transmission such as close contact from movement within the bus or fomites could not be excluded.

An investigation by Lu et al. into a COVID-19 outbreak in a restaurant in Guangzhou, China involving three families sitting in close proximity for more than 1 hour concluded that the air conditioning (AC) ventilation likely contributed to transmission.[63] In this scenario, there was between 53–73 min of contact between the presymptomatic index case and secondary cases. The location of a consistently running AC unit (the outlet and exhaust flanked the table of the index case) was in the airflow path of the secondary cases and was in an enclosed environment. No secondary cases occurred at adjacent tables that were outside of the likely "air column." The furthest distance between index and secondary cases was approximately 3 m.

Recent outbreaks with detailed reporting are less likely to be explained completely by droplet or contact routes (Miller et al., Brlek et al.).[64,65] In a choir group, 53 of 60 individuals (excluding the index patient) were confirmed or strongly suspected to have been infected during a 2.5 hour rehearsal in a main hall. Individuals who moved to another area of the building from the index case to practice for 45 min were less likely to have become infected than those who remained in the main hall for the full duration of the rehearsal.[64,65] In another study, infection was documented from exposure in a squash court used by patrons after a recently symptomatic index patient had played for 1 hour. Two sets of patrons using the court after the index patient were also infected (up to 90 min later). Aerosol persistence in a poorly ventilated squash court, re-aerosolization of virus from the squash court floor due to rapid movement of players, or fomite transmission were possible routes of transmission. However, this case investigation strongly supports indirect transmission of SARS-CoV-2, most likely through persistence of aerosols in a poorly ventilated space.

In an outbreak in a nursing home, de Man et al. reported that the outbreak involved 81% (n=17) of residents and 50% (n=17) of health care workers. The authors concluded that AC units and a ventilation system that did not provide adequate air exchanges contributed to the outbreak.[66] However, it should be noted that health care workers did not wear masks during non-patient care activities and the mobility and interaction between residents was not considered.

In a call center in South Korea, half of one floor of the office building experienced an outbreak in 94/216 employees.[67] The outbreak description is limited in providing further detail because the index patient was not known, ventilation parameters were not reported (especially whether air circulation was shared on both sides of the building), and daily mingling habits were not described. A handful of infected individuals were detected on two other floors, but no outbreaks occurred in those areas and the infected individuals could not be linked to the outbreak.

The importance of ventilation is described in a modeling study by Jones, who suggested that exposure to inhalable particles are mostly (80%) experienced within close proximity to the patient.[68] Even in rooms with high air exchanges, Tang et al.'s review of SARS-CoV-2 aerosols indicates that viral RNA copies can still be detected in air samples from patient rooms (1.8–3.4 viral RNA copies/m^3), toilet rooms (19 copies/m^3), and PPE doffing rooms (18–42 copies/m^3).[69]

Airborne Transmission during AGMPs

There were no documented cases of airborne transmission of SARS-CoV-2 during AGMPs in the peer-reviewed literature we examined. We note the lack of transmission in these settings may be due to the appropriate use PPE during AGMPs, with few unprotected close-contact exposures.

Evidence for transmission of SARS-CoV-2 during AGMPs:

There is little evidence demonstrating AGMPs as a contributor to health care worker transmission. In a case-control study involving health care workers, Lentz et al. reported that while AGMPs were not associated with an increased risk of SARS-CoV-2 infection, respirator use during AGMPs lowered the risk of infection (adjusted OR: 0.4; 95% CI: 0.2–0.8; p=0.005).[70]

While airborne transmission does not appear to be the predominant mode of transmission (i.e., such as in households and in routine patient care), medical procedures that generate aerosols may be associated with an increased risk of transmission.[71] During the SARS outbreak in 2003, infections disproportionately occurred among healthcare workers, with those involved in AGMPs and manipulation of the airway (i.e., at the time of intubation) at greatest risk.[72] An investigation into a nosocomial outbreak of SARS in Toronto concluded that the epidemiological links described in their investigation support the hypothesis that SARS-CoV-1 was transmitted primarily through respiratory droplets and direct contact, noting that transmission occurred during high-risk procedures (i.e. intubation) when only a surgical mask was utilized, in the absence of protective eyewear.[73] Infected healthcare workers were no less likely to contract SARS-CoV-1 while wearing an N95 respirator (vs. surgical mask), suggesting that it may have been doffing (taking off) of PPE where transmission occurred.[74] AGMPs do not appear to be a significant risk factor for SARS-CoV-2 transmission among health care workers, potentially related to improved health care worker precautions for AGMPs and/or the lower infectiousness of SARS-CoV-2 in the second week of illness (in contrast to SARS-CoV-1).[70,75-78]

Fecal-oral (Feces, Wastewater) Transmission

While fecal-oral transmission of SARS-CoV-2 is possible, it is unclear the extent to which this transmission route plays in the epidemiology of COVID-19. The evidence supporting fecal-oral transmission was limited.

Researchers have documented angiotensin-converting enzyme 2 (ACE-2; proposed receptor used by SARS-CoV-2 to enter cells) receptor expression in gastrointestinal epithelial cells; SARS-CoV-2 infects these glandular cells, as evidenced by RNA detection and intracellular staining of viral nucleocapsid protein in gastric, duodenal and rectal epithelia.[79] Gastrointestinal symptoms occur in about 9.5% of adults and children with COVID-19.[80] Tissues in the oral cavity express ACE-2 receptors.[81] SARS-CoV-2 RNA and live virus have been detected in the stool of patients with COVID-19. Given detection of infectious virus in stool and that virus can infect via the oral mucosa, fecal-oral transmission is possible.

Evidence for SARS-CoV-2 RNA detection and shedding in feces:

In systematic reviews, the mean prevalence of SARS-CoV-2-RNA-positive stool in patients with COVID-19 ranged from approximately 40% to 50% and viral RNA shedding in stool lasted longer than in nasopharyngeal (NP) swabs. In a systematic review and meta-analysis of 4,243 patients, Cheung et al. reported the prevalence of viral RNA in stool was 48.1% (95% CI: 38.3–57.9).[82] In a meta-analysis by van Doorn et al., the pooled prevalence of viral RNA in stool or anal swabs was 51.8% (95% CI: 43.8%–59.7%); and fecal samples remained positive for a mean duration of 12.5 days after negative NP swabs in 282/433 (64%) of patients who had serial test results for both respiratory and GI specimens.[83] A systematic review by Gupta et al. noted that 53.9% (291/540) of COVID-19 patients had viral RNA-positive fecal samples; duration of fecal shedding ranged from 1 to 33 days after negative NP swabs.[84] Parasa et al. reported on a meta-analysis of 407 patients with COVID-19, where the prevalence of viral RNA-positive stool was 40.5% (95% CI: 27.4–55.1).[85] In a meta-analysis, Wong MC et al. reported a pooled detection rate of viral RNA in fecal samples among patients was 43.7% (95% CI: 32.6–55.0).[86]

In studies detecting viral RNA in various clinical samples other than NP swabs, researchers more commonly detect viral RNA in stool of patients with COVID-19. In a systematic review of 569 patients by Roshandel et al., prevalence of viral RNA was higher in stool (39.5%) than blood (21.3%) and urine (8%).[87] In another systematic review, Morone et al. reported the prevalence of viral RNA-positive stool (48.8%) was higher than positive blood (17.5%) and urine (16.4%) samples; median duration of viral shedding in stool was significantly longer than shedding in respiratory samples (19 days vs. 14 days; $p<0.001$).[88] Comparing viral RNA detection in serum, urine and stool in 74 patients, Kim et al. reported a detection rate of 2.8% (9/323 samples), 0.8% (2/247) and 10.1% (13/129), respectively.[89] The mean viral load was 1,210 ± 1,861, 79 ± 30 and 3,176 ± 7,208 copies/µL, respectively, and no viable virus was detected in cell cultures. In a review, Jones et al. noted that the abundance of viral RNA in urine (10^2–10^5 genome copies [gc]/ml) and feces (10^2–10^7 gc/ml) was lower than in NP swabs (10^5–10^{11} gc/ml).[90]

In a study of 69 children, 86% had viral RNA-positive stool/rectal/anal swabs and the mean duration of viral shedding was 23.6 ± 8.8 days from symptom-onset.[91] In a study of 69 patients with COVID-19, patients with positive fecal samples were significantly younger compared to patients with negative fecal samples (mean age: 43 vs. 52 years; $p=0.003$).[92] Viral shedding in stool persisted for over 3 weeks since symptom-onset and the severity of COVID-19 was not associated with duration of viral shedding in stool.[93,94]

Kang et al. reported on an outbreak of COVID-19 in a high-rise apartment building in Guangzhou, China, where the proposed mode of transmission was through fecal aerosols via the pipes in the building.[95] However, the authors did not demonstrate the exact mode of transmission; i.e., through direct contact or indirectly through inhalation of aerosolized virus or touching contaminated surfaces.

Environmental sampling in health care and non-health care settings detected viral RNA on toilets and other bathroom surfaces.[43,55,96-99] While readily detected, it is not clear if the source of viral RNA in bathrooms was the result of respiratory droplets or from fecal contamination.

Evidence for live SARS-CoV-2 detection in feces:

Live virus has been cultured in stool samples of patients with COVID-19.[100,101] In a systematic review, viable virus was detected in the stool of six out of 17 patients, where culturing of virus was attempted.[83] It is important to note that the authors did not define positive and negative controls in these studies. While researchers detect live virus in feces, the extent of fecal-oral transmission in COVID-19 epidemiology is unclear.

Evidence for SARS-CoV-2 RNA in wastewater:

Viral RNA detection in wastewater systems in areas experiencing outbreaks; however, the risk of transmission through contaminated wastewater is low.[102,103] In a study of treated and raw sewage in Germany, the authors detected viral RNA, but not viable virus.[104] Where wastewater contaminates recreational or drinking water (especially in resource-limited countries), there is a theoretical risk of transmission; however, there is no documented transmission in these settings.[105]

In a study of eight patients with COVID-19 in a densely populated area of Guangzhou, China, the postulated mode of transmission was through the fecal-oral route, initiated from contaminated sewage in street puddles (viral RNA-positive).[106] In this study, there was an increased risk of infection when patients worked as cleaners/waste pickers, wore outdoor shoes inside their homes and cleaned dirty shoes. The authors did not confirm transmission via sewage in this study, as the authors did not detect viable virus from samples and they did not rule out other modes of transmission.

Conjunctival Transmission

To date, there is a low risk of COVID-19 infection through the conjunctiva.

Transmission through the ocular surface is a possible route of transmission of SARS-CoV-2 based on the detection of viral RNA in ocular samples of patients with COVID-19 and indirect evidence that eye protection decreases the risk of infection.[107] The risk of tears or ocular secretions acting as a source of infection is low, given that only one study has successfully cultured viable virus in these samples.

Several studies have demonstrated the expression of ACE-2 and transmembrane serine protease 2 (TMPRSS2) receptors in the eye's surface epithelium (i.e., conjunctiva, limbus and cornea) and corneal endothelium, indicating a potential entry point for SARS-CoV-2.[108-111] The conjunctiva has been proposed as a possible site of initial infection, where it can spread to the upper respiratory tract via the nasolacrimal system.[112] Deng et al. demonstrated that rhesus macaques developed mild disease after inoculation of the conjunctiva, providing further animal-study evidence of conjunctival transmission.[113]

Evidence for conjunctival transmission:

In a case report, Lu et al. described a healthcare worker who became infected after caring for a patient with COVID-19; the health care worker was wearing an N95 respirator, but no eye protection.[114] The health care worker developed eye redness and then pneumonia.

In a study of an ophthalmologist with COVID-19, 142 patients were exposed; however, only a single patient developed symptoms (but PCR negative), indicating the use of face shields, masks and performing hand hygiene prevented infection.[115] In the meta-analysis by Chu et al., eye protection provided significant protection against coronavirus infections (unadjusted RR: 0.34; 95% CI: 0.22–0.52), suggesting that transmission through the conjunctiva was possible.[116]

Fomite (Surfaces, Objects, Food) Transmission

SARS-CoV-2 can survive on a variety of surfaces, potentially leading to transmission via fomites; however, the evidence supporting fomite transmission of COVID-19 was limited and based primarily on studies of virus stability under laboratory-controlled conditions.

Evidence for fomite transmission of SARS-CoV-2:

From a detailed investigation, including whole genome sequencing, into an inter-facility outbreak of up to 135 nosocomial COVID-19 cases (including 88 staff and 47 patients) in South Africa, Lessells et al. concluded that a patient in the emergency department likely spread the infection to at least five hospital units, a local nursing home and an outpatient dialysis unit on campus.[117] Based on the pattern of transmissions, the authors concluded that indirect contact and fomite transmission were the predominant modes of transmission, facilitated by frequent patient movement between wards.

In an epidemiological and environmental study of two family clusters (n=5 patients) of COVID-19 in Guangzhou, China, Xie et al. reported potential transmission via contaminated surfaces.[118] In this case, the proposed link between the two families was through nasal secretions, in which a patient had touched a contaminated elevator button. In this study, other modes of transmission cannot be ruled out and no viable virus was detected on surfaces (only viral RNA detection).

As mentioned previously, transmission in a squash court occurred in players that used the space after it was occupied by the index case for one hour.[65] In this case, there is a possibility of aerosol persistence; however, transmission via fomites is possible (e.g., on high-touch surfaces).

Evidence for SARS-CoV-2 RNA detection on surfaces:

In health care settings, studies documented the presence of viral RNA on high-touch surfaces in the environment of symptomatic and asymptomatic patients with COVID-19 (especially medical equipment, phones, bed rails, door handles and toilets).[41,42,46,47,56,96,119-121] In a hospital in Wuhan, China, Ye et al. reported that the most contaminated surfaces were self-service printers for patient use, keyboards and doorknobs.[122] In Italy, researchers detected viral RNA on the external surface of Continuous Positive Airway Pressure (CPAP) helmets worn by COVID-19 patients; however, samples did not grow in viral culture.[123] A study reported viral RNA on surfaces (keyboards, telephones and scanners) in a clinical microbiology laboratory testing COVID-19-patient respiratory samples.[124] In a multicenter study in South Korea, contamination of surfaces was common, especially in places not adequately sanitized.[55]

Cheng et al. reported that the median load of viral RNA on surfaces was 9.2×10^2 copies/mL (range: 1.1×10^2 to 9.4×10^4 copies/mL) and positivity rates on surfaces increased with increasing viral loads in clinical samples.[96]

In non-healthcare settings (patient homes, work places), viral RNA has also been detected on surfaces (especially in bathrooms and bedrooms).[95,98,125] In a study of 39 patients and 259 environmental samples from their homes (Guangzhou, China), surfaces most commonly contaminated with viral RNA were in the bathroom on high touch surfaces (toilets, door knobs, faucets).[43]

Evidence for the detection of live SARS-CoV-2 on surfaces:

In most of the studies we examined, researchers failed to detect viable virus on surfaces or detection of viable virus was inconsistent.[41,49] Ben-Shmuel et al. investigated the viability of SARS-CoV-2 from 97 samples from surfaces of patients.[53] None of the samples grew in viral culture. In controlled experiments, virus viability on plastic and metal ceased after 4 days at ambient temperature (22°C) and decreases in virus viability negatively correlated with increasing temperature. Nonetheless, some studies indicate that under ideal conditions, SARS-CoV-2 remains viable on surfaces for several days.

Van Doremalen et al. compared surface stability of SARS-CoV-2 and SARS-CoV-1.[38] The authors noted an exponential decay in virus titre for both viruses in all experimental conditions. At 40% relative humidity and 21°C–23°C, both SARS-CoV-2 and SARS-CoV-1 were detectable for up to 24 h on cardboard and up to 2–3 d on plastic and stainless steel. On copper, the authors did not find live SARS-CoV-2 and SARS-CoV-1 after 4 h and 8 h, respectively. The estimated median half-lives for SARS-CoV-2 on these surfaces were 0.7 h for copper, 3.5 h for cardboard, 5.6 h for stainless steel, and 6.8 h for plastic. While the van Doremalen et al. study concluded that fomite transmission is possible given detection of SARS-CoV-2 on a number of surfaces, they did not demonstrate that it occurs.

Riddell et al. tested the stability of SARS-CoV-2 under controlled conditions on seven surface types (stainless steel, plastic, paper bank notes, polymer bank notes, vinyl, cotton and glass).[126] The authors concluded that infectious virus survived on non-porous surfaces for at least 28 d at 20°C and 50% relative humidity in the dark. In addition, virus titres decreased by 90% by 10 d post-inoculation at 20°C on all surfaces.

Chan et al. reported that at room temperature (20°C–25°C), SARS-CoV-2 in dried form or solution remained viable 3–5 d and 7 d, respectively; virus remained viable in solution or dried for 14 d at 4°C and about 1 d at 37°C.[127] SARS-CoV-2 was detected at pH 4 to pH 11 for several days.

Chin et al. investigated the surface stability of SARS-CoV-2 at 22°C and 65% relative humidity.[128] the authors did not detect infectious virus on printing and tissue paper 3 h after inoculation. Infectious virus was no longer present on glass or paper money by day 4 and on day 7 for plastic and stainless steel. The authors state, “The virus is highly stable at 4°C, but sensitive to heat. At 4°C, there was about a 0.7 log-unit reduction of infectious titre on day 14. With the incubation temperature increased to 70°C, the time for virus inactivation was reduced to 5 min. SARS-CoV-2 can be highly stable in favourable environments, but it is also susceptible to standard disinfection methods.”

Evidence for food-borne transmission of SARS-CoV-2:

To date, there is no evidence for food-borne transmission of SARS-CoV-2. No peer-reviewed studies investigated SARS-CoV-2 survival or detection on food and no peer-reviewed studies reported on infection through eating contaminated food. There is likely a risk of transmission from droplet or close contact during eating (from an infectious person); in addition, there is a possibility of fecal-oral transmission during eating with contaminated utensils.

Several studies have identified viral RNA on food preparation surfaces and utensils, which could potentially be a source of infection through the oral mucosa; however, the contribution of this mode of transmission is unknown. In a study of surfaces in health care settings, researchers have detected viral RNA on food preparation areas.[129] Liu et al. reported the detection of viral RNA on wooden chopsticks handled by asymptomatic and presymptomatic patients with COVID-19.[130]

Vertical (Intrauterine) Transmission

To date, there is growing evidence supporting vertical transmission, specifically intrauterine transmission, of SARS-CoV-2; however, the degree to which this mode of transmission occurs is unclear.

In a commentary, Schwartz et al. proposed that confirming vertical, intrauterine transmission requires detection of SARS-CoV-2 in chorionic villous cells using immunohistochemistry or *in situ* hybridization.[131] Early onset of COVID-19 or detection of viral RNA soon after birth in neonates, along with immunological response in neonates and RNA-positive swabs of whole placenta are not sufficient to confirm

intrauterine transmission. In addition, vertical transmission would require the detection of viral RNA in umbilical cord tissue or blood.

Evidence against vertical transmission of SARS-CoV-2:

In five systematic reviews and meta-analyses, ranging from 87 to 1,316 births, there were SARS-CoV-2 RNA-positive newborns but no evidence of vertical transmission.[132-136] In a systematic review of 1,125 mothers and 1,141 newborns, Dhir et al. concluded that the majority of infections in newborns occurred in the post-partum period (41/45; 4 infections were reported as congenital).[137]

In a multicenter observational cohort study of 242 pregnant women in Spain, Marin Gabriel et al. found no evidence of vertical transmission in newborns.[138] Yan et al. reported no vertical transmission in a series of 99 mothers with COVID-19, in which no children (n=100) tested positive.[139] Liu et al. reported no vertical transmission after delivery in 19 mothers with COVID-19; neonates tested negative by PCR (throat swab, urine, feces); amniotic fluid and breast milk also tested negative by PCR.[140]

Evidence for post-partum infection (SARS-CoV-2 RNA not detected in placenta or umbilical cord):

There are several studies where newborns tested positive (viral RNA, antibodies) soon after birth under strict infection control and prevention precautions; however, testing of chorionic villous cells or umbilical cord were negative or not performed.[141-148] In a systematic review of 275 pregnant women with COVID-19 and 246 neonates, the testing of additional samples for viral RNA did not produce positive samples (cord blood, n=30; amniotic fluid, n=24; cervical/vaginal fluids, n=7; placenta, n=6).[149]

Kirtsman et al. reported a case of probable vertical transmission of SARS-CoV-2 in a neonate born to a mother who tested positive for viral RNA by PCR on NP swab and put on airborne, droplet and contact precautions.[150] The baby was born by semi-urgent Caesarean section and placed in a resuscitator 2 m away from the mother. The NP swab was positive for viral RNA at birth and on day 2 and 7. Neonatal plasma was viral RNA-positive on day 4 and on day 7 in stool. However, viral RNA was not detected by PCR on the umbilical cord tissue and cord blood was not available for testing.

Knight et al. report the results from a prospective national population-based cohort study using the UK Obstetric Surveillance System, which included 427 pregnant women admitted to hospital with COVID-19.[151] Twelve (5%) of 265 infants tested positive by PCR for viral RNA, six within 12 h of birth. The authors did not attempt viral detection on the umbilical cord blood, placenta or vaginal secretions and did not describe infection prevention and control practices after birth.

Evidence for vertical transmission of SARS-CoV-2:

Using immunofluorescence, Taglauer et al. examined the location of SARS-CoV-2 spike glycoprotein (CoV2 SP) and two viral entry proteins (ACE-2, TMPRSS2) in placentas of 15 COVID-19-positive mothers and 10 COVID-19-negative mothers.[152] CoV2 SP and ACE-2 were localized in the outer syncytiotrophoblast layer placental villi. However, several other studies report that the expression of ACE-2 and TMPRSSR in the placenta is low.[153,154]

In a systematic review and meta-analysis of 122 neonates, Raschetti et al. reported that 5.7% of infections were confirmed as congenital, 4.9% were probable congenital infections and 1.6% were possible congenital infections.[155]

Patanè et al. found viral RNA on the fetal side of the placenta in two mothers infected with COVID-19.[156] Both children were also positive by PCR from NP swabs taken at birth. Hosier et al. analyzed the

placenta from a woman in her second trimester with symptomatic COVID-19 infection, complicated by preeclampsia and placental abruption.[157] Hosier et al. detected viral RNA predominantly in the syncytiotrophoblast cells at the maternal-fetal interface of the placenta. Additionally, Zhang et al. reported virus in syncytiotrophoblast cells, atrophic endometrial glandular epithelium and subchorionic plate (Langhan's fibrinoid) through *in situ* hybridization (2/53 placentas).[158]

Breastfeeding (Breast Milk) Transmission

Currently, there is no evidence to support mother-to-child transmission of COVID-19 through breast milk. Researchers inconsistently detect SARS-CoV-2 RNA in breast milk, with no evidence of live virus in breast milk. There have been no documented cases where breast milk is the suggested mode of transmission to an infant.

During breastfeeding, an infected mother can transmit COVID-19 to the child through respiratory droplets and close-contact transmission. In a systematic review and meta-analysis, Raschetti et al. reported that close contact of mother and child in the first 72 hours of life increased the risk of infection in the child (aOR: 6.6; 95% CI: 2.6–16.0; p<0.0001), while breastfeeding did not (aOR: 2.2; 95% CI: 0.09–1.18; p=0.15).[155]

In experiments that inoculated breast milk with live SARS-CoV-2, Holder pasteurization inactivated the virus; therefore, suggesting donated breast milk that is pasteurized may be safe for recipient children and care providers.[159]

Evidence for SARS-CoV-2 RNA detection in breast milk:

The majority of the literature agrees that there is no transmission of SARS-CoV-2 through breast milk and the benefits of breastfeeding newborns far outweigh any risks of infection.[160-163] In most studies of mothers with COVID-19, breast milk was negative for viral RNA by PCR.[140,144,164,165] While uncommon, there are case reports of mothers with viral RNA-positive breast milk; however, there were no detections of viable virus from breast milk.[166-168] In a living systematic review, Centeno-Tablante et al. reported that 9 of 68 breast milk samples were viral RNA-positive, but concluded that COVID-19 transmission did not occur through breast milk.[169]

A case report detected viral RNA in the breast milk of a breastfeeding mother with COVID-19.[170] The breastfed child developed symptoms one day after his mother, at which time he tested positive by NP swab. The transmission route in this case could not be established.

Groß et al. report on a study of two women who tested positive for viral RNA by PCR after birth and were breastfeeding.[171] Breast milk was viral RNA-positive in one of the two women at 10–13 days after birth. The authors did not attempt to culture the virus. Both infants tested positive for viral RNA (at day 8 and 11), but it is unknown if breastfeeding led to the infection in one of the infants, as the two women and infants had shared a room for some time after delivery.

Evidence for SARS-CoV-2 antibodies in breast milk:

Antibodies to SARS-CoV-2 have been detected from breast milk. In a study of 14 mothers with COVID-19, Gao et al. did not detect viral RNA in breast milk; however, three out of four mothers had breast milk with IgG and IgM antibodies.[172] In another immunological study of 18 women with COVID-19, both IgG and IgA were detected in all 37 of breast milk samples.[173]

Bloodborne (Blood, Blood Products, Organs) Transmission

While SARS-CoV-2 RNA has been detected in the blood of patients with COVID-19, all systematic reviews and studies indicated that the risk of bloodborne or organ transplant transmission is exceedingly low. Compared to upper respiratory samples, the detection of viral RNA in blood and blood products is relatively uncommon and, to our knowledge, there has been no detection of viable virus from these sources.

Evidence for SARS-CoV-2 RNA detection in blood:

Several studies have reported detection of viral RNA, in either the plasma or serum of patients with COVID-19.[18,93,100,174] In Germany, viral RNA was not detected in whole blood or serum of 18 asymptomatic and symptomatic patients; however, viral RNA (low-level RNA: 179 copies/mL) was detected in the plasma of one patient.[175] In a systematic review including 1,348 recovered patients, 17.5% of blood samples were positive for viral RNA; however, no viable virus was cultured.[88]

Evidence against blood-borne transmission:

Several case reports and case series indicate the risk of SARS-CoV-2 transmission in blood products is exceedingly low.[176,177] In a review, Kiely et al. noted that bloodborne transmission is only a theoretical possibility and that a blood phase for COVID-19 infection is brief, uncommon and usually associated with severe disease.[178] In an immunocompromised child, COVID-19 did not develop after platelet transfusion from an asymptomatic donor with COVID-19.[179] In France, low levels of viral RNA were detected in three blood products (pathogen-reduced platelet concentrate, plasma, red blood cell units) from asymptomatic COVID-19-positive donors; none of the four recipients developed disease even though they all had immune system compromise.[180] In the French study, positive plasma samples did not grow virus in culture attempts. Dres et al. reported no transmission of SARS-CoV-2 through extracorporeal membrane oxygenation and dialysis membranes.[181]

No studies have documented transmission of SARS-CoV-2 through organ transplantation. While research has not demonstrated permanent damage to non-lung organs, the consensus is that active COVID-19 infection in donors (living or deceased) is a contraindication for organ donation.[182,183] Hong et al. reported a possible infection in a liver donor recipient, in which the donor was infected at time of donation; however, transmission may have been through direct close contact.[184]

Sexual (Semen, Vaginal Secretions, Urine) Transmission

Sexual transmission may occur through direct contact and through respiratory droplets. The risk of transmission via semen or vaginal secretions is low and the evidence supporting transmission via semen or vaginal secretions was limited.

Based on viral detection in feces, some have proposed possible transmission of SARS-CoV-2 through certain sexual behaviours involving oral-anal contact.[185] In addition, the detection of viral RNA and live virus detected in the saliva of COVID-19 patients represents a potential mode of transmission during sex or intimate contact.[186,187] Jing et al. reviewed the literature on ACE-2 expression in the female reproductive system and noted expression of ACE-2 receptors in the vagina.[188] ACE-2 receptors are also present in testes (i.e., spermatogonia, Leydig and Sertoli cells).[189] While receptors for SARS-CoV-2 are present in reproductive organs, currently there is no evidence for sexual transmission. There was no evidence for the detection of live virus in semen or vaginal secretions.

Evidence for SARS-CoV-2 RNA detection in semen and vaginal secretions:

To date, most studies have failed to detect viral RNA in semen or vaginal secretions in patients with COVID-19 patients.[166,172,190] In a study of 23 male patients with active infection or recovering from infection, Guo et al. did not detect viral RNA in semen samples.[191] Similarly, a study of nine males recovering from mild COVID-19 infection did not show evidence of viral shedding in semen.[192]

Li et al. reported that 15.8% (6/38) of male COVID-19 patients had viral RNA present in their semen. The authors collected semen samples from two clinically recovered patients and four patients at the acute stage of infection.[193] In the Li et al. study, the authors detected viral RNA up to 16 d after the onset of symptoms. Massarotti et al. hypothesized that viral RNA detections in semen are due to viral RNA-contamination by patient urine.[194]

Evidence for SARS-CoV-2 RNA detection in urine:

Researchers report detection of viral RNA in urine; however, the risk of transmission via urine is low. We are only aware of one instance where infectious virus was isolated from the urine of a patient with COVID-19.[195]

In a systematic review and meta-analysis, Roshandel et al. reported that 8.1% of (46/569; see Table 3 in paper) patients showed viral RNA shedding in urine (compared to 42.1% [210/499] for stool and 21.3% [100/469] for stool; see Figure 2 in paper) and viral RNA shedding in urine increases with disease severity.[87] In a systematic review, 16.4% (60/366) of patients were positive for viral RNA in urine.[88] In another systematic review of 549 patients, 6.9% showed evidence of viral RNA in their urine; however, culturing attempts were not successful.[196] In a study of 74 patients hospitalized with COVID-19, Kim et al. found that 0.8% (2/247) of urine samples were positive for viral RNA (viral load: 79 ± 30 copy/µL; compared to 3,176 ± 7,208 copy/µL in stool); however, no viable virus was cultured.[197]

Zoonotic transmission

Evidence for zoonotic transmission from companion, domestic and wild animals to humans was limited. Most of the evidence to date indicated that non-human animals are more at risk of infection from humans, especially companion and domestic animals.[198] Further research is needed to identify potential reservoirs of SARS-CoV-2 and what risk they pose to humans and animals.

Early research revealed SARS-CoV-2 is a close relative of SARS-CoV-1 and MERS-CoV, and all are βCoVs that originated from bats (*Rhinolophus* species).[199,200] Natural infection of animals with SARS-CoV-2, were all exposed to symptomatic humans. Infected animals include companion animals (domestic dogs [*Canis lupus*], domestic cats [*Felis catus*], farmed animals (American mink [*Neovison vison*], and zoo animals (lions [*Panthera leo*], tigers [*Panthera tigris*]).[201-203]

Evidence for animal-to-human and animal-to-animal transmission:

Currently, the intermediate source of the initial COVID-19 infections in humans is unknown and the risk of transmission from animals to humans is low.

Malayan pangolins (*Manis javanica*) have been postulated as the intermediate host based on the presence of viruses closely related to SARS-CoV-2; however, this hypothesis has not been confirmed.[204-206] Recently, Freuling et al. reported that raccoon dogs (*Nyctereutes procyonoides*) are susceptible to SARS-CoV-2 infection and may represent an important intermediate and reservoir host.[207] Authors in

this study infected raccoon dogs through the intranasal route, which led to animal-to-animal transmission through direct contact, with high-level viral shedding with mild disease. Raccoon dogs are widespread in China and raised for their fur. It is important to note that there are no reports of SARS-CoV-2 natural infection in raccoon dogs.

In the Netherlands, there was evidence that COVID-19 transmission occurred from an infectious American mink to human.[208] It should be noted that in most circumstances, transmission of SARS-CoV-2 involving animals is human-to-animal or animal-to-animal.[203] In a laboratory experiment, ferrets can transmit the virus to other ferrets through respiratory droplets and direct contact,[209] and potentially via small aerosols.[210]

In a laboratory experiment, dogs and cats were susceptible to COVID-19; however, neither developed clinical disease.[203,211] Cats transmitted the virus to other cats through close contact. Cats shed virus for 5 days post infection; however, there was no viral shedding in dogs. Authors noted oral and nasal viral shedding 7 days after exposure in two in-contact cats. Therefore, there is a possibility that transmission could occur from cats to humans. In addition, Shi et al. reported that experimental exposure in cats resulted in subclinical and symptomatic infections, and juvenile cats were at a higher risk of severe infection or death.[212]

Evidence for human-to-animal transmission (reverse zoonosis):

The first documented instance of human-to-animal transmission occurred between an infected person in Hong Kong and their companion dog, soon after there was a report of human-to-cat transmission in Hong Kong.[205] There is evidence that human-to-dog transmission may be limited due to cross-reaction of SARS-CoV-2 and canine respiratory coronavirus (CRCoV), providing some immunological cross-protection.[213] The most commonly reported human-to-animal transmission has involved domestic cats, where most cats have a reported close contact with a confirmed human case of COVID-19.[203,214] In Wuhan, China, 14.7% (15/102) of cats seroconverted to SARS-CoV-2 early during the pandemic.[215]

Several researchers have highlighted the need to monitor wild animals, to ensure that reverse zoonosis does not occur (human-to-animal transmission). Olival et al. reported that there is a risk of immunologically naïve North American bats acquiring SARS-CoV-2.[216] Researchers also demonstrated that deer mice (*Peromyscus maniculatus*) are susceptible to infection and are potential reservoirs of SARS-CoV-2 in North America.[217]

To date, laboratory studies indicate that domestic ducks (*Anas platyrhynchos domesticus*), chickens (*Gallus gallus domesticus*) and pigs (*Sus scrofa*) were not susceptible to SARS-CoV-2.[212,218]

Other susceptible animals, used in laboratory experiments or as animal models, include ferrets (*Mustela putorius*), fruit bats (*Rousettus aegyptiacus*), rhesus monkeys (*Macaca mulatta*) and Syrian hamsters (*Mesocricetus auratus*).[212,219]

Conclusions

Transmission of SARS-CoV-2 occurs predominantly through respiratory droplets during close (<2 m), unprotected contact. Airborne transmission over longer distances (>2 m) through the inhalation of small respiratory droplets or aerosols is less common, but possible under certain conditions such as prolonged exposure in a poorly ventilated space.

Relatively uncommon routes of transmission of SARS-CoV-2 include conjunctival, vertical, fecal-oral, fomite and zoonotic. These routes of transmission are possible; however, their contribution to COVID-19 epidemiology is unclear. While modes of transmission such as through semen, breast milk or urine are theoretically possible, the probability of these occurring is exceedingly low.

PHO will continue to monitor the scientific evidence on transmission routes of COVID-19, updating this document as necessary.

Appendix A. Glossary of Terms for COVID-19 Routes of Transmission

Advisory

The glossary below contains definitions that may be changing with the understanding of evidence. Definitions may be different from how the same terms are used in other contexts or even seen as controversial due to different use within the same context by different organizations. Therefore, these definitions are provided to support the understanding of the COVID-19 – What We Know So Far About… Routes of Transmission document. This glossary is not exhaustive and may be updated with new terms or revised at any time.

Key Terms

Airborne transmission: Transmission of infection occurring due to the inhalation of aerosols that have remained suspended for a long period of time or have been suspended on air currents over long distances.

Air sampling for virus: Collection of volumes of air by a device to determine if aerosols may contain virus. Collection can vary by aerodynamic size captured, duration of collection, volume per second collected, and media on which samples deposit. Air samples can then be tested by molecular methods and/or viral culture.

Aerosol: Aerosols are defined by National Institute for Occupational Safety and Health (NIOSH) as a suspension of particles (solids) or droplets (liquids) in the air.[1] The diameter of microorganism-containing aerosols relevant to inhalation ranges from 0.01 to 100 µm. Discussion of respiratory infections focus on droplets rather than particles because the sources of infectious aerosols are assumed to be from respiratory mucosa or epithelium, which will be droplets (liquids) that contain infectious biological material. Droplets >100um are too large to be suspended in the air, and are therefore not considered aerosols.[2] Droplets generally lose mass while suspended in air as aerosols due to evaporation of volatile components or water. The droplets that result from the process of evaporation are often referred to as droplet nuclei. The final size of a droplet will depend on a variety of environmental factors.

Aerosol generating medical procedures: Aerosol generating medical procedures (AGMPs) are defined as medical procedures that result in the production of aerosols that create the potential for airborne transmission of infections that may otherwise only be transmissible by the droplet route, and are epidemiologically associated with an increased risk of acquisition of infection.[3]

Contact transmission: Transmission of infection through direct contact.

Direct transmission: Transmission of infection through contact or droplet transmission.

Droplet transmission: Transmission of infection occurring due to impaction of large droplets (usually >100 um) that are too large to be suspended in air for long durations. Infection may follow by direct impaction onto mucosal surfaces (mouth, eyes, nose), or contaminate a person's body/clothing which then makes direct or indirect contact with susceptible surfaces (e.g., mucosal surfaces for COVID-19).

Indirect transmission: Includes any mode of transmission where direct contact or droplet transmission is not involved (e.g., fomite transmission, airborne transmission, and vectors).

Fomite/Fomite transmission: Objects that may become contaminated with microorganisms and serve as vehicles of transmission.[4]

Polymerase Chain Reaction (PCR): A molecular method used to amplify nucleic acids. If nucleic acids of the microorganism of interest is present in a sample, then PCR can be used for the identification of that microorganism. This method cannot determine whether or not the microorganisms detected are viable.

Viral culture: Viral culture is used to determine whether a sample containing virus is capable of replication. Replication is a surrogate measure for inducing infection. Other methods to detect virus in a sample such as PCR cannot determine the viability of the organism in the sample. A sample is applied to a susceptible culture of cells and incubated up to a few weeks to detect morphological changes such as plaques that would indicate the presence of a viable virus.

COVID-19 Transmission Through Large Respiratory Droplets and Aerosols… What We Know So Far

Introduction

Public Health Ontario (PHO) is actively monitoring, reviewing and assessing relevant information related to Coronavirus Disease 2019 (COVID-19). "What We Know So Far" documents provide a rapid review of the evidence on a specific aspect or emerging issue related to COVID-19. Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is transmitted in different ways; however, this document will focus on transmission by respiratory droplets and aerosols.

Key Findings

- The historical dichotomy of droplet versus airborne transmission, while useful in implementing infection prevention and control (IPAC) strategies, does not accurately recognize the complexity of viral respiratory transmission, including for SARS-CoV-2.
- SARS-CoV-2 is transmitted most frequently and easily at short range through exposure to respiratory particles that range in size from large droplets which fall quickly to the ground to smaller droplets, known as aerosols, which can remain suspended in the air.
- There is evidence to suggest long-range transmission can occur under the right set of favourable conditions, implicating aerosols in transmission.
- The relative role of large respiratory droplets versus smaller droplet particles in short-range transmission is challenging to quantify. Their contributions to a specific case-contact interaction vary based on contextual factors including source/receptor characteristics (e.g., forceful expulsions such as singing, coughing, sneezing; viral load) and pathway characteristics (e.g., duration of exposure; environmental conditions such as ventilation, temperature, humidity, ultraviolet light; source control; and use of personal protective equipment).
- Translation of this summary into control measures needs to take into consideration other information, such as evidence around the effectiveness of control measures to date. Several control measures applied together in a layered approach are likely to be effective irrespective of the relative contribution of droplets or aerosols, including achieving high vaccination coverage and avoiding the "3 C's" (closed spaces, crowded places and close contact).

Background

The diameter of microorganism-containing respiratory particles relevant for respiratory infections ranges from approximately 0.01 micrometres (µm) to greater than 100 µm.[1] Particles larger than about 100 µm play a role in respiratory infection transmission by impacting on mucosal surfaces, such as the nostrils, mouth and eyes. Particles smaller than 100 µm can be inhaled or impact on mucosal surfaces. Some particles are small enough that they can be suspended in the air for various periods of time (known as aerosols).[2] Environmental factors such as local air currents and humidity affect these particles, e.g., how they move, evaporate, and how long they remain in air.[3] Therefore, the mode of transmission is influenced by three key elements: the source, the pathway, and the receptor. Depending on the unique characteristics of each element, certain modes may be more likely than others.

Traditionally, respiratory particles >5 or 10 µm have been termed droplets and were thought to impact directly on mucous membranes, while smaller particles were thought to be inhaled. This dichotomy of transmission routes has been applied to infection prevention controls within health care settings worldwide. However, these transmission routes are not mutually exclusive as droplets well over 5 µm are capable of remaining suspended in air for some time and can be inhaled. At short range within about 2 metres (m), infection can occur from inhaled aerosols as well as droplets landing on mucous membranes (short-range transmission). Herein, we refer to what was traditionally called airborne transmission via inhalation of aerosols that have remained suspended over long distances and periods of time[4,5] as long-range transmission.

We describe transmission through epidemiological studies, experimental or simulation of transmission studies, and statistical or mathematical modelling. Modelling shows what is possible, experimental studies what is plausible, and epidemiologic studies observe what is actually occurring, and each type of evidence is subject to limitations. However, exact routes of SARS-CoV-2 transmission in real-life scenarios can only be inferred based on the available data.

The purpose of this rapid review is to outline the evidence for droplets and aerosols in SARS-CoV-2 transmission. We have summarized the evidence as either short-range transmission from large respiratory droplets and small droplets or aerosols, or long-range transmission from aerosols.

Methods and Scope

In considering feasibility, scope and timelines, we undertook a rapid review to update our summary of SARS-CoV-2 transmission from large respiratory droplets and aerosols. A rapid review is a knowledge synthesis where certain steps of the systematic review process are omitted in order to be timely (e.g., duplicate screening).[6]

We conducted literature searches in MEDLINE (April 22, 2021) and National Institutes of Health COVID-19 Portfolio (Preprints) (April 27, 2021), search strategies are available upon request. We searched PubMed and Google Scholar on April 28, 2021 for additional articles of interest.

English-language peer-reviewed and non-peer-reviewed records that described large respiratory droplet and aerosol routes of transmission of COVID-19 were included. We restricted the search to articles published after January 1, 2020. This rapid review concentrated on evidence from systematic reviews and meta-analyses, supplemented by primary literature where appropriate. We reviewed citations from included articles to identify additional research.

Prior to publishing, PHO subject-matter experts review all What We Know So Far documents. As the scientific evidence is expanding rapidly, the information provided in this document is only current as of the date of respective literature searches.

Out-of-scope for this document was a review of IPAC practices appropriate for individual transmission scenarios and settings. Application of a hierarchy of control measures for non-health care settings is briefly discussed in the conclusions. For additional information related to IPAC in health care settings, please see PHO's technical briefing *IPAC Recommendations for Use of Personal Protective Equipment for Care of Individuals with Suspect or Confirmed COVID-19* and *Interim Guidance for Infection Prevention and Control of SARS-CoV-2 Variants of Concern for Health Care Settings*.[7,8] Please note that the *Ministry of Health's Directive 1* is the provincial baseline standard for provision of personal protective equipment for hospitals, long-term care homes and retirement homes and that the *Ministry of Health's Directive 5* provides agency to health care workers to make professional decisions regarding the appropriate personal protective equipment when dealing with suspected, probable or confirmed COVID-19 patients or residents.[9,10] Evidence for contact/fomite transmission, and virus and host (source/receptor) factors were not reviewed in this document, but are acknowledged as contributors to short- and long-range transmission. Other routes of transmission are reviewed in PHO's synthesis *COVID-19 Routes of Transmission – What We Know So Far*.[11]

Short-range Transmission

Main Findings

SARS-CoV-2 is transmitted most frequently and easily at short range. Short-range transmission generally occurs within 2 m of an infectious individual (e.g., during a conversation with inadequate distancing, no barriers, no personal protective equipment). Theoretically, short-range transmission may occur due to droplets or aerosols, but the relative contribution of either is specific to each case-contact interaction which varies based on contextual factors including source/receptor and pathway characteristics.

Environmental Factors Affecting Short-range Droplets and Aerosols

In addition to virus and host factors, environmental factors are associated with short-range viral transmission. The distance travelled by large respiratory droplets is generally <2 m, although it can reach up to 8 m in certain circumstances. In a study by Guo et al. (2020), SARS-CoV-2 virus was detected on the floor up to 4 m away from a patient.[12] In a systematic review of studies assessing the horizontal distance travelled by respiratory droplets, Bahl et al. (2020) reported that droplets could travel up to 8 m.[13] In a mathematical model, Chen et al. (2021) reported that respiratory droplets >100 µm in diameter are only important in transmission at a distance of less than 0.2 m when the infector is talking, or within 0.5 m when the infector is coughing.[14] Modelling by Wang et al. (2021) (preprint) suggested droplets >100 µm would most often not travel past 1.75 m (most droplets >100 µm diameter settle before 1.25 m).[15]

In a review of respiratory virus transmission, Leung (2021) reported that environmental factors affecting transmission include temperature, relative humidity, ventilation, airflow and ultraviolet (UV) light.[16] Ventilation, airflow and forceful expulsion (sneezing or coughing) can make respiratory particles travel further than 2 m through momentum.[14,17] High temperature and low humidity contributes to shrinking of droplets such that they may remain suspended in air for longer periods of time.[18]

Even at short-range distances, ventilation may affect transmission. De Oliveira et al. (2021) modelled infection risk in ventilated (10 air changes per hour [ACH]) and unventilated spaces without respiratory protection during a 1-hour exposure at 2-m distance.[19] The impact of decreasing concentration of virus in the air through ventilation was notable. Estimates of infection risk were reduced by at least three times based on the parameters and assumptions of their model. The authors also commented that the direction of airflow can have a significant impact – upward air streams can maintain aerosols at face height significantly increasing infectious risk.

Indoor settings are a predominant risk factor for transmission. In a systematic review of 5 studies, Bulfone et al. (2020) reported that the odds of indoor transmission were 18.7 times (95% confidence interval [CI]: 6.0–57.9) higher than outdoor settings, and less than 10% of infections occurred outdoors.[20] Very few superspreading events have been described from exclusively outdoor exposures. The explanation for this observation is likely multifactorial which includes important differences in ventilation, UV light, humidity, as well as possible differences in behaviour.

Epidemiological and Modelling Studies Describing Short-range Transmission

The following section reviews the epidemiologic and modelling evidence supporting short-range transmission of COVID-19. It reviews the reproductive number and summarizes the epidemiological and modelling studies by setting, including transportation, health care and sports.

The reproductive number (R_0) of SARS-CoV-2 is less suggestive of long-range transmission commonly occurring, as viruses where long-range transmission commonly occurs tend to have a higher R_0.[16] For example, in a systematic review by Guerra et al. (2017), the R_0 for the measles virus in the pre-vaccine era was 6.1–27.0,[21] compared to the median range of R_0 (2.7–3.3) reported for SARS-CoV-2.[22] It is important to note that R_0 is not a direct measure or indication of transmission route, as R_0 can be setting and population-specific, and be impacted by factors such human behaviours. The R_0 for SARS-CoV-2 also displays overdispersion, where the overall R_0 is lower than pathogens that commonly transmit through aerosols at long-range, but a small proportion of cases are associated with reproductive numbers in the range typical of viruses that commonly transmit through aerosols at long-range (i.e., superspreader events).[23] Such cases illustrate the potential variability in COVID-19 transmission, depending on differences in source/receptor characteristics and environment.

Short-range transmission was favoured in a retrospective cohort study of 18 short-to-medium haul flights (median flight time 115 minutes) to England from the beginning of the pandemic.[24] The attack rate was 0.2% (95% confidence interval [CI]: 0.1–0.5) for all aircraft-acquired cases, and was higher at 3.8% (95% CI: 1.3–10.6) if a subgroup analysis was performed only on contacts within a two-seat radius. It was assumed that no masks were worn given that it was early in the pandemic.

Family gatherings for meals are high-risk scenarios for transmission. Lo Menzo et al. (2021) reported transmission of lineage B.1.1.7 variant of concern to 8 of 9 family members during a dinner gathering.[25] The only uninfected family member was presumed to have immunity acquired from a previous infection (high antibody titres and polymerase chain reaction (PCR) negative result). Contact and fomite transmission cannot be excluded from this type of event.

In a case-control study of 154 patients 18 years and older in the United States (US), Fisher et al. (2020) reported that close contact with a person with COVID-19 was reported more often among cases (42.2%) than controls (14.5%) ($p<0.01$).[26]

Short-range transmission has been documented in school settings. Four student-to-student and one student-to-teacher transmission events were reported in Salt Lake County, Utah.[27] For four transmission events, unprotected, short-range exposures were noted. There was a lack of transmission to other students that were a median of 1 m away during class, but adhered to control measures implemented in the school. However, when household transmission associated with the secondary cases was evaluated, transmission was high for 3 of the 5 households of secondary patients. In these three households, 6 of 8 household members were also infected and may be related to challenges with physical distancing, masking, and shared surfaces in the household.

Using whole genome sequencing of SARS-CoV-2 clinical samples (n=50) in Dublin, Ireland, Lucey et al. (2020) investigated cases of hospital-acquired COVID-19 and reported that the majority of infections were among patients who required extensive and prolonged care by health care providers.[28] The authors concluded that the likely mode of transmission from health care workers to patients was through short-range transmission and close contact, rather than long-range transmission. Notably, the use of masks by health care providers was not universal and patients were not wearing masks either.

Three short-range health care-associated transmission events have been reported where large respiratory droplet transmission was less likely because masks were worn by either the source or the contact and in two of three events, the contact was also wearing eye protection.[29] In case 1, an asymptomatic, unmasked patient transmitted infection to two health care workers who wore medical masks and face shields, following multiple hours of exposure in a room with 6 ACH. A second case occurred where a presymptomatic masked health care worker transmitted infection to an unmasked patient in a room with 6 ACH. A third case involved a presymptomatic masked patient transmitting infection to a health care worker who was wearing a mask and goggles during a 45 minute face-to-face discussion at 1 m. Notably in the third case, the patient's mask was removed temporarily for oropharynx inspection. While each case was verified by whole genome sequencing, there was a lack of detail about the specific encounters (e.g., distance, duration, if direct contact occurred, if doffing errors occurred), and no airflow studies were conducted.

An analysis of SARS-CoV-2 infections in an outdoor rugby league, including video evaluation of close contact due to tackling inherent in the game, indicated that no cases among players in the league could be linked to close-contact during the outdoor rugby games.[30] Instead, transmissions were linked to other indoor short-range transmission events. While this study demonstrates examples where outdoor close-contact transmission did not occur, there were not enough close-contacts documented to provide evidence that close-contact transmission could not have occurred in the context of outdoor rugby.

In a modelling study, Zhang and Wang (2020) reported that the median infection risk via long-range aerosol transmission (10^{-6}–10^{-4}) was significantly lower than the risk via close contact (10^{-1}).[31] The model was based on a 1-hour exposure in a room with an area of 10–400 m^2, with one infected individual and a ventilation rate of 0.1–2.0 ACH. In a modelling study by Hu et al. (2020), the transmission risk from epidemiological data among train passengers as 0%–10.3% (95% CI: 5.3%–19.0%).[32] Travellers directly adjacent to the index patient had a much higher infection risk (relative risk [RR]: 18.0; 95% CI: 13.9–23.4), and the attack rate decreased with increasing distance.

Household and Non-Household Secondary Attack Rates

The consensus among systematic reviews is that household settings, where physical distancing, consistent source control mask-wearing, and disinfection of shared surfaces are potentially not feasible, are associated with a higher risk of infection compared to casual-contact settings (17%–27% compared

to 0%–7%). However, the secondary household attack rates are not as high as would be expected if SARS-CoV-2 easily spread through long-range transmission (e.g., >90% in measles).[16,33]

In a systematic review and meta-analysis of 54 studies and 77,758 patients, Madewell et al. (2020) reported that the household secondary attack rate was 16.6% (95% CI: 14.0–19.3).[34] In a systematic review and meta-analysis of 45 studies, Thompson et al. (2021) estimated the household secondary attack rate as 21.1% (95% CI: 17.4–24.8; 29 studies).[35] Non-household settings had lower secondary attack rates: 1) social settings with family and friends (5.9%; 95% CI: 0.3–9.8; 7 studies); 2) travel (5.0%; 95% CI: 0.3–9.8; 5 studies); 3) health care facilities (3.6%; 95% CI: 1.0–6.9; 10 studies); workplaces (1.9%; 95% CI: 0.0–3.9; 7 studies); and casual social contacts with strangers (1.2%; 95% CI: 0.3–2.1; 7 studies). Koh et al. (2020), in a meta-analysis of 43 studies, reported that the household secondary attack rate was 18.1% (95% CI: 15.7–20.6; 43 studies), much higher than the secondary attack rate in health care settings (0.7%; 95% CI: 0.4–1.0; 18 studies).[36] In a systematic review and meta-analysis of 24 studies, Lei et al. (2020) reported that the secondary attack rate in households was 27% (95% CI: 21−32); the risk of secondary infection was 10 times higher in households compared to non-household settings (odds ratio [OR]: 10.7; 95% CI: 5.7–20.2; p<0.001).[37] Tian and Huo (2020), in a meta-analysis of 18 studies, reported that the household secondary attack rate was 20% (95% CI: 15–28; 15 studies; n=3,861 patients), followed by social gatherings at 6% (95% CI: 3–10; 5 studies; n=2,154 patients) and health care settings at 1% (95% CI: 1–2; 4 studies; n=1,320 patients).[38]

Long-range Transmission

Main Findings

Transmission of SARS-CoV-2 over longer distances (generally >2 m) and time occurs through inhalation of aerosols under favourable circumstances, such as prolonged exposure in an inadequately ventilated space. Current evidence supports long-range transmission of SARS-CoV-2 occurring “opportunistically”, in that long-range transmission can occur under some circumstances, but inconsistently, and is not the predominant situation in which transmission occurs. Epidemiological and modelling studies support that long-range transmission via aerosols occurs. All of these examples include combinations of favourable source/receptor and pathway conditions such as inadequate ventilation, prolonged exposure time, high viral load, with certain activities (singing, exercising, yelling, etc.), and lack of masking for source control by the index case.

Environmental Factors Affecting Long-range Aerosols

In experimental models, researchers have demonstrated the potential for long-range transmission. In a series of experiments, simulations and modelling, Wang et al. (2021) (preprint) reported that aerosols could remain suspended for a longer period than historically predicted.[15] In general, viral copies/millilitre (ml) or concentration decreased as distance from source increased. The work showed that the evaporation time for large respiratory droplets is longer than predicted, especially at higher relative humidity (90%). In a sneeze plume, the largest respiratory droplets (>100 µm) are centrally located within the plume, with smaller respiratory droplets and aerosols at the periphery. The largest droplets contain more virus copies but are less abundant as they settle quickly to the ground, while smaller droplets carry fewer virus copies but are more abundant and remain in the air. The authors conclude that while aerosol transmission is important past 1 m from the source, aerosol transmission is likely even more important at shorter ranges.

Modelling studies have also highlighted the potential for aerosol transmission at varying distances. Xu et al. (2021) analysed the data of 197 symptomatic COVID-19 cases in the Diamond Princess cruise ship outbreak and concluded that long-range transmission did not occur between cabins based on the random distribution of symptomatic cases on all decks and the lack of spatial clusters of close contact (within cabin) infection.[39] The authors inferred that most transmission had occurred in public areas before the quarantine, possibly due to crowding and insufficient ventilation in those spaces. The authors also inferred that there was no transmission between passenger rooms during the quarantine period, and suggested that the ship's central heating, ventilation, and air conditioning (HVAC) system did not play a role in SARS-CoV-2 transmission. However, the authors noted that the lack of data on 109 of the 306 symptomatic individuals and on the 328 asymptomatic individuals may alter their estimation. In addition, their estimation did not take into consideration possible transmission between crew and passengers. Another model of the same outbreak estimated that the contribution of short-range transmission (from large droplets or aerosols) accounted for a median of 36% (mean: 35%) of transmission events, fomite (median: 21%; mean: 30%) and long-range (median: 41%; mean: 35%) contributing to the remainder.[40]

A study of aerosol particles (<5 μm diameter) by Dobramysl et al. (2021) (preprint) reported that time to infection increases approximately linearly as distance from source increases, the most important parameter for time to infection.[41] Exposure to a person breathing normally (simulating an asymptomatic individual) at a distance of 1 m led to infection after 90 minutes; however, coughing every 5 minutes led to infection in 15 minutes. Mask use and even minimal ventilation increased time to infection at a given distance. The importance of ventilation is also described in a modelling study by Jones (2020) which suggested that exposure to inhalable particles mostly (80%) occurs within close proximity to the patient.[42] In still air, aerosols will rise above head-level; however, turbulent air can change the trajectory of virus-laden aerosols, bringing aerosols closer to the head.[43-45] A modelling study by Sen (2021) found that when the ceiling-mounted elevator fan was off, about 11% of the droplets expelled by coughing fell to the ground while 89% evaporated and became smaller.[46] After travelling downward in cough-induced turbulence for approximately 6 seconds, droplets about 50 μm tended to move up and spread in the upper part of the elevator. If the cough happened at 30° to another rider, up to 40% of the droplets may fall on the face of another elevator rider. However, when the fan is operating, up to 50% of the droplets were dragged down to the floor in less than 3 seconds.

The basement of a large wholesale market was investigated as the source of a major outbreak in Beijing, China.[47] Many factors contributed to spread across multiple possible modes of transmission including long-range transmission. A field study of the area using fluorescent powders and microspheres as tracers allowed authors to conclude that while air was circulated, the air was unfiltered and there was very little fresh air, there was high humidity, low temperature, inadequate hand sanitization supplies in washrooms, and significant contamination of surfaces possibly due in part to resuspension of droplets from wet floors.

Given that persistence of aerosols over time is a factor in long-range transmission, the viability of SARS-CoV-2 in aerosols is important to consider. The half-life of SARS-CoV-2 in aerosols is approximately 1 hour.[48,49] Humidity seems to have less of an effect on SARS-CoV-2 viability in aerosols compared to the effect of sunlight or temperature.[50,51] Increasing temperature is associated with a reduction in the half-life of SARS-CoV-2 in aerosols.[52-54] Using a rotating drum experiment similar to other studies for viability of SARS-CoV-2, simulated sunlight (UVA/UVB) was applied to aerosolized virus through a window on the drum.[51] Results indicated 90% inactivation of virus within 20 minutes.

Inadequate ventilation can contribute to spread of aerosols, where the buildup of infectious aerosols is inversely proportional to the number of air exchanges.[55-57] In a modelling study, Schijven et al. (2021) assessed the risk of aerosol transmission of SARS-CoV-2 at a distance beyond 1.5 m from continuous breathing, speaking, or singing, or from one cough or one sneeze, in an indoor environment of 100 m^3.[58] Where there was no ventilation, the mean risk of transmission (derived from dose-response data for human coronavirus 229E) after 20 minutes of exposure to a person with 10^7 RNA copies/ml of mucous was estimated at 0.1%, except for sneezing with high aerosol volume (40,000 picolitres/sneeze). The mean risk of transmission increased to above 30% for sneezing with high aerosol volume and above 10% for singing after an exposure of 2 hours to a person with mucous RNA concentration above 10^8 copies/ml. Ventilation at 1 ACH reduced the risk by approximately half and at 6 ACH, the risk of transmission was reduced by a factor of 8–13 for sneezing and coughing, and by a factor of 4–9 for singing, speaking and breathing.

Estimates for minimum infectious dose, amount of viable virus in aerosols and quantified exposure rates are lacking. One preprint study assessed superspreading events related to long-range transmission in order to determine a minimum infectious dose for transmission.[59] The model used rate of aerosolized virion shedding based on data from other coronaviruses and a destabilization rate measured for SARS-CoV-2. They reported a critical exposure threshold for aerosol transmission of 50 virions. A computational characterization of inhaled droplets by Basu (2021) reported an estimated inhaled infectious dose around 300 virions, which was similar to estimates of 500 virions for ferrets.[60] The author acknowledged that this estimate could vary widely depending on environmental and individual biological factors.

Epidemiological and Modelling Studies Describing Long-range Transmission

Epidemiological case studies have reported long-range transmission of SARS-CoV-2, exclusively in indoor settings (e.g., bus, church, restaurant, concert halls, apartment building, office building).[61-67] In most of these case studies, long-range transmission was inferred as the dominant route of transmission, given that infectees were usually further than 2 m away from index cases. In addition, in these case studies, susceptible people were exposed to index cases for prolonged periods (>50 minutes) in indoor environments with inadequate ventilation and, in some instances, with increased respirations (e.g., singing, yelling, or exercising) and/or no face mask use (by case and/or contact). As with most epidemiological studies on transmission events, it was difficult to exclude other contributing routes of transmission. We summarize a few of these case studies, highlighting settings and contributing contextual factors to long-range transmission.

Stagnant indoor conditions can contribute to aerosol transmission. One example is a series of transmissions linked to an individual who developed symptoms around the time they were playing squash in an unventilated squash court.[68] Players who arrived hours after the index case and played in the same squash court were later identified as positive cases, though the role of other potential routes (e.g. unidentified staff contacts, shared surfaces) may have contributed as well and the source of transmission could not be confirmed. In contrast, a post-operative analysis of susceptible patients (no previous SARS-CoV-2 infection or vaccination) in a surgical suite within 48 hours following the use of the suite by SARS-CoV-2 positive patients indicated that there were no transmission events. The event rate was lower than the number of events in a control group (0% vs. 1.9%).[69] Ventilation was likely a significant factor that prevented transmission in the surgical suite.

In a study of six indoor singing events (five with transmission) in the Netherlands, Shah et al. (2021) (preprint) reported that long-range transmission was the likely route of transmission (short-range transmission possibly contributing to transmission at three of these events and indirect contact transmission possibly contributing to transmission at one of the events).[62] The authors assigned transmission likelihood as either less likely or possible; however, the authors do not state how these were defined. Attack rates at these events ranged from 25%–74% (9–21 people aged 20–79 years attended the events) and authors hypothesize that singing led to transmission. The authors note that they cannot quantify the contribution of each route of transmission. Genomic sequencing was not performed to help rule out other sources of SARS-CoV-2.

In a choir group (Washington, US), 53 of 60 individuals (excluding the index patient) were confirmed or strongly suspected to have been infected during a 2.5 hour rehearsal in a main hall.[64] Individuals who moved to another area of the building from the index case to practice for 45 minutes were less likely to become infected than those who remained in the main hall for the full duration of the rehearsal.

Twelve secondary cases of SARS-CoV-2 were linked to an index case, an 18-year-old chorister with high viral load who sang at four 1-hour services.[70] The index case was seated at a piano raised approximately 3 m from the ground floor and facing away from the secondary cases. Secondary cases sat between 1–15 m (horizontal distance) from the index case. Use of masks was not in place and there was minimal ventilation during the service (ventilation system was off, fans were off and doors and windows were largely closed). Interestingly, no new cases were linked to exposure that occurred the day of respiratory symptom-onset, and no explanation could be provided for why only a certain section near the chorister was affected and other sections (including those directly in front of the index case) were not.

In a case study by Shen et al. (2020), passengers who were not wearing masks were exposed to a presymptomatic index patient for 100 minutes while on a bus in eastern China.[61] Twenty-four of 67 passengers became infected, including several passengers seated beyond 2 m distance. The bus containing the index patient was heated and air was recirculated without filtration. Infections occurred in individuals at either end of the bus and the index case was located roughly in the middle. Risk of infection was only moderately higher for individuals sitting closer to the index patient. In contrast, seven of 172 other people attending the same religious event were positive for SARS-CoV-2. Some of the cases became positive after 14 days from exposure; thus, transmission likely did not occur on the bus for these case. The authors of this study postulate that the poor ventilation in the bus supports aerosol transmission in this cluster; however, other routes of transmission such as close contact from movement within the bus or fomites could not be excluded.

Vehicles are also potential environments for short-range and long-range transmission. A patient transport van was implicated in long-range aerosol transmission despite physical distancing observed by the infected drivers in two distinct transmission events.[71] One driver did not wear a mask, but all passengers wore a single-layer mask. The passengers were exposed for 2 hours during both events. Transmission was confirmed by whole genome sequencing. Fans were on medium speed and windows were closed. Airflow experiments were conducted with different size aerosols demonstrating plausibility of spread from the driver.

An epidemiological investigation of a chain of transmissions was reported beginning with a flight from India to New Zealand, a bus ride to a quarantine facility, a stay at a quarantine facility, a bus ride to the airport, and subsequent household transmissions.[72] Based on positivity test dates, genome sequencing, flight positions and hotel room placement the transmission events were ascribed to both short-range and long-range transmission on flights, within the quarantine facility, and within households. Masks

were required on flights and bus rides. One of the transmission events occurred between two adjacent hotel rooms in the quarantine facility. The authors used recorded video and observed >20 hours between any shared items and no direct contact. The authors concluded that fomite transmission was unlikely and attributed transmission to aerosols in the corridor outside of the hotel rooms wherein the space was enclosed and unventilated. Notably, the hotel rooms themselves, based on a review of the ventilation system, exerted positive pressure relative to the corridor.

An investigation by Lin et al. (2021) into an outbreak of nine COVID-19 cases from three families living in vertically-aligned units of an apartment building in Wuhan, China supported the possibility of long-range transmission.[66] Phylogenetic analysis of respiratory samples showed that all cases were infected by the same strain of SARS-CoV-2. Epidemiological investigation revealed that 4/5 cases of the index family in apartment 15-b had a travelling history to Wuhan, while the other four cases in apartments 25-b and 27-b had neither a travelling history to Wuhan nor close contact with any COVID-19 cases prior to their infection. Transmission through close contact in the elevators was considered unlikely as video records in the elevator did not show any close contact between the index family and the cases from units 25-b and 27-b. However, there was an incident where one unmasked occupant of unit 27-b took the elevator 8 minutes after two unmasked occupants from the index family had left the elevator. Epidemiologically, the infection rate for residents in units b was significantly higher ($p<0.05$) than that in units a and c. Testing of wind speed at the bathtub drain and floor drain found that the airflow produced by toilet flushing on one storey can influence the entire building as the drain pipes for toilets and the sewage pipes connected with floor drains were connected with the exhaust pipe. An experiment with a tracer gas indicated that gas could spread from one storey to another via the drainage and vent systems, especially as the seals in U-shaped traps in the floor drains were dried out in some units and the use of exhaust fans could create a negative pressure in the pipeline system. A similar situation was reported involving air ducts in a naturally ventilated apartment complex in Seoul, South Korea.[67] There were no valves blocking air from entering the bathrooms from the shared natural ventilation shafts (not for building or apartment unit ventilation). Limitations of this outbreak investigation included no genome sequencing or air sampling. Direct applicability to Canadian contexts may be limited by different building construction standards and practices.

Independent of ventilation, movement of air from an infected individual to others nearby can be an important factor in long-range transmission. Direct airflow was deemed responsible for a long-range transmission event in a restaurant in Korea.[73] The suspected index case sat 4.8 m and 6.5 m away and directly upwind of the airflow from two secondary cases at different tables. Nine other visitors in the restaurant did not test positive for SARS-CoV-2 even though at least two were closer to the index case for longer but not in the direct path of airflow originating from the index case. Notably the transmission in one case was suspected to have occurred from an exposure as short as five minutes, and three patrons sitting with the secondary cases but facing away from the index cases were not infected.

An investigation by Lu et al. (2020) into a COVID-19 outbreak in a restaurant in Guangzhou, China involving three families sitting at three tables in close proximity for about 1 hour concluded that the air conditioning (AC) system likely contributed to transmission.[63] In this scenario, a presymptomatic index case and secondary cases were present in the same area for 53–73 minutes. The location of a consistently running AC unit was in the airflow path of the secondary cases and was in an enclosed environment. No secondary cases occurred in staff or at adjacent tables that were outside of the likely "air column". The furthest distance between index and secondary cases was approximately 3 m. Additional investigation indicated that the exhaust fans had been closed due to cold outside temperatures.[74] The airflow assessment indicated that air was recirculating in a defined area, which exposed the three families.

A report involving group exercise at three facilities in Hawaii, US calculated attack rates of 25%–100%.[75] There was no fresh air ventilation and exposure occurred over a duration of 1 hour. Extended close contact and lack of masks in some cases were concluded as contributing to the transmission.

An outbreak in a multi-bed hospital room occurred wherein three patients and six health care workers became infected despite the use of masks and presence of ventilation of 3–4 ACH.[76] The presymptomatic index case was a parent located in a chair beside their child's bed who constantly wore a surgical mask, near the entrance to the room. Notably the air conditioning unit appeared to be located on the ceiling and no details were given about how it operated (e.g., constant versus timed/triggered) and what amount of fresh air circulation it provided. There were no exhaust vents indicated on the room diagram. Exposures for health care workers were in the range of 10–15 minutes, most at distances further than 2 m from the index patient. The report noted that masks were worn as personal protective equipment by health care workers. Transmission was based on the epidemiology of the outbreak without corroboration by genomic analysis of infections.

Detection of SARS-CoV-2 in Air Samples

Air sampling for virus refers to the process of collecting volumes of air by a device to determine if aerosols may contain virus. Collection can vary by aerodynamic size captured, duration of collection, volume per second collected, and media on which samples deposit. Air samples can then be tested by molecular methods such as reverse transcription PCR (RT-PCR) to amplify viral nucleic acids and/or viral culture. RT-PCR cannot determine whether the microorganisms detected are viable. Viral culture is used to determine whether a sample containing the virus is capable of replication. While there are several factors that contribute to the probability of infection, replication is a surrogate measure for inducing infection. To detect viability, researchers apply a sample to a susceptible cell culture and incubate up to a few weeks to detect morphological changes.

Detection of SARS-CoV-2 RNA in air samples has been inconsistent.[77] Multiple air sampling studies performed in proximity to confirmed COVID-19 cases were unable to detect any virus by RT-PCR.[78-86] Kenarkoohi et al. detected SARS-CoV-2 RNA by RT-PCR in 1/5 samples from a ward containing intubated, severely ill patients, but did not find any positive air samples in other areas of the hospital such as wards with suspected, confirmed and mild patients (culturing of virus was not attempted in this study).[87] Chia et al. (2020), in an extended study of Ong et al. (2020), detected SARS-CoV-2 RNA by RT-PCR in air samples collected within 1 m of patients in two of three airborne infection isolation rooms (AIIRs) (no culture of virus attempted).[88] Lei et al. (2020) reported limited detection of SARS-CoV-2 RNA virus by air sampling in open wards, private isolation rooms and bathrooms.[85] One PCR-positive air sample was obtained during an endotracheal intubation within 10 cm of the patient's head in a naturally ventilated room (window open with fan attached), eleven other air samples near patients and 17 samples outside patient rooms and at nursing stations were PCR-negative.[89] The stage of infection and level of infectiousness of the patient populations sampled were not reported.

In a study of SARS-CoV-2 RNA in air samples collected from a variety of settings, Liu et al. (2020) reported that the highest concentration of viral RNA was reported from patient and staff areas of hospitals, compared to public areas.[90] Gharehchahi et al. (2021) (preprint) found SARS-CoV-2 RNA in 7/17 (41.2%) of air samples in a hospital for COVID-19 patients, including a mechanically-ventilated temporary waste storage area, two naturally-ventilated offices (one in the admission and discharge area, the other in an administrative department), and within 2 m of patients' beds in two intensive care units (ICUs), a negative pressure room, and an accident and emergency ward that are mechanically-ventilated with or without natural ventilation.[91] SARS-CoV-2 RNA was not detected from the four

samples at nursing stations 2–5 m from patients' beds. The authors speculated that the detection of RNA in non-clinical areas could be due to inadequate ventilation and the occasional presence of infected health care workers.

Stern et al. (2021) sampled air in locations outside of patient care areas in an acute care hospital and found 8/90 (9%) of the samples positive for SARS-CoV-2 RNA, with concentrations ranging from 5–51 copies/m^3.[92] The size of the RNA-positive samples ranged from ≤2.5 to ≥10 μm. Locations adjacent to negative-pressured wards designated for COVID-19 patients did not appear to increase the likelihood of detecting viral RNA, having higher viral concentration, or finding particles of specific sizes in air samples. However, a significant positive association was observed between the average number of COVID-19 patients staying in the hospital during each sampling period, and the likelihood of an air sample testing positive for SARS-CoV-2 RNA. Furthermore, areas where staff congregated during times of high community rates of COVID-19 were associated with positive air samples. Of note, one RNA-positive air sample was taken when the unit was closed for cleaning and not under negative pressure, and the unit doors were left open for cleaning staff who had to pass by the air sampler to access the area for cleaning.

When air samples were RT-PCR-positive, culturing attempts were infrequently successful. In a systematic review and meta-analysis of 24 studies, Birgand et al. (2020) reported that 17.4% (82/471) of air samples from patient environments were RNA-positive (there was no difference in positivity at ≤1 m [2.5%] or 1–5 m [5.5%]; p=0.22), while culturing produced viable virus in 8.6% (7/81; 2 out of 5 studies) of samples.[93] A study by Guo et al. (2020) detected SARS-CoV-2 by RT-PCR in 35% (14/40) of air samples in an ICU and 12.5% (2/16) of air samples in the general ward that managed patients with COVID-19. Fifteen of 16 RT-PCR-positive air samples were from within 2 m of patients, with 1/8 samples positive at 4 m away.[12] Ben-Shmuel et al. (2020) conducted limited sampling (generally one air sample per area) in rooms with ventilated and non-ventilated patients, at a nursing station, and in private and public areas of a quarantine hotel.[94] RT-PCR-positive air samples were detected in a room with a ventilated patient (distance from patient was not reported) (n=1/1), at a nursing station (n=1/1), and in a quarantine hotel room (n=1/1). However, there were no positive air samples in rooms of non-ventilated patients (n=0/3), a doffing area (n=0/1), and a public area of a quarantine hotel (n=0/1). The authors attempted viral culturing; however, no samples were positive.

At this time, only three studies, two from the same research group and one preprint from July 2020, have successfully cultured viable virus from the air. The preprint and one published study were already referred to above in the summary of Birgand et al. (2020). Sampling techniques and equipment may have caused the lack of culture viability despite RT-PCR detection in other studies. Future studies should aim to replicate the use of equipment and culture methods as these studies.

Lednicky et al. (2021) used a prototype and commercial version of an air sampler and custom RT-PCR probes for detection of SARS-CoV-2 in a patient room with two patients. One patient was discharged soon after sampling periods began and after receiving a negative RT-PCR test.[95] The remaining patient began experiencing respiratory illness two days prior to admission to the room. The study detected RT-PCR-positive air samples following 3 hours of sampling as well as positive viral cultures. Researchers positioned samplers 2–4.8 m from the recently symptomatic patient's head. The ventilation unit provided 6 ACH, filtering air and treating air with UV irradiation before recycling the air. Estimates of virus per volume of air ranged from 6–74 tissue culture infective dose $(TCID)_{50}$ units/L of air. Recently, a second study by Lednicky et al. was performed to detect viable SARS-CoV-2 virus from the front passenger seat area of a car driven by a SARS-CoV-2-positive patient without cough symptoms.[96] This study involved a sampler affixed to the sun visor in the passenger seat collecting particles sizes in ranges

of <0.25 µm, 0.25–0.50 µm, 0.50–1.0 µm, 1.0–2.5 µm and >2.5 µm. The patient drove for 15 minutes with the windows up and air conditioner on. The sampler was turned off 2 hour after the patient completed the 15 minute drive. Viable virus was cultured only from the 0.25–0.5 µm fraction, which also had the highest quantity of detectable copies of viral RNA.

Further research is needed to reconcile differences in viral RNA detection and virus viability in air samples, despite RT-PCR-positive samples found on the surfaces of ventilation units.[97] Differences may be due to several factors, including: 1) air sampling devices are potentially not capable of maintaining viability of captured virus; 2) timing of air sampling varies by time since onset of symptoms, severity of disease or viral load; and 3) the conditions of ventilation (engineering controls) reducing concentrations of viral aerosols to undetectable levels. Even in rooms with high air exchanges, Tang et al.'s review of SARS-CoV-2 aerosols indicates that viral RNA copies can still be detected in air samples from patient rooms (1.8–3.4 viral RNA copies/m^3), toilet rooms (19 copies/m^3), and personal protective equipment doffing rooms (18–42 copies/m^3).[98] In a series of distinct room types (two AIIR with 15+ ACH, an isolation room without negative pressure and a shared cohort room) for patients admitted within 7 days of symptom-onset, Kim et al. reported that 32 air samples were negative and 20 air samples from anterooms were also negative.[86] Culturing viruses is technically challenging; therefore, the lack of positive cultures does not necessarily indicate an absence of infectious virus. On the other hand, the detection of SARS-CoV-2 viral RNA on surfaces that are rarely touched suggests that the virus may be transported through the air to those no-touch surfaces.[99]

Conclusions

Respiratory virus transmission occurs on a spectrum, from larger droplets that spread at short range, to aerosols that are present at short ranges but may also contribute to long-range transmission. As a result, categorizing SARS-CoV-2 transmission as either droplet or airborne does not accurately reflect this spectrum. Other respiratory viruses, like influenza, have similarly been described to demonstrate a spectrum of droplet sizes contributing to transmission.[100,101]

The highest risk of SARS-CoV-2 transmission likely occurs via close (<2 m), unprotected exposure (lacking multiple prevention measures) to an infectious individual. While there is a lower risk of transmission at longer distances with unprotected exposure, this kind of transmission has only been documented to occur under certain conditions, usually involving inadequate ventilation or with recirculation of unfiltered or untreated air in combination with activities involving increased exhalation/expulsion (e.g., shouting, singing, exercising), and often with a lack of source control masking.[102] Defining measures or cutoffs for inadequate ventilation was not possible based on the available descriptions of the contexts in which inadequate ventilation was reported to contribute to transmission. However, they included situations where air is circulated without filtration or exchange with fresh air, where there is no ventilation (e.g., windowless rooms without a ventilation system), and where the size of the room and ventilation rate relative to the quantity of infectious aerosols generated exceeds an unknown threshold of risk for infection. VOCs may be more effectively transmitted across all modes of transmission; however, there is no evidence that any VOCs transmit by fundamentally different routes.[103-105]

The delineation of relative contributions of short-range large respiratory droplets and aerosols and long-range aerosols to overall transmission patterns is complicated by the variable confluence of dynamic source/receptor factors and pathway factors. For example, each infector/infectee interaction is affected by source activities and amount of source viral load (e.g., forceful expulsion of droplets during coughing or singing, and timing in the course of illness), source/receptor adherence to preventative measures in place (e.g., hand hygiene, physical distancing, surface disinfection, mask-wearing and ventilation), and

pathway factors that include airflow, UV, temperature, and humidity in indoor or outdoor environments.[16] It is likely that the relative contribution of respiratory particle size to transmission will depend on these combination of factors.

A large body of evidence is emerging related to SARS-CoV-2. Studies related to identification of a specific mode of transmission are generally low quality. Moreover, data from different fields (e.g., epidemiology versus modelling) can be at odds with respect to conclusions drawn about the role of different sized droplets in short-range transmission and relative importance of long-range transmission events. Ongoing study is needed for further evidence regarding the quantity of viral particles required to cause infection. Additional assessment of SARS-CoV-2 viability in aerosols is needed. Lastly, elucidation of setting-specific risk factors for transmission (e.g., differences between source/receptor and pathway factors in health care settings, residential buildings, schools, warehouses, transportation) may provide further insight into mechanisms for transmission.

The COVID-19 pandemic has identified the importance of interdisciplinary collaboration towards understanding and having a common lexicon for describing virus transmission. When the analysis and interpretation of data is challenged by variable terminology used between and within public health, clinicians, aerosol scientists and the public, this can limit progress towards identification and application of appropriate mitigation measures.[106]

Implications for Practice

This document summarizes the evolving evidence on transmission through respiratory particles and acknowledges the role for both larger droplets and aerosols in transmission. While our understanding of how transmission occurs has evolved and the relative contribution of droplets and aerosols continues to be studied, this may not necessitate a change in infection control measures, but highlights the importance of incorporating multiple infection control layers to mitigate transmission. Translation of this information into recommendations for control measures also needs to take into consideration evidence not reviewed in this document on the overall effectiveness of control measures to date: 1) effectiveness of measures in isolation and in combination as layered mitigation; 2) effectiveness in the community vs. health care settings; and 3) effectiveness and the impact of implementation fidelity.

A detailed assessment of the evidence for infection prevention and control measures was out of scope for this document and thus limits discussion of recommendations for specific measures in different contexts. Of note, vaccination against SARS-CoV-2 is a relatively recent measure that is very effective at reducing transmission regardless of the mode of transmission and should be the priority control measure both in health care and community settings.[107]

In health care settings, recommendations for IPAC measures are described in *IPAC Recommendations for Use of Personal Protective Equipment for Care of Individuals with Suspect or Confirmed COVID-19* and *Interim Guidance for Infection Prevention and Control of SARS-CoV-2 Variants of Concern for Health Care Settings*.[7,8] These documents integrate the existing evidence around droplet, aerosol and contact transmission with jurisdictional experience with control measures and outbreak management to date, and recommends the use of the hierarchy of hazard controls to reduce the risk of transmission.

The bulk of disease transmission occurs in the community and in workplaces, not in health care settings. As SARS-CoV-2 transmits early in the course of infection, most commonly in the asymptomatic or presymptomatic period[108-111] and within the first two days of symptom-onset, cases may not seek health care during their most transmissible phase. In all settings it is necessary to utilize multiple control

measures to mitigate the dynamic transmission factors and address potential routes of transmission. Infection prevention controls should also be context-dependent and take into account vaccination status/coverage, the ability to physically distance and avoid crowding, the feasibility of proper wearing of appropriate personal protective and source control equipment, training and education on the appropriate use of personal protective equipment, hand hygiene, surface disinfection, indoor ventilation, and early identification and isolation of infectious persons. Finally, application of measures should also be in the context of overall rates of community transmission and risk of exposure.

Several resources exist for community guidance (e.g., non-health care workplaces, public and private spaces) on how to reduce the risk of SARS-CoV-2 transmission through a layered approach of multiple public health measures designed to mitigate short-range and long-range transmission.[112-114] In general these involve avoiding the "3 C's": closed spaces, crowded places, and close contact. The degree to which various mitigation layers are necessary or possible will depend on the setting and risk context. Transmission can be mitigated through:

- Getting vaccinated[115,116] (higher vaccine coverage in the population can reduce risk for individuals unable to receive a vaccine)
- Staying home when sick[117,118] (e.g., active and passive screening prior to entry into public settings)
- Limiting the number and duration of contacts with individuals outside your household
- Physical distancing[114] and avoiding crowded spaces
- Consistently and appropriately using a well-fitted, well-constructed (2-3-layer) mask for source control and personal protective equipment.[119-122]
- Ensuring that ventilation systems[123] are well-maintained and optimized with the support of professionals according to relevant recommendations (e.g., from American Society of Heating, Refrigerating and Air-Conditioning Engineers) and/or using outdoor environments whenever possible.
- Performing hand hygiene, respiratory etiquette, and environmental cleaning[124]

The above measures are effective means of reducing risk of transmission irrespective of the relative contribution of larger droplets or aerosols to transmission. Some controls will be more effective than others and it is the combination and consistent application of these controls that is most effective for reducing disease spread.

COVID-19 – What We Know So Far About… Asymptomatic Infection and Asymptomatic Transmission

Introduction

PHO is actively monitoring, reviewing and assessing relevant information related to Coronavirus Disease 2019 (COVID-19). "What We Know So Far" documents are intended to provide a rapid review of the evidence related to a specific aspect or emerging issue related to COVID-19.

The development of these documents includes a systematic search of the published literature as well as scientific grey literature (e.g., ProMED, CIDRAP, Johns Hopkins Situation Reports) and media reports, where appropriate. Relevant results are reviewed and data extracted for synthesis. All "What We Know So Far" documents are reviewed by PHO subject-matter experts before posting.

As the COVID-19 outbreak continues to evolve and the scientific evidence rapidly expands, the information provided in these documents is only current as of the date of posting.

Key Points

This document summarizes the evidence regarding asymptomatic infection and transmission of SARS-CoV-2, the virus that causes COVID-19, by individuals who are asymptomatic. For clarity, in this document we will use the term COVID-19 to refer to both the virus and the disease.

Asymptomatic infection:

- **There is clear evidence of asymptomatic infection with COVID-19**. Estimates of the proportion of laboratory-confirmed cases who are asymptomatic may vary by age group, study setting and study methodology, ranging from 8.2% (infants under 1 year of age),[1] 18.2% (contact tracing in a conference outbreak),[2] 36.7% (travellers),[3] 43.2% (universal screening in a town),[4] up to 87.8% (outbreak investigation in a homeless shelter)[5] (see Asymptomatic Infection). The method of detection of asymptomatic cases (i.e., mass screening or testing contacts of cases), and the duration of follow-up to ensure asymptomatic individuals do not subsequently develop symptoms may influence the proportion of cases who are reported to be asymptomatic.

Asymptomatic transmission:

- There is some epidemiological and virological evidence of transmission from people who are asymptomatic and never develop symptoms. On the other hand, there is **more epidemiological and virological evidence as well as inferences from modelling and statistically analyses, that**

transmission can occur from presymptomatic COVID-19 patients (where transmission takes place during their incubation period). In particular, epidemiological investigations and virological findings have suggested that **transmission can occur as early as six days before symptom onset** and possibly even earlier, although alternative unrecognized sources of infection cannot be ruled out. Other studies have estimated the serial interval (time from onset of symptoms in one case to the onset of symptoms in the person they infect) and found that it is shorter than the length of the incubation period, suggesting transmission during the incubation period (see Modelling and Statistical Analysis below).

Background

Asymptomatic infection occurs when an individual is infected but experiences no symptoms, while asymptomatic transmission occurs when an infected individual without symptoms transmits the virus to another person. There are two mechanisms by which asymptomatic transmission can potentially occur:

1. Transmission from an individual who never develops symptoms—if the infected person is asymptomatic throughout his/her infection but nevertheless is infectious.

2. Transmission from an individual during their incubation period—if the infected person is infectious before he/she develops symptoms.

Asymptomatic Infection

Evidence of asymptomatic COVID-19 infection has been reported in studies that report on contact tracing activities, as well as in outbreak investigations and surveillance data. Asymptomatic infections have been reported in all age groups, occurring in various proportions of confirmed cases in different settings. Several studies reported that a substantial portion of COVID-19 patients remained asymptomatic at the end of their isolation period.

Asymptomatic Infections by Settings

The following highlights the proportion of asymptomatic COVID-19 cases from contact tracing activities, outbreak investigations and surveillance activities in various settings.

HEALTH CARE SETTING

A number of studies reported rates of asymptomatic infections after a period of isolation:

- Among the 138 cases detected in Brunei from March 5 to April 24, 2020, all were hospitalized and followed until viral clearance; 42 (30%) were presymptomatic at the time of diagnosis but later developed symptoms and **16/138 (12%) remained asymptomatic until viral clearance**.[3]

- 13/23 (57%) resident cases identified at a point-prevalence screening in a long-term care skilled nursing facility in Washington, United States with a COVID-19 outbreak were asymptomatic; only **3/23 (13.0%) remained asymptomatic at rescreening one week later**.[6]

- 14/19 (74%) resident cases and 4/8 (50%) staff cases identified at multiple point-prevalence screenings in a long-term care skilled nursing facility in California, United States with a COVID-19 outbreak were asymptomatic; **6/19 (31.6%) resident cases remained asymptomatic after at least 17 days of observation**.[7]

- 29/33 (87.9%) pregnant women who tested positive for SARS-CoV-2 at two New York obstetric centres were asymptomatic when screened at delivery; **26/33 (78.8%) remained asymptomatic until discharge**.[8] In another report from about a week before to a week after universal screening was started at these same two centres, 14/43 (32.6%) SARS-CoV-2–positive pregnant women were found to be asymptomatic on admission (two because they later developed symptoms and 12 by screening); 4/43 (9.3%) were asymptomatic throughout their postpartum courses.[9]

- **28/131 (21.4%)** COVID-19 confirmed hemodialysis patients from 65 centres in Wuhan, China remained **asymptomatic throughout** the course of their infection.[10]

- 30/1,012 (3%) patients admitted during February 7-12 to a make-shift hospital for non-critically ill COVID-19 patients in Wuhan, China were asymptomatic on admission. **14/1,012 (1.4%) patients remained asymptomatic after a median duration of 24 days** from exposure (interquartile range: IQR: 22-27).[11]

- Of 31 patients who were asymptomatic on admission to a hospital in Guangzhou, China, **9/31 (29.0%) remained symptom-free during hospitalization**. The viral load was higher in those who subsequently developed symptoms than in those who remained symptom-free.[12]

- 13/328 (4.0%) adult **patients admitted** to a public health centre in Shanghai, China were asymptomatic; **10/328 (3.0%) remained asymptomatic from 5 to 21 days after admission**, although all but one patient had radiologic abnormalities on chest CT.[13]

- **13/71 (18.3%) admitted patients** at a hospital in South Korea were **asymptomatic on admission. 10/71 (14.1%) remained asymptomatic for the entire quarantine period**, and the other 3 cases developed symptoms within 2 days of admission.[14]

CONGREGATE LIVING SETTINGS

High prevalence of asymptomatic infections at the time of testing have been reported in a few congregate settings:

- 87.8% of 147 adult COVID-19 cases identified through screening at a homeless shelter in Boston.[5]

- More than 350 of 615 (>57%) COVID-19 cases on the Theodore Roosevelt aircraft carrier.[15]

- 3 of the 4 resident cases identified at a senior independent and assisted living community in Seattle, Washington reported feeling well between the 14 days prior to and 14-21 days after testing.[16]

- 410/696 (58.9%) confirmed passenger and crew COVID-19 cases in the Diamond Princess cruise ship outbreak.[17] Adjusting for the possible future development of symptoms (right censoring) using a statistical model, Mizumoto et al. estimated the asymptomatic proportion to be 17.9% (95% credible interval (CrI): 15.5 to 20.2%).[18]

COMMERCIAL PREMISES

Two outbreak reports identified cases that remained asymptomatic through the follow-up period:

- In a call centre outbreak in Seoul, 4/97 (4.1%) confirmed COVID-19 cases were presymptomatic and another **4/97 (4.1%) remained asymptomatic throughout a 14-day isolation period**.[19]

- In a conference outbreak in Munich, Germany, **2/12 (17%)** infected attendees **remained asymptomatic after weeks of follow-up**.[2]

COMMUNITY

There are regional and national surveillance reports on the presence of asymptomatic infection in the community:

- A national surveillance report by the Chinese Center for Disease Control and Prevention reported 889/45,561 (2%) of laboratory-confirmed cases as asymptomatic at the time testing as of February 11.[20]

- 94/728 (12.9%) laboratory-confirmed children reported to the Chinese Center for Disease Control and Prevention during January 16-February 8, 2020 were asymptomatic (from 8.2% in children <1 year of age [7/85] to 17.6% for those 6-10 years of age [30/170]).[1]

- Integrated surveillance of COVID-19 in Italy reported 28.6% of the 33,189 cases with clinical data were asymptomatic as of May 20.[21]

- Analysis of regional surveillance data from one day in Lombardy, Italy found 17/380 (4.5%) cases as asymptomatic.[22]

- 35/81 (43.2%) cases identified in two point-prevalence surveys of all inhabitants of the municipality of Vò, Italy were asymptomatic at the time of testing.[4]

- 30/112 (26.8%) cases in a cluster of fitness dance classes in South Korea were asymptomatic at the time of testing.[23]

There are also studies reporting community-based infections that remained asymptomatic after a period of time:

- **50/1,015 (4.9%) confirmed cases** (41 adults and 9 children) in Huangshi, China were **asymptomatic throughout a quarantine period of at least 14 days**, according to publicly available disease databases of Hubei Provincial Health Committee up to March 27, 2020.[24]

- **5/48 (10.4%) secondary cases** among close contacts in Zhuhai, China **remained asymptomatic through a 21-day follow-up**.[25]

- Wan R et al. described 2 close contacts of confirmed patients. Case 1 was exposed at work to a COVID-19 patient and diagnosed 16 days later by reverse transcription polymerase chain reaction (RT-PCR). He **remained asymptomatic up to the end of the isolation period 25 days after exposure**; two chest radiographs taken during his isolation period were negative. Case 2 was the adult son of a COVID-19 patient. Case 2 was isolated the day after the parent's diagnosis and he **remained asymptomatic throughout 26 days of isolation**. Two chest radiographs taken during his isolation were also negative.[26]

TRAVELLERS

A few countries that tested their repatriated passengers or travellers from countries at high-risk of COVID-19 also reported asymptomatic infections:

- 40/783 (5.1%) repatriated passengers to Greece during March 20-25, 2020 who tested positive for SARS-CoV-2 reported no general or respiratory symptoms.[27]
- 2/114 (1.8%) repatriated passengers to Germany on February 1 were asymptomatically infected and remained afebrile 7 days after diagnosis, although one patient developed a faint rash and minimal pharyngitis.[28]
- Out of the 30 arrivals to Brunei who tested positive for SARS-CoV-2 between March 21 and April 24, 11 (36.7%) were presymptomatic and 3 (10%) were asymptomatic.[3]
- In a cluster of 6 travellers and 6 secondary cases in Vietnam, 1/12 cases (8.3%) remained asymptomatic but viral RNA was detected by RT-PCR throughout the 9-day follow-up period.[29]

Abnormal Chest Imaging

Asymptomatically infected individuals can have abnormal chest imaging.

- Hu Z et al. showed that 12/19 asymptomatic adults and children had abnormal chest CT scans.[30]
- Chan JF et al. described an abnormal chest CT in a 10-year old asymptomatic child.[31]
- Wang Y et al. noted pneumonia in CT findings in 37/55 of asymptomatic cases on admission. Note that all 55 cases developed symptoms during hospitalization: 14 had mild infection, 39 had ordinary symptoms and 2 had severe COVID-19.[32]
- Zhou X et al. reported that 9/10 asymptomatic patients hospitalized at a public health centre had signs of pneumonia on their chest CT scans.[13]
- Zhou R et al. noted bilateral abnormalities in chest CT scans typical of pneumonia in 4/9 patients who remained asymptomatic throughout hospitalization.[12]
- Inui S et al. reported that chest CT findings consistent with pneumonia were seen in 41/76 (54%) asymptomatic passengers on Diamond Princess cruise ship.[33]

Asymptomatic Transmission

There is some **evidence of transmission from people who are asymptomatic and never develop symptoms**, and **more evidence of transmission from people who are in their incubation period** (i.e. people who transmit infection while asymptomatic, but prior to their development of symptoms).

Transmission From People who Never Developed Symptoms

Findings from epidemiological and virological investigation have been published to support the observation that transmission can occur from people who never developed symptoms after their infection.

EPIDEMIOLOGICAL EVIDENCE FOR ASYMPTOMATIC TRANSMISSION

Several authors reported clusters of infections in China where epidemiological findings suggest the possibility of transmission by asymptomatic patients.

- Zhou J et al. reported two transmission events by asymptomatic patients in ZhuZhou, China.[34]

    - A 37-year-old woman was isolated for observation after returning from Wuhan on January 22, 2020. Viral RNA was only detected in the 5th specimen taken on February 15, and she remained asymptomatic up to March 2 when her test turned negative and showed no pulmonary imaging changes. Meanwhile, her father was diagnosed of COVID-19 on February 12, 3 days before viral RNA was detected in the woman's specimen.

    - An asymptomatic patient who returned from Wuhan appears to have infected her mother-in-law and father-in-law.

    Zhou et al. conclude that asymptomatic SARS-CoV-2 carriers can spread the virus before viral RNA was detected. It should be noted that they did not provide any information on potential alternate sources of infection or on the reliability of the testing done.

- Zhang J et al. reported a family cluster of 5 in Beijing. The index case was the only one in the cluster who had been to Wuhan; he returned to Beijing in January and invited his nephew (M/32) for dinner that day. This nephew became ill 3 days later and was diagnosed 2 days after symptom onset. Around that time, the index patient's wife (F/45) had a fever and they heard of a relative in Wuhan having COVID-19. As a result, the index patient and family visited a hospital to be assessed and the index and 4 family members (including the nephew and wife) were diagnosed with COVID-19. Both the index patient and a family member remained asymptomatic throughout the observation up to the end of February. The index patient's chest radiograph showed ground glass opacities but that of the other asymptomatic family member was normal. The authors believe the index patient passed the infection on to his family despite having no symptoms himself. However, details of other family members' contact history were not given to rule out potential alternate sources of infection.[35]

- A study by Bai Y et al. reported on an asymptomatic individual who transmitted COVID-19 to five family members in Anyang. She tested positive 18 days after her presumed exposure, with a negative test on day 16 and two negative tests on days 26 and 29. Although the authors argue that the asymptomatic individual was the source of infection for the family members, the family visited a hospital as well. Although the hospital reported no COVID-19 cases at that time, this is a potential alternative source of exposure.[36]

- Hu Z et al. reported on an asymptomatic case who appears to have acquired his infection in Hubei province and transmitted his infection to his wife, son and daughter-in-law who lived with him in Nanjing. His family members denied any other known exposures to confirmed or suspect COVID-19 patients.[30]

- Lavezzo E et al. reported on 3 cases who appeared to have acquired their infection based on contact with asymptomatic individuals. The cases were identified on the second of two point-prevalence surveys that took place at the end of a two-week lockdown of the municipality of Vò, Italy: case 1 had exposure to 4 infected relatives who did not have any symptoms at the time of contact; case 2 had a meeting with an asymptomatic case before the lockdown; case 3 shared

the same flat with two asymptomatic relatives. The authors noted that all the asymptomatic individuals never developed symptoms during the two-week lockdown.[4]

VIROLOGICAL EVIDENCE FOR ASYMPTOMATIC TRANSMISSION

Several studies reported high viral loads in asymptomatic individuals as measured by real-time RT-PCR.

- Arons MM et al.[37] cultured the real time RT-PCR-positive specimens from two point-prevalence surveys in a skilled nursing facility as part of an outbreak investigation, as described in Kimball A et al.[6] above. Viral growth was observed for 13/20 symptomatic residents, 17/24 presymptomatic residents, 1/3 asymptomatic residents. **Viable virus was isolated from 6 days before to 9 days after symptom onset**. In addition, **high viral RNA loads were detected in all groups with median cycle threshold values at 24.8 in those with typical symptoms and 25.5 for those who were asymptomatic**. This suggests the potential for substantial viral shedding in asymptomatic cases. No correlation was observed between cycle threshold values and time from symptom onset.[37]

- Zou L et al. noted that an asymptomatic individual had similar viral loads from nasal and throat swabs compared to 17 symptomatic individuals.[38]

- Roxby AC et al. noted that the viral load in 3 generally asymptomatic residents (one developed a mild cough) of an independent living community were similar to those reported among ill hospitalized patients.[16]

- Kam K et al. noted a high viral load in a nasopharyngeal specimen from a generally well baby. Nasopharyngeal specimens were positive for 16 days and one stool specimen was also positive.[39]

- Hoehl S et al. observed COVID-19 virus in cell culture in throat specimens from two repatriated passengers who tested positive by RT-PCR. One patient developed slight rash and minimal pharyngitis the day after testing but both persons remained well and afebrile during the 7 days after hospital isolation.[28]

- Cereda D et al. noted that the median viral RNA levels in nasal swabs were not statistically different between 295 symptomatic and 17 asymptomatic obstetric cases:
5.0 $\log_{10}$ RNA copies/mL (range 1.7-10.1) vs 4.7 $\log_{10}$ copies/mL (range 2.1-7.1), (P=.51).[22]

Transmission During the Incubation Period

There is both epidemiological and virological evidence, as well as inferences from modelling and statistical analysis, that point to transmission from people prior to their symptom onset.

EPIDEMIOLOGICAL EVIDENCE FOR PRESYMPTOMATIC TRANSMISSION

Several studies describe potential transmission prior to symptom onset, i.e., in the incubation period. In most instances, the contacts who acquired the infection reported no other known sources of exposure other than a case who was in their incubation or early symptomatic period.

- Hijnen D et al. reported an outbreak amongst at least 11/13 attendees (one attendee was not tested) from seven countries at a 2-day conference in Munich, Germany in February, when under 20 cases of COVID-19 had been diagnosed in the country. The **index patient** (a physician

was believed to have been infected when examining a patient in Italy two days before the start of the conference) **developed symptoms only after he had left the conference**.[2]

- Rothe C et al. reported an outbreak in Germany resulting from a business meeting in late January.[40] Böhmer MM et al. reconstructed the transmission events with epidemiological findings and whole genome sequencing of 13 of the 16 subsequent cases.[41] The index case was a Chinese resident from Shanghai who had had contact with her parents from Wuhan before visiting Germany in January for work reasons. Presymptomatic transmission likely occurred from patient 4 (symptom onset on January 24) to patient 5, as patient 5 did not meet the index case but had encounters with patient 4 on January 22 when they sat back to back in the canteen and patient 5 turned to ask patient 4 to borrow the salt shaker from their table. Böhmer MM et al. noted that **presymptomatic transmission is strongly supported by virus sequence analysis**. In addition, presymptomatic transmission could possibly have occurred for 5 more cases.[41]

- Jang S et al. reported on the active surveillance results of a COVID-19 cluster associated with fitness dance classes. On February 15, 2020, a 4-hour workshop for 27 fitness instructors took place in Cheonan, South Korea (approximately 200 km from Daegu where an outbreak was emerging). After discovering cases in Cheonan linked to fitness dance classes, the workshop was investigated. Eight of the 27 instructors at the workshop were found to be infected with SARS-CoV-2. One of these instructors was from Daegu, and therefore was the presumed source case for the outbreak, and developed symptoms on February 18, 2020, three days after the workshop.[23]

- Cheng HY et al. conducted a prospective study that enrolled all the initial 100 confirmed cases in Taiwan from January 15 to March 18, 2020 and their 2,761 close contacts. All close contacts were quarantined at home for 14 days after their last exposure to the index case, and any typical symptoms triggered testing. High-risk contacts (e.g., household and hospital contacts) were tested regardless of symptoms. No secondary clinical cases were detected from all 91 close contacts of the 9 asymptomatic patients. Cheng et al. identified 22 secondary cases, 18 of whom had symptoms. They determined a secondary clinical infection risk of 0.7% (95% confidence interval (CI): 0.4% - 1.0%) among 2,761 close contacts. **For the 299 contacts with exclusive presymptomatic exposures to the index case, the secondary clinical attack rate was 0.7% (95% CI, 0.2%-2.4%)**. The authors noted that the actual contribution of early transmission could be greater as they did not completely identify contacts before symptom onset of the index cases.[42]

- Wei WE et al. reviewed the clinical and epidemiological records of all 243 cases in Singapore to determine whether presymptomatic transmission might have occurred. Of these cases, **157 were locally acquired with 10 (6.4%) attributed to presymptomatic transmission within 7 clusters**, where investigation did not identify any other potential sources of infection. The authors noted that although an unknown source might have caused some of these infections, given that COVID-19 prevalence was very low during the period under investigation and strong surveillance systems were in place, presymptomatic transmission was deemed the most likely mode of transmission. The authors also note that recall bias related the onset date of symptoms might add uncertainty to the duration of the presymptomatic period.[43]

Multiple authors also reported clusters of infections in China where the transmission histories suggest the occurrence of presymptomatic transmission. It should be noted that due to circulation of COVID-19 in China during that time, it is possible that there was another unrecognized source of infection, in addition to the cases reported.

- Gao Y et al. reported a 15-person cluster with 4 generations of transmission and 6 asymptomatic cases in Wuxi. Except the index case, none of the other 14 cases had any history of suspicious exposure except for contact with the previous generation case(s). In this cluster, infections are believed to have spread to the next generation before onset in the previous generation as follows: 2-7 days before onset (1st to 2nd generation), 6-7 days before onset (2nd to 3rd generation), and 3-8 days and 9 days before onset (3rd to 4th generation). The authors noted that generation 2 might also have been infected from other sources while touring in Japan. However, the transmission history of the other generations support the idea of presymptomatic transmission.[44]

- Luo SH et al. reported a cluster of 4 adults in Anqing. Epidemiological evidence suggests that one patient was infected by her husband during the presymptomatic stage of his infection. Neither the wife nor husband had travelled to Wuhan or adjacent areas or had recent exposure to wild animals. However, the husband likely acquired his infection from a relative while the relative was symptomatic.[45]

- Huang L et al. reported a cluster of 8 teenagers and young adults aged 16-23 years in Hefei, originating from a 22-year-old male returning from Wuhan. Six secondary cases became infected after contact of several hours duration with the index case one day before his symptom onset; another secondary case was likely exposed 3 days before the index case's symptom onset. None of the secondary cases had visited Wuhan or had any exposure to wet markets, wild animals, or medical institutes within the previous 3 months.[46]

- Li C et al. described transmission in a familial and hospital settings in Xuzhou. The source case is believed to have acquired his infection on January 14, 2020 during a 6-hour transfer in a train station in Wuhan when travelling to Xuzhou and developed symptoms on January 19, 2020. While caring for his son-in-law in hospital he interacted with another patient and that patient's son from January 15 to 18 (1 to 4 days before the source patient's onset of symptoms); both the other patient and his son became infected. The source case also infected several members of his family whom he was with both before and after the onset of symptoms. Other source(s) of infection, particularly in the hospital setting may also be possible, although were not mentioned by the authors.[47]

- Li P et al. describe a familial cluster of 4 in Zhoushan, who had close contact with a presymptomatic family member 4 to 7 days before the index case's symptom onset. Other than the index case, the family reported no contact with people with fever or respiratory symptoms in Wuhan or other areas with persistent local COVID-19 transmission in the 14 days prior to their symptom onset, and no history of contact with wild animals or poultry.[48]

- Ye F et al. reported a cluster of 5 people from 2 families in Luzhou. The three members of Family 1 traveled from Wuhan to Luzhou on January 22, and met with the two members of Family 2 between January 23 and 25 and on January 30. Family 2 had not left Luzhou and their only contact with anyone from Wuhan was Family 1. The first and last contact between Family 1 and 2 was 13 and 6 days before the first case in Family 1 developed symptoms on February 5. All five family members developed symptoms and the symptoms in the first case in Family 2 started on February 1, 2020, 4 day before the symptoms in Family 1.[49]

- Yu P et al. described an 88-year-old man from Shanghai who developed symptoms 5 days after the arrival of two visitors from Wuhan. The two visitors developed symptoms after the man,

with the earliest symptom onset among the two visitors occurring 11 hours after the man's first symptoms. This suggests that at least one of the visitors had spread infection in their incubation period. Assuming the visitor with the earliest symptom onset transmitted infection to the man, **the earliest the infection could have occurred is from 5 days before onset of illness in that visitor**, based on the date of the visitors' arrival.[50]

- Huang R et al. described a patient from near Wuhan who visited her family in Nanjing and did not develop symptoms until 4 days after leaving Nanjing. She infected six family members, some of whom she lived with and some with whom she attended one or more dinners with, including one on the day before her departure. Two family members, who appear to have been infected at the family dinner with the visiting woman the day before her departure, attended another family dinner with three different relatives. This occurred on the day after the dinner with the visiting woman, and 3 and 4 days before the onset of symptoms. The three relatives subsequently developed symptoms and were found to be infected with COVID-19. **This suggests that transmission can occur at least 5 days before symptom onset and that transmission may occur as early as 1 day following exposure**.[51]

- Tong ZD et al. reported a case of COVID-19 from Wuhan who attended a conference in Zhoushan three days before illness onset. Two colleagues from Zhoushan also attended the conference and dined with the case the following day (2 days before illness onset), sharing the same serving plates. The two colleagues were subsequently confirmed to be infected. **This suggests that the source patient likely infected his two colleagues at least 2 days prior to symptom onset**.[52]

VIROLOGICAL EVIDENCE FOR PRESYMPTOMATIC TRANSMISSION

In addition to epidemiological reports that attribute the source of infection to presymptomatic COVID-19 patients, we found an article that reports on finding viable COVID-19 virus in specimens from patients prior to their symptom onset. Another two studies reported high viral loads in presymptomatic individuals as measured by real-time RT-PCR.

- Arons MM et al. cultured the real time RT-PCR-positive specimens from two point-prevalence surveys in a skilled nursing facility as part of an outbreak investigation (see also Virological Evidence for Asymptomatic Transmission). **Viable virus was isolated from 6 days before to 9 days after symptom onset**. In addition, **high viral RNA loads were detected in all groups with median cycle threshold values at 24.8 in those with typical symptoms and 23.1 for the presymptomatic**. This suggests the potential for substantial viral shedding in presymptomatic cases. No correlation was observed between cycle threshold values and time from symptom onset.[37]

- Kim SE et al. noted very high viral loads (cycle threshold values <20) in specimens from 2 presymptomatic patients two days before symptom onset.[14]

- Zhou R et al. noted significantly higher viral load in nasopharyngeal specimens from presymptomatic patients (median cycle threshold value: 34.5 [IQR 32.2-37.0]) than those from asymptomatic patients (median cycle threshold value: 39.0 [IQR 37.5-39.5]).[12]

MODELLING AND STATISTICAL ANALYSIS

We found a modelling study which estimated that **infectiousness started from 2.3 days (95% CI: 0.8-3.0 days) before symptom onset and peaked at 0.7 days** (95% CI: 2.0 days before symptom onset to 0.2 days after onset). In addition, a number of authors have compared the incubation period with the serial interval of COVID-19. The serial interval is the time from onset of symptoms in one case to the time of symptom onset in the case(s) they infect. When the serial interval is shorter than the incubation period, some transmission is likely to have occurred in the incubation period.

- He X et al. assessed viral RNA load from 414 throat swabs of 94 patients from symptom onset up to 32 days after onset. Viral load based on RT-PCR was observed to be high soon after symptom onset and then declined. The authors then identified 77 transmission pairs from publicly available international sources. Using a mean incubation period of 5.2 days, the serial interval was estimated to have a median of 5.2 days (95% CI: 4.1-6.4 days), with 7.6% having negative serial intervals (which occur when the secondary case's symptom onset precedes that of the primary case). The estimated proportion of presymptomatic transmission was 44% (95% CI: 25-69%).[53]

- From 22 transmission pairs out of 100 confirmed cases in Taiwan, Cheng HY et al. estimated a median incubation period of 4.1 days (95% credible interval, 0.4-15.8) and a median serial interval of 4.1 days (95% credible interval, 0.1-27.8).[42]

- Analyzing published data of 18 transmission pairs with onset dates clearly defined in published articles, Nishiura H et al. estimated a median serial interval of 4.6 days (95% CrI: 3.5-5.9), which was shorter than a mean incubation of approximately 5 days from other published sources.[54]

- Analyzing 16 cases in four transmission generations, Böhmer MM et al. estimated a median incubation period of 4.0 days (IQR 2.3-4.3) and a median serial interval of 4.0 days (IQR 3.0-5.0).[41]

- Assuming a single source of infection for each household, Wu J et al. analyzed 48 secondary cases from index cases in 35 households in Zhuhai, China and estimated a median incubation period of 4.3 days (95% CI: 3.4-5.3) and a serial interval of 5.1 days (95% CI: 4.3-6.2).[25]

- From a cluster of seven people (1 teenager, 6 young adults) infected by a 22 year-old in Hefei, China, Huang L et al. estimated a median incubation period of 2 days (range 1-4) and a median serial interval of 1 day (range 0-4).[46]

Wearing Masks in Public and COVID-19 – What We Know So Far

Introduction

"What We Know So Far" documents are intended to provide an overview of some of the published and unpublished reports related to emerging issues with respect to Coronavirus Disease 2019 (COVID-19). The reports are found through ongoing scanning of the published literature and scientific grey literature (e.g., ProMed, CIDRAP, Johns Hopkins Situation Reports), as well as media reports. For this report, library information specialists at Public Health Ontario searched Ovid MEDLINE, Embase, PsycINFO, EBSCOhost, CINAHL, and Scopus from January 1, 2000 to August 31, 2020 (search strategy available upon request). It is recognized that there may be additional information not captured in this document. As this is a rapidly evolving outbreak, the information will only be current as of the date the document was written.

Key Points

- Public mask-wearing is **likely beneficial as source control** when worn by persons shedding infectious SARS-CoV-2 virus.
- **Mandatory public mask policies** have been associated with a decrease in new COVID-19 cases compared to regions without such policies.
- **Studies evaluating masking in children are limited and have demonstrated variable results** with respect to their effectiveness for source control. However, studies have consistently shown lower adherence, especially in younger children.
- Masking to **protect the wearer is unlikely to be effective in non-healthcare settings**. Existing evidence demonstrates that wearing a mask within households after an illness begins is not effective at preventing secondary respiratory infections.
- There is variability in the effectiveness of homemade and cloth masks. Some materials adequately filter the expulsion of viral droplets from the wearer making them theoretically suitable for **source control**.
- There are theoretical risks of harms from public mask use including self-contamination from improper use and facial dermatitis or discomfort. Children may experience more discomfort from wearing a mask compared to adults. Though there are studies that observe subtle physiologic changes caused by N95 use, there is currently **no evidence that surgical or cloth masks exacerbate respiratory diseases**.

Background

Masks have two potential functions. They may protect the wearer of the mask from exposure (personal protective equipment), or protect individuals from exposure to respiratory aerosols/droplets from the mask wearer, referred to as source control. The use of masks for the general public has been recommended as one of several COVID-19 pandemic mitigation strategies. The Canadian and Ontario governments are currently recommending non-medical face masks or homemade face coverings to be worn by the public when physical distancing cannot be maintained.[1,2] The World Health Organization revised their guidance on June 5, 2020 that "governments should encourage the general public to wear masks in specific situations and settings as part of a comprehensive approach to suppress SARS-CoV-2 transmission".[3,4] These recommendations have been made largely due to the increasing recognition of the importance of pre-symptomatic and asymptomatic transmission and the potential benefit for source control.[5,6] As part of Ontario's school re-opening plans, masks are recommended for children in junior kindergarten (JK) to grade 3 and mandatory for grades 4-12.[7] This *What We Know So Far* was updated on September 8, 2020 and reviews the available evidence for wearing a mask to prevent respiratory viral infections in non-healthcare settings including evidence surrounding homemade masks and evidence specific to children.

Mask-wearing in Non-Healthcare Settings - COVID-19 Studies

No randomized trials have been published so far on mask use by the public during the COVID-19 pandemic. However, observational and ecological studies suggest that mask-wearing provides source control and public mask-wearing mandates have led to reduced daily COVID-19 growth rates.[8-11]

- An ecological report from Germany released in June 2020 utilized Synthetic Control Methodology (SCM) to evaluate the impact of mandatory mask use on public transportation and in sales shops in the city of Jena.[10] On March 30th, the local government in Jena announced that masks would be mandatory starting April 6th, 2020. Masks became mandatory in the rest of Germany between April 20 and 29th, 2020. SCM involves identifying synthetic control groups which were following the same COVID-19 trend as Jena prior to April 6th. The weighted average of this synthetic control group of regions where masks did not become mandatory on April 6th were used as a counterfactual to evaluate the causal effect of mandatory masking. The authors concluded that mandatory masking reduced the daily growth rate of COVID-19 in Jena by 40%. It is not known from this ecological analysis the extent and quality of uptake of mask wearing, the type of masks worn, and if the demonstrated benefit is related to source control, protecting the wearer, or a combination thereof. It is possible there were other public health measures taken in Jena at this time that confound this finding (i.e. physical distancing), and the impact of behavioural change due to mandatory masking was not addressed. However, the authors do note that the timing of the introduction of face masks was not affected by other overlapping public health measures as a general "lock down" had been in place for two weeks. This report has not been peer-reviewed.[10]
- Lyu et al. 2020 performed an observational event analysis, similar to a difference-in-differences design, which provides evidence that states in the United States (US) mandating face mask use in public had a greater decline in daily COVID-19 cases compared to states that did not issue mandates.[11] Sixteen regions issued mask mandates between April 8th and May 15th. Compared to states without mandates, daily COVID-19 growth rates significantly declined by 0.9%, 1.1%,

1.4%, 1.7%, and 2.0% at 1-5, 6-10, 11-15, 16-20, and 21 or more days following the state mandate, respectively. In another analysis, the authors evaluated the impact of employee-only mandates (no public community requirement) and did not find a significant impact from those more targeted mask mandates. While the authors attempted to adjust for other public health measures in their models, residual confounding is possible. This study was unable to assess masking adherence by the public, but provides supporting evidence that state-level mask mandates may have been effective in reducing COVID-19 case numbers.[11]

- Xu et al. 2020 conducted an interrupted time series evaluating trends in new COVID-19 cases and deaths in the US.[12] The authors report slope changes which they attribute to stay-at-home orders on March 23rd (slope change: -0.18, 95% CI: -0.22 to -0.14) and face mask recommendations by the US Centers for Disease Control and Prevention (CDC) on April 3rd (slope change: -0.10, 95% CI: -0.18 to -0.08). Two delayed slope changes were also identified in new deaths on April 9th (slope change: -0.17, 95% CI: -0.21 to -0.14) and April 19th (slope change: -0.13, 95% CI: -0.25 to -0.07). There is a high risk of residual confounding in this study. The attribution of the initial slope change to these two policy interventions is very close together and it is unlikely that the CDC recommendation on April 3rd would result in an immediate change in incidence of new cases. Furthermore, this observational study was unable to account for the multiple simultaneous public health interventions occurring.[12]
- Cheng et al. 2020 report COVID-19 data from Hong Kong with 11 clusters (113 cases) from "mask-off" settings (dining, karaoke, fitness clubs) compared to 3 clusters (11 cases) from "mask-on" settings in workplaces (p=0.036).[13] However, this study cannot differentiate if the differences are related to masks versus physical distancing and increased expulsion of droplets (i.e., singing, exercising) in these settings. They also describe COVID-19 epidemiology in Hong Kong, which had a daily mask compliance of >95%, compared to representative countries in North America, Europe, and Asia and describe significantly lower COVID-19 incidence in Hong Kong. These findings also have potential confounding from broad public health measures of strict quarantine and physical distancing guidance early on in the pandemic in Hong Kong.[13]
- Wang et al. 2020 conducted a retrospective cohort study of household contacts of COVID-19 cases for predictors of secondary transmission in Beijing, China.[9] The overall secondary attack rate was 23% and they found that if it was reported that one or more family members (primary case or family contacts) wore face masks **prior to the development of symptoms**, then there was a 79% reduction in transmission (OR=0.21, 95%CI: 0.06-0.79). Of note in this study was no protective effect of mask-wearing by household contacts if initiated after symptom-onset in the primary case. The findings are associated with the inherent limitations with telephone interview including recall bias.[9]
- Hong et al. 2020 conducted contact tracing of 197 residents in Taizhou, China exposed to 41 presymptomatic COVID-19 positive cases who returned from Wuhan in January 2020.[8] The secondary attack rates from 28 mask-wearing presymptomatic cases was 8.1% (10/123) compared to 19.0% (14/74) from 13 non-mask-wearing presymptomatic cases (p<0.001).[8]
- A contact investigation of two hairstylists with respiratory symptoms and confirmed COVID-19 who wore cloth face masks during close contact with 139 clients did not result in any secondary transmissions (67 of whom tested negative for SARS-CoV-2 by RT-PCR).[14]
- Two case reports describe no in-flight transmission aboard an airplane with symptomatic COVID-19 cases who wore masks during the flight.[15,16]
- Chou et al. 2020 are conducting a living rapid systematic review on the effectiveness of mask use in both healthcare and community settings.[17] As of their most recent update on September

1st, 2020, they have identified one study by Wang et al., discussed above. Updates are expected every 1-2 months.[17]

Mask-wearing as Source Control – Non-COVID-19 Studies

Studies to date have found that the use of medical masks may reduce the amount of aerosol/droplet shedding of some bacteria and viruses from symptomatic individuals, but have inconsistently demonstrated a reduction in secondary cases in household or other close contact studies.

- MacIntyre et al. 2020 re-analyzed data from a previous clinical trial using only seasonal coronavirus data.[18] They identified 10 index cases in the mask group and 9 controls. There was no secondary transmission in either group, although 5/9 control index cases reported wearing a mask.[18]
- Barasheed et al. 2014 conducted a pilot study randomizing tents at the Hajj to 'supervised mask use' (mask use 76%) or 'no supervised mask use' (mask use 12%) for both individuals with influenza-like illness (ILI) and their contacts who slept within 2 meters.[19] They found less ILI among contacts in the mask group (31% versus 53%, p=0.04); however, there were no differences in laboratory-confirmed respiratory virus detections.[19]
- MacIntyre et al. 2016 performed a cluster randomized controlled trial (RCT) of surgical masks for patients with ILI (n=123) compared to controls (n=122) evaluating the risk of secondary cases in household contacts.[20] There were no statistically significant differences in clinical respiratory illness (relative risk (RR) 0.61, 95% CI 0.18 to 2.13), ILI (RR 0.32, 95% CI 0.03 to 3.13) or laboratory-confirmed viral infections (RR 0.97, 95% CI 0.06 to 15.54). As one third of controls wore masks, the authors conducted a post-hoc per protocol analysis and there was a statistically significant protective effect in clinical respiratory infections (RR 0.22, 95% CI 0.06 to 0.86), but not laboratory-confirmed respiratory infections.[20]
- Stockwell et al. 2018 found that mask-wearing significantly reduced the release of *Pseudomonas aeruginosa* aerosols during coughing in people with cystic fibrosis compared to uncovered coughing.[21] The results were similar for surgical masks and N95 respirators.[21]
- Milton et al. 2013 examined exhaled breath samples from symptomatic people infected with seasonal influenza viruses and found that surgical masks reduced the amount of viral aerosol shedding by 3.4 fold overall, ranging from 2.8 to 25 fold depending on particle size.[22]
- Dharmadhikari et al. 2012 studied patients with multidrug-resistant tuberculosis and demonstrated that surgical mask-wearing significantly reduced transmission in experimental conditions.[23]
- Leung et al. 2020 studied surgical mask-wearing in 246 symptomatic individuals with influenza, rhinovirus, and seasonal coronaviruses.[24] They found a significant reduction in virus by polymerase chain reaction testing of exhaled breath droplets and aerosols in the 124 individuals randomized to wearing masks (4/10 versus 0/11, p=0.04). This study did not confirm if the quantity of virus was infectious.[24]

Evidence for Mask Use in Children

There have been no studies evaluating mask use for COVID-19 source control in children. However, there have been 4 cluster RCTs evaluating mask use for influenza prevention in the community that included children as the index cases. Two studies found a possible protective effect for masking and hand hygiene (HH) together, particularly if the intervention was implemented within 36 hours of symptom-onset in the index case,[25,26] while two studies found no apparent protective effect.[27,28]

However, in all studies, mask-adherence when reported was generally poor and the effects may have been related to adults in the study wearing masks, children wearing masks for source control, or a combination thereof. The one study which evaluated masking alone for source control (33% of the index cases were children) did not demonstrate any benefit.[27] One observational study in Japan found a small reduction in influenza infections from self-reported mask-wearing in schools.[29]

- Canini et al. 2010 performed a cluster RCT of masking the index patient for five days after testing positive for influenza on a rapid test to prevent secondary household transmission. ILI was reported in 16.2% of contacts where the index case was masked, and 15.8% when the index case was not masked; there were no significant differences between surgical mask and control groups. This study included 35 (33%) children <15 years as the index case. The analysis was not stratified by age; however, children were significantly more likely to report mask discomfort (i.e., reported feeling pain), compared to adults (3/12 [25%] vs. 1/39 [2.6%], p=0.036).[27]
- Suess et al. 2012 conducted a cluster RCT comparing masking, masking + HH, or control in 84 households, including index cases, with influenza infection in the 2009/10 and 2010/11 seasons.[25] There was no significant effect from either intervention in the primary analysis. Almost all index cases were children <14 years (81/84 [96%]). The average daily adherence to masking by index patients ranged from 40-60% and decreased over time. There was a potential effect observed in the subgroup that implemented masking + HH within 36 hours of symptom-onset of the index case (adjusted odds ratio (OR): 0.16, 95% CI: 0.03-0.92).[25]
- Simmerman et al. 2011 performed a cluster RCT of 442 households in Thailand during the influenza H1N1 pandemic comparing HH, HH + masking with surgical masks, or control to prevent influenza transmission in households with an influenza-positive child.[28] 50% (221/442) of the index patients were <6 years of age. There were no differences in clinical or laboratory-confirmed influenza in either intervention arm (HH + mask compared to control; OR: 1.16; 95% CI: 0.74-1.82). Adults wore their masks for a median of 153 (IQR: 40-411) minutes per day compared to 35 (IQR: 4-197) minutes in the child index cases.[28]
- Larson et al. 2010 conducted a cluster RCT in 509 households and 2,788 individuals (47.3% children ≤ 17 years) comparing health education (HE), HE + HH, or HE + HH + masking with surgical masks on incidence and secondary transmission of upper respiratory tract infections and influenza.[26] There was a significant decrease in secondary respiratory infections in the HE + HH + mask group compared to HE alone (OR: 0.82, 95% CI: 0.70-0.97). This study did not evaluate a masking-only group and while index cases were encouraged to wear masks in the masking group, adherence to mask use was reported as poor by the authors.[26]
- Uchida et al. 2017 conducted an observational questionnaire-based study with 10,524 school-aged children in Japan, of whom 5,474 (52.0%) reported wearing masks.[29] In the multivariable logistic regression model, wearing a mask was associated with reduced risk of influenza infection (OR: 0.86; 95% CI: 0.78-0.95). 21.5% of non-mask-wearing children in grades 4-6 were diagnosed with influenza compared to 18.9% of mask-wearing children (relative effectiveness 12.0%, absolute risk reduction 2.6%). 21.3% of non-mask-wearing children in grades 1-3 were diagnosed with influenza, compared to 20.2% of mask-wearing children (relative effectiveness 5.3%, absolute risk reduction 1.1%). No statistical analysis was performed on the subgroups by age.[29]
- Chen et al. 2020 conducted a survey of 3,649 school-aged children 6-13 years of age about mask use.[30] 51.6% reported good mask-wearing behaviour, with older children (grades 5-6 compared to grades 1-2; OR 1.21, 95% CI; 1.03-1.43), and parental educational level, being associated with better reported mask-wearing behaviour.[30]

- Allison et al. 2010 conducted a survey of teachers after distributing masks to both teachers and students for 4 weeks.[31] Teachers reported that 39% of them thought mask use was not disruptive and 35% reported they would use masks again the following winter. However, 97% reported they would use masks during a pandemic. By direct observation only 30% of students wore masks in week 1 of the study, which decreased to 15% in week 2.[31]
- Stebbins et al. 2009 conducted a parent and teacher survey on nonpharmaceutical interventions to prevent influenza in schools.[32] Student mask-wearing was among the lowest acceptable interventions by both parents and teachers.[32]
- Van der Sande et al. 2008, discussed further in the next section, compared homemade tea cloth masks, surgical masks, and FFP-2 (European equivalent of N95 respirators) in 28 healthy adult volunteers and 11 children between the ages of 5-11 years performing various physical maneuvers and measured quantitative differences in particles with a Portacount®.[33] There were no differences in median protection factors between adults and children.[33]

Protective Effects to the Mask-wearer in Non-Healthcare Settings - Non-COVID-19 Viral Respiratory Infections

Randomized Trials

There have been several cluster randomized studies on the use of medical masks outside of the hospital setting. These studies have evaluated the effectiveness of masking household members and individuals in other confined spaces (e.g. university residences, airplanes) to prevent acquisition of respiratory infections. In the majority of studies, no significant benefit from wearing masks was identified. Studies that demonstrated a benefit were associated with enhanced hand hygiene measures. No RCTs evaluating the effectiveness of mask use by the public to decrease COVID-19 infections have been completed, however there is a trial in Denmark under way (NCT04337541).[34]

- Dugre et al. 2020 performed an umbrella systematic review of masks in healthcare workers and the public.[35] They identified 11 systematic reviews, with 18 RCTs, of which 12 were in the community. In their meta-analysis, mask-wearing by the public did not reduce clinical respiratory infection (RR=1.06, 95% CI; 0.82-1.36; I^2=0%) or confirmed influenza or other viral respiratory infection.[35] The authors pooled the two studies below by Aiello from 2010 and 2012 and identified a significant protective effect on mask-wearing in university dormitories for ILI (RR=0.83, 95% CI; 0.69-0.99; I^2=0%; NNT=24).[36,37]
- Aggarwal et al. 2020 pooled controlled trials and did not identify a significant effect for either mask use alone versus control (5 studies, pooled effect size (pES) -0.17, 95%CI -0.43 to 0.10) or mask use with HH versus control (6 studies, pES -0.09, 95%CI -0.58 to 0.40), in reducing ILI in household and university settings.[38]
- Aiello et al. 2012 conducted a cluster RCT in university residents comparing three arms: HH + masking, masking alone, or control. They found no effect in the primary analysis of ILI or laboratory-confirmed respiratory infections. However, there was a significant effect on ILI in weeks 3-6 of the study in the mask + HH arm (RR = 0.25, 95% CI, 0.07 to 0.87), but not in the mask-only arm, suggesting the effect may have been due to HH.[37]
- Aiello et al. 2010 performed a cluster RCT in university residence halls with 3 arms; masking with surgical masks, masking + HH, or no intervention. In the primary adjusted analysis there were no

significant differences in the mask only group (relative risk (RR) 0.90, 95% confidence interval (CI) 0.77-1.05) or mask + HH group (RR 0.87, 95% CI 0.73-1.02).[36]

- Cowling et al. 2009 performed a cluster RCT of 259 households with confirmed influenza patients.[39] Households (≥3 people) were randomized to either HE (control), HH, or HH + masking with surgical masks. The study included 189 (73%) index cases <16 years. There was no statistically significant difference in either laboratory-confirmed or clinical influenza infection between the 3 groups. In a post-hoc analysis limited to those that applied the intervention within 36 hours of symptom-onset in the index case, mask + HH reduced laboratory-confirmed influenza infections (OR: 0.33, 95% CI; 0.13-0.87), but not clinically-defined influenza. Self-reported mask adherence + HH for index cases and contacts was 49% and 26%, respectively. The authors conclude that if applied early, masks + HH for household contacts of influenza-infected individuals may be effective.[39]
- MacIntyre et al. 2009 performed a cluster RCT of adult household members masking after a child was diagnosed with a respiratory illness. They compared surgical mask, N95 respirator, or control. There were no significant differences between either type of mask and control; however, mask adherence was low.[40]

Non-randomized Studies

Systematic reviews and meta-analyses of observational studies for non-COVID infections have found protective effects from mask-wearing. In contrast to the largely negative randomized trials above, the results of these studies should be interpreted cautiously considering the substantial biases present from the original studies used in these meta-analyses.

- Liang et al. 2020 performed a systematic review and meta-analysis of mask effectiveness. Of the 21 identified studies for inclusion, 8 were in non-healthcare workers.[41] The pooled results of these 8 studies published from 2004-2014 showed a significant protective effect from mask-wearing (OR: 0.53; 95% CI; 0.36-0.79, I^2=45%). However, a number of trials were not included and the observed effect was predominately driven by observational studies (not RCTs).[41]
- Chu et al performed a systematic review and meta-analysis utilizing observational data from Severe Acute Respiratory Syndrome (SARS), Middle East Respiratory Syndrome (MERS), and COVID-19 health-care and non-health care studies to evaluate the protective effects of physical distancing, mask use, and eye protection.[42] Overall, mask use (non-medical, medical or respirator) was effective (unadjusted studies OR 0.34, 95%CI 0.26-0.45; adjusted studies OR 0.15, 95%CI 0.07-0.34); however, from the three included non-healthcare settings (all patients with SARS) masks were significantly less protective compared to healthcare settings (OR 0.56, 95%CI 0.40-0.79, $p_{intereraction}$=0.049). The applicability of these studies to non-healthcare transmission of COVID-19 are questionable.[42]
- Saunders-Hastings et al. 2017 conducted a systematic review and meta-analysis on the effect of personal protective measures on pandemic influenza transmission.[43] The meta-analysis found regular HH provided a significant protective effect against pandemic viral transmission (OR = 0.62; 95% CI 0.52–0.73), but the effect of facemask use was not statistically significant (OR = 0.53; 95% CI 0.16–1.71).[43]
- There is a body of literature on wearing masks at mass gatherings (e.g. Hajj). Barasheed et al. 2016 performed a systematic review of 25 studies.[44] The studies were heterogeneous and generally of poor quality; however, the authors pooled results from 13 studies of masking involving 7,652 participants and found a small but significant protective effect against respiratory infections (RR 0.89 95% CI 0.84-0.94).[44]

- Zhang et al. 2013 conducted an observational study that evaluated the risk of influenza pH1N1 on two flights, after several passengers developed infections.[45] They found that on one flight from New York to Hong Kong there were 9 infections in passengers compared to 32 asymptomatic controls. None of the infected passengers wore masks compared to 15 (47%) of the controls who did wear masks. The index case was never identified. The authors concluded that wearing a mask on this flight was potentially protective.[45]

Homemade and Cloth Masks

Given the challenges in maintaining personal protective equipment supply during the COVID-19 pandemic, the use of homemade and/or cloth masks is the recommended mask type for use in non-healthcare settings. Broadly speaking, there are two types of studies on the effectiveness of cloth masks: studies that evaluate filter efficiency in a laboratory setting, and studies that evaluate infection risk to the wearer and those around them. There are more of the former studies which generally agree that at least some filtration occurs under certain conditions; the latter have observed some evidence for reduction of viral respiratory transmission at the population level, although have not proven such masks effective at an individual level. Overall, the evidence suggests there is variability in the effectiveness of cloth masks and that they are generally inferior to medical masks. One study in a healthcare setting demonstrated that cloth masks were associated with an increased risk of infection and they should not be used to protect healthcare workers.[46] However, the body of evidence supports that certain cloth materials provide sufficient filtration to be a suitable option for source control in non-healthcare settings. With respect to the materials used in cloth masks, a few studies looked at filtration efficiency in a lab setting, and generally agreed that cotton materials with high thread count were more efficient than other materials. There was some variability in findings of filtration efficiency with respect to layered designs and combining materials. Adding electrostatic charge was also noted to improve filtration efficiency.

- Ho et al. 2020 compared a 3-layer 100% cotton mask versus surgical mask and found 86.4% and 99.9% filtration efficiency, respectively.[47] They recruited 211 infected adult volunteers (205 influenza, 6 suspected COVID-19) and compared particle concentrations without masks, with medical masks, and with cotton masks. Both surgical and cotton masks significantly reduced ($p=0.03$) filtered particles, compared to no mask, with no significant differences between mask types.[47]
- Ma et al. 2020 conducted an experiment, using an avian influenza virus, on the comparable efficiency between N95, surgical masks, and homemade masks (made from 4 layers of “kitchen paper” plus 1 layer of polyester cloth) to block nebulizer-produced aerosols.[48] They found that the masks blocked 99.9%, 97.1%, and 95.2% of aerosols, respectively.[48]
- Davies et al. 2013 in an experimental study found that masks made from 100% cotton t-shirts had about 50% the median-fit factor of surgical masks.[49] Both masks blocked microorganisms expelled; however, surgical masks were three times more effective.[49]
- Dato et al. 2006 fashioned a nine-ply (one outer layer and eight inner layers) face mask out of heavy-weight 100% cotton T-shirt material, and achieved a maximum fit factor of 67 using quantitative measurements (a Portacount Fit Tester), with minimal discomfort or difficulty breathing reported in the three test subjects.[50] Note that National Institute for Occupational Safety and Health (NIOSH)-approved N95 respirators are required to have a fit factor of 100.[50]
- Rengasamy et al. 2010 similarly found in experimental conditions that cloth masks and various fabric materials were much less efficient than N95 respirators at filtering various size aerosols.[51] Sodium chloride (NaCl) aerosol penetration tests were run at face velocities of 5.5 and 16.5 cm/s

flow rates, using a NIOSH particulate respirator certification method for polydisperse (various size) NaCl aerosol and a TSI 3160 Fractional Efficiency Tester for monodisperse (specific size) NaCl aerosol. Percentage penetration (ratio of downstream to upstream concentration) for cloth masks and fabric ranged from 40-90% for polydisperse aerosols, compared to N95 penetrations of 0.12% and <5% at the lower and higher velocities, respectively. For monodisperse aerosols, penetration varied by particle size and fabric type in the 20-1000 nm range. Certain fabrics (e.g., towels and scarves) had slightly lower penetration (around 20-80% for towels, increasing with particle diameter), which was noted by the authors to be comparable to other studies of surgical mask penetration levels (measured in cited studies ranging from 51-89%). They conclude that fabric materials provide minimal respiratory protection to the wearer from aerosol-sized particles, but that "the use of improvised fabric materials may be of some value compared to no protection at all when respirators are not available."[51]

- MacIntyre et al. 2015 conducted a cluster RCT (N=1,607) on the effectiveness of cloth or surgical masks, compared to routine practices (personal protective equipment as needed), in hospital healthcare workers.[46] The primary outcomes were rates of ILI or laboratory-confirmed respiratory viral infection. Infection rates were highest in the cloth mask group, with an RR for ILI of 13 compared to the medical mask arm, an RR for ILI of 6.6 compared to the control arm, and an RR for laboratory-confirmed virus of 1.7 compared to the medical mask group. Penetration of particles in cloth masks was 97%, compared to 44% in the medical masks.[46]
- Van der Sande et al. 2008 compared homemade tea cloth masks, surgical masks, and FFP-2 (European equivalent of N95 respirators) in healthy volunteers performing various physical maneuvers and measured quantitative differences in particles with a Portacount®.[33] They calculated median protection factors (or PFs, the ratio of particle concentrations sized 0.02-1 µm outside to inside the mask) of 2.2-3.2 for cloth masks, 4.1-5.3 for surgical masks, and 66-113 for FFP-2 respirators among the adult volunteers. Marginal protection was seen for all mask types when testing for reduction in outgoing transmission of respiratory particles.[33]
- Konda et al. 2020 evaluated filtration efficiency for particle sizes in the 10nm to 10µm range for 15 different cloth types (e.g. cotton, silk, flannel, etc.).[52] These were evaluated in different configurations (e.g. layers, combinations, and with simulated "gaps" in seal as may be expected in real-world use), and compared to N95 and surgical masks, using an aerosol generator. They observed that combinations of materials (e.g. high threads-per-inch cotton along with silk, chiffon, or flannel) filtered particles across the tested size spectrum (<300nm-6um), and that was likely due to the combined effects of electrostatic and physical filtering, with efficiencies that were generally >80%. They also noted a significant drop in filter efficiency with simulated gaps, 60% drop in the >300 nm range, and this was observed for all materials including N95 and surgical masks.[52]
- Zhao et al. 2020 evaluated filtration efficiency for various common household materials (e.g. cotton, silk, nylon), as well as materials used in N95 and surgical masks (i.e. polypropylene).[53] Filtration efficiency for polypropylene in N95 masks was >95%, whereas for most other materials (including polypropylene from surgical masks) ranged from 5-30%. The authors noted that the testing did not account for leakage that would be expected in real-world settings, which would reduce efficiency further.[53]
- Lustig et al. 2020 evaluated filtration efficiency using simulated cough/sneeze-generated aerosols comprised of fluorescent aqueous droplets (intended to simulate viruses), testing over 70 different common fabric combinations.[54] Combinations of materials with hydrophilic, hydrophobic, and absorbent layers were most efficient, and were comparable to materials in N95 respirators in this laboratory setting.[54]

- Zangmeister et al. 2020 evaluated 32 different cloth materials and combinations of materials using NaCl aerosols of diameters of 50-825nm, and found that 3 of 5 top performing materials were high thread-count cottons.[55]

Risks Associated with Wearing Masks

Mask use by the general public could be associated with a theoretical elevated risk of COVID-19 through decreased physical distancing and self-contamination. The external surface of the mask may become contaminated and touching one's face is a common practice.[56] Continuous mask use may be associated with facial skin lesions, irritant dermatitis, impaired vision in those wearing glasses, or worsening acne.[4,57,58] One study observed physiologic respiratory changes from the use of N95 respirators in healthcare workers (with prolonged use), these finding were subtle and not considered clinically relevant.[59] Another study in healthcare workers reported various subjective complaints (e.g. headache, impaired cognition); however, only skin effects (e.g. irritation, acne) were consistently noted.[60] The Canadian Thoracic Society position statement on mask use for the public states, "There is NO evidence that wearing a face mask will exacerbate (cause a 'flare up' of) an underlying lung condition."[61] Studies in children have identified low adherence to proper use in school settings.[30-32] No study has evaluated the impact of mask use on children's education quality. Further studies are needed on optimal methods for optimizing mask use in children.

SYNOPSIS

02/02/2021

Review of "Rapid review on the characteristics of effective non-medical face masks in reducing the risk of SARS-CoV-2 transmission"

Article citation: Young K, Otten A. Rapid review on the characteristics of effective non-medical face masks in reducing the risk of SARS-CoV-2 transmission [Internet]. Ottawa, ON: Public Health Agency of Canada; 2021 [cited 2021 Jan 27]. Available upon request from: https://www.nccmt.ca/covid-19/covid-19-evidence-reviews/261

One-Minute Summary

- This rapid review examined the evidence on the characteristics and efficacy of non-medical masks in reducing severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) transmission.
- **Primary findings of the rapid review:**
  - Experimental simulation studies have found that non-medical masks were more effective for source control (i.e., preventing the spread of SARS-CoV-2 if worn by an infectious person) than preventing infections in the person wearing the mask.
  - Non-medical masks reduced the distance respiratory droplets travelled during indoor talking, coughing and sneezing.
  - The filtration efficiency of non-medical face masks (with variable designs and fabrics) ranged from less than 10% to more than 95% in 42 studies.
  - The efficacy of non-medical masks depended on: 1) filtration efficiency, 2) breathability, and 3) fit.
    - When non-medical masks were made from high quality fabrics consisting of multiple layers and snug fit, they reduced the expulsion of respiratory droplets, although to a lesser extent than medical masks.
- **The characteristics of non-medical masks that reduced the risk of spreading or contracting SARS-CoV-2 included:**
  - Tight-fitting, double-layer masks with different material types (e.g., combed cotton and polyester) or masks made from one type of material but with greater than 2 layers exhibited similar source reduction efficiencies as medical masks (>90%). Loose-fitting non-medical masks reduced filtration effectiveness by more than 50% in some studies.
  - Multiple-layer non-medical masks improved filtration efficiency, but masks with more than three layers reduced breathability.
  - Fabrics should be of high-quality and tightly woven, including hydrophobic fabrics (e.g., polyester, spunbound polypropylene, polyaramid); fabrics that can capture charged particles (e.g., polyester, silk); or fabrics with hydrophilic properties that increase comfort

and longevity (e.g., cotton). The filtration efficiencies of most household fabrics were higher for larger, low-velocity respiratory droplets.
    - A triple-layered mask made of a hydrophobic exterior, blended non-woven fabric middle, and hydrophilic interior was the ideal combination for source reduction and potential infection prevention.
- The authors stated that "The existing research on how effective non-medical masks are is of low quality and results will likely change with additional research".

Additional Information

- The authors included 54 primary research articles in their rapid review. Twenty-two studies investigated non-medical masks as source control and 37 studies investigated how non-medical masks can prevent infection. Studies used human volunteers (n=15), manikins (n=15), filter-holders (n=34) and animal models (n=1). Of note, filter holder studies use fabric samples mounted in place by a filter holder and do not take fit of a human face into account.
- Non-medical masks, whether homemade or manufactured, are not considered personal protective equipment since they do not undergo standardized testing. Non-medical masks are not recommended for use by healthcare professionals and those with an increased risk of infection where physical distancing cannot be maintained.
- **Fabrics and designs to avoid in non-medical face masks:**
    - Avoid using vacuum cleaner bags as fabric, as they may contain harmful ingredients and fibers.
    - Avoid loosely-folded face masks, bandana-style face masks, and single-layered neck gaiters, as they do not effectively block respiratory droplets.
    - Avoid respirators with an exhalation valve, as these masks are not effective for source control.
- **Limitations:**
    - The majority of included studies were experimental and used non-human models. None of the studies identified how effective specific types of non-medical masks are in real-world settings.
    - The types and composition of non-medical masks used in the included studies, along with variability in fit and methodologies, made comparisons among studies difficult.
    - Studies that examined filtration efficiency used a variety of methods that targeted a wide variety of droplet sizes (<1 to >5 µm in diameter) using artificial materials. This variability made it difficult to compare filtration efficiencies between studies.

PHO Reviewer's Comments

- The evidence comparing non-medical masks to medical grade masks is limited to experimental studies evaluating filtering efficiency and is not based on clinical or real-world settings. The clinical data on public mask-wearing has been reviewed separately.[1]
- The body of evidence supports mask-wearing in public as effective for source control with possible synergistic effects for infection prevention if both the source and contact are appropriately wearing well-fitted non-medical masks.
- Experimental data supports higher quality masks, such as 3-layer non-medical masks or medical grade masks, as providing superior filtering efficiency. By inference, this may reduce the potential for transmission.

- Variants of Concern (VOC) have emerged in Ontario which have been associated with increased transmissibility. At the time of posting no studies have evaluated the relative effectiveness of different mask types in mitigating transmission from SARS-CoV-2 VOCs.[2]

Mask use in the context of COVID-19

Interim guidance

1 December 2020

World Health Organization

This document, which is an update of the guidance published on 5 June 2020, includes new scientific evidence relevant to the use of masks for reducing the spread of SARS-CoV-2, the virus that causes COVID-19, and practical considerations. It contains updated evidence and guidance on the following:

- mask management;
- SARS-CoV-2 transmission;
- masking in health facilities in areas with community, cluster and sporadic transmission;
- mask use by the public in areas with community and cluster transmission;
- alternatives to non-medical masks for the public;
- exhalation valves on respirators and non-medical masks;
- mask use during vigorous intensity physical activity;
- essential parameters to be considered when manufacturing non-medical masks (Annex).

Key points

- The World Health Organization (WHO) advises the use of masks as part of a comprehensive package of prevention and control measures to limit the spread of SARS-CoV-2, the virus that causes COVID-19. A mask alone, even when it is used correctly, is insufficient to provide adequate protection or source control. Other infection prevention and control (IPC) measures include hand hygiene, physical distancing of at least 1 metre, avoidance of touching one's face, respiratory etiquette, adequate ventilation in indoor settings, testing, contact tracing, quarantine and isolation. Together these measures are critical to prevent human-to-human transmission of SARS-CoV-2.
- Depending on the type, masks can be used either for protection of healthy persons or to prevent onward transmission (source control).
- WHO continues to advise that anyone suspected or confirmed of having COVID-19 or awaiting viral laboratory test results should wear a medical mask when in the presence of others (this does not apply to those awaiting a test prior to travel).
- For any mask type, appropriate use, storage and cleaning or disposal are essential to ensure that they are as effective as possible and to avoid an increased transmission risk.

<u>Mask use in health care settings</u>

- WHO continues to recommend that health workers (1) providing care to suspected or confirmed COVID-19 patients wear the following types of mask/respirator in addition to other personal protective equipment that are part of standard, droplet and contact precautions:
  - medical mask in the absence of aerosol generating procedures (AGPs)
  - respirator, N95 or FFP2 or FFP3 standards, or equivalent in care settings for COVID-19 patients where AGPs are performed; these may be used by health workers when providing care to COVID-19 patients in other settings if they are widely available and if costs is not an issue.
- In areas of known or suspected community or cluster SARS-CoV-2 transmission WHO advises the following:
  - universal masking for all persons (staff, patients, visitors, service providers and others) within the health facility (including primary, secondary and tertiary care levels; outpatient care; and long-term care facilities)
  - wearing of masks by inpatients when physical distancing of at least 1 metre cannot be maintained or when patients are outside of their care areas.
- In areas of known or suspected sporadic SARS-CoV-2 transmission, health workers working in clinical areas where patients are present should continuously wear a medical mask. This is known as targeted continuous medical masking for health workers in clinical areas;
- Exhalation valves on respirators are discouraged as they bypass the filtration function for exhaled air by the wearer.

<u>Mask use in community settings</u>

- Decision makers should apply a risk-based approach when considering the use of masks for the general public.
- In areas of known or suspected community or cluster SARS-CoV-2 transmission:
  - WHO advises that the general public should wear a non-medical mask in indoor (e.g. shops, shared workplaces, schools - see Table 2 for details) or outdoor settings where physical distancing of at least 1 metre cannot be maintained.
  - If indoors, unless ventilation has been be assessed to be adequate[1], WHO advises that the general public should wear a non-medical mask, regardless of whether physical distancing of at least 1 metre can be maintained.

[1] For adequate ventilation refer to regional or national institutions or heating, refrigerating and air-conditioning societies enacting ventilation requirements. If not available or applicable, a recommended ventilation rate of 10 l/s/person should be met (except healthcare facilities which have specific requirements). For more information consult "Coronavirus (COVID-19) response

  - Individuals/people with higher risk of severe complications from COVID-19 (individuals ≥ 60 years old and those with underlying conditions such as cardiovascular disease or diabetes mellitus, chronic lung disease, cancer, cerebrovascular disease or immunosuppression) should wear medical masks when physical distancing of at least 1 metre cannot be maintained.
- In any transmission scenarios:
  - Caregivers or those sharing living space with people with suspected or confirmed COVID-19, regardless of symptoms, should wear a medical mask when in the same room.

Mask use in children (2)

- Children aged up to five years should not wear masks for source control.
- For children between six and 11 years of age, a risk-based approach should be applied to the decision to use a mask; factors to be considered in the risk-based approach include intensity of SARS-CoV-2 transmission, child's capacity to comply with the appropriate use of masks and availability of appropriate adult supervision, local social and cultural environment, and specific settings such as households with elderly relatives, or schools.
- Mask use in children and adolescents 12 years or older should follow the same principles as for adults.
- Special considerations are required for immunocompromised children or for paediatric patients with cystic fibrosis or certain other diseases (e.g., cancer), as well as for children of any age with developmental disorders, disabilities or other specific health conditions that might interfere with mask wearing.

Manufacturing of non-medical (fabric) masks (Annex)

- Homemade fabric masks of three-layer structure (based on the fabric used) are advised, with each layer providing a function: 1) an innermost layer of a hydrophilic material 2) an outermost layer made of hydrophobic material 3) a middle hydrophobic layer which has been shown to enhance filtration or retain droplets.
- Factory-made fabric masks should meet the minimum thresholds related to three essential parameters: filtration, breathability and fit.
- Exhalation valves are discouraged because they bypass the filtration function of the fabric mask rendering it unserviceable for source control.

Methodology for developing the guidance

Guidance and recommendations included in this document are based on published WHO guidelines (in particular the WHO Guidelines on infection prevention and control of epidemic- and pandemic-prone acute respiratory infections in health care) (2) and ongoing evaluations of all available scientific evidence by the WHO ad hoc COVID-19 Infection Prevention and Control Guidance Development Group (COVID-19 IPC GDG) (see acknowledgement section for list of GDG members). During emergencies WHO publishes interim guidance, the development of which follows a transparent and robust process of evaluation of the available evidence on benefits and harms. This evidence is evaluated through expedited systematic reviews and expert consensus-building through weekly GDG consultations, facilitated by a methodologist and, when necessary, followed up by surveys. This process also considers, as much as possible, potential resource implications, values and preferences, feasibility, equity, and ethics. Draft guidance documents are reviewed by an external review panel of experts prior to publication.

Purpose of the guidance

This document provides guidance for decision makers, public health and IPC professionals, health care managers and health workers in health care settings (including long-term care and residential), for the public and for manufactures of non-medical masks (Annex). It will be revised as new evidence emerges.

WHO has also developed comprehensive guidance on IPC strategies for health care settings (3), long-term care facilities (LTCF) (4), and home care (5).

Background

The use of masks is part of a comprehensive package of prevention and control measures that can limit the spread of certain respiratory viral diseases, including COVID-19. Masks can be used for protection of healthy persons (worn to protect oneself when in contact with an infected individual) or for source control (worn by an infected individual to prevent onward transmission) or both.

However, the use of a mask alone, even when correctly used (see below), is insufficient to provide an adequate level of protection for an uninfected individual or prevent onward transmission from an infected individual (source control). Hand hygiene, physical distancing of at least 1 metre, respiratory etiquette, adequate ventilation in indoor settings, testing, contact tracing, quarantine, isolation and other infection prevention and control (IPC) measures are critical to prevent human-to-human transmission of SARS-CoV-2, whether or not masks are used (6).

Mask management

For any type of mask, appropriate use, storage and cleaning, or disposal are essential to ensure that they are as effective as possible and to avoid any increased risk of transmission. Adherence to correct mask management practices varies, reinforcing the need for appropriate messaging (7).

WHO provides the following guidance on the correct use of masks:

- Perform hand hygiene before putting on the mask.
- Inspect the mask for tears or holes, and do not use a damaged mask.
- Place the mask carefully, ensuring it covers the mouth and nose, adjust to the nose bridge and tie it securely to minimize any gaps between the face and the mask. If using ear loops, ensure these do not cross over as this widens the gap between the face and the mask.

resources from ASHRAE and others''
https://www.ashrae.org/technical-resources/resources

- Avoid touching the mask while wearing it. If the mask is accidently touched, perform hand hygiene.
- Remove the mask using the appropriate technique. Do not touch the front of the mask, but rather untie it from behind.
- Replace the mask as soon as it becomes damp with a new clean, dry mask.
- Either discard the mask or place it in a clean plastic resealable bag where it is kept until it can be washed and cleaned. Do not store the mask around the arm or wrist or pull it down to rest around the chin or neck.
- Perform hand hygiene immediately afterward discarding a mask.
- Do not re-use single-use mask.
- Discard single-use masks after each use and properly dispose of them immediately upon removal.
- Do not remove the mask to speak.
- Do not share your mask with others.
- Wash fabric masks in soap or detergent and preferably hot water (at least 60° Centigrade/140° Fahrenheit) at least once a day. If it is not possible to wash the masks in hot water, then wash the mask in soap/detergent and room temperature water, followed by boiling the mask for 1 minute.

Scientific evidence

Transmission of the SARS-CoV-2 virus

Knowledge about transmission of the SARS-CoV-2 virus is evolving continuously as new evidence accumulates. COVID-19 is primarily a respiratory disease, and the clinical spectrum can range from no symptoms to severe acute respiratory illness, sepsis with organ dysfunction and death.

According to available evidence, SARS-CoV-2 mainly spreads between people when an infected person is in close contact with another person. Transmissibility of the virus depends on the amount of viable virus being shed and expelled by a person, the type of contact they have with others, the setting and what IPC measures are in place. The virus can spread from an infected person's mouth or nose in small liquid particles when the person coughs, sneezes, sings, breathes heavily or talks. These liquid particles are different sizes, ranging from larger 'respiratory droplets' to smaller 'aerosols.' Close-range contact (typically within 1 metre) can result in inhalation of, or inoculation with, the virus through the mouth, nose or eyes (8-13).

There is limited evidence of transmission through fomites (objects or materials that may be contaminated with viable virus, such as utensils and furniture or in health care settings a stethoscope or thermometer) in the immediate environment around the infected person (14-17). Nonetheless, fomite transmission is considered a possible mode of transmission for SARS-CoV-2, given consistent finding of environmental contamination in the vicinity of people infected with SARS-CoV-2 and the fact that other coronaviruses and respiratory viruses can be transmitted this way (12).

Aerosol transmission can occur in specific situations in which procedures that generate aerosols are performed. The scientific community has been actively researching whether the SARS-CoV-2 virus might also spread through aerosol transmission in the absence of aerosol generating procedures (AGPs) (18, 19). Some studies that performed air sampling in clinical settings where AGPs were not performed found virus RNA, but others did not. The presence of viral RNA is not the same as replication- and infection-competent (viable) virus that could be transmissible and capable of sufficient inoculum to initiate invasive infection. A limited number of studies have isolated viable SARS-CoV-2 from air samples in the vicinity of COVID-19 patients (20, 21).

Outside of medical facilities, in addition to droplet and fomite transmission, aerosol transmission can occur in specific settings and circumstances, particularly in indoor, crowded and inadequately ventilated spaces, where infected persons spend long periods of time with others. Studies have suggested these can include restaurants, choir practices, fitness classes, nightclubs, offices and places of worship (12).

High quality research is required to address the knowledge gaps related to modes of transmission, infectious dose and settings in which transmission can be amplified. Currently, studies are underway to better understand the conditions in which aerosol transmission or superspreading events may occur.

Current evidence suggests that people infected with SARS-CoV-2 can transmit the virus whether they have symptoms or not. However, data from viral shedding studies suggest that infected individuals have highest viral loads just before or around the time they develop symptoms and during the first 5-7 days of illness (12). Among symptomatic patients, the duration of infectious virus shedding has been estimated at 8 days from the onset of symptoms (22-24) for patients with mild disease, and longer for severely ill patients (12). The period of infectiousness is shorter than the duration of detectable RNA shedding, which can last many weeks (17).

The incubation period for COVID-19, which is the time between exposure to the virus and symptom onset, is on average 5-6 days, but can be as long as 14 days (25, 26).

Pre-symptomatic transmission – from people who are infected and shedding virus but have not yet developed symptoms – can occur. Available data suggest that some people who have been exposed to the virus can test positive for SARS-CoV-2 via polymerase chain reaction (PCR) testing 1-3 days before they develop symptoms (27). People who develop symptoms appear to have high viral loads on or just prior to the day of symptom onset, relative to later on in their infection (28).

Asymptomatic transmission – transmission from people infected with SARS-CoV-2 who never develop symptoms – can occur. One systematic review of 79 studies found that 20% (17–25%) of people remained asymptomatic throughout the course of infection. (28). Another systematic review, which included 13 studies considered to be at low risk of bias, estimated that 17% of cases remain asymptomatic (14%–20%) (30). Viable virus has been isolated from specimens of pre-symptomatic and asymptomatic individuals, suggesting that people who do not have symptoms may be able to transmit the virus to others. (25, 29-37)

Studies suggest that asymptomatically infected individuals are less likely to transmit the virus than those who develop symptoms (29). A systematic review concluded that individuals who are asymptomatic are responsible for transmitting fewer infections than symptomatic and pre-symptomatic cases (38). One meta-analysis estimated that there is a 42% lower relative risk of asymptomatic transmission compared to symptomatic transmission (30).

Guidance on mask use in health care settings

Masks for use in health care settings

Medical masks are defined as surgical or procedure masks that are flat or pleated. They are affixed to the head with straps that go around the ears or head or both. Their performance characteristics are tested according to a set of standardized test methods (ASTM F2100, EN 14683, or equivalent) that aim to balance high filtration, adequate breathability and optionally, fluid penetration resistance (39, 40).

Filtering facepiece respirators (FFR), or respirators, offer a balance of filtration and breathability. However, whereas medical masks filter 3 micrometre droplets, respirators must filter more challenging 0.075 micrometre solid particles. European FFRs, according to standard EN 149, at FFP2 performance there is filtration of at least 94% solid NaCl particles and oil droplets. US N95 FFRs, according to NIOSH 42 CFR Part 84, filter at least 95% NaCl particles. Certified FFRs must also ensure unhindered breathing with maximum resistance during inhalation and exhalation. Another important difference between FFRs and other masks is the way filtration is tested. Medical mask filtration tests are performed on a cross-section of the masks, whereas FFRs are tested for filtration across the entire surface. Therefore, the layers of the filtration material and the FFR shape, which ensure the outer edges of the FFR seal around wearer's face, result in guaranteed filtration as claimed. Medical masks, by contrast, have an open shape and potentially leaking structure. Other FFR performance requirements include being within specified parameters for maximum CO_2 build up, total inward leakage and tensile strength of straps (41, 42).

A. Guidance on the use of medical masks and respirators to provide care to suspected or confirmed COVID-19 cases

Evidence on the use of mask in health care settings

Systematic reviews have reported that the use of N95/P2 respirators compared with the use of medical masks (see mask definitions, above) is not associated with statistically significant differences for the outcomes of health workers acquiring clinical respiratory illness, influenza-like illness (risk ratio 0.83, 95%CI 0.63-1.08) or laboratory-confirmed influenza (risk ratio 1.02, 95%CI 0.73-1.43); harms were poorly reported and limited to discomfort associated with lower compliance (43, 44). In many settings, preserving the supply of N95 respirators for high-risk, aerosol-generating procedures is an important consideration (45).

A systematic review of observational studies on the betacoronaviruses that cause severe acute respiratory syndrome (SARS), Middle East respiratory syndrome (MERS) and COVID-19 found that the use of face protection (including respirators and medical masks) is associated with reduced risk of infection among health workers. These studies suggested that N95 or similar respirators might be associated with greater reduction in risk than medical or 12–16-layer cotton masks. However, these studies had important limitations (recall bias, limited information about the situations when respirators were used and limited ability to measure exposures), and very few studies included in the review evaluated the transmission risk of COVID-19 (46). Most of the studies were conducted in settings in which AGPs were performed or other high-risk settings (e.g., intensive care units or where there was exposure to infected patients and health workers were not wearing adequate PPE).

WHO continues to evaluate the evidence on the effectiveness of the use of different masks and their potential harms, risks and disadvantages, as well as their combination with hand hygiene, physical distancing of at least 1 metre and other IPC measures.

Guidance

WHO's guidance on the type of respiratory protection to be worn by health workers providing care to COVID-19 patients is based on 1) WHO recommendations on IPC for epidemic- and pandemic-prone acute respiratory infections in health care (47); 2) updated systematic reviews of randomized controlled trials on the effectiveness of medical masks compared to that of respirators for reducing the risk of clinical respiratory illness, influenza-like illness (ILI) and laboratory-confirmed influenza or viral infections. WHO guidance in this area is aligned with guidelines of other professional organizations, including the European Society of Intensive Care Medicine and the Society of Critical Care Medicine, and the Infectious Diseases Society of America (48, 49).

The WHO COVID-19 IPC GDG considered all available evidence on the modes of transmission of SARS-CoV-2 and on the effectiveness of medical mask versus respirator use to protect health workers from infection and the potential for harms such as skin conditions or breathing difficulties.

Other considerations included availability of medical masks versus respirators, cost and procurement implications and equity of access by health workers across different settings.

The majority (71%) of the GDG members confirmed their support for previous recommendations issued by WHO on 5 June 2020:

1. In the absence of aerosol generating procedures (AGPs)[2], WHO recommends that health workers providing care to patients with suspected or confirmed COVID-19 should wear a medical mask (in addition to other PPE that are part of droplet and contact precautions).
2. In care settings for COVID-19 patients where AGPs are performed, WHO recommends that health workers should wear a respirator (N95 or FFP2 or FFP3 standard, or equivalent) in addition to other PPE that are part of airborne and contact precautions.

In general, health workers have strong preferences about having the highest perceived protection possible to prevent COVID-19 infection and therefore may place high value on the potential benefits of respirators in settings without AGPs. WHO recommends respirators primarily for settings where AGPs are performed; however, if health workers prefer them and they are sufficiently available and cost is not an issue, they could also be used during care for COVID-19 patients in other settings. For additional guidance on PPE, including PPE

[2] The WHO list of AGPs includes tracheal intubation, non-invasive ventilation, tracheotomy, cardiopulmonary resuscitation, manual ventilation before intubation, bronchoscopy, sputum induction using nebulized hypertonic saline, and dentistry and autopsy procedures.

beyond mask use by health workers, see WHO IPC guidance during health care when COVID-19 infection is suspected (3) and also WHO guidance on the rational use of PPE (45).

Exhalation valves on respirators are discouraged as they bypass the filtration function for exhaled air.

B. Guidance on the use of mask by health workers, caregivers and others based on transmission scenario

Definitions

Universal masking in health facilities is defined as the requirement for all persons (staff, patients, visitors, service providers and others) to wear a mask at all times except for when eating or drinking.

Targeted continuous medical mask use is defined as the practice of wearing a medical mask by all health workers and caregivers working in clinical areas during all routine activities throughout the entire shift.

Health workers are all people primarily engaged in actions with the primary intent of enhancing health. Examples are: nursing and midwifery professionals, doctors, cleaners, other staff who work in health facilities, social workers, and community health workers.

Evidence on universal masking in health care settings

In areas where there is community transmission or large-scale outbreaks of COVID-19, universal masking has been adopted in many hospitals to reduce the potential of transmission by health workers to patients, to other staff and anyone else entering the facility (50).

Two studies found that implementation of a universal masking policy in hospital systems was associated with decreased risk of healthcare-acquired SARS-CoV-2 infection. However, these studies had serious limitations: both were before-after studies describing a single example of a phenomenon before and after an event of interest, with no concurrent control group, and other infection control measures were not controlled for (51, 52). In addition, observed decreases in health worker infections occurred too quickly to be attributable to the universal masking policy.

Guidance

Although more research on universal masking in heath settings is needed, it is the expert opinion of the majority (79%) of WHO COVID-19 IPC GDG members that universal masking is advisable in geographic settings where there is known or suspected community or cluster transmission of the SARS-CoV-2 virus.

1. In areas of known or suspected community or cluster SARS-CoV-2 transmission, universal masking should be advised in all health facilities (see Table 1).

- All health workers, including community health workers and caregivers, should wear a medical mask at all times, for any activity (care of COVID-19 or non-COVID-19 patients) and in any common area (e.g., cafeteria, staff rooms).
- Other staff, visitors, outpatients and service providers should also wear a mask (medical or non-medical) at all times
- Inpatients are not required to wear a mask (medical or non-medical) unless physical distancing of at least 1 metre cannot be maintained (e.g., when being examined or visited at the bedside) or when outside of their care area (e.g., when being transported).
- Masks should be changed when they become soiled, wet or damaged or if the health worker/caregiver removes the mask (e.g., for eating or drinking or caring for a patient who requires droplet/contact precautions for reasons other than COVID-19).

2. In the context of known or suspected sporadic SARS-CoV-2 virus transmission, WHO provides the following guidance:

- Health workers, including community health workers and caregivers who work in clinical areas, should continuously wear a medical mask during routine activities throughout the entire shift, apart from when eating and drinking and changing their medical masks after caring for a patient who requires droplet/contact precautions for other reasons. In all cases, medical masks must be changed when wet, soiled, or damaged; used medical masks should be properly disposed of at the end of the shift; and new clean ones should be used for the next shift or when medical masks are changed.
- It is particularly important to adopt the continuous use of masks in potentially high transmission risk settings including triage, family physician/general practitioner offices; outpatient departments; emergency rooms; COVID-19 designated units; haematology, oncology and transplant units; and long-term health and residential facilities.
- Staff who do not work in clinical areas (e.g., administrative staff) do not need to wear a medical mask during routine activities if they have no exposure to patients.

Whether using masks for universal masking within health facilities or targeted continuous medical mask use throughout the entire shift, health workers should ensure the following:

- Medical mask use should be combined with other measures including frequent hand hygiene and physical distancing among health workers in shared and crowded places such as cafeterias, break rooms, and dressing rooms.
- The medical mask should be changed when wet, soiled, or damaged.
- The medical mask should not be touched to adjust it or if displaced from the face for any reason. If this happens, the mask should be safely removed and replaced, and hand hygiene performed.
- The medical mask (as well as other personal protective equipment) should be discarded and changed after caring for any patient who requires contact/droplet precautions for other pathogens, followed by hand hygiene.
- Under no circumstances should medical masks be shared between health workers or between others wearing them. Masks should be appropriately disposed of whenever removed and not reused.

- A particulate respirator at least as protective as a United States of America (US) National Institute for Occupational Safety and Health-certified N95, N99, US Food and Drug Administration surgical N95, European Union standard FFP2 or FFP3, or equivalent, should be worn in settings for COVID-19 patients where AGPs are performed (see WHO recommendations below). In these settings, this includes continuous use by health workers throughout the entire shift, when this policy is implemented.

Note: Decision makers may consider the transmission intensity in the catchment area of the health facility or community setting and the feasibility of implementing a universal masking policy compared to a policy based on assessed or presumed exposure risk. Decisions need to take into account procurement, sustainability and costs of the policy. When planning masks for all health workers, long-term availability of adequate medical masks (and when applicable, respirators) for all workers should be ensured, in particular for those providing care for patients with confirmed or suspected COVID-19. Proper use and adequate waste management should be ensured.

The potential harms and risks of mask and respirator use in the health facility setting include:

- contamination of the mask due to its manipulation by contaminated hands (53, 54);
- potential self-contamination that can occur if medical masks are not changed when wet, soiled or damaged; or by frequent touching/adjusting when worn for prolonged periods (55);
- possible development of facial skin lesions, irritant dermatitis or worsening acne, when used frequently for long hours (56-58);
- discomfort, facial temperature changes and headaches from mask wearing (44, 59, 60);
- false sense of security leading potentially to reduced adherence to well recognized preventive measures such as physical distancing and hand hygiene; and risk-taking behaviours (61-64);
- difficulty wearing a mask in hot and humid environments
- possible risk of stock depletion due to widespread use in the context of universal masking and targeted continuous mask use and consequent scarcity or unavailability for health workers caring for COVID 19 patients and during health care interactions with non-COVID-19 patients where medical masks or respirators might be required.

Alternatives to medical masks in health care settings

The WHO's disease commodity package (DCP) for COVID-19 recommends medical masks for health workers to be type II or higher (65). Type II medical masks provide a physical barrier to fluids and particulate materials and have bacterial filtration efficiency of ≥98% compared to Type I mask, which has bacterial filtration efficiency of ≥95% and lower fluid resistance (66) In case of stock outs of type II or higher medical masks, health workers should use a type I medical mask as an alternative. Other alternatives such as face shields or fabric masks should be carefully evaluated.

Face shields are designed to provide protection from splashes of biological fluid (particularly respiratory secretions), chemical agents and debris (67, 68) into the eyes. In the context of protection from SARS-CoV-2 transmission through respiratory droplets, face shields are used by health workers as personal protective equipment (PPE) for eye protection in combination with a medical mask or a respirator (69, 70) While a face shield may confer partial protection of the facial area against respiratory droplets, these and smaller droplets may come into contact with mucous membranes or with the eyes from the open gaps between the visor and the face (71,67).

Fabric masks are not regulated as protective masks or part of the PPE directive. They vary in quality and are not subject to mandatory testing or common standards and as such are not considered an appropriate alternative to medical masks for protection of health workers. One study that evaluated the use of cloth masks in a health care facility found that health care workers using 2 ply cotton cloth masks (a type of fabric mask) were at increased risk of influenza-like illness compared with those who wore medical masks (72).

In the context of severe medical mask shortage, face shields alone or in combination with fabric mask may be considered as a last resort (73). Ensure proper design of face shields to cover the sides of the face and below the chin.

As for other PPE items, if production of fabric masks for use in health care settings is proposed locally in situations of shortage or stock out, a local authority should assess the product according to specific minimum performance standards and required technical specifications (see Annex).

Additional considerations for community care settings

Like other health workers, community health workers should apply standard precautions for all patients at all times, with particular emphasis regarding hand and respiratory hygiene, surface and environmental cleaning and disinfection and the appropriate use of PPE. When a patient is suspected or confirmed of having COVID-19, community health workers should always apply contact and droplet precautions. These include the use of a medical mask, gown, gloves and eye protection (74).

IPC measures that are needed will depend on the local COVID-19 transmission dynamics and the type of contact required by the health care activity (see Table 1). The community health workforce should ensure that patients and workforce members apply precautionary measures such as respiratory hygiene and physical distancing of at least 1 metre (3.3 feet). They also may support set-up and maintenance of hand hygiene stations and community education (74). In the context of known or suspected community or cluster transmission, community health workers should wear a medical mask when providing essential routine services (see Table 1).

Table 1. Mask use in health care settings depending on transmission scenario, target population, setting, activity and type*

Transmission scenario	Target population (who)	Setting (where)	Activity (what)	Mask type (which one) *
Known or suspected community or cluster transmission of SARS-CoV-2	Health workers and caregivers	Health facility (including primary, secondary, tertiary care levels, outpatient care, and long-term care facilities)	For any activity in patient-care areas (COVID-19 or non-COVID-19 patients) or in any common areas (e.g., cafeteria, staff rooms)	Medical mask (or respirator if aerosol generating procedures performed)
	Other staff, patients, visitors, service suppliers		For any activity or in any common area	Medical or fabric mask
	Inpatients	In single or multiple-bed rooms	When physical distance of at least 1 metre cannot be maintained	
	Health workers and caregivers	Home visit (for example, for antenatal or postnatal care, or for a chronic condition)	When in direct contact with a patient or when a distance of at least 1 metre cannot be maintained.	Medical mask
		Community	Community outreach programmes/essential routine services	
Known or suspected sporadic transmission of SARS-CoV-2 cases	Health workers and caregivers	Health facility (including primary, secondary, tertiary care levels, outpatient care, and long-term care facilities)	In patient care area- irrespective of whether patients have suspected/confirmed COVID-19	Medical mask
	Other staff, patients, visitors, service suppliers and all others		No routine activities in patient areas	Medical mask not required. Medical mask should be worn if in contact or within 1 metre of patients, or according to local risk assessment
	Health workers and caregivers	Home visit (for example, for antenatal or postnatal care, or for a chronic condition)	When in direct contact or when a distance of at least 1metre cannot be maintained.	Medical mask
		Community	Community outreach programs (e.g., bed net distribution)	
No documented SARS-CoV-2 transmission	Health workers and caregivers	Health facility (including primary, secondary, tertiary care levels, outpatient care, and long-term care facilities)	Providing any patient care	Medical mask use according to standard and transmission-based precautions
		Community	Community outreach programs	
Any transmission scenario	Health workers	Health care facility (including primary, secondary, tertiary care levels, outpatient care, and long-term care facilities), in settings where aerosol generating procedures (AGP) are performed	Performing an AGP on a suspected or confirmed COVID-19 patient or providing care in a setting where AGPs are in place for COVID-19 patients	Respirator (N95 or N99 or FFP2 or FFP3)

**This table refers only to the use of medical masks and respirators. The use of medical masks and respirators may need to be combined with other personal protective equipment and other measures as appropriate, and always with hand hygiene.*

Guidance on mask use in community settings

Evidence on the protective effect of mask use in community settings

At present there is only limited and inconsistent scientific evidence to support the effectiveness of masking of healthy people in the community to prevent infection with respiratory viruses, including SARS-CoV-2 (75). A large randomized community-based trial in which 4862 healthy participants were divided into a group wearing medical/surgical masks and a control group found no difference in infection with SARS-CoV-2 (76). A recent systematic review found nine trials (of which eight were cluster-randomized controlled trials in which clusters of people, versus individuals, were randomized) comparing medical/surgical masks versus no masks to prevent the spread of viral respiratory illness. Two trials were with healthcare workers and seven in the community. The review concluded that wearing a mask may make little or no difference to the prevention of influenza-like illness (ILI) (RR 0.99, 95%CI 0.82 to 1.18) or laboratory confirmed illness (LCI) (RR 0.91, 95%CI 0.66-1.26) (44); the certainty of the evidence was low for ILI, moderate for LCI.

By contrast, a small retrospective cohort study from Beijing found that mask use by entire families before the first family member developed COVID-19 symptoms was 79% effective in reducing transmission (OR 0.21, 0.06-0.79) (77). A case-control study from Thailand found that wearing a medical or non-medical mask all the time during contact with a COVID-19 patient was associated with a 77% lower risk of infection (aOR 0.23; 95% CI 0.09–0.60) (78). Several small observational studies with epidemiological data have reported an association between mask use by an infected person and prevention of onward transmission of SARS-CoV-2 infection in public settings. (8, 79-81).

A number of studies, some peer reviewed (82-86) but most published as pre-prints (87-104), reported a decline in the COVID-19 cases associated with face mask usage by the public, using country- or region-level data. One study reported an association between community mask wearing policy adoption and increased movement (less time at home, increased visits to commercial locations) (105). These studies differed in setting, data sources and statistical methods and have important limitations to consider (106), notably the lack of information about actual exposure risk among individuals, adherence to mask wearing and the enforcement of other preventive measures (107, 108).

Studies of influenza, influenza-like illness and human coronaviruses (not including COVID-19) provide evidence that the use of a medical mask can prevent the spread of infectious droplets from a symptomatic infected person to someone else and potential contamination of the environment by these droplets (75). There is limited evidence that wearing a medical mask may be beneficial for preventing transmission between healthy individuals sharing households with a sick person or among attendees of mass gatherings (44, 109-114).

A meta-analysis of observational studies on infections due to betacoronaviruses, with the intrinsic biases of observational data, showed that the use of either disposable medical masks or reusable 12–16-layer cotton masks was associated with protection of healthy individuals within households and among contacts of cases (46). This could be considered to be indirect evidence for the use of masks (medical or other) by healthy individuals in the wider community; however, these studies suggest that such individuals would need to be in close proximity to an infected person in a household or at a mass gathering where physical distancing cannot be achieved to become infected with the virus. Results from cluster randomized controlled trials on the use of masks among young adults living in university residences in the United States of America indicate that face masks may reduce the rate of influenza-like illness but showed no impact on risk of laboratory-confirmed influenza (115, 116).

Guidance

The WHO COVID-19 IPC GDG considered all available evidence on the use of masks by the general public including effectiveness, level of certainty and other potential benefits and harms, with respect to transmission scenarios, indoor versus outdoor settings, physical distancing and ventilation. Despite the limited evidence of protective efficacy of mask wearing in community settings, in addition to all other recommended preventive measures, the GDG advised mask wearing in the following settings:

1. In areas with known or suspected community or cluster transmission of SARS-CoV-2, WHO advises mask use by the public in the following situations (see Table 2):

   Indoor settings:

- in public indoor settings where ventilation is known to be poor regardless of physical distancing: limited or no opening of windows and doors for natural ventilation; ventilation system is not properly functioning or maintained; or cannot be assessed;
- in public indoor settings that have adequate[3] ventilation if physical distancing of at least 1 metre cannot be maintained;
- in household indoor settings: when there is a visitor who is not a household member and ventilation is known to be poor, with limited opening of windows and doors for natural ventilation, or the ventilation system cannot be assessed or is not properly functioning, regardless of whether physical distancing of at least 1 metre can be maintained;
- in household indoor settings that have adequate ventilation if physical distancing of at least 1 metre cannot be maintained.

[3] For adequate ventilation refer to regional or national institutions or heating, refrigerating and air-conditioning societies enacting ventilation requirements. If not available or applicable, a recommended ventilation rate of 10 l/s/person should be met (except healthcare facilities which have specific requirements). For more information consult "Coronavirus (COVID-19) response resources from ASHRAE and others'' https://www.ashrae.org/technical-resources/resources

Table 2. Mask use in community settings depending on transmission scenario, setting, target population, purpose and type*

Transmission scenario	Situations/settings (where)	Target Population (who)	Purpose of mask use (why)	Mask type (which one)
Known or suspected community or cluster transmission of SARS-CoV-2	Indoor settings, where ventilation is known to be poor or cannot be assessed or the ventilation system is not properly maintained, regardless of whether physical distancing of at least 1 meter can be maintained	General population in public* settings such as shops, shared workplaces, schools, churches, restaurants, gyms, etc. or in enclosed settings such as public transportation. For households, in indoor settings, when there is a visitor who is not a member of the household	Potential benefit for source control	Fabric mask
	Indoor settings that have adequate [4] ventilation if physical distancing of at least 1 metre cannot be maintained			
	Outdoor settings where physical distancing cannot be maintained	General population in settings such as crowded open-air markets, lining up outside a building, during demonstrations, etc.		
	Settings where physical distancing cannot be maintained, and the individual is at increased risk of infection and/or negative outcomes	Individuals/people with higher risk of severe complications from COVID-19: • People aged ≥60 years • People with underlying comorbidities, such as cardiovascular disease or diabetes mellitus, chronic lung disease, cancer, cerebrovascular disease, immunosuppression, obesity, asthma	Protection	Medical mask
Known or suspected sporadic transmission, or no documented SARS-CoV-2 transmission	Risk-based approach	General population	Potential benefit for source control and/or protection	Depends on purpose (see details in the guidance content)
Any transmission scenario	Any setting in the community	Anyone suspected or confirmed of having COVID-19, regardless of whether they have symptoms or not, or anyone awaiting viral test results, when in the presence of others	Source control	Medical mask

**Public indoor setting includes any indoor setting outside of the household*

[4] For adequate ventilation refer to regional or national institutions or heating, refrigerating and air-conditioning societies enacting ventilation requirements. If not available or applicable, a recommended ventilation rate of 10l/s/person should be met (except healthcare facilities which have specific requirements).). For more information consult "Coronavirus (COVID-19) response resources from ASHRAE and others'' https://www.ashrae.org/technical-resources/resources

In outdoor settings:

- where physical distancing of at least 1 metre cannot be maintained;
- individuals/people with higher risk of severe complications from COVID-19 (individuals ≥ 60 years old and those with underlying conditions such as cardiovascular disease or diabetes mellitus, chronic lung disease, cancer, cerebrovascular disease or immunosuppression) should wear medical masks in any setting where physical distance cannot be maintained.

2. In areas with known or suspected sporadic transmission or no documented transmission, as in all transmission scenarios, WHO continues to advise that decision makers should apply a risk-based approach focusing on the following criteria when considering the use of masks for the public:

- **Purpose of mask use**. Is the intention source control (preventing an infected person from transmitting the virus to others) or protection (preventing a healthy wearer from the infection)?
- **Risk of exposure to SARS-CoV-2**. Based on the epidemiology and intensity of transmission in the population, is there transmission and limited or no capacity to implement other containment measures such as contact tracing, ability to carry out testing and isolate and care for suspected and confirmed cases? Is there risk to individuals working in close contact with the public (e.g., social workers, personal support workers, teachers, cashiers)?
- **Vulnerability of the mask wearer/population**. Is the mask wearer at risk of severe complications from COVID-19? Medical masks should be used by older people (≥ 60 years old), immunocompromised patients and people with comorbidities, such as cardiovascular disease or diabetes mellitus, chronic lung disease, cancer and cerebrovascular disease (117).
- **Setting in which the population lives**. Is there high population density (such as in refugee camps, camp-like settings, and among people living in cramped conditions) and settings where individuals are unable to keep a physical distance of at least 1 metre (for example, on public transportation)?
- **Feasibility**. Are masks available at an affordable cost? Do people have access to clean water to wash fabric masks, and can the targeted population tolerate possible adverse effects of wearing a mask?
- **Type of mask**. Does the use of medical masks in the community divert this critical resource from the health workers and others who need them the most? In settings where medical masks are in short supply, **stocks should be prioritized for health workers and at-risk individuals.**

The decision of governments and local jurisdictions whether to recommend or make mandatory the use of masks should be based on the above assessment as well as the local context, culture, availability of masks and resources required.

3. In any transmission scenario:

- Persons with any symptoms suggestive of COVID-19 should wear a medical mask and (5) additionally:
  - self-isolate and seek medical advice as soon as they start to feel unwell with potential symptoms of COVID-19, even if symptoms are mild);
  - follow instructions on how to put on, take off, and dispose of medical masks and perform hand hygiene (118);
  - follow all additional measures, in particular respiratory hygiene, frequent hand hygiene and maintaining physical distance of at least 1 metre from other persons (46). If a medical mask is not available for individuals with suspected or confirmed COVID-19, a fabric mask meeting the specifications in the Annex of this document should be worn by patients as a source control measure, pending access to a medical mask. The use of a non-medical mask can minimize the projection of respiratory droplets from the user (119, 120).
  - Asymptomatic persons who test positive for SARS-CoV-2, should wear a medical mask when with others for a period of 10 days after testing positive.

Potential benefits/harms

The potential advantages of mask use by healthy people in the general public include:

- reduced spread of respiratory droplets containing infectious viral particles, including from infected persons before they develop symptoms (121);
- reduced potential for stigmatization and greater of acceptance of mask wearing, whether to prevent infecting others or by people caring for COVID-19 patients in non-clinical settings (122);
- making people feel they can play a role in contributing to stopping spread of the virus;
- encouraging concurrent transmission prevention behaviours such as hand hygiene and not touching the eyes, nose and mouth (123-125);
- preventing transmission of other respiratory illnesses like tuberculosis and influenza and reducing the burden of those diseases during the pandemic (126).

The potential disadvantages of mask use by healthy people in the general public include:

- headache and/or breathing difficulties, depending on type of mask used (55);
- development of facial skin lesions, irritant dermatitis or worsening acne, when used frequently for long hours (58, 59, 127);
- difficulty with communicating clearly, especially for persons who are deaf or have poor hearing or use lip reading (128, 129);
- discomfort (44, 55, 59)
- a false sense of security leading to potentially lower adherence to other critical preventive measures such as physical distancing and hand hygiene (105);
- poor compliance with mask wearing, in particular by young children (111, 130-132);
- waste management issues; improper mask disposal leading to increased litter in public places and environmental hazards (133);
- disadvantages for or difficulty wearing masks, especially for children, developmentally challenged persons, those with mental illness, persons with cognitive impairment, those with asthma or chronic respiratory or breathing problems, those who have had facial trauma or recent oral maxillofacial surgery and those living in hot and humid environments (55, 130).

Considerations for implementation

When implementing mask policies for the public, decision-makers should:

- clearly communicate the purpose of wearing a mask, including when, where, how and what type of mask should be worn; explain what wearing a mask may achieve and what it will not achieve; and communicate clearly that this is one part of a package of measures along with hand hygiene, physical distancing, respiratory etiquette, adequate ventilation in indoor settings and other measures that are all necessary and all reinforce each other;
- inform/train people on when and how to use masks appropriately and safely (see mask management and maintenance sections);
- consider the feasibility of use, supply/access issues (cleaning, storage), waste management, sustainability, social and psychological acceptance (of both wearing and not wearing different types of masks in different contexts);
- continue gathering scientific data and evidence on the effectiveness of mask use (including different types of masks) in non-health care settings;
- evaluate the impact (positive, neutral or negative) of using masks in the general population (including behavioural and social sciences) through good quality research.

Mask use during physical activity

Evidence

There are limited studies on the benefits and harms of wearing medical masks, respirators and non-medical masks while exercising. Several studies have demonstrated statistically significant deleterious effects on various cardiopulmonary physiologic parameters during mild to moderate exercise in healthy subjects and in those with underlying respiratory diseases (134-140). The most significant impacts have been consistently associated with the use of respirators and in persons with underlying obstructive airway pulmonary diseases such as asthma and chronic obstructive pulmonary disease (COPD), especially when the condition is moderate to severe (136). Facial microclimate changes with increased temperature, humidity and perceptions of dyspnoea were also reported in some studies on the use of masks during exercise (134, 141). A recent review found negligeable evidence of negative effects of mask use during exercise but noted concern for individuals with severe cardiopulmonary disease (142).

Guidance

WHO advises that people should not wear masks during vigorous intensity physical activity (143) because masks may reduce the ability to breathe comfortably. The most important preventive measure is to maintain physical distancing of at least 1 meter and ensure good ventilation when exercising.

If the activity takes place indoors, adequate ventilation should be ensured at all times through natural ventilation or a properly functioning or maintained ventilation system (144). Particular attention should be paid to cleaning and disinfection of the environment, especially high-touch surfaces. If all the above measures cannot be ensured, consider temporary closure of public indoor exercise facilities (e.g., gyms).

Face shields for the general public

At present, face shields are considered to provide a level of eye protection only and should not be considered as an equivalent to masks with respect to respiratory droplet protection and/or source control. Current laboratory testing standards only assess face shields for their ability to provide eye protection from chemical splashes (145).

In the context of non-availability or difficulties wearing a non-medical mask (in persons with cognitive, respiratory or hearing impairments, for example), face shields may be considered as an alternative, noting that they are inferior to masks with respect to droplet transmission and prevention. If face shields are to be used, ensure proper design to cover the sides of the face and below the chin.

Medical masks for the care of COVID-19 patients at home

WHO provides guidance on how to care for patients with confirmed and suspected COVID-19 at home when care in a health facility or other residential setting is not possible (5).

- Persons with suspected COVID-19 or mild COVID-19 symptoms should wear a medical mask as much as possible, especially when there is no alternative to being in the same room with other people. The mask should be changed at least once daily. Persons who cannot tolerate a medical mask should rigorously apply respiratory hygiene (i.e., cover mouth and nose with a disposable paper tissue when coughing or sneezing and dispose of it immediately after use or use a bent elbow procedure and then perform hand hygiene).
- Caregivers of or those sharing living space with people with suspected COVID-19 or with mild COVID-19 symptoms should wear a medical mask when in the same room as the affected person.

Annex: Updated guidance on non-medical (fabric) masks

Background

A non-medical mask, also called fabric mask, community mask or face covering, is neither a medical device nor personal protective equipment. Non-medical masks are aimed at the general population, primarily for protecting others from exhaled virus-containing droplets emitted by the mask wearer. They are not regulated by local health authorities or occupational health associations, nor is it required for manufacturers to comply with guidelines established by standards organizations. Non-medical masks may be homemade or manufactured. The essential performance parameters include good breathability, filtration of droplets originating from the wearer, and a snug fit covering the nose and mouth. Exhalation valves on masks are discouraged as they bypass the filtration function of the mask.

Non-medical masks are made from a variety of woven and non-woven fabrics, such as woven cotton, cotton/synthetic blends, polyesters and breathable spunbond polypropylene, for example. They may be made of different combinations of fabrics, layering sequences and available in diverse shapes. Currently, more is known about common household fabrics and combinations to make non-medical masks with target filtration efficiency and breathability (119, 146-150). Few of these fabrics and combinations have been systematically evaluated and there is no single design, choice of material, layering or shape among available non-medical masks that are considered optimal. While studies have focussed on single fabrics and combinations, few have looked at the shape and universal fit to the wearer. The unlimited combination of available fabrics and materials results in variable filtration and breathability.

In the context of the global shortage of medical masks and PPE, encouraging the public to create their own fabric masks may promote individual enterprise and community integration. Moreover, the production of non-medical masks may offer a source of income for those able to manufacture masks within their communities. Fabric masks can also be a form of cultural expression, encouraging public acceptance of protection measures in general. The safe re-use of fabric masks will also reduce costs and waste and contribute to sustainability (151-156).

This Annex is destined intended for two types of readers: homemade mask makers and factory-made masks manufacturers. Decision makers and managers (national/sub-national level) advising on a type of non-medical mask are also the focus of this guidance and should take into consideration the following features of non-medical masks: breathability, filtration efficiency (FE), or filtration, number and combination of fabric layers material used, shape, coating and maintenance.

Evidence on the effectiveness of non-medical (fabric) masks

A number of reviews have been identified on the effectiveness of non-medical masks (151-156). One systematic review (155) identified 12 studies and evaluated study quality. Ten were laboratory studies (157-166), and two reports were from a single randomized trial (72, 167). The majority of studies were conducted before COVID-19 emerged or used laboratory generated particles to assess filtration efficacy. Overall, the reviews concluded that cloth face masks have limited efficacy in combating viral infection transmission.

Homemade non-medical masks

Homemade non-medical masks made of household fabrics (e.g., cotton, cotton blends and polyesters) should ideally have a three-layer structure, with each layer providing a function (see Figure 1) (168). It should include:

1. an innermost layer (that will be in contact with the face) of a hydrophilic material (e.g., cotton or cotton blends of terry cloth towel, quilting cotton and flannel) that is non-irritating against the skin and can contain droplets (148)
2. a middle hydrophobic layer of synthetic breathable non-woven material (spunbond polypropylene, polyester and polyaramid), which may enhance filtration, prevent permeation of droplets or retain droplets (148, 150)
3. an outermost layer made of hydrophobic material (e.g. spunbond polypropylene, polyester or their blends), which may limit external contamination from penetrating through the layers to the wearer's nose and mouth and maintains and prevents water accumulation from blocking the pores of the fabric (148).

Although a minimum of three layers is recommended for non-medical masks for the most common fabric used, single, double or other layer combinations of advanced materials may be used if they meet performance requirements. It is important to note that with more tightly woven materials, breathability may be reduced as the number of layers increases. A quick check may be performed by attempting to breathe, through the mouth, through the multiple layers.

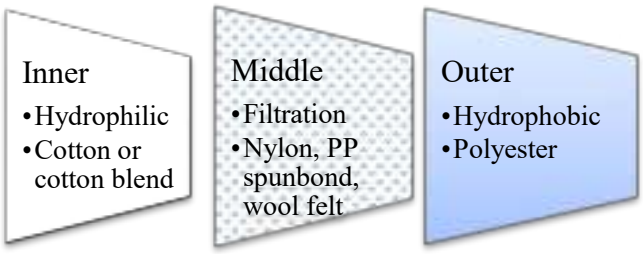

Figure 1. Non-medical mask construction using breathable fabrics such as cotton, cotton blends, polyesters, nylon and polypropylene spunbond that are breathable may impart adequate filtration performance when layered. Single- or double-layer combinations of advanced materials may be used if they meet performance requirements (72).

Assumptions regarding homemade masks are that individual makers only have access to common household fabrics and do not have access to test equipment to confirm target performance (filtration and breathability). Figure 1 illustrates a multi-layer mask construction with examples of fabric options. Very porous materials, such as gauze, even with multiple layers, may provide very low filtration efficiency (147). Higher thread count fabrics offer improved filtration performance (169). Coffee filters, vacuum bags and materials not meant for clothing should be avoided as they may contain injurious content when breathed in. Microporous films such as Gore-Tex are not recommended (170).

Factory-made non-medical masks: general considerations for manufacturers

The non-medical mask, including all components and packaging, must be non-hazardous, non-toxic and child-friendly (no exposed sharp edges, protruding hardware or rough materials). Factory-made non-medical masks must be made using a process that is certified to a quality management system (e.g., ISO 9001). Social accountability standards (e.g., SAI SA8000) for multiple aspects of fair labour practices, health and safety of the work force and adherence to UNICEF's Children's Rights and Business Principles are strongly encouraged.

Standards organizations' performance criteria

Manufacturers producing masks with consistent standardized performance can adhere to published, freely available guidance from several organizations including those from: the French Standardization Association (AFNOR Group), The European Committee for Standardization (CEN), Swiss National COVID-19 Task Force, the American Association of Textile Chemists and Colorists (AATCC), the South Korean Ministry of Food and Drug Safety (MFDS), the Italian Standardization Body (UNI) and the Government of Bangladesh.

Essential parameters

The essential parameters presented in this section are the synthesis of the abovementioned regional and national guidance. They include filtration, breathability and fit. Good performance is achieved when the three essential parameters are optimized at the preferred threshold (Figure 2).

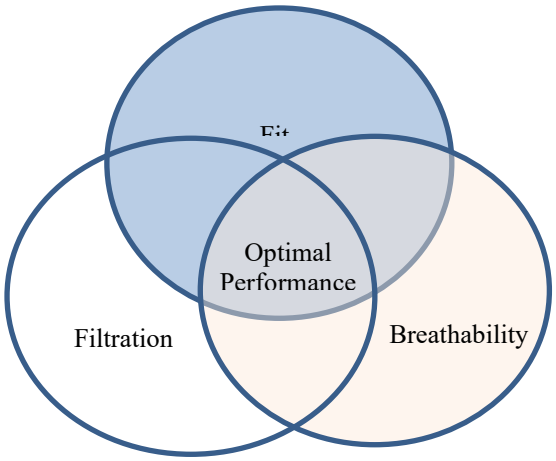

Figure 2. Illustration of the three essential parameters of filtration, breathability and fit.

The summary of the three essential parameters can be found in Table 1 and the additional performance considerations in Table 2. The minimum threshold is the minimum acceptable parameter, while the preferred threshold is the optimum.

Filtration and breathability

Filtration depends on the filtration efficiency (in %), the type of challenge particle (oils, solids, droplets containing bacteria) and the particle size (see Table 1). Depending on the fabrics used, filtration and breathability can complement or work against one another. The selection of material for droplet filtration (barrier) is as important as breathability. Filtration is dependent on the tightness of the weave, fibre or thread diameter. Non-woven materials used for disposable masks are manufactured using processes to create polymer fibres that are thinner than natural fibres such as cotton and that are held together by partial melting.

Breathability is the difference in pressure across the mask and is typically reported in millibars (mbar) or Pascals (Pa) or, normalized to the cm^2 in $mbar/cm^2$ or Pa/cm^2. Acceptable breathability of a medical mask should be below 49 Pa/cm^2. For non-medical masks, an acceptable pressure difference, over the whole mask, should be below 60 Pa/cm^2, with lower values indicating better breathability.

Non-medical fabric masks consisting of two layers of polypropylene spunbond and two layers of cotton have been shown to meet the minimum requirements for droplet filtration and breathability of the CEN CWA 17553 guidance. It is preferable not to select elastic material to make masks as the mask material may be stretched over the face, resulting in increased pore size and lower filtration through multiple usage. Additionally, elastic fabrics are sensitive to washing at high temperatures thus may degrade over time.

Coating the fabric with compounds like wax may increase the barrier and render the mask fluid resistant; however, such coatings may inadvertently completely block the pores and make the mask difficult to breathe through. In addition to decreased breathability unfiltered air may more likely escape the sides of the mask on exhalation. Coating is therefore not recommended.

Valves that let unfiltered air escape the mask are discouraged and are an inappropriate feature for masks used for the purpose of preventing transmission.

Table 1. Essential parameters (minimum and preferred thresholds) for manufactured non-medical mask

Essential Parameters	Minimum threshold	Preferred threshold
1. Filtration*		
1.1. filtration efficiency	70% @ 3 micron	> 70%, without compromising breathability
1.2. Challenge particle	Solid: sodium chloride (NaCl), Talcum powder, Holi powder, dolomite, Polystyrene Latex spheres Liquid: DEHS Di-Ethyl-Hexyl-Sebacat, paraffin oil	Based on availability
1.3. Particle size	Choose either sizes: 3 µm, 1 µm, or smaller	Range of particle sizes
2. Breathability		
2.1. Breathing resistance**	≤60 Pa/cm^2	Adult: ≤ 40 Pa/cm^2 Paediatric: ≤ 20 Pa/cm^2
2.2 Exhalation valves	Not recommended	N/A
3. Fit		
3.1. Coverage	Full coverage of nose and mouth, consistent, snug perimeter fit at the nose bridge, cheeks, chin and lateral sides of the face; adequate surface area to minimize breathing resistance and minimize side leakage	Same as current requirements
3.2 Face seal	Not currently required	Seal as good as FFR (respirator): Fit factor of 100 for N95 Maximum Total Inward Leakage of 25% (FFP1 requirement)
3.2. Sizing	Adult and child	Should cover from the bridge of the nose to below the chin and cheeks on either side of the mouth Sizing for adults and children (3-5, 6-9, 10-12, >12)
3.3Strap strength		> 44.5 N

* Smaller particle may result in lower filtration.
** High resistance can cause bypass of the mask. Unfiltered air will leak out the sides or around the nose if that is the easier path.

Fit: shape and sizing

Fit is the third essential parameter, and takes into consideration coverage, seal, sizing, and strap strength. Fit of masks currently is not defined by any standard except for the anthropometric considerations of facial dimensions (ISO/TS 16976-2) or simplified to height mask (South Korean standard for KF-AD). It is important to ensure that the mask can be held in place comfortably with as little adjustment of the elastic bands or ties as possible.

Mask shapes typically include flat-fold or duckbill and are designed to fit closely over the nose, cheeks and chin of the wearer. Snug fitting designs are suggested as they limit leaks of unfiltered air escaping from the mask (148). Ideally the mask should not have contact with the lips, unless hydrophobic fabrics are used in at least one layer of the mask (148). Leaks where unfiltered air moves in and out of the mask may be attributed to the size and shape of the mask (171).

Additional considerations

Optional parameters to consider in addition to the essential performance parameters include if reusable, biodegradability for disposal masks, antimicrobial performance where applicable and chemical safety (see Table 2).

Non-medical masks intended to be reusable should include instructions for washing and must be washed a minimum of five cycles, implying initial performance is maintained after each wash cycle.

Advanced fabrics may be biodegradable or compostable at the end of service life, according to a recognized standard process (e.g., UNI EN 13432, UNI EN 14995 and UNI / PdR 79).

Manufacturers sometimes claim their NM masks have antimicrobial performance. Antimicrobial performance may be due to coatings or additives to the fabric fibres. Treated fabrics must not come into direct contact with mucous membranes; the innermost fabric should not be treated with antimicrobial additives, only the outermost layer. In addition, antimicrobial fabric standards (e.g., ISO 18184, ISO 20743, AATCC TM100, AATCC 100) are generally slow acting. The inhibition on microbial growth may take full effect after 2- or 24-hour contact time depending on the standard. The standards have generally been used for athletic apparel and substantiate claims of odour control performance. These standards are not appropriate for non-medical cloth masks and may provide a false sense of protection from infectious agents. If claims are maid, manufacturers should specify which standard supports antimicrobial performance, the challenge organism and the contact time.

Volatile additives are discouraged as these may pose a health risk when inhaled repeatedly during wear. Certification according to organizations including OEKO-TEX (Europe) or SEK (Japan), and additives complying with REACH (Europe) or the Environmental Protection Agency (EPA, United States of America) indicate that textile additives are safe and added at safe levels.

Table 2. Additional parameters for manufactured non-medical masks

Additional parameters	Minimum thresholds
If reusable, number of wash cycles	5 cycles
Disposal	Reusable If biodegradable (CFC-BIO), according to UNI EN 13432, UNI EN 14995
Antimicrobial (bacteria, virus, fungus) performance	ISO 18184 (virus) ISO 20743 (bacteria) ISO 13629 (fungus) AATCC TM100 (bacteria)
Chemical safety	Comply with REACH regulation, including inhalation safety

Abbreviations: Δ, deletion; VOC, variant of concern

For additional information on VOCs and interpreting this table, please refer to PHO's *Companion Guide to Variants of Concern (VOCs)*[1]

* VOCs are classified according to the national definitions for Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) variants established by the Canadian SARS-CoV-2 Variant Surveillance Group.[2]

† B.1.617 contains three sub-lineages (B.1.617.1; B.1.617.2; B.1.617.3) which differ by few potentially relevant mutations in the spike protein and their global prevalence of detection.[3] Designation of the sublineages in Canada may change as evidence on their attributes are being reviewed by the Canadian SARS-CoV-2 Variant Surveillance Group.[2]

‡ Based on the odds ratio of secondary household transmission using a household study of VOC transmission in Ontario (forthcoming). For methods, see (https://doi.org/10.1093/cid/ciab186).[4]

§ Unknown indicates that it is under investigation or there is currently no data for assessment.

¶ Spike (S) gene target failure (SGTF) is observed for variants with the Δ69-70 mutation using some SARS-CoV-2 molecular assays that target this region of the S gene. These are multiple gene target assays that will still detect SARS-CoV-2 via the additional targets.

Laboratory evidence suggests resistance to certain therapeutic monoclonal antibodies and/or slightly reduced neutralization by convalescent sera.

** Reduced effectiveness to AstraZeneca and Johnson & Johnson.

†† Laboratory evidence to suggest reduced effectiveness by AstraZeneca, Moderna mRNA-1273, and Pfizer-BioNTech vaccines.

‡‡ Mutations in other genes are not represented in this table.

§§ A small subset of B.1.1.7 variants have been found to have the E484K mutation.

SYNTHESIS

05/26/2021

COVID-19 B.1.617 Variant of Concern – What We Know So Far

Introduction

Public Health Ontario (PHO) is actively monitoring, reviewing and assessing relevant information related to Coronavirus Disease 2019 (COVID-19). "What We Know So Far" documents provide a rapid review of the evidence related to a specific aspect or emerging issue related to COVID-19.

Key Findings

- Lineage B.1.617 is a new variant of concern (VOC) of Severe Acute Respiratory Syndrome coronavirus 2 (SARS-CoV-2) and is associated with the notable mutations L452R and E484Q, which have the potential for greater transmissibility and reduced vaccine effectiveness.
- B.1.617 was first reported in India in late March 2021 and has spread to over 40 other countries around the world in less than two months' time. However, its geographic distribution and incidence trends are not fully understood due to inconsistent testing and sequencing in different regions of the world.
- Field evidence from the United Kingdom (UK), where most B.1.617.2 sequences outside of India have been reported, suggest higher transmissibility for this lineage. Data to date are insufficient to determine if B.1.617 causes more severe disease.
- Preliminary in-vitro studies suggest that B.1.617 has reduced neutralization by vaccine-induced sera and convalescent sera, while an observational study suggests a possible small reduction in effectiveness after full vaccination.

Background

On March 24, 2021, the Ministry of Health and Family Welfare of India reported a new variant that contains two mutations in the Spike gene of SARS-CoV-2: E484Q and L452R.[1] The discovery of this "double mutant" generated concern in India as it took place when the incidence of Coronavirus Disease 2019 (COVID-19) surged rapidly after a long decline from late September 2020 to mid-February 2021.

In less than a month's time, this variant was detected in several other countries including the UK, Singapore, Australia and the United States (US), and was named B.1.617.[2] Public health scientists internationally have noted that the E484Q and L452R mutations may enable B.1.617 to transmit more easily and render vaccines less effective.[3,4]

In the UK, sublineage B.1.617.1 was designated as a Variant Under Investigation (VUI-21APR-01) on April 1, 2021, given its mutation profile and increasing incidence in England, while sublineages B.1.617.2 (with

a different mutation profile) and B.1.617.3 (rapid spread not apparent) were under surveillance.[5] On May 6, 2021, sublineage B.1.617.2 was escalated in its designation to VOC (VOC-21APR-02) when its transmissibility was assessed to be at least equivalent to that of the VOC B.1.1.7. Meanwhile, B.1.617.3 became a VUI (VUI-21APR-03) as of April 27, 2021.[6]

On May 10, 2021, the World Health Organization characterized B.1.617 as a VOC lineage which contains three sublineages: B.1.617.1, B.1.617.2 and B.1.617.3. The designation was based on early evidence of rapid increases in prevalence observed in multiple countries (for B.1.617.1 and B.1.617.2), preliminary laboratory findings of reduced effectiveness of monoclonal therapeutic antibody Bamlanivimab, and potentially slight reduction in neutralization abilities of vaccinee sera.[7]

On May 14, 2021, the Canadian SARS-CoV-2 Variant Surveillance Group classified B.1.617 as a VOC, noting that the designation of the sublineages may change as evidence on their attributes is reviewed (See Appendix A for the Canadian definitions of variant of concern).[8]

Methods

From January 17 to May 26, 2021, PHO Library Services conducted daily searches of primary and preprint literature using the MEDLINE database (search strategies available upon request). In addition, we performed grey literature searches daily using news feeds in the Shared Library Services Partnership. English-language peer-reviewed and non-peer-reviewed (preprint) records that described "double mutant" or B.1.617 were included.

Prior to posting, PHO subject-matter experts reviewed the content of this document.

As the COVID-19 outbreak continues to evolve and the scientific evidence rapidly expands, the information provided in this document is only current as of the date of respective literature searches.

Jurisdictional scan of involving data from England involved keyword searches conducted on May 17 and 18, 2021 in the Google search engine for literature related to COVID-19 epidemiology, vaccination programs, and public health measures in England. A formal database search was not conducted due to time constraints; thus, some relevant articles may not be included.

Epidemiology

- The first B.1.617 genome noted in the global database (GISAID) dates back to October 5, 2020. It was first detected in the UK on February 22, 2021 and in the US on February 23, 2021.[9] As of May 17, 2021, the three sublineages of B.1.617 (B.1.617.1, B.1.617.2 and B.1.617.3) have been reported in 50 countries from Asia, Europe, North America and Australia.[5,9,10] The relative frequency of B.1.617 and the sublineages in different countries is unknown due to the different sequencing capacities and strategies.

- B.1.617 was first detected in India where the majority of this lineage (412 reports as of April 22, 2021) was reported.[10,11] On March 24, 2021, the Indian SARS-CoV-2 Consortium on Genomics reported that about 15%–20% of samples from Maharashtra carry the E484Q and L452R mutations, and there was an increase in the percentage of samples carrying these two mutations since December 2020. Subsequently, B.1.617 was classified as a VOC in India.[1] B.1.617 was found in 61% of 361 cases sequenced between January and March, 2021 in Maharashtra, India. However, the scale of testing was too small to conclude if this lineage was driving the surge in COVID-19 cases in Maharashtra.[9,12]

- In the UK, B.1.617.1 was first detected in mid-February 2021. Its daily incidence rose quickly in April to peak at 15 cases in mid-April, then declined quickly in late April to <4 cases as of early May 2021.[13] B.1.617.3 was first detected in late March 2021 and its daily incidence has remained low, peaking at 3 cases a day in mid-April and dropping to a case occasionally.[13] On the other hand, the daily incidence of B.1.617.2 had remained low from first detection in mid-March 2021 before slowly increasing in early April, after which it rose quickly to 235 cases a day in early May 2021.[13] The proportion of specimens belonging to the B.1.617.2 sublineage among all variants sequenced in the UK increased from 1% in the first week of April 2021, to 26% in the first week of May 2021, and reached 58% by the week of May 16, 2021.[14] (See What's Happening in England? for further epidemiological context and response measures).

- In the US, B.1.617.1 comprised 0.2% (95% confidence interval [CI]: 0.1%–0.2%) of VOCs and variants of interest (VOIs) sequences collected through the Centers for Disease Control and Prevention's national genomic surveillance; B.1.617.2 0.5% (95% CI: 0.3%–0.7%); and <10 observations of B.1.617.3 between April 11 and 24, 2021.[15]

- In Canada, B.1.617 and the sublineages have been reported in one territory and all provinces.[16] The first patient identified in Quebec was reported to have been vaccinated against COVID-19 two months prior.[17]

Genomic Features

B.1.617 contains three sublineages: B.1.617.1; B.1.617.2 and B.1.617.3 with different mutation profiles (see Appendix B). Common spike gene mutations of concern across the sublineages are L452R, P681R and D614G. In addition, B.1.617.1 and B.1.617.3 carry the amino acid mutations E484Q and G142D[7] (the latter may also be found in some B.1.617.2 sequences[18]).

- L452R: this amino acid mutation occurs in the receptor-binding domain and has been associated with **immune escape** from therapeutically relevant monoclonal antibodies and convalescent sera,[9,19,20] and **enhanced receptor binding affinity and transmissibility**.[5] A preprint by Jacobson et al. reported on the detection of L452R in **breakthrough infections** by SARS-CoV-2 after vaccination; however, the risk ratios were not elevated for this mutation when community prevalence was taken into consideration.[21] It is also found in other variants including B.1.427 and B.1.429 (both first detected in California and are estimated to have increased transmissibility by up to 24%),[18,22] and B.1.526.1 (first detected in New York).[18]

- P681R: this mutation occurs near the furin cleavage site and is similar to P681H. The P681R/H mutation is also found in B.1.1.7 and has been shown to optimise spike cleavage by furin with **potentially enhanced transmissibility**.[19]

- D614G: this mutation occurs in the receptor-binding domain and is **linked to increased transmissibility, infectivity and viral loads**.[23-26]

- E484Q: this amino acid mutation has **not been associated with any change in receptor-binding avidity**,[19] unlike mutation E484K which is found in VOCs B.1.351 and P.1, and which have been linked to immune escape and potentially decreased vaccine effectiveness.[27] Findings of a preprint by Chen et al. suggest that **clinical effectiveness of some monoclonal antibodies may be compromised** by the E484Q mutation.[28] Another preprint by Ranjan et al. finds lower binding energy against antibody (CR3022) and higher binding affinity for angiotensin-converting enzyme 2 (ACE2) receptor by the E484Q and L452R mutations, compared to wild-type (not defined), and suggests **reduced vaccine efficacy**.[29]

- G142D: this mutation is associated with **immune escape from some monoclonal antibodies** but further studies are required to determine the impact on the effectiveness of vaccine and convalescent serum.[19]

Potential Public Health Impacts

Data on potential public health impacts are mostly for B.1.617.1 and B.1.617.2; there have been very few cases of B.1.617.3 globally.

Transmissibility

Epidemiological data from India and the UK, as well as two modelling studies from the UK, indicate that **B.1.617.1 and B.1.617.2 may be more easily transmitted** than non-variant strains of SARS-CoV-2.

B.1.617.1

- In India, the **proportion of B.1.617.1** among the sequenced viruses uploaded to GISAID **has increased to about 50% in late March 2021** before starting to decline in April 2021.[30]

B.1.617.2

- In India, the **proportion of B.1.617.2** among the sequenced viruses uploaded to GISAID **has been increasing since early March to become the dominant variant reported in mid-April 2021**.[30]

- In the UK, the Scientific Advisory Group for Emergencies (SAGE) reported on May 13, 2021 with high confidence that **B.1.617.2 can be up to 50% more transmissible than the VOC B.1.1.7**.[31] This is based on an observed rise in the number of sequenced cases of B.1.617.2 and of the proportion of spike-gene (S-gene)–positives being B.1.617.2 in a small number of areas.[32] S-gene–positives are specimens with cycle threshold values ≤ 30 in all S, N and ORF1ab gene targets of a specific 3-target assay (TaqPath assay) used in some laboratories. The proportion of B.1.617.2 in S-gene–positives rose from 72.2% (570/754) in the second half of April to 93% (368/397) in early May of 2021,[32] and to 97.3% in the week of May 11, 2021.[33] This happened when the proportion of B.1.1.7 among all VOCs and VOIs was declining, so local contact and behaviour patterns alone could not account for the rapid rise in B.1.617.2. However, many of these increases were detected in a small number of local regions, some of which had a higher proportion of specimens tested in laboratories using the TaqPath assay. The B.1.617.2 sublineage may also have been overrepresented as a result of targeted contact tracing in outbreak settings.[32]

- A modelling study by the Centre for Mathematical Modelling of Infectious Diseases COVID-19 Working Group **estimated the reproduction number (R) of B.1.617.2 as 1.64 (95% CI: 1.61–1.67)**. The working group used data on imported and local cases between February 1 and April 27, 2021 and assumed the same generation interval for B.1.617.2 and other strains. Imported cases of B.1.617.2 were estimated from three data sources: reported cases in India, proportion of sequenced cases that were B.1.617.2, and reported imported cases into the UK from India. The authors noted that the estimates may not generalize to other areas in the UK.[34]

- Another modelling study by the Joint Universities Pandemic and Epidemiological Research Consortium using S-gene–positives as proxy of B.1.617.2 **estimated that B.1.617.2 may have a transmission advantage of >1.4 compared to S-gene negatives**. The authors used primarily community-based COVID-19 testing data and there were significant delays in sequencing results. The authors also noted that the conclusion of increased transmissibility of B.1.617.2 could not be made due to the following factors: S-gene positives may contain other VOCs, wild-type, even

some B.1.1.7; different population and behavioural patterns and superspreading events could not be ruled out; travelling status of cases were not available; uneven geographic distribution of laboratories that test for S-gene positives.[35]

- A cluster analysis by Public Health England found that the size of COVID-19 **clusters initiated by travellers from India** tended to be larger if the index cases were infected with B.1.617.2 vs. B.1.1.7. However, the **difference in cluster sizes was not statistically significant (P=0.19)** after adjusting for the number of travellers at the origin of each cluster.[33]

SECONDARY ATTACK RATES

Data from the UK between March 29 and May 4, 2021 estimate **higher secondary attack rates for contacts of individuals infected with B.1.617.2 than those infected with B.1.1.7 or B.1.617.1**.[33]

- For contacts of cases with travel history:
    - B.1.617.2: 2.9% (174/5,908); 95% CI: 2.5%–3.4%
    - B.1.617.1: 2.2% (56/2,509); 95% CI: 1.7%–2.9%
    - B.1.1.7: 1.7% (452/26,934); 95% CI: 1.5%–1.8%
- For contacts of cases with no or unknown travel history:
    - B.1.617.2: 13.5% (537/3,977); 95% CI: 12.5%–14.6%
    - B.1.617.1: 11.0% (33/301); 95% CI: 7.9%–15.0%
    - B.1.1.7: 8.1% (5,587/68,713); 95% CI: 7.9%–8.3%

UK contact tracing data between March 29 and May 4, 2021 estimate **higher secondary attack rates among household and non-household contacts of the 1,446 cases with B.1.617.2 compared to those of cases with B.1.1.7 and with no or unknown travel history**.[33]

- For household contacts of cases with no or unknown travel history:
    - B.1.617.2: 15.0% (490/3,274); 95% CI: 13.8%–16.2%
    - B.1.1.7: 8.9% (5,019/56,374); 95% CI: 8.7%–9.1%
- For non-household contacts of cases with no or unknown travel history:
    - B.1.617.2: 6.7% (47/703); 95% CI: 5.1%–8.8%
    - B.1.1.7: 4.6% (568/12,339); 95% CI: 4.2%–5.0%

Serial Interval and Incubation Period

Contact tracing data from the UK between March 29 and May 5, 2021 estimate that the median serial interval (time between symptom-onset or testing date of index cases and symptom-onset household contacts) is 4 days for both B.1.617.2 (n=618; range 2–10 days) and B.1.1.7 (n=5,376; range 2–12 days). For non-household contacts, the median incubation period (time between exposure and symptom-onset) is 5 days for B.1.617.2 (n=160; range 2–7 days) and 4 days for B.1.1.7 (n=888; range 2–10 days).[33] In progress are longitudinal sampling studies to provide a clearer picture by overcoming some of the challenges in recall error.

Disease Severity

In India, anecdotal evidence from clinicians suggests that B.1.617 is less virulent (most patients do not require hospitalization).[12] However, a sharp rise in death rates was observed at the time of increasing incidence of B.1.617, but patient-level data are not available to determine if the increase death rates was due to higher transmission and/or suboptimal access to health care services.[30]

In the UK, there have been 12 deaths out of 5,599 cases due to B.1.617.2 as of May 25, 2021, with a case fatality rate of 0.2% (95% CI: 0.1%–0.4%), compared to 2.0% (95% CI: 1.9%–2.0%) for B.1.1.7. The actual case fatality rate may change as a high proportion of recent cases have not completed a follow up of 28 days. Meanwhile, there have been no deaths reported out of 406 cases of B.1.617.1 and 14 cases of B.1.617.3.[33]

From February 1 to May 25, 2021, 0.8% (34/5,599) of the patients with B.1.617.2 who presented to emergency departments were admitted, compared to 1.5% (2,079/136,048) of those with B.1.1.7 and 0.5% (2/406) of those with B.1.617.1.[33] There is insufficient information to date to determine if any sublineages of B.1.617 would result in more severe infections, as most cases were very recent.[36]

Impact on Testing

There is no evidence to date that indicates reduced effectiveness of molecular tests in use for diagnosing B.1.617.[30] While the detection capability of antigen tests for B.1.617 detection has not been assessed, it is unlikely that their performance would be affected. However, it is unclear at this time if B.1.617 and the sublineages may impact on serological tests.

Immunity and Reinfection

As of 25 May, 2021, 2 cases of re-infection with B.1.617.1 and 54 cases of re-infection with B.1.617.2 have been reported in the UK, as expected with any prevalent variant.[33] Also, the SARS-CoV-2 Immunity and Reinfection Evaluation (The SIREN study), which monitors COVID-19 infections among National Health Service health care workers in the UK, reported only one reinfection (VOC status not reported) between April 22 and May 21, 2021.[14]

On the other hand, SAGE speculates on some **potential reduction in protection offered by natural infection or vaccine due to the observed antigenic distance between B.1.617.2 and wild-type virus**, which is less than that for B.1.351, similar to that for B.1.617.1; greater than that for B.1.1.7.[37] Four preprints of in vitro neutralization experiments also report on **reduced neutralization of B.1.617 or the sublineages B.1.617.1 and B.1.617.2 by convalescent sera**.

- Edara et al. reported that 19/24 (79%) of convalescent sera were able to neutralize live virus of B.1.617.1 despite a significant 6.8-fold reduction in neutralization titre, compared to that against the WA1/2020 wild-type.[38]
- Planas et al. reported 6-fold reduction in neutralization titres against live virus of B.1.617.2 compared to B.1.1.7 by convalescent sera of a cohort of unvaccinated individuals (n=56) at 6 months post-infection.[39]
- Hoffmann et al. reported an approximately 2-fold reduction in neutralization titre against pseudovirus bearing B.1.617 S protein by convalescent sera (n=15), compared to the Wuhan-1 wild-type. The authors suggest that B.1.617 might evade with moderate efficiency humoral immunity in convalescent patients.[40]

- Tada et al. reported approximately 2-fold reduction in neutralization titre against pseudovirus bearing L452R/E4384Q/P681R S protein by convalescent sera (n=8), compared to the wild-type with D614G mutation.[41]

Vaccine Effectiveness

REAL-WORLD EXPERIENCE FROM THE UK: B.1.617.2

Lopez Bernal et al. compared the vaccine effectiveness against symptomatic COVID-19 in individuals tested for COVID-19 in the UK up to May 16, 2021. The authors reported that **after only one dose, vaccine effectiveness against symptomatic COVID-19 with B.1.617.2 was reduced by approximately 20% compared to that for B.1.1.7**: 33.2% (95% CI: 8.3%–51.4%) vs. 49.2% (95% CI: 42.6%–55.0%) for the Pfizer vaccine, 32.9% (95% CI: 19.3%–44.3%) vs. 51.4% (95% CI: 47.3%–55.2%) for the ChAdOx1 (i.e., AstraZeneca) vaccine. However, the **reduction in vaccine effectiveness after two doses of vaccine was very small**: 87.9% (78.2%–93.2%) vs. 93.4% (95% CI: 90.4%–95.5%) for the Pfizer vaccine; 59.8% (95% CI: 28.9%–77.3%) vs. 66.1% (95% CI: 54.0%–75.0%) for the ChAdOx1 vaccine. The study included 12,675 sequenced COVID-19 variant cases (11,621 cases with B.1.1.7 and 1,054 cases with B.1.617.2). The authors noted that shorter follow-up time after two doses of ChAdOx1 (i.e., AstraZeneca) vaccine may explain the lower vaccine effectiveness.[42]

Experience from Bolton, UK (where clusters of B.1.617.2 are have been detected) **suggests that COVID-19 vaccines are effective against B.1.617.2**, as nearly 90% of the 25 people hospitalized with COVID-19 as of May 19, 2021 were not fully vaccinated.[43] (COVID-19 vaccines used in the UK include Pfizer BNT162b2 mRNA, Moderna mRNA-1273, and Oxford/AstraZeneca.)[44]

IN VITRO NEUTRALIZATION ASSAYS

Findings from seven preprints and one peer-reviewed study, however, **suggest potential slight to moderate reduction in effectiveness** of four COVID-19 vaccines (Pfizer-BioNTech BNT162b2 mRNA, Moderna mRNA-1273, AstraZeneca, and Covaxin) compared to the wild-type or the B.1.1.7 strains. Three of the studies looked at B.1.617 while the other four focused on sublineage B.1.617.1.

B.1.617

- Hoffmann et al. reported approximately **3-fold reduction in neutralization ability by sera from fully-vaccinated Pfizer vaccinees** (n=15) against pseudovirus with B.1.617 S protein, compared to the Wuhan-1 wild-type.[40]

- Yadav et al. reported a **2-fold reduction in neutralization ability by sera from Covaxin vaccinees** (n=28; vaccination status not reported) against live virus of B.1.617, compared to the B.1 (D614G) prototype and VOC B.1.1.7.[45]

- Tada et al. reported approximately **4-fold reduction in neutralization ability by sera from Pfizer vaccinees** (n=6; vaccination status not reported) **and Moderna vaccinees** (n=3; vaccination status not reported) against pseudovirus with L452R, E484Q and P681R spike mutations, compared to the wild-type with D614G mutation.[41]

B.1.617.1

- Ferreira et al. reported **significant reduction in neutralization ability** (actual titre not reported) compared to the Wuhan-1 D614G wild-type, when pseudovirus bearing spike mutations in L452R and E484Q (proxy of B.1.617.1) were tested with sera from Pfizer vaccinees (n=9; vaccination status not reported).[46]

- Edara et al. reported that **all sera from Moderna fully-vaccinated vaccinees (n=15) and Pfizer fully-vaccinated vaccinees (n=10) were able to neutralize live virus** of B.1.617.1 despite a **significant 6.8-fold reduction in neutralization ability** compared to that against the WA1/2020 wild-type.[38]

- Yadav et al. reported that 22/43 (51%) of sera from fully-vaccinated Covishield vaccinees without prior COVID-19 infection did not show any neutralizing antibodies against B.1.617.1. A **significant 2-fold reduction in neutralization ability** against B.1.617.1 was observed compared to the B.1 (D614G) prototype. With a geometric mean titre of 21.92 ± 4.42 (95% CI: 24.4–62.64) against B.1.617.1, the authors speculate that the vaccine are likely to protect against severe infection and death from that sublineage.[47]

- Shi et al. reported that **all sera from Pfizer fully-vaccinated vaccinees (n=20) were able to neutralize pseudovirus** bearing mutations in G142D, E154K, L452R, E484Q, D614G, P618R, Q1071H, H1101D and D111 as proxy of B.1.617.1, despite a 0.26 times reduction in plaque reduction neutralization testing ($PRNT_{50}$) compared to that of the wild-type WA1/2020.[48]

B.1.617.2

- Planas et al. reported that 94% of sera (n=16) at 8 weeks after two doses of **Pfizer** vaccine were **able to neutralize live virus of B.1.617.2, despite a 3-fold reduction in neutralization titres compared to that for B.1.1.7**. Even at 16 weeks after vaccination, neutralization ability was retained by 85% of the sera. On the other hand, **only 8% of sera (n=12) from vaccinees with one dose of AstraZeneca vaccine were able to neutralize the virus**. However, even one dose of vaccine (9 with Pfizer, 9 with AstraZeneca, 3 with Moderna) was observed to increase the median neutralizing titres in convalescent sera (n=23) by 130-fold against both B.1.1.7 and B.1.617.2 even at 12 months after infection, suggesting a **single dose of vaccine could boost cross-neutralizing antibody responses**.[39]

What's Happening in England?

Epidemiological Context

- The 7-day rolling average daily cases of COVID-19 rose slowly from late February 2020 to plateau around 4,500 to 4,800 in April 2020, then declined to stay below 700 during late-June to late-July 2020. Daily cases started to climb in September 2020 and plateaued around 21,000 and 24,600 from mid-October to mid-November 2020, dipped quickly to around 14,500 in late November before shooting to the peak of 61,239 in early January 2021. Since then, daily cases have been declining rapidly to around 12,000 in mid-February, then slowly to a low of 1,847 at the end of April 2021, and hovering around 1,900 to 2,100 for the first week of May. As of May 15, 2021, the 7-day rolling average number of daily new COVID-19 cases in England was 1,563 (22 cases per 100,000). As of May 14, 2021, the cumulative number of cases in England was 4.4 million.[49]

- The 7-day average daily admission to hospitals due to COVID-19 rose sharply from late March 2020 to a peak at 3,116 in early April 2020, then dropped slowly to a low of 97 in late August 2020. Daily admission then rose to a high of 1,777 in mid-November 2020 and peaked at 4,232 in mid-January 2021. Daily admission was at 234 at the start of April and hovered around 100 and 120 for the first week of May in 2021.[50]

- In the past 7 days (as of May 17, 2021) the areas with the greatest rates of cases per 100,000 were the Yorkshire and The Humber regions (2151 cases or 39.1 per 100,000) and the North West region (2764 cases or 37.7 per 100,000)[51]

- On April 9, 2021, B.1.617.2 made up 0.1% of COVID-19 cases in England, and by May 7, 2021, the lineage made up 19.6% of cases.[52] UK experts expect B.1.617.2 to become the dominant lineage by the end of the week of May 18, 2021, if not already.[53] As of May 17, 2021, there were 2,323 confirmed cases of B.1.617 in the UK, which represents a 77% increase from just five days earlier.[54]

- North West and South Central England have the highest proportions of B.1.617.2 cases, but cases are being reported across the country.[54]

- In Blackburn and Bolton (North West England) where the B.1.617 variant are spreading the fastest,[55] the number of cases among those under 60 years of age has increased significantly more than among those over 60 (who are more likely to be vaccinated) suggesting the effectiveness of vaccines.[56] The majority of the cases in Bolton were individuals in their teens, 20s and 30s, most of whom had not been vaccinated against Covid-19.[57]

Vaccine Context

- As of May 18, 2021, 57.9 million doses of the COVID-19 vaccine had been administered; 70.2% of the population had received at least one dose of the COVID-19 vaccine and 39.6% were fully vaccinated.[58]

- As of May 13, 2021, the vaccine is currently being offered to: individuals aged 36 and over and individuals who will turn 36 before July 1, 2021, individuals at high risk from COVID-19 (clinically extremely vulnerable), individuals who live or work in care homes, health and social care workers, individuals with a condition that puts them at higher risk (clinically vulnerable), individuals with a learning disability, and individuals who are a main carer for someone at high risk from COVID-19.[44]

- To address the rising cases of B.1.617.2, the government announced on May 14, 2021 that it would shorten the interval for second doses from 12 weeks to 8 weeks for the country's top 9 priority groups.[59] England is also accelerating COVID-19 vaccinations in regions with a high proportion of B1.617.2 cases.

Public Health Measures

- As of May 17, 2021, the English government started loosening restrictions for a variety of public health measures, including indoor settings such as hospitality and organized sports.[55]

- The government recommends that particular caution be used in certain areas of England (i.e., Bolton Metropolitan Borough and Blackburn with Darwen Borough) where variants are spreading the fastest.[55]

- In a press conference on May 14, 2021, the prime minister stated that if the B.1.617 variant turns out to be only marginally more transmissible, the country can continue to move forwards with their re-opening plan; however, if it is significantly more transmissible the roadmap to re-opening may have to be delayed or adapted (particular Step 4 in June[60] which involves removing all legal limits on social contact[61]).

Actions Taken to Control the Spread of Variants

- A press release from May 13, 2021 stated that due to the recent surge in B.1.617.2 cases in select regions, "a new Surge Rapid Response Team is being deployed in Bolton, additional surge testing will shortly launch in areas such as Formby, and enhanced contact tracing is in place across England".[62] Additionally, in areas where clusters of cases have been identified additional contact tracing, increased genomic sequencing of positive cases, increased community engagement and support for individual to get tested and self-isolate, and ensure access to vaccination and encourage uptake.

- England has also accelerated genomic sequencing, enhanced contact tracing and implemented surge testing in the North West in efforts to rapidly break chains of B.1.617.2 transmission.[63]

Ontario Context

- Currently, all positive SARS-CoV-2 specimens in Ontario with a cycle threshold (Ct) value ≤35 are tested for presence of the N501Y and E484K mutations, and only specimens positive for E484K mutation with Ct value ≤30 will be sequenced.[64] It is unclear at this time whether the current E484K assay will detect the E484Q mutation associated with B.1.617.

- Approximately 90%–95% of positive specimens that undergo VOC testing in Ontario have either N501Y and/or E484K mutations.[65] As these mutations are not associated with the B.1.617 lineage, the vast majority of specimens in Ontario are highly unlikely to be B.1.617. A proportion of non-VOC specimens are routinely sent for sequencing, in addition to all travel-related positive specimens, as part of Ontario's ongoing surveillance for emerging variants.

- As of May 19, 2021, there have been 260 cases with B.1.617 detected in Ontario (an increase from 45 as of May 12). Of the 260 cases, 203 were tested by the National Microbiology Laboratory as part of international travel arrival quarantine procedures, while 57 were detected by PHO, most of whom were associated with out-of-country travel.[66]

Risk Assessment and Practice Implications

Overall risk assessment: The risk of B.1.617 transmission in Ontario is moderate to high and depends on the number of existing B.1.617 cases and continued introductions into the province. Given the rapid emergence of B.1.617, PHO's level of confidence in the existing primary literature, preprint literature and grey literature is low but building up quickly with emergence of new evidence. This overall risk assessment may change as new evidence emerges.

- **Transmissibility:** The risk of increased transmissibility by B.1.617 is high, with a relatively low degree of uncertainty.

- **Disease severity:** The risk of B.1.617 causing severe disease is unknown.

- **Immunity and re-infection:** The risk of re-infection with B.1.617 in convalescent patients is low, with a high degree of uncertainty.

- **Vaccine effectiveness:** The risk of B.1.617 causing lowered vaccine effectiveness is moderate, with a moderate degree of uncertainty.

- **Surveillance:** The risk of B.1.617 cases not being detected in Ontario's surveillance program is moderate, with a moderate degree of uncertainty.

Surveillance testing (including genomic sequencing of a sufficient sample of positive cases) will help us better understand the epidemiology of B.1.617. Currently, there is no indication that individual or societal public health measures such as case and contact management, vaccination rollout and non-pharmaceutical interventions such as physical distancing in Ontario need to be changed. However, ongoing monitoring of single-dose vaccine effectiveness and the impact of England's shortened second-dose schedule will help to inform Ontario's second-dose roll-out. Heightened surveillance, close monitoring of case rate indicators, and local assessment of transmissibility are also needed to inform public health measures and Ontario's new recovery plan.[67]

Appendix A

For the purposes of this document, the definition of variants of interest (VOI) and variants of concern (VOC) as proposed by the Canadian SARS-CoV-2 Variants Expert Working Group (CSVEWG) are used.[8]

Variant of Interest (VOI)

A SARS-CoV-2 variant is a variant of interest (VOI) if it:

- has a genome with mutations associated with changes in epidemiology, antigenicity, or virulence, or changes that potentially have a negative impact on available diagnostics, vaccines, therapeutics or public health measures; AND is known to cause community transmission/multiple COVID-19 cases/clusters in Canada or has been detected in multiple countries; OR
- is otherwise assessed to be a VOI by WHO; OR
- is otherwise assessed to be a VOI by the CSVEWG.

Variant of Concern (VOC)

A variant is a VOC if, through a comparative assessment, it:

- has been demonstrated to be associated with one or more of the following:
    - increased transmissibility or detrimental change in COVID-19 epidemiology;
    - increased virulence or change in clinical disease presentation;
    - decreased effectiveness of available diagnostics, vaccines, therapeutics or public health measures; OR
- is otherwise assessed to be a VOC by WHO; OR
- is otherwise assessed to be a VOC by the CSVEWG.

Appendix B

Notable mutations in the spike protein (non-synonymous) found in the B.1.617 sublineages[§7]

Amino acid substitution or deletion	B.1.617.1	B.1.617.2	B.1.617.3
D614G	**Yes**	**Yes**	**Yes**
D950N	No	**Yes**	**Yes**
E484Q	**Yes**	No	**Yes**
G142D	**Yes**	**Yes**	No
E154K	**Yes**	No	No

DAILY EPIDEMIOLOGICAL SUMMARY

COVID-19 in Ontario: January 15, 2020 to July 3, 2021

This report includes the most current information available from CCM as of **July 3, 2021**.

Please visit the interactive Ontario COVID-19 Data Tool to explore recent COVID-19 data by public health unit, age group, sex, and trends over time.

A weekly summary report is available with additional information to complement the daily report.

This **daily** report provides an epidemiologic summary of recent COVID-19 activity in Ontario. The change in cases is determined by taking the cumulative difference between the current day and the previous day.

Highlights

- There are a total of 545,803 confirmed cases of COVID-19 in Ontario reported to date.
- Compared to the previous day, this represents:
    - An increase of 213 confirmed cases (percent change of +1.9%)
    - An increase of 9 deaths (percent change of 0.0%)
    - An increase of 286 resolved cases (percent change of +9.2%)

In this document, the term 'change in cases' refers to cases publicly reported by the province for a given day. Data corrections or updates can result in case records being removed and or updated from past reports and may result in subset totals for updated case counts (i.e., age group, gender) differing from the overall updated case counts.

The term public health unit reported date in this document refers to the date local public health units were first notified of the case.

Case Characteristics

Table 1a. Summary of recent confirmed cases of COVID-19: Ontario

	Change in cases July 2, 2021	Change in cases July 3, 2021	Percentage change July 3, 2021 compared to July 2, 2021	Cumulative case count as of July 3, 2021
Total number of cases	209	213	+1.9%	545,803
Number of deaths	9	9	0.0%	9,214
Number resolved	262	286	+9.2%	534,558

Note: The number of cases publicly reported by the province each day may not align with case counts reported to public health on a given day; public health unit reported date refers to the date local public health was first notified of the case. Data corrections or updates can result in case records being removed and or updated from past reports.
Data Source: CCM

Table 1b. Summary of recent confirmed cases of COVID-19 by age group and gender: Ontario

	Change in cases July 2, 2021	Change in cases July 3, 2021	Cumulative case count as of July 3, 2021
Gender: Male	109	111	271,959
Gender: Female	96	95	270,054
Ages: 19 and under	57	51	87,920
Ages: 20-39	83	64	204,406
Ages: 40-59	42	53	155,746
Ages: 60-79	19	37	72,521
Ages: 80 and over	7	8	25,110

Note: Not all cases have a reported age or gender reported. Data corrections or updates can result in case records being removed and or updated from past reports and may result in subset totals (i.e., age group, gender) differing from past publicly reported case counts.
Data Source: CCM

Table 2. Summary of recent confirmed cases of COVID-19 in school aged children by age group, August 30, 2020 to July 3, 2021: Ontario

	Change in cases July 2, 2021	Change in cases July 3, 2021	Cumulative case count from August 30, 2020 to July 3, 2021
Ages: 4 to 8	18	11	16,260
Ages: 9 to 13	8	14	20,360
Ages: 14 to 17	8	10	20,720

Note: Includes all confirmed cases of COVID-19 for specified ages, regardless of school attendance. Data corrections or updates can result in case records being removed and or updated from past reports and may result in subset totals (i.e., age group) differing from past publicly reported case counts.
Data Source: CCM

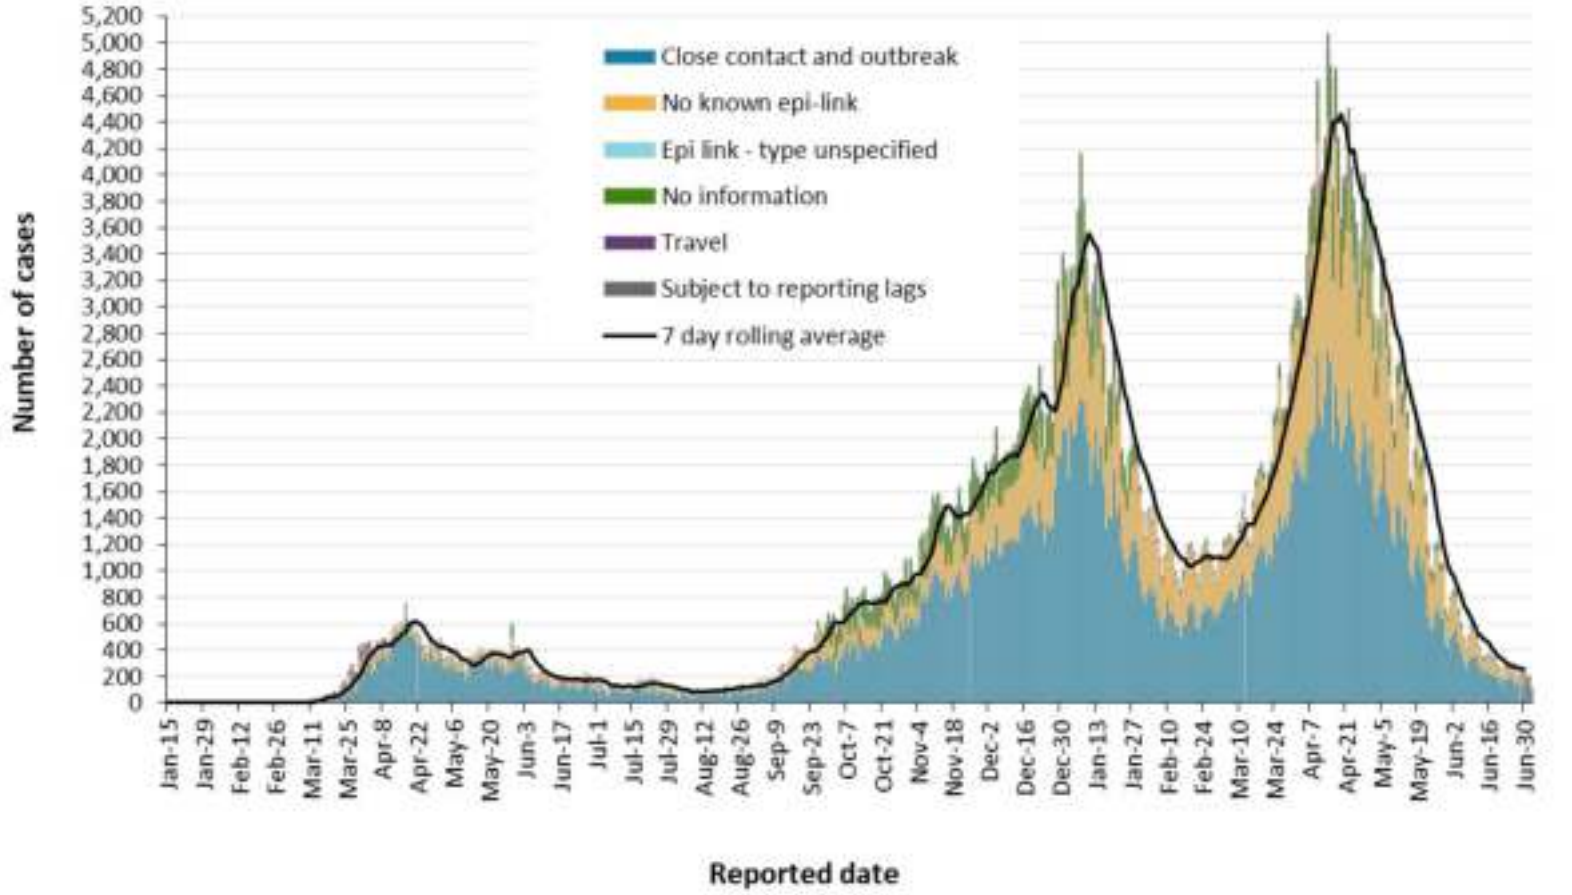
Table 3. Summary of recent confirmed cases of COVID-19 in long-term care homes: Ontario

Long-term care home cases	Change in cases July 2, 2021	Change in cases July 3, 2021	Cumulative case count as of July 3, 2021
Residents	1	1	15,400
Health care workers	1	0	7,195
Deaths among residents	0	1	3,971
Deaths among health care workers	0	0	10

Note: Information on how long-term care home residents and health care workers are identified is available in the technical notes. Also, the change in cases in these categories may represent existing case records that have been updated.
Data Source: CCM

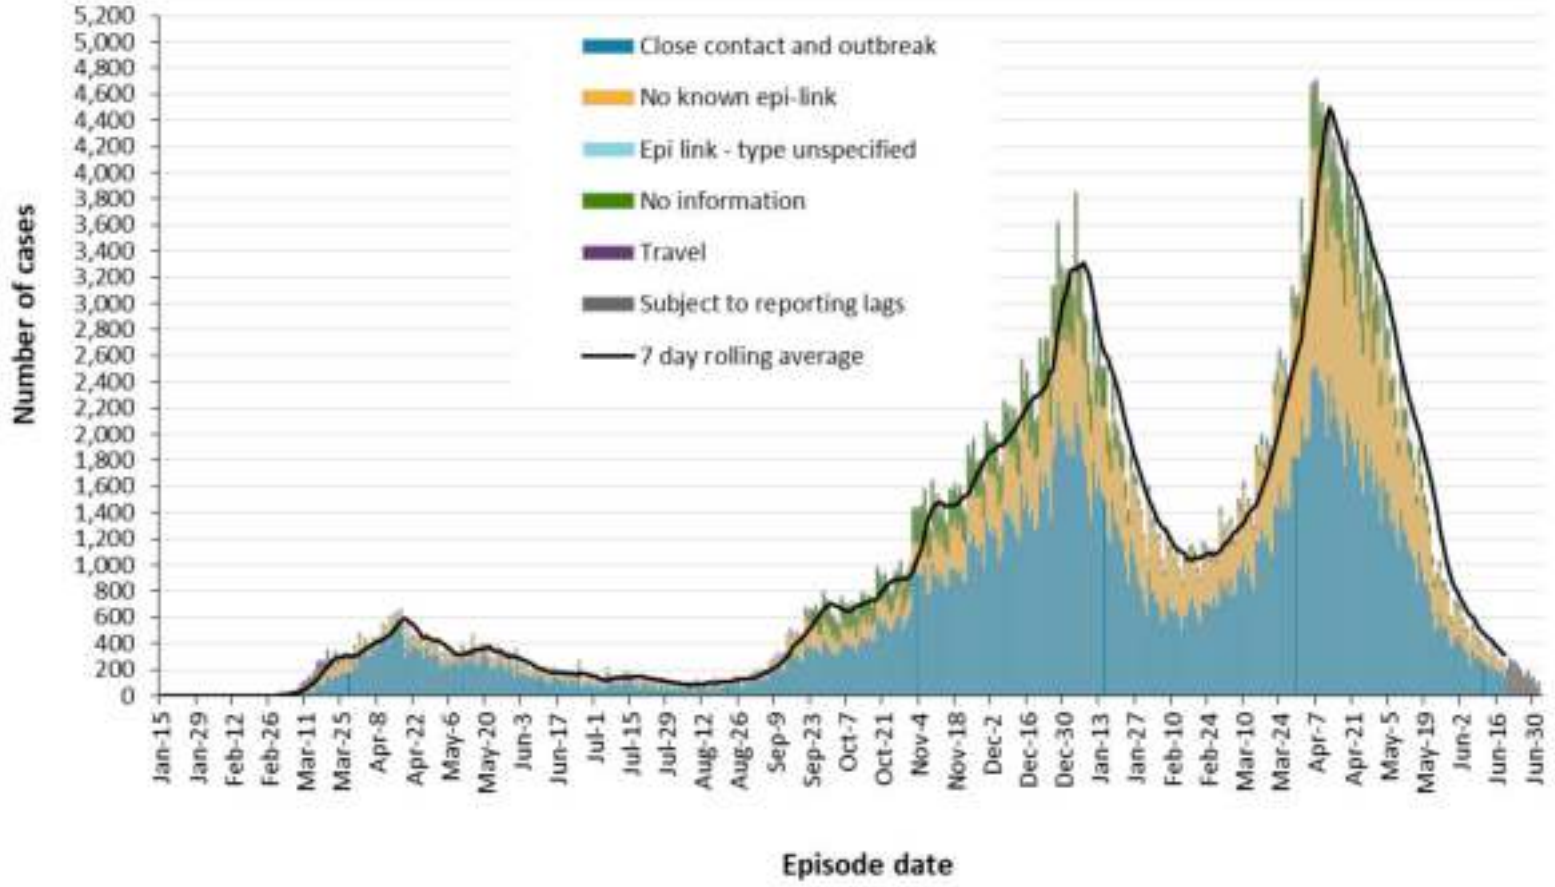
Time

Figure 1. Confirmed cases of COVID-19 by likely acquisition and public health unit reported date: Ontario, January 15, 2020 to July 3, 2021



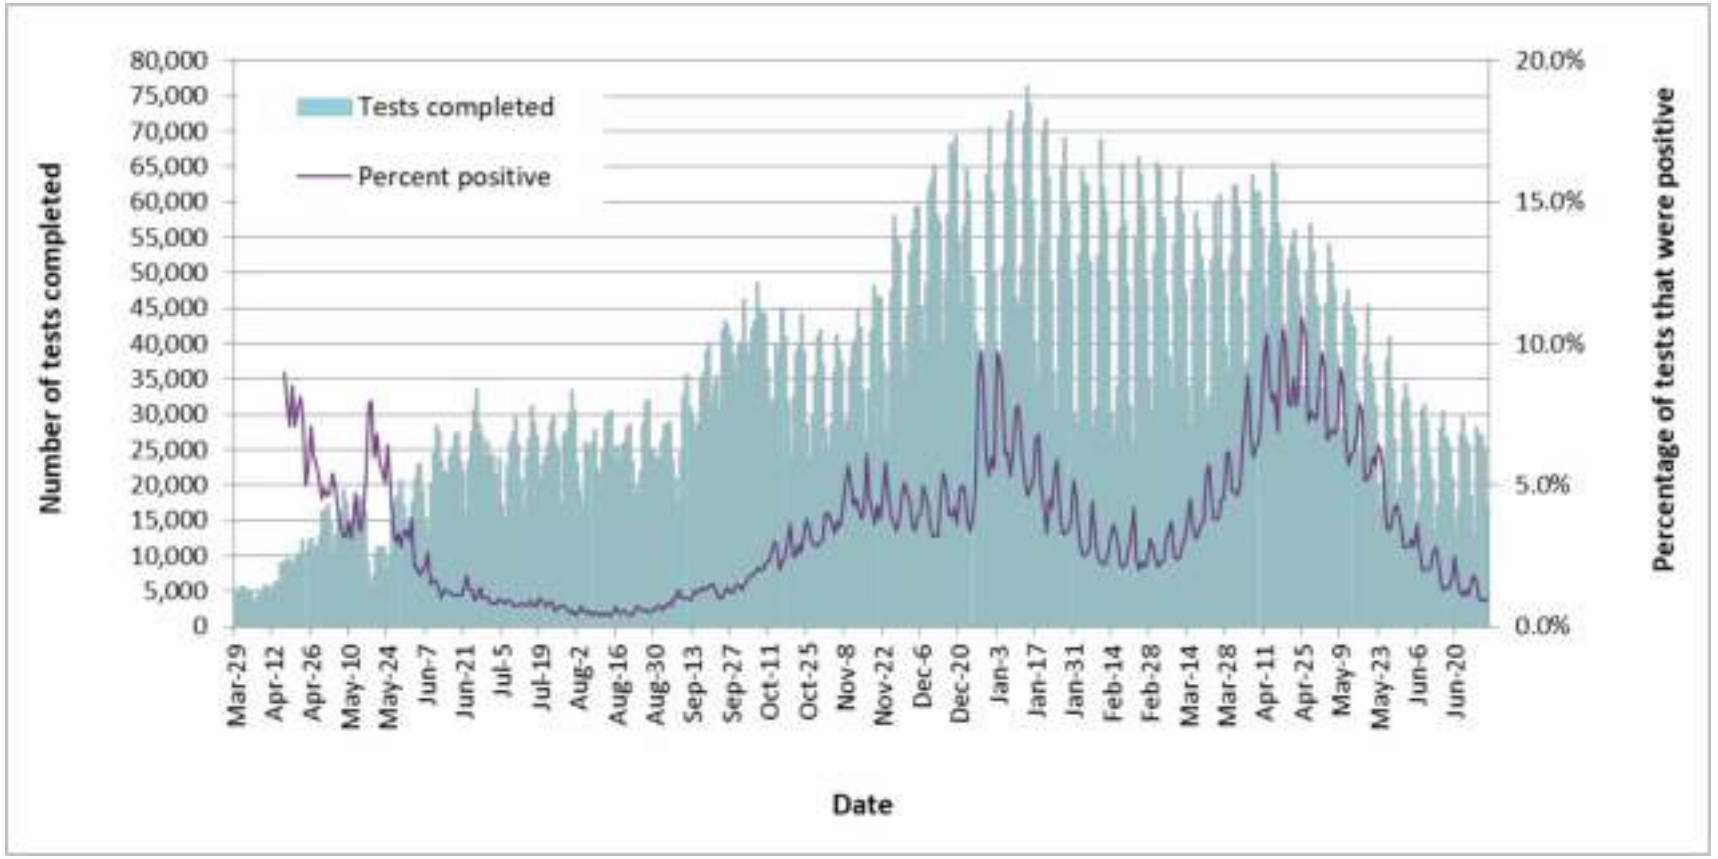
Data Source: CCM

Figure 2. Confirmed cases of COVID-19 by likely acquisition and approximation of symptom onset date: Ontario, January 15, 2020 to July 3, 2021



Note: Not all cases may have an episode date and those without one are not included in the figure. Episode date is defined and available in the technical notes.
Data Source: CCM

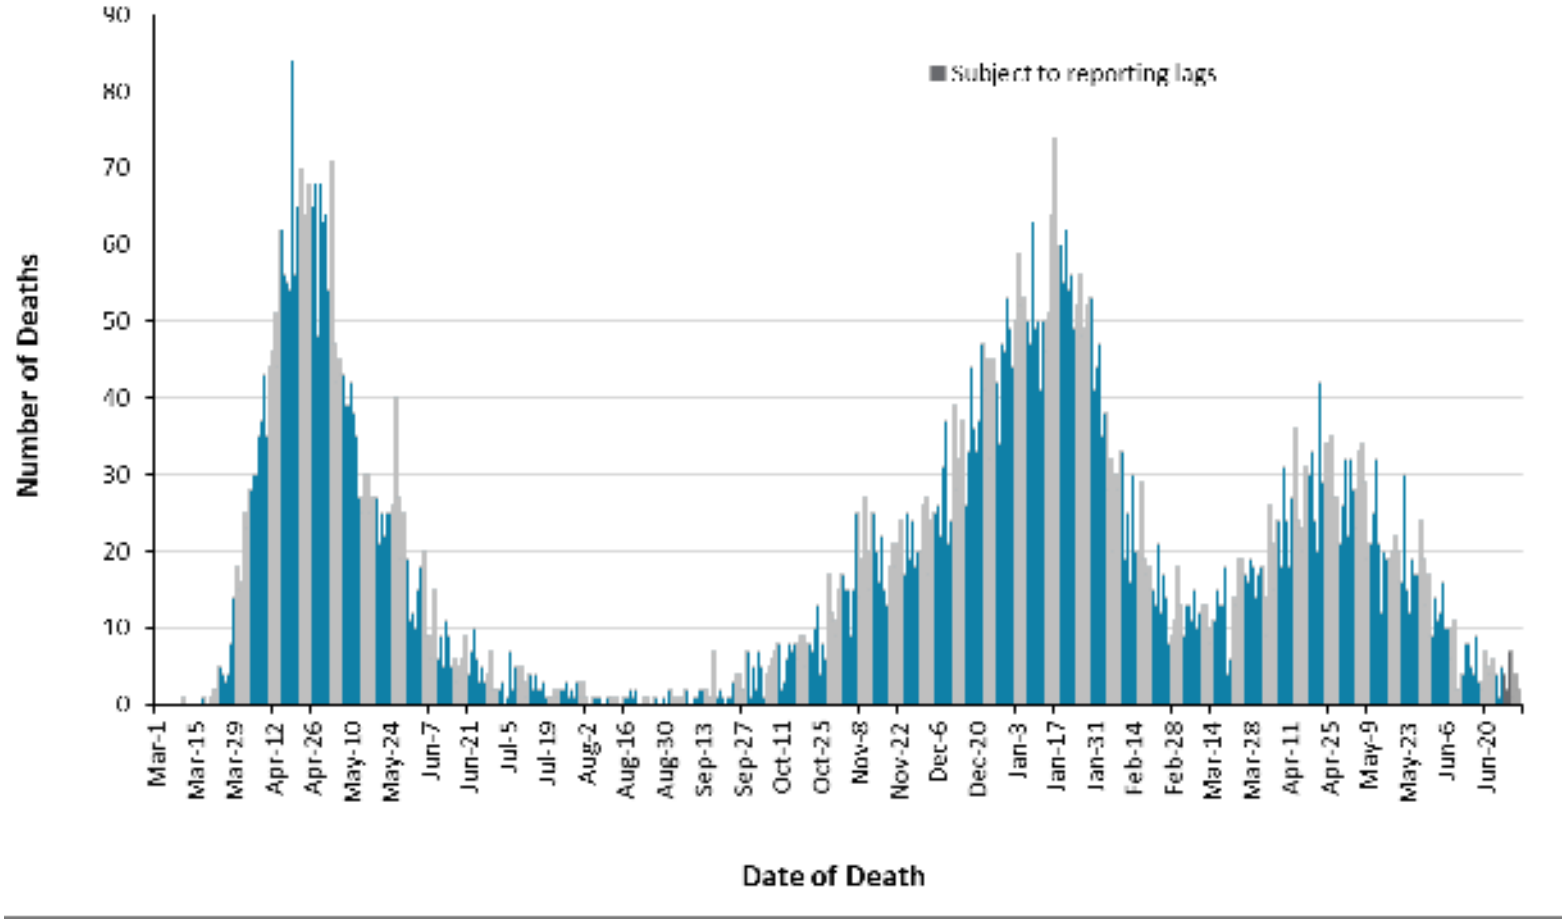
Figure 3. Number of COVID-19 tests completed and percent positivity: Ontario, March 29, 2020 to July 2, 2021



Note: The number of tests performed does not reflect the number of specimens or persons tested. More than one test may be performed per specimen or per person. As such, the percentage of tests that were positive does not necessarily translate to the number of specimens or persons testing positive.
Data Source: The Provincial COVID-19 Diagnostics Network, data reported by member microbiology laboratories.

Severity

Figure 4. Confirmed deaths among COVID-19 cases by date of death: Ontario, March 1, 2020 to July 3, 2021



Note: Cases without a death date are not included in the figure.
Data Source: CCM

Table 4. Confirmed cases of COVID-19 by severity: Ontario

	Cumulative case count as of July 3, 2021	Percentage of all cases
Cumulative deaths reported (please note there may be a reporting delay for deaths)	9,214	1.7%
Deaths reported in ages: 19 and under	4	<0.1%
Deaths reported in ages: 20-39	82	<0.1%
Deaths reported in ages: 40-59	581	0.4%
Deaths reported in ages: 60-79	2,937	4.0%
Deaths reported in ages: 80 and over	5,609	22.3%
Ever in ICU	5,378	1.0%
Ever hospitalized	27,962	5.1%

Note: Not all cases have an age reported. Data corrections or updates can result in case records being removed and/or updated and may result in totals differing from past publicly reported case counts.
Data Source: CCM

Geography

TOTAL ONTARIO	**209**	**213**	**545,803**	**3,671.9**

Notes: Health units with data corrections or updates could result in records being removed from totals, leading to negative or zero counts.
Data Source: CCM

Outbreaks

Table 6. Summary of recent confirmed COVID-19 outbreaks reported in long-term care homes, retirement homes and hospitals by status: Ontario

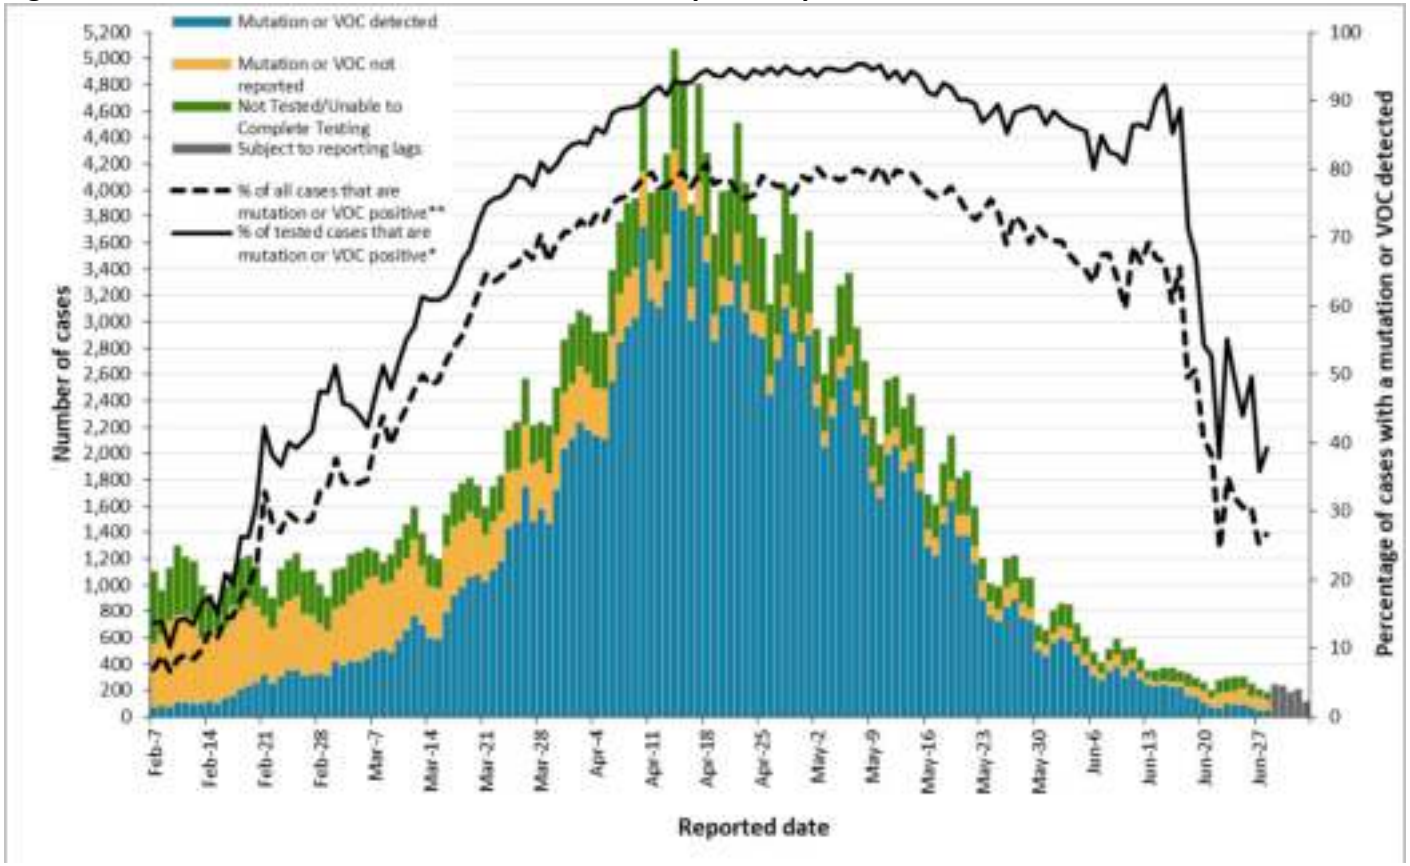
Institution type	Change in outbreaks July 2, 2021	Change in outbreaks July 3, 2021	Number of ongoing outbreaks	Cumulative number of outbreaks reported
Long-term care homes	0	1	4	1,486
Retirement homes	0	0	3	871
Hospitals	2	0	7	575

Note: Ongoing outbreaks include all outbreaks that are 'Open' in CCM without a 'Declared Over Date' recorded, or where the outbreak started more than five months ago, even for outbreaks where the Outbreak Status value selected in CCM is 'OPEN'. The start of the outbreak is determined by the onset date of first case, or if missing the outbreak reported date, or else if that is also missing, then the outbreak created date.
Data Source: CCM

Variant COVID-19 Cases

The laboratory detection of a variant of concern (VOC) is a multi-step process. Samples that test positive for SARS-CoV-2 and have a cycle threshold (Ct) value ≤ 35 can be tested for mutations common to variants of concern. If positive for the mutation of interest with a Ct value of ≤ 30, these samples may then undergo genomic analyses to identify the VOC lineage. VOC lineages may still be confirmed using genomic analysis despite specific S gene mutation(s) being documented as 'unable to complete' due to poor sequence quality at the genome position. For more information about whole genome sequencing, please see the SARS CoV-2 Whole Genome Sequencing in Ontario report.

Figure 5. Number of confirmed COVID-19 cases and percent positive for mutations or VOCs: Ontario, February 7, 2021 to July 3, 2021



Note: Data used to calculate the number of cases tested for mutations common to VOCs or lineages using genomic analyses are obtained using information from the Laboratory object in CCM in addition to the data from the Investigation Subtype field. Therefore, comparisons to counts using only information from the Investigation Subtype field may not align. The percent of cases due to a VOC may be higher than described in this report.
*The denominator includes only confirmed COVID-19 cases that were able to be tested for VOCs (e.g. those identified as 'Detected' or 'Not Detected'). Mutations tested for routinely are the N501Y and E484K mutations. Mutations common to the B.1.617.2 lineage are not included in the current VOC mutation test. However, cases identified as B.1.617.2 after whole genome sequencing is completed are included in the VOC detected category.
**The denominator includes all confirmed COVID-19 cases, including those that were unable to be tested for VOCs (e.g. those identified as 'Detected', 'Not Detected' and 'Not Tested/Unable to Complete Testing').
Data Source: CCM

Table 7. Summary of confirmed COVID-19 cases with a mutation or VOC detected: Ontario

	Change in cases July 2, 2021	Change in cases July 3, 2021	Cumulative case count up to July 3, 2021
Variant of Concern			
Lineage B.1.1.7 (Alpha)*	34	32	143,899
Lineage B.1.351 (Beta)**	0	0	1,415
Lineage P.1 (Gamma) ***	3	0	4,631
Lineage B.1.617.2 (Delta)†	32	14	2,041
Mutations			
N501Y and E484K	-1	4	4,709
N501Y (E484K unknown)‡	-4	3	13,957
E484K (N501Y negative)	5	3	5,810
E484K (N501Y unknown)	-3	-4	452
Mutation not detected§	19	7	11,693

Note: Interpret the VOC and mutation trends with caution due to the varying time required to complete VOC testing and/or genomic analysis following the initial positive test for SARS-CoV-2. Due to the nature of the genomic analysis, test results may be completed in batches. Data corrections or updates can result in case records being removed and/or updated and may result in totals differing from past publicly reported case counts. Data for calculating the change in cases and the cumulative case counts uses data from the Investigation Subtype field only. Changes to the VOC testing algorithm may impact counts and trends. Further details can be found in the data caveats section.

*Includes all confirmed COVID-19 cases where lineage B.1.1.7 was identified by genomic analysis and those presumed to be B.1.1.7 based on positive N501Y and negative E484K mutation in the Investigation Subtype field

**Includes B.1.351 cases identified by genomic analysis and those presumed to be B.1.351 based on 'Mutation K417N+ and N501Y+ and E484K+' in the Investigation Subtype field

***Includes P.1 cases identified by genomic analysis and those presumed to be P.1 based on 'Mutation K417T+ and N501Y+ and E484K+' in the Investigation Subtype field

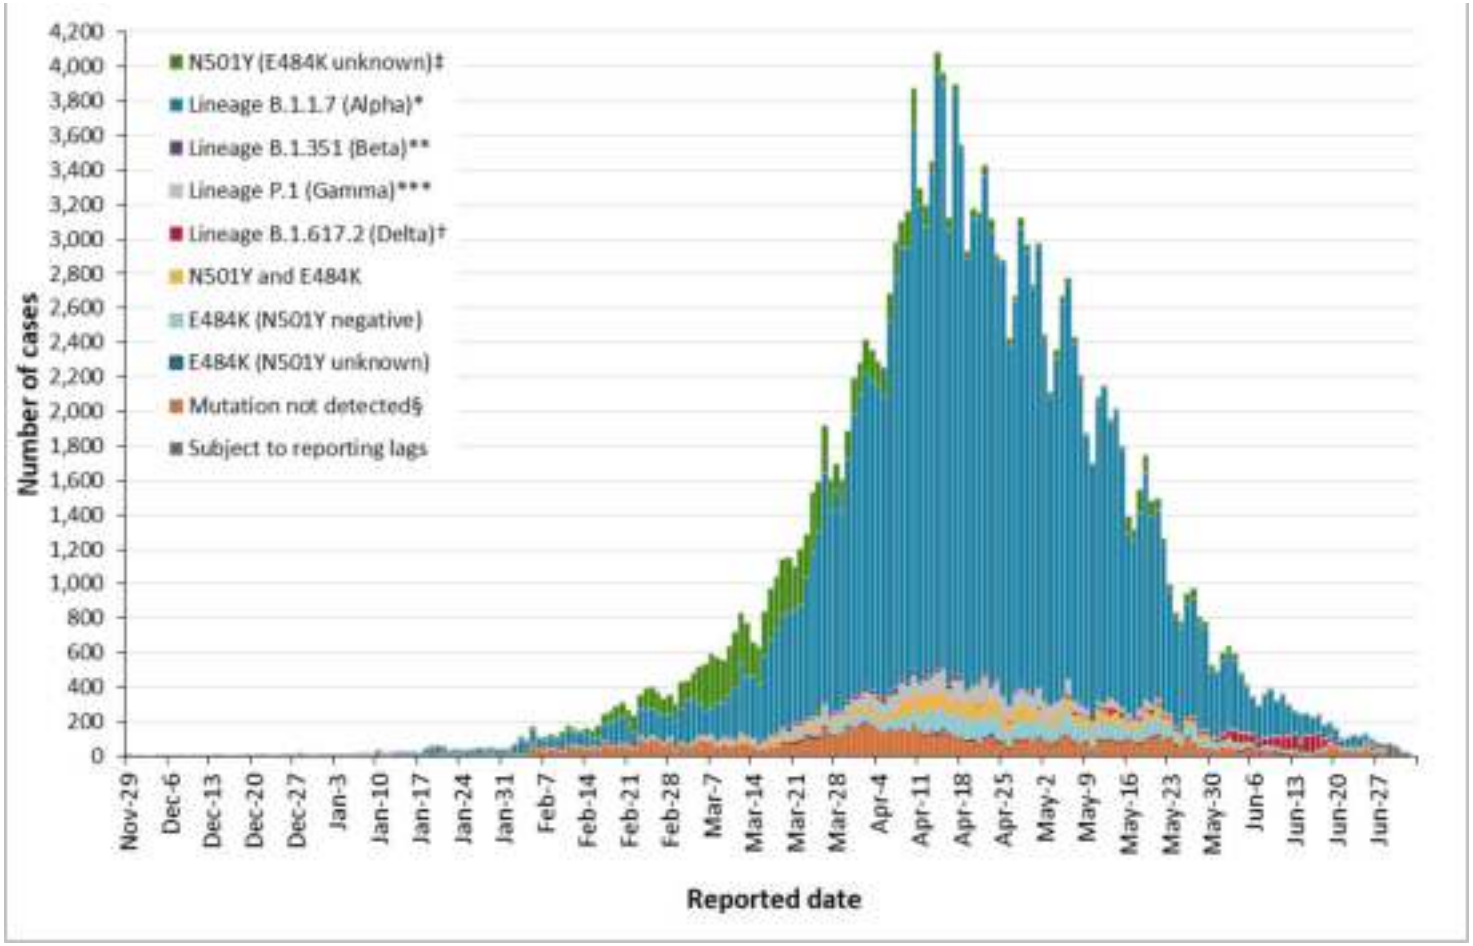
†Includes B.1.617.2 cases identified by genomic analysis. Mutations common to B.1.617.2 are not included in the current VOC mutation test.

‡The category 'N501Y (E484K unknown)' mainly consists of results from before the introduction of the E484K test. Counts will shift from this category into a VOC lineage category as E484K tests or genomic analysis are completed.

§Includes cases identified as 'Mutation not detected' or 'Mutation N501Y- and E484K-' in the Investigation Subtype field only.

Data Source: CCM

Figure 6. Confirmed COVID-19 cases with a mutation or VOC detected by public health unit reported date: Ontario, November 29, 2020 to July 3, 2021



Note: Reported date is based on the date the case was reported, not the date that the VOC or mutation was identified. Further details on testing for variants of concern can be found in the technical notes. Interpret the VOC and mutation trends with caution due to the varying time required to complete testing and/or genomic analysis following the initial positive test for SARS-CoV-2. Data for calculating the change in cases and the cumulative case count uses data from the Investigation Subtype field only. Data for cases with a B.1.1.7, B.1.351, P.1 and B.1.617.2 lineage detected or any of the mutations listed above are determined using the

Investigation Subtype field only. Changes to the VOC testing algorithm may impact counts and trends. Further details can be found in the data caveats section. As of March 22, 2021, positive specimens with a Ct ≤ 35 are tested for both the N501Y and E484K mutation, with all E484K positive specimens with a Ct ≤ 30 forwarded for further genomic analysis. If found to be positive for the N501Y mutation only, no further genomic analysis are performed as these are presumed to be B.1.1.7. As of May 26, 2021, cases where an E484K mutation is detected will no longer be reflexed for sequencing as VOC testing labs switched to a representative sampling method where only a proportion of all positives with a Ct ≤ 30 are forwarded for further genomic analysis.

*Includes all confirmed COVID-19 cases where lineage B.1.1.7 was identified by genomic analysis and those presumed to be B.1.1.7 based on positive N501Y and negative E484K mutation in the Investigation Subtype field

**Includes B.1.351 cases identified by genomic analysis and those presumed to be B.1.351 based on 'Mutation K417N+ and N501Y+ and E484K+' in the Investigation Subtype field

***Includes P.1 cases identified by genomic analysis and those presumed to be P.1 based on 'Mutation K417T+ and N501Y+ and E484K+' in the Investigation Subtype field

†Includes B.1.617.2 cases identified by genomic analysis. Mutations common to B.1.617.2 are not included in the current VOC mutation test.

‡The category 'N501Y (E484K unknown)' mainly consists of results from before the introduction of the E484K test. Counts will shift from this category into a VOC lineage category as E484K tests or genomic analysis are completed.

§Includes cases identified as 'Mutation not detected' or 'Mutation N501Y- and E484K-' in the Investigation Subtype field only.

Data Source: CCM

Technical Notes

Data Sources

- The data for this report were based on information successfully extracted from the Public Health Case and Contact Management Solution (CCM) for all PHUs by PHO as of **July 3, 2021 at 1 p.m**. for cases reported from February 1, 2021 onwards and as of **July 2, 2021 at 9 a.m.** for cases reported up to January 31, 2021.

- VOC data for this report were based on information successfully extracted from CCM for all PHUs by PHO as of **July 3, 2021 at 1 p.m.** for cases reported from April 1, 2021 onwards and as of **July 2, 2021 at 9 a.m.** for cases reported up to March 31, 2021.

- CCM is a dynamic disease reporting system, which allows ongoing updates to data previously entered. As a result, data extracted from CCM represent a snapshot at the time of extraction and may differ from previous or subsequent reports.

- Ontario population projection data for 2020 were sourced from Ministry, IntelliHEALTH Ontario. Data were extracted on November 26, 2019.

- COVID-19 test data were based on information from The Provincial COVID-19 Diagnostics Network, reported by member microbiology laboratories.

Data Caveats

- The data only represent cases reported to public health units and recorded in CCM. As a result, all counts will be subject to varying degrees of underreporting due to a variety of factors, such as disease awareness and medical care seeking behaviours, which may depend on severity of illness, clinical practice, changes in laboratory testing, and reporting behaviours.

- Data cleaning for older cases is incorporated on Mondays and may impact the case count published on Tuesdays

- Lags in CCM data entry due to weekend staffing may result in lower case counts than would otherwise be recorded.

- Only cases meeting the confirmed case classification as listed in the MOH Case Definition – Coronavirus Disease (COVID-19) document are included in the report counts from CCM

- Cases of confirmed reinfection, as defined in the provincial case definitions, are counted as unique investigations.

- Case classification information may be updated for individuals with a positive result issued from a point-of-care assays.

- The number of tests performed does not reflect the number of specimens or persons tested. More than one test may be performed per specimen or per person. As such, the percentage of tests that were positive does not necessarily translate to the number of specimens or persons testing positive.

- Reported date is the date the case was reported to the public health unit.

- Case episode date represents an estimate of disease onset. This date is calculated based on the earliest date of symptom onset, specimen collection/test date, or the date reported to the public health unit.

- Resolved cases are determined only for COVID-19 cases that have not died. Cases that have died are considered fatal and not resolved. The following cases are classified as resolved:

    - Cases that are reported as 'recovered' in CCM

    - Cases that are not hospitalized and are 14 days past their episode date

    - Cases that are currently hospitalized (no hospital end date entered) and have a status of 'closed' in CCM (indicating public health unit follow-up is complete) and are 14 days past their symptom onset date or specimen collection date

- Hospitalization includes all cases for which a hospital admission date was reported or hospitalization/ICU was reported as 'Yes' at the time of data extraction. It includes cases that have been discharged from hospital as well as cases that are currently hospitalized. Emergency room visits are not included in the number of reported hospitalizations.

- ICU admission includes all cases for which an ICU admission date was reported at the time of data extraction. It is a subset of the count of hospitalized cases. It includes cases that have been treated or that are currently being treated in an ICU.

- Orientation of case counts by geography is based on the diagnosing health unit (DHU). DHU refers to the case's public health unit of residence at the time of illness onset and not necessarily the location of exposure. Cases for which the DHU was reported as MOH-PHO (to signify a case that is not a resident of Ontario) have been excluded from the analyses.

- Likely source of acquisition is determined by examining the epidemiologic link and epidemiologic link status fields in CCM. If no epidemiologic link is identified in those fields the risk factor fields are examined to determine whether a case travelled, was associated with a confirmed outbreak, was a contact of a case, had no known epidemiological link (sporadic community transmission) or was reported to have an unknown source/no information was reported. Some cases may have no information reported if the case is untraceable, was lost to follow-up or referred to FNIHB. Cases with multiple risk factors were assigned to a single likely acquisition source group which was determined hierarchically in the following order:

    - For cases with an episode date *on or after* April 1, 2020: Outbreak-associated > close contact of a confirmed case > travel > no known epidemiological link > information missing or unknown

    - For cases with an episode date *before* April 1, 2020: Travel > outbreak-associated > close contact of a confirmed case > no known epidemiological link > information missing or unknown

- Deaths are determined by using the outcome field in CCM. Any case marked 'Fatal' is included in the deaths data. The CCM field Type of Death is not used to further categorize the data.

    - The date of death is determined using the outcome date field for cases marked as 'Fatal' in the outcome field.

- COVID-19 cases from CCM for which the Classification and/or Disposition was reported as ENTERED IN ERROR, DOES NOT MEET DEFINITION, IGNORE, DUPLICATE or any variation on these values have been excluded. The provincial case count for COVID-19 may include some duplicate records, if these records were not identified and resolved.

- Ongoing outbreaks include all outbreaks that are 'Open' in CCM without a 'Declared Over Date' recorded, or where the outbreak started more than five months ago, even for outbreaks where the Outbreak Status value selected in CCM is 'OPEN'. The start of the outbreak is determined by the onset date of first case, or if missing the outbreak reported date, or else if that is also missing, then the outbreak created date.

- 'Long-term care home residents' includes cases that reported 'Yes' to the risk factor 'Resident of a long-term care home'; or 'Yes' to the risk factor 'Resident of nursing home or other chronic care facility' and reported to be part of an outbreak assigned as a long-term care home (via the Outbreak number or case comments field); or were reported to be part of an outbreak assigned as a long-term care home (via the outbreak number or case comments field) with an age over 70 years and did not report 'No' to the risk factors 'Resident of long-term care home' or 'Resident of nursing home or other chronic care facility'. 'Long-term care home residents' excludes cases that reported 'Yes' to any of the health care worker occupational risk factors.

- The 'health care workers' variable includes cases that reported 'Yes' to any of the occupation of health care worker, doctor, nurse, dentist, dental hygienist, midwife, other medical technicians, personal support worker, respiratory therapist, first responder.

- 'Health care workers associated with long-term care outbreaks' includes 'health care workers' reported to be part of an outbreak assigned as a long-term care home (via the outbreak number or case comments field). Excludes cases that reported 'Yes' to risk factors 'Resident of long-term care home' or 'Resident of nursing home or other chronic care facility' and 'Yes' to the calculated 'health care workers' variable.

- Percent change is calculated by taking the difference between the current period (i.e., daily count or sum of the daily count over a 7-day period) and previous period (i.e., daily count or sum of the daily count over a 7-day period), divided by the previous period.

- Public Health Ontario conducts testing and genomic analyses for SARS-CoV-2 positive specimens using the criteria outlined here: https://www.publichealthontario.ca/en/laboratory-services/test-information-index/covid-19-voc

- Lineage nomenclature is dynamic. PANGO lineage naming and assignment may change as more samples are sequenced and analyzed.

- Variant status may be updated based on scientific evidence. Variants designated as a VOC in Canada is available on the Public Health Agency of Canada's SARS-CoV-2 Variants webpage.

- Changes to the VOC testing algorithm may occur over time and trends should be interpreted with caution. Since February 3, 2021 all PCR positive SARS-Co-V-2 specimens with Ct values ≤ 35 are tested for a N501Y mutation. As of March 22, 2021, positive specimens with a Ct ≤ 35 are tested for both the N501Y and E484K mutation, with all E484K positive specimens with a Ct ≤ 30 forwarded for further genomic analysis. If found to be positive for the N501Y mutation only, no further genomic analysis are performed as these are presumed to be B.1.1.7. As of May 26, 2021, cases where a E484K mutation is detected will no longer be reflexed for sequencing as

VOC testing labs switched to a representative sampling method where only a proportion of all positives with a Ct ≤ 30 are forwarded for further genomic analysis.

- The laboratory detection of a variant of concern is a multi-step process. Samples that test positive for SARS-CoV-2 and have a cycle threshold (Ct) value ≤ 35 can be tested for mutations common to variants of concern. If positive for the mutation of interest with a Ct value of ≤30, these samples may then undergo genomic analyses to identify the VOC lineage. VOC lineages may still be confirmed using genomic analysis despite specific S gene mutation(s) being documented as 'unable to complete' due to poor sequence quality at the genome position.

- VOC testing data are analyzed for cases with a reported date on or after February 07, 2021. VOC testing data are based on CCM information reported within the laboratory object for select Logical Observation Identifiers Names and Codes (LOINC) and supplemented with information from the Investigation Subtype field. A confirmed Case Investigation is assigned a VOC test value (e.g., VOC test detected, VOC test not detected) based on the following hierarchy:

    - If multiple laboratory results are identified, a VOC test value is assigned based on the following hierarchy: Detected > Not Detected > Unable to complete

    - If a laboratory result is 'Not Detected' or 'Unable to complete', but data on the Investigation Subtype field is listed as a lineage or mutation common to a VOC, then the VOC test value is set to 'Detected'

- If a VOC is identified through genomic analysis cases initially classified as a mutation may be updated and moved to the appropriate lineage (B.1.1.7, B.1.351, P.1 and B.1.617.2)

- LOINCs are a set of internationally used result description codes. In the absence of a standard LOINC, Ontario Health can create local result codes, which are identified with an 'XON' prefix. LOINCs incorporate details of the result value (e.g. test method, target detected - such as IgG, DNA, isolate etc.) and are unique to each result.

- VOC testing data in this report are assigned on a per case basis. Multiple laboratory results may be associated to a single case investigation, but for analysis purposes are only counted once.

    - The percent of cases that test VOC positive is calculated by taking the number of VOC test positive, divided by the total number of confirmed COVID-19 cases for a given reported date.

- The VOC percent positive may be higher than described in this report. As testing algorithms change, the VOC percent positivity may not be reflective of the exact number of COVID-19 cases due to VOCs

- Only CCM case investigations with a CONFIRMED classification have their laboratory records with VOC testing information included in the percent positivity calculations

Appendix A

Table A1. Weekly rates of confirmed COVID-19 cases per 100,000 population over recent rolling 7-day periods, by reported date and public health unit: Ontario, June 18 to June 30, 2021

Public Health Unit Name	June 18 to June 24	June 19 to June 25	June 20 to June 26	June 21 to June 27	June 22 to June 28	June 23 to June 29	June 24 to June 30	% change from June 18 – June 24 to June 24 - June 30

TOTAL ONTARIO	**143,899**	**1,415**	**4,631**	**2,041**	**24,928**

Note: Interpret the VOC and mutation trends with caution due to the varying time required to complete VOC testing and/or genomic analysis following the initial positive test for SARS-CoV-2. Due to the nature of the genomic analysis, test results may be completed in batches. Data corrections or updates can result in case records being removed and/or updated and may result in totals differing from past publicly reported case counts. Data for calculating the change in cases and the cumulative case count uses data from the Investigation Subtype field only. Changes to the VOC testing algorithm may impact counts and trends. Further details can be found in the data caveats section.

*Includes all confirmed COVID-19 cases where lineage B.1.1.7 was identified by genomic analysis and those presumed to be B.1.1.7 based on positive N501Y and negative E484K mutation.

**Includes B.1.351 cases identified by genomic analysis and those presumed to be B.1.351 based on 'Mutation K417N+ and N501Y+ and E484K+' in the Investigation Subtype field

***Includes P.1 cases identified by genomic analysis and those presumed to be P.1 based on 'Mutation K417T+ and N501Y+ and E484K+' in the Investigation Subtype field

†Includes B.1.617.2 cases identified by genomic analysis. Mutations common to B.1.617.2 are not included in the current VOC mutation test.

‡Mutations includes all confirmed COVID-19 cases with the following mutations detected, reported from the Investigation Subtype field: N501Y and E484K, N501Y (E484K unknown), E484K (N501Y negative), E484K (N501Y unknown).

If a VOC is identified through genomic analysis, the change in cases and/or cumulative case counts for mutations will fluctuate as the case is moved to one of the listed lineages.

Note: Data for calculating the number of cases tested for mutations common to VOCs or lineages using genomic analyses are obtained using information from the Laboratory object in CCM in addition to the data from the Investigation subtype field. Therefore, comparisons to counts using only information from the Investigation Subtype field may not align. The percent of cases due to a VOC may be higher than described in this report. While all confirmed COVID-19 cases are included in the denominator, not all cases were able to be tested for VOCs. Percent positivity is based on the sum of the daily cases that test positive divided by the number of cases reported during the date ranges specified in each column.
Data Source: CCM

AFFIDAVIT OF MATTHEW HODGE
(Affirmed July 2, 2021)

I, MATTHEW HODGE, of the [redacted] in the Province of Ontario, **AFFIRM**:

I. BACKGROUND

1. I am a licensed medical practitioner who practices Public Health & Preventive Medicine ("**PHPM**") and Emergency Medicine in Ontario.[1] I joined Public Health Ontario ("**PHO**") in October 2020 and was the co-lead for Epidemiology & Surveillance activities within the Incident Management System ("**IMS**") structure of the Health Protection division of PHO from November, 2020 until April 9, 2021. The global COVID-19 pandemic (the "**Pandemic**") constitutes a public health emergency, so many organizations, including PHO, have established IMS structures to redeploy staff and prioritize activities. In my role within IMS, I was responsible for strategic input and work on data management, analyses and reporting. Currently, I work as a consultant with PHO. Throughout the pandemic, I have continued practicing emergency medicine at the Scarborough General site of the Scarborough Health Network. My work there includes caring for patients with COVID-19 infections over the past sixteen months.

2. I graduated with an MD (1996) and PhD (Epidemiology & Biostatistics, 1995) from McGill University and completed PHPM specialty training at the University of Toronto in 2000. Over the past twenty-one years, my practice has included multiple roles in public health, including Associate Medical Officer of Health, City of Hamilton (2005-2007), United Nations agencies (WHO: 1999-2001, UNICEF: 2001-2002, UNFPA: 2008-2010), Cancer Care Ontario (2010-2011), two positions with the Ontario Ministry of Health and Long-Term Care (2003-2004, 2015-2016), and a wide range of consulting work. I also completed Harvard's Masters in Health Care

[1] Public health and preventative medicine is a population or society focused discipline. This can be contrasted with infectious disease medicine which is focused on individual patients.

Management in 2011. I am also a peer reviewer for the Canadian Medical Association Journal and occasionally for the Canadian Journal of Public Health.

3. Following the province's declaration of an emergency in response to the Pandemic on March 17, 2020, I worked for six months assisting Peel Public Health's Pandemic response. My work there included guiding the implementation of the provincial Case & Contact Management system.

4. My *curriculum vitae* is attached to this affidavit as **Exhibit "A"**.

5. I have been asked to provide an expert opinion answering the questions relevant to this court proceeding that are set out below. My signed Acknowledgment of Expert's Duty is attached to this Affidavit as **Exhibit "B"**. Where I have relied on a document or data in forming my opinion, I have set out the citation to that document or data in the footnotes. Where I have relied on information provided to me by others, I have stated the source of that information and I believe it to be true.

II. OVERVIEW

6. I have been asked to answer the following questions in this expert affidavit:

   a. What are the harms caused by COVID-19 disease?

   b. How is COVID-19 disease transmitted?

   c. What are the risk factors for transmission?

   d. Why are measures to limit COVID-19 transmission needed in Ontario?

   e. Why do limits on religious gatherings contribute to reducing COVID-19 transmission and harms from COVID-19?

   f. Can the risk of transmission at indoor religious gatherings be adequately addressed by rules requiring physical distancing and face coverings or other personal protective equipment?

g. Do you agree or disagree with the affidavits of Dr. Warren dated April 6, 2021, Dr. Schabas and Dr. Kettner?

7. My answers are detailed below. I make three preliminary observations. First, my opinions are informed by the realities of public health practice in Ontario, including the need to prepare advice and make decisions with imperfect information, and the challenge of minimizing adverse effects of measures that establish limits on human behaviour. Ontario's Health Plan for an Influenza Pandemic, ("OHPIP"), cited by experts retained by the Applicant, explicitly recognizes this reality of incomplete information, noting that 'the OHPIP severity model includes an initial stage before severity is known when the limited availability of surveillance data does not allow for confident identification of severity. The severity may not be clearly known until after an influenza pandemic is over'.[2] For COVID-19, the rise of variants with increased transmissibility and, for some variants, increased severity of illness, adds additional uncertainty.

8. Second, public health measures in Ontario must take into account the precautionary principle. The OHPIP states 'The MOHLTC does not await scientific certainty before taking action to protect health'.[3] The application of the precautionary principle is particularly relevant during the early stages of a pandemic when scientific evidence on the severity of a novel virus is limited or, for COVID-19, as new variants are identified whose transmissibility and severity are incompletely understood at the time that government must make decisions to protect Ontarians from infection, illness and death.[4]

9. Third, my opinions are informed by the burden model, which recognizes that it is generally appropriate to implement more restrictive public health measures when an infectious disease

[2] See **Exhibit "C":** Ontario, Ministry of Health and Long-Term Care, Emergency Management Branch, *Ontario's Health Plan for an Influenza Pandemic* (March 2013) at p. 14, online: https://www.health.gov.on.ca/en/pro/programs/emb/pan_flu/docs/ch_01.pdf. See also pp. 10-13.
[3] See **Exhibit "C"**, *supra* note 2 at p. 11.
[4] For an example in the context of influenza, see **Exhibit "C"**, *supra* note 2 at p. 11.

imposes a higher burden. This notion of burden can be understood as a function of the prevalence of the disease (i.e. number of cases in a population), the exposure risk (i.e. the probability that one infected person will infect others), and the consequences of infection, such as hospitalization and death.

10. When Ontario enacted more stringent public health measures during each of the three waves of the pandemic to date, there was increasing community prevalence of COVID-19, growing numbers of new cases, and concerns about hospital and ICU occupancy. Accordingly, in my opinion it was a reasonable public health measure to restrict religious gatherings temporarily while community spread of COVID-19 posed this potential (wave 1) or real (waves 2 & 3) burden on Ontario's health care system. Furthermore, the emergence of variants of concern ("VOC"), with initial uncertainty about their transmissibility and severity, borne out by evidence of higher transmissibility (alpha & delta variants) and more severe illness (alpha variant) mandated a more stringent public health response. The pace of easing temporary limits on indoor religious gatherings is one of a suite of measures designed to keep Ontario from entering a fourth wave of the pandemic.

III. WHAT ARE THE HARMS CAUSED BY COVID-19?

11. COVID-19 illness is caused by a coronavirus that infects the respiratory system. Infection causes symptoms of upper respiratory tract infection including cough, fever and sore throat. COVID-19 infection also appears to cause a characteristic loss of taste and smell for many infected people. Based on Ontario's COVID-19 experience, 5% of people with COVID-19 will require hospital-based care, typically for oxygen at a minimum and often, ICU-level care. Complications leading to ICU admission or death may include respiratory failure, acute respiratory distress syndrome, sepsis and septic shock, thromboembolism, and/or multiorgan failure, including injury

of the heart, liver or kidneys.[5] As of June 24, 2021 in Ontario, 543,571 people have been diagnosed with COVID-19, and 9,101 (approximately 1.7%) have died.[6] The number of cumulative cases of COVID-19 in Ontario is likely higher than the number of recorded cases since some individuals who acquire COVID-19 are not tested and diagnosed. This was particularly the case during the early months of the COVID-19 pandemic.

12. The number of reported COVID-19 infections, hospitalizations, and deaths as of June 24, 2021 (Ontario), June 29, 2021 (Canada), or June 30, 2021 (global) are set out in the table below:

TABLE 1: Cases, hospitalizations, and deaths

	Cases	Hospitalizations	Deaths
Ontario[7]	543,571	27,643	9,101
Canada[8]	1,414,736	74,044	26,273
Global[9]	181,521,067	Unavailable	3,937,437

13. COVID variants are expected to arise due to high rates of viral transmission globally. Over the sixteen months of the pandemic, Ontario's context has evolved with increases in the prevalence of VOCs. As an example of the impact of VOCs in Ontario, the B117 variant (recently designated as the alpha variant) was reported to be more transmissible and cause more severe illness, contributing to an increased percentage of people with COVID-19 who need hospitalization and

[6] See **Exhibit "E":** Public Health Ontario, "Ontario COVID-19 Data Tool", online: <https://www.publichealthontario.ca/en/data-and-analysis/infectious-disease/covid-19-data-surveillance/covid-19-data-tool?tab=summary> (accessed 24 June 2021).
[7] See **Exhibit "E"**, *supra* note 6.
[8] See **Exhibit "F":** Canada, "COVID-19 Daily Epidemiology Update" (June 29, 2021), online: <https://health-infobase.canada.ca/covid-19/epidemiological-summary-covid-19-cases.html?stat=num&measure=total&map=pt#a2>.
[9] **Exhibit "G"**: World Health Organization, "WHO Coronavirus (COVID-19) Dashboard" (June 30, 2021), online: <https://covid19.who.int/> .

ICU care, including younger people in their 40s and 50s.[10] The alpha variant that drove the third wave during early 2021 is currently being supplanted by the delta variant about which knowledge is rapidly evolving.[11]

14. The number of COVID-19 cases and hospitalizations in Ontario have increased with each of the three COVID 'waves', periods marked by rising case loads and concomitant rising pressures on Ontario's health system. Numbers of hospitalizations are relevant to COVID-19 decision-making because Ontario has the lowest rate of hospital beds per 1000 population (1.4) compared to the Canadian average (2.0). Overall, Canada's hospital capacity is among the lowest of the OECD countries, with 20% more in the USA (2.4/1000), 30% more in Italy (2.6/1000) and 55% more in France (3.1/1000).[12] Given that Canada has relatively few beds and Ontario has the fewest in Canada, the threshold above which the burden of COVID-19 infections and illness could push Ontario' acute care system past the point of being able to provide care to patients is logically lower than in other countries or even other Canadian provinces.

15. Ontario's response to COVID hospitalizations has, by virtue of this lower number of hospital beds compared to other comparable jurisdictions, involved moving substantial numbers of patients from the hospital at which they arrived to one with an available bed, often far from their community[13] and, at a societal level, implementing non-pharmaceutical interventions ("NPIs").

[13] Kelly Grant, "How COVID-19 exposed long-term health-care issues at Brampton hospital" (June 21, 2021) *The Global and Mail,* online: <https://www.theglobeandmail.com/canada/article-how-the-covid-19-pandemic-exposed-long-term-health-care-issues-at/>. Ontario Health data cited by the Globe and Mail note 3219 transfers between mid-November, 2020 and the end of May, 2021.

NPIs comprise a bundle of measures, including temporary restrictions on mobility and gatherings, designed to reduce COVID-19 transmission and thus hospitalization and death, both to mitigate threats to the integrity of health care and to 'minimize serious illness and overall deaths through appropriate management of Ontario's health system.'[14]

16. A health system in which every available bed is occupied by someone infected with COVID-19 has no way to respond to people with heart attacks, hip fractures or strokes, potentially adding to the elevated mortality attributable to COVID-19. Put simply, the harms caused by COVID-19 would be compounded with additional preventable deaths due to heart attacks, hip fractures and other health conditions if there are no beds and no staff available to care for patients with these conditions. Once overwhelmed, the acute care system would likely face a prolonged recovery period, hence the relevance of the precautionary principle to decision making aiming to ensure the integrity of the health system.

17. Given that different jurisdictions have applied a different mix of policy responses to the COVID-19 pandemic, and that there are real harms associated with the restrictive nature of the temporary public health measures implemented across dozens of countries, it may be instructive to examine these in comparative terms. At its simplest, a key question is 'what would have been the mortality from COVID-19 if Ontario had chosen less restrictive measures?'; the table below summarizes the results from three jurisdictions described as less restrictive by the Applicant's expert, Dr. Schabas, as compared to Ontario's mortality rate.

[14] See **Exhibit "C"**, *supra* note 2 at p. 10 (Objective #1).

TABLE 2

	Ontario	Sweden	Brazil	Florida
Population	14,000,000	10,159,183	213,956,756	21,600,000
COVID-19 Deaths	9,101[15]	14,619[16]	507,109[17]	37,772[18]
Crude Death Rate[19]	0.65/1000	1.44/1000	2.37/1000	1.75/1000
Projected Additional Deaths in Ontario[20]	NA (zero)	+11,060 (+122%)	+24,080 (+265%)	+15,400 (+169%)

IV. HOW IS THE VIRUS TRANSMITTED?

18. COVID-19 is caused by the SARS-CoV-2 virus and its variants (together, "**COVID-19**" or the "**Virus**"), which spreads between people, through respiratory particles of varying sizes, mainly when an infected person is in close contact with another person.[21]

19. COVID-19 can spread from an infected person's mouth or nose in small liquid particles when they cough, sneeze, speak, sing, or breathe heavily. These liquid particles are different sizes, ranging from larger respiratory droplets to smaller aerosols. While the science is still evolving, these particles travel further indoors than outdoors and their survival on surfaces appears to be

[19] Number of reported cases/population; age-adjustment would yield slightly more accurate figures but the change due to age adjustment is insufficient to explain the greater than 2-fold variation.
[20] Calculated as (death rate in jurisdiction – death rate in Ontario)*population of Ontario.
[21] See **Exhibit "J":** Public Health Ontario, "Synthesis: COVID-19 Transmission Through Large Respiratory Droplets and Aerosols…What We Know So Far" (May 21, 2021), online: <https://www.publichealthontario.ca/-/media/documents/ncov/covid-wwksf/2021/05/wwksf-transmission-respiratory-aerosols.pdf?la=en>.

greater indoors than outdoors. Whether indoors or outdoors, people can contract COVID-19 when the Virus enters their mouth, nose, or eyes.[22]

20. Many people infected with COVID-19 show no symptoms (asymptomatic) or experience several days between when they are infected and when they develop symptoms (presymptomatic). This is particularly challenging as transmission risk seems to be highest prior to symptoms appearing, meaning that most infected people will unknowingly infect others before they themselves have symptoms.[23] Thus, to reduce COVID-19 transmission and the harms, including hospitalization and death that such transmission can cause, NPIs need to apply to people who do not exhibit COVID-19 symptoms in order to be effective.

V. WHAT ARE THE RISK FACTORS FOR TRANSMISSION?

21. Risk factors for virus transmission include being in close contact for prolonged periods, higher voice volume, being indoors, inconsistent use of face coverings (such as removing a face covering to talk or shout, eat or drink), improper use of face coverings (e.g. not covering the nose or wearing one that is too loosely fitted), and background infection rates in the community(s) from which a gathering's attendees are drawn.

22. The World Health Organization provides the '3C' framework for assessing risks of COVID-19 transmission: crowded places, close contact, confined spaces. Risks of Virus transmission are increased when two or more of these conditions occur together.[24] In addition, risks increase with increasing degrees of the 3Cs, including:

---

[22] See **Exhibit "K":** World Health Organization, "Coronavirus disease (COVID-19): How is it transmitted?" (updated April 30, 202), online: <https://www.who.int/emergencies/diseases/novel-coronavirus-2019/question-and-answers-hub/q-a-detail/coronavirus-disease-covid-19-how-is-it-transmitted>.

[23] *Ibid*.

[24] See attached **Exhibit "L"**: World Health Organization, "Avoid the Three Cs", online: <https://www.who.int/images/default-source/wpro/countries/malaysia/infographics/three-3cs/final-avoid-the-3-cs-poster.jpg?sfvrsn=638335c1_2>.

a. being in close contact for longer periods causes greater risk than shorter periods;[25]

b. higher voice volume likely increases both droplet production and projection;[26]

c. being indoors increases risk, as droplets persist in indoor environments longer than outdoors;[27] and

d. inconsistent or improper use of face coverings, such as removing a face covering to sing or consume food and beverages or leaving the nose uncovered, increases risk.

23. The risk from any particular setting is also determined by the likelihood that other persons present are infected with COVID-19. Community prevalence describes the percentage or rate of COVID-19 infection in a population. When community prevalence is elevated, even lower risk activities can contribute to pressures on the integrity of the health system as more infections lead to increased numbers of persons needing hospitalization.

24. After the first wave of COVID-19 in Ontario when COVID-19 spread widely within institutional settings such as long-term care homes ("LTCHs"), transmission risks now appear to be highest in non-institutional settings such as workplaces and households. Secondary attack rates (the number of cases among contacts of a case) within households have been estimated to be 5-10 fold higher than in non-institutional , non-household settings.[28] The transmissibility of COVID-19 within households is complex and determined by still poorly understood interactions of density (persons per room), social interaction patterns among household members, use of personal

[25] See **Exhibit "J"**, *supra* note 21.
[26] See **Exhibit "M"**: Valentyn Stadnytskyi et al, "The airborne lifetime of small speech droplets and their potential importance in SARS-CoV-2 transmission", (2020) 119:22 PNAS 11875-11877, online: <https://www.pnas.org/content/117/22/11875>.
[27] See **Exhibit "J"**, *supra* note 21.
[28] See **Exhibit "N":** Sarah A. Buchan et al., "Increased household secondary attack rates with Variant of Concern SARS-CoV-2 index cases" (March 31, 2021), *Public Health Ontario* (April 5, 2021 pre-print), online: <https://www.medrxiv.org/content/10.1101/2021.03.31.21254502v1> (accessed 26 June 2021).

protective equipment within the home, and social and cultural norms determining roles and behaviours within households. As these are not amenable to policy action on the time scale of COVID-19 transmission, the cornerstone of evidence-informed actions to reduce the burden of COVID-19 in Ontario is reducing risks of COVID-19 being introduced into households, thus reducing COVID-19 transmission and subsequent incidences of clinical illness, hospitalization and death.

25. At a population level, the overall risk of transmission is further increased when community prevalence of the Virus is higher, since any encounter carries a higher chance of involving a person infected with COVID-19. In addition, gatherings that draw individuals from different households together increase risks of transmission to more households, increasing the expected burden of COVID-19. High rates of household transmission, with entire families being hospitalized during the most recent period of heightened incidence, highlight the importance of implementing public health measures that reduce the chances of COVID-19 entering a household.

Risk of transmission at religious gatherings

26. As set out above, the risk of COVID-19 transmission at an event or gathering depends on a number of factors, including the number of people attending, adherence to physical distancing, mask wearing, duration of the event or gathering, ventilation, whether there is singing or high-volume talking, and background infection rates in the community(s) from which the gathering's attendees are drawn.

27. Religious gatherings often feature several heightened risk factors for COVID-19 transmission, including singing or high-volume speaking, chanting or preaching. The scientific basis for this is understood to be greater production of respiratory particles with increasing

volume.[29] While it is uncertain whether there is an independent increased risk from singing when compared to speech at the same volume, it appears reasonable that even if the singing effect is a pure volume effect, the reality that singing occurs at higher volumes than speaking confers increased risk of producing COVID-19-containing respiratory particles.

28. Ontario COVID-19 outbreak data suggest that when COVID-19 outbreaks occur in association with religious gatherings, more cases are identified than from outbreaks in other non-institutional settings. Through June 18, 2021, Ontario's 34 local public health units reported 59 outbreaks associated with places of worship with 526 associated cases, for an average of 8.9 cases per outbreak. While not diminishing the toll of COVID-19 in LTCHs and other institutional settings (4032 outbreaks, 49304 associated cases) and acknowledging that while places of worship may be workplaces (2616 outbreaks, 24000 associated cases) for some persons, appropriate comparable settings would be other indoor locations into which individuals from different households voluntarily enter, such as restaurants, retail establishments and recreational fitness establishments. This grouping of other settings comprises 979 outbreaks with 5283 associated cases, for an average of 5.4 cases per outbreak.

29. Taken together, these Ontario data on declared COVID-19 outbreaks in places of worship indicate that the number of cases per outbreak is 65% higher in places of worship than in comparable non-workplace settings (8.9 versus 5.4). From the point of view of reducing COVID-19 transmission, these data support temporary limits on religious gatherings as part of a bundle of measures designed to reduce COVID-19 transmission since outbreaks associated with places of

[29] See **Exhibit "O":** Sima Asadi et al., "Aerosol emission and superemission during human speech increase with voice loudness" (2019) 9:2348 *Nature,* online: <https://www.nature.com/articles/s41598-019-38808-z> (accessed 26 June 2021).

worship yield more identified infections than outbreaks in comparable non-institutional, non-workplace[30] settings.

D. WHY ARE MEASURES TO LIMIT COVID-19 TRANSMISSION NEEDED IN ONTARIO?

30. Seeking to protect persons from mortality and morbidity from COVID-19 and to reduce the likelihood the acute care system would be overwhelmed by persons requiring hospital care for COVID-19 infection, the government of Ontario has implemented a bundle of temporary public health measures, generally referred to as non-pharmacologic interventions ("NPIs"). NPIs seek to reduce close contact among persons from different households, and thus reduce COVID-19 transmission risk. NPIs implemented temporarily in Ontario are broadly similar to those implemented in most if not all OECD jurisdictions and include limits on occupancy of indoor spaces, mobility limits, limits on and prohibitions of gatherings and events, and school closures.

31. These policy interventions are complemented by individual-focused**,** evidence-based mitigation measures such as requirements for face covering and physical distancing. Together these measures, both individual and policy level, can reduce, but not eliminate, the risk of COVID-19 transmission. Vaccination, once high levels of population coverage are achieved, is expected to obviate the need for NPIs. Ontario's *Roadmap to Reopening* explicitly links the end of NPIs to increasing levels of vaccination among Ontarians. It is hoped that vaccinations will eventually render these NPIs unnecessary, however with only 30% of Ontario's adult population fully vaccinated as of June 29, 2021,[31] levels of vaccination coverage are as yet insufficient to cease all NPIs.

---

[30] Data summarized by Public Health Ontario as of June 18, 2021.

E. WHY DO LIMITS ON RELIGIOUS GATHERINGS CONTRIBUTE TO REDUCING COVID-19 TRANSMISSION AND HARMS FROM COVID-19?

32. In a society as diverse as Ontario, religious gatherings encompass a wide range of practices which may include singing, preaching, close contact for the purposes of greetings or other verbal and/or physical exchanges, and the passing of religiously significant physical material from person to person.

33. From an epidemiologic perspective, all gatherings as a class pose risks that rise with the number of attendees, reflecting the declining probability that every person present will be COVID-free as the number of persons increases. Experts retained by the Applicants have attempted to estimate this risk. Acknowledging that any such model involves estimates and assumptions, the table below asks a more basic policy-relevant question: for gatherings of different numbers of people and with different proportions of COVID-19 infection in the community, what is the chance that at least one person who is infected with COVID-19 will be present and thus able to transmit COVID-19 to others?

34. The 1 case/500 people proportion column aligns with the Applicant's expert's (Dr. Kettner's) estimated incidence of 1 case/5000 people/day with correction for the epidemiologic reality that infected people can transmit COVID-19 to others for roughly 10 days. Furthermore, from a community perspective, effects are multiplicative, such that a community with 10 gatherings of 10 attendees where 1 out of every 500 attendees has COVID-19 has a greater than 18% chance of someone having COVID at at least one gathering. If ten gatherings are held once/week for 10 weeks, that risk of having at least one attendee with COVID-19 at any one of those 100 gatherings rises to greater than 86%. Put another way, over 10 weeks, 10-person gatherings for religious services in 10 locations within a community yields an 86% chance that at least one attendee at at least one service has COVID-19. While the gathering-specific transmission

risks would be determined by multiple factors including mask use, ventilation and distancing, the 86% chance of COVID-19 being present highlights the importance of temporary limits on gatherings, religious or otherwise.

TABLE 3

Table entries are % chance of at least one attendee with COVID-19, where higher numbers mean a greater chance of someone with COVID-19 attending a gathering[32]

Number of People Attending	1 of Every 100 Attendees Have COVID-19	1 of Every 500 Attendees Have COVID-19	1 of Every 1000 Attendees Have COVID-19
10	9.5%	2%	<1%
100	63%	18%	9.5%
1000	>99.9%	86%	63%

35. In addition, specific religious practices such as those listed above increase risks of transmission, notably when voice volume is increased, as with singing and preaching, and when people are in close contact. In addition, entry and egress into many places of worship will bring people into close contact due to the near-simultaneous arrival of attendees to points of entry and egress.

36. Data on outbreaks associated with places of worship gathered by Public Health Ontario summarized above in para. 28 highlight the greater transmission risks among identified outbreaks associated with places of worship when compared to comparable non-institutional, non-workplace settings.

37. Both Drs. Schabas & Kettner, experts retained by the Applicants, have noted that few deaths are directly attributable to transmission in places of worship, yet overlook the reality that

[32] Assuming independence of infection risk among attendees, prob (at least one attendee with COVID-19) = (1-(Prob that all are uninfected) = (1-% of attendees with COVID)^number of attendees.

many people who attend religious gatherings also work outside their homes, whether as essential workers in LTCHs or transit operators or dentists who, if infected at a place of worship can then transmit COVID-19 to those they care for, drive for or serve, in addition to transmitting COVID-19 to uninfected household members. As a transmission location cannot be identified for many of the thousands of cases of COVID-19 deemed to be community transmission, temporary restrictions have been imposed on a wide range of settings and gatherings. Given that reducing COVID-19 transmission (as the upstream cause of COVID-19 harms including illness, hospitalization and death) is a major policy focus of government action regarding COVID-19, temporary limits on gatherings are a reasonable element of the bundle of NPIs aiming to reduce COVID-19 transmission and subsequent harms.

38. The Applicants' experts make reference to 'safety plans' (Dr. Kettner) and provide an admonition that 'public health should work constructively with religious congregations to find ways to allow religious services to continue to function at an acceptable risk' (Dr. Schabas). Given the diversity of religious practices and the venues where religious gatherings occur, the policy rationale for diverting sparse public health resources to working with individual religious organizations seems based on the assertion that cooperation will be forthcoming from all groups, which experience (including the experience of some of the applicants in this case) teaches may not happen in practice.

39. It may be theoretically possible to argue that contact tracing would be a reasonable alternative, arguing that if an infection occurred, then attendees could be contacted and advised to self-isolate, be tested or follow other public health advice. However, contact tracing requires being able to identify by name people who may have been in contact with a confirmed case of COVID-19 so that these persons can be directed to testing and advised to self-isolate. This argument, if

valid, assumes three critical elements: that people are truthful and complete when asked about places they have been, that an accurate and complete list of attendees for each place of worship is maintained by every place of worship and that society has the resources to contact each identified person. Even if all three elements are present, the significant likelihood of asymptomatic or presymptomatic COVID-19 transmission means infection of others is expected to occur before the index case is confirmed which is the necessary step that would trigger contact tracing. Ontario's COVID-19 experience to date suggests that the theoretical impact of contact tracing has not been realized, due to both the biology of COVID-19 and the reality that any single case will likely have infected others before test results are available to initiate contact tracing.

40. In keeping with Ontario's commitment to reduce illness and mortality from pandemic infectious disease, and noting the far higher death rates seen in jurisdictions that opted for less restrictive measures than in Ontario, the Province of Ontario implemented temporary limits on gatherings, including those at places of worship and for religious observance. As discussed above, in addition to the risk associated with any gathering, COVID-19 outbreaks have been reported from places of worship and these have been more severe than outbreaks in other settings as demonstrated by the increased number of cases per outbreak.

41. Specific features of religious services including singing, preaching and close contact all increase risks of COVID-19 transmission. Furthermore, persons who attend places of worship may become infected and transmit to others in their households and workplaces. Taken together, these factors lead me to conclude that temporarily limiting religious gatherings is a public health measure which contributes to reducing COVID-19 transmission and thus harms from COVID-19. At such time as COVID-19 incidence rates decline significantly, reducing and eventually eliminating temporary limits on religious gatherings would be appropriate, as occurred when

regions moved into lower zones of Ontario's *Keeping Ontario Safe and Open Framework*, and as is already happening with the current *Roadmap to Reopening*.[33]

VI. CAN THE RISK OF TRANSMISSION AT INDOOR RELIGIOUS GATHERINGS BE ADEQUATELY ADDRESSED BY RULES REQUIRING PHYSICAL DISTANCING AND MASKS OR OTHER PERSONAL PROTECTIVE EQUIPMENT ("PPE")?

42. Evidence-based mitigation measures such as face covering and physical distancing can reduce, but not eliminate, the risk of Virus transmission. The ongoing global pandemic highlights the reality that adherence with these measures is imperfect, and the imposition of regulatory fines has not eliminated non-compliance.

43. At religious gatherings, rules requiring the use of face coverings and physical distancing are inadequate to prevent COVID-19 transmission when community transmission is heightened. First, individuals may refuse to comply with such rules and reactive measures (i.e. enforcement actions) such as penalties or other sanctions for non-compliance imposed after the fact will do nothing to stop a COVID-19 outbreak caused by transmission that has already occurred at a gathering. At the height of the third wave, given the high prevalence of COVID-19 variants and the pressures on Ontario's hospital and ICU capacity, even isolated incidents of non-compliance with physical distancing and face covering requirements at religious gatherings would have had grave public health implications.

44. Second, the risks associated with religious gatherings further include the risk that participants may acquire or spread COVID-19 when they travel to and from the place of worship. As noted above, these risks are increased when community prevalence of COVID-19 is heightened.

---

[33] See **Exhibit "P":** Ontario, "Reopening Ontario", online: <https://www.ontario.ca/page/reopening-ontario#section-1> (accessed July 1 2021).

45. Although a religious leader, (e.g. Rabbi, Imam, Pastor, etc.) if present, may be able to ensure compliance with physical distancing and face covering requirements, the sense of community at religious gatherings may also prompt people to approach within two metres of each other to exchange greetings or sing at a high volume, particularly when such activities are an integral part of observance, increasing the risk of transmission. Further, a religious leader's ability to monitor and promote compliance risks being compromised in larger gatherings where it is more difficult to keep track of all participants. Even isolated incidents of non-compliance with physical distancing and face covering requirements at religious gatherings may lead to COVID-19 transmission, hospitalizations, and add to the significant pressures on Ontario's health care system.

VII. DO YOU AGREE OR DISAGREE WITH THE AFFIDAVITS OF DR. WARREN, DR. SCHABAS, AND DR. KETTNER?

i) Dr. Warren's affidavit

46. I have reviewed the affidavit of Dr. Warren.

47. With regard to Dr Warren's analogy of tuberculosis for COVID-19, the differing burden of each of these infectious diseases renders this analogy inapt. As discussed above, the notion of burden can be understood as a function of the prevalence of the disease (i.e., number of cases in a population), the exposure risk (i.e., the probability that one infected person will infect others), and the consequences of infection, such as hospitalization and death. To summarize, approximately 300 cases of tuberculosis are diagnosed in the City of Toronto each year.[34] Even if all 300 persons diagnosed with tuberculosis required hospitalization (which would be unheard of), 300 hospitalizations over a year is insignificant in comparison to the 25-35 hospitalizations/day from

[34] See **Exhibit "Q":** City of Toronto, "Programs & Services for Tuberculosis (TB)", online: <https://www.toronto.ca/community-people/health-wellness-care/health-programs-advice/tuberculosis-tb/programs-services-for-tuberculosis-tb/> (accessed April 22, 2021).

COVID-19 in April 2021 alone. For public health practice, higher burdens are an important motivator for more restrictive measures.

48. Similar considerations apply to Dr. Warren's reliance on influenza. While the prevalence of influenza is higher than tuberculosis, the consequences of acquiring influenza are generally less severe, with significantly lower mortality and hospitalization rates. Accordingly, seasonal outbreaks of influenza do not result in the same pressures on hospital and ICU capacity. It should also be pointed out that influenza has been thoroughly studied whereas COVID-19 is a new disease with even newer variants. The public health response to influenza has been finely tuned over the years – while obvious, it bears noting that there simply has not been the same lengthy period available for finely tuned public health measures to COVID-19.

49. In short, the important differences between COVID-19 and tuberculosis and influenza obligate public health officials to recommend a different public health response commensurate with the relative burdens of each infectious disease.

50. The limits on religious gatherings have been an important part of Ontario's broader public health response to the COVID-19 pandemic. If no limits were placed on religious gatherings, as Dr. Warren urges, this could be expected to push infection rates higher, increase the number of people hospitalized with COVID-19, and bring Ontario's health system nearer to the point where it would be unable to care not only for people infected with COVID-19 but also for others who need hospital based care.

51. Accordingly, I do not agree with Dr. Warren's statement that no limits should be placed on religious gatherings aside from physical distancing. The burden associated with COVID-19 in Ontario's health system, the higher risks of transmission associated with aspects of religious gatherings such as singing, and the greater number of cases per outbreak all support my opinion

that temporary limits on religious gatherings are a reasonable measure to protect Ontarians from COVID-19 and Ontario's health system from collapse due to COVID-19.

ii) Dr. Schabas' affidavit

52. I have reviewed the affidavit of Dr. Schabas. The affidavit makes repeated references to an undefined notion of 'lockdown'. It seems reasonable to assess Dr Schabas' assertions about lockdowns with regard to temporary limits on religious gatherings which is the matter at issue in this proceeding. Dr Schabas asserts the following points with my response set out below each point:

1. Temporary limits on religious gatherings have been arbitrary and capricious because they are not necessary or effective.

Temporary limits on religious gatherings are neither arbitrary nor capricious when considered in light of the evidence of elevated risks of COVID-19 transmission associated with elements of religious observance (e.g. singing) and Ontario's COVID-19 outbreak data showing 65% more cases from outbreaks associated with places of worship than with comparable non-institutional, non-workplace settings. Moreover, these temporary limits have been part of a bundle of NPIs which, when implemented with increasing stringency in each of the three waves to date, have been followed by decreases in the daily case count and growth rates.

2. Temporary limits on religious gatherings cause more harm (to mental health) than good (preventing COVID-19 related mortality and morbidity).

Dr. Schabas provides no evidence to support this assertion. Seeking the mental health benefits of attending religious gatherings, adherents to a wide range of diverse observances have established virtual gatherings, drive-in gatherings, and as conditions have improved, outdoor gatherings and larger indoor gatherings, suggesting that it is possible both to reap the health benefits of observance for adherents and to reduce risks of COVID-19 transmission in the wider population.

3. The initial temporary limits on religious gatherings in March 2020 were based on inaccurate models, including an overestimate of the Infection Fatality Rate ("IFR") by at least four times (especially outside of LTCs).

Dr. Schabas provides no details of the models which he describes as 'inaccurate'. The precautionary principle, coupled with the novelty of COVID-19 provides an adequate basis for implementing NPIs in line with Ontario's pandemic plan.

4. Temporary limits on religious gatherings have not been used in the past for respiratory contagions, including for influenza. Currently tobacco is more deadly than COVID-19.

My response regarding respiratory contagions, including influenza, is detailed in my response to Dr. Warren. Tobacco is not comparable as it is not a communicable disease and thus does not require restrictions on gatherings to reduce its transmission to others. Moreover, the government

of Ontario, as many other governments, has implemented significant permanent restrictions on the ability to smoke in places where second-hand smoke could cause harm to others (see e.g. *Smoke-free Ontario Act*).

5. COVID is a serious public health problem but affects mostly old people. The measure of years of life lost must be used to recognize this reality. Diarrheal illness in children has a greater impact than COVID-19.

Years of lives lost is just one measure of the deadliness of a virus. Since the matter at issue in this proceeding is actions taken by the government of Ontario, a more appropriate comparison would be years of life lost or deaths from diarrhea in Ontario.[35]

6. Public Health data shows that incidence of spread at religious gatherings is low. In any event, it is very low where there is no overcrowding, singing and well-ventilated.

Fifty-nine outbreaks have been identified at places of worship with an average of 8.9 cases per outbreak. While reducing or eliminating overcrowding and singing and improving ventilation would all contribute to lower risks of transmission, the role of the government in a pandemic emergency context is generally to establish rules for each sector rather than to inspect and create safety plans for each individual place of worship. If Dr. Schabas is of the view that such detailed plans should be created by the government, some evidence of precedent and/or operational consideration for how this would take place in thousands of places of worship would seem a reasonable expectation from an expert in public health.

7. VOCs are more transmissible – and therefore require stricter temporary limits on religious gatherings. It is not the right path to impose increasingly stricter measures.

The precautionary principle behooves government to be more cautious, not less cautious, when dealing with uncertainty. The biology of COVID-19 variants (notably alpha and delta), by being more transmissible than the variants they displaced, increases the risk of overwhelming the health system, suggesting that more stringent public health measures should be put in place, not less stringent measures. Dr. Schabas acknowledges that the science related to "many aspects of covid is uncertain" and recognizes that decisions on which public health measures to employ "are of necessity based on judgment as much as science."

iii) Dr. Kettner's affidavit

53. I have reviewed the affidavit of Dr. Kettner. In my opinion, Dr. Kettner provides a flawed modelling approach as the basis for his conclusions that the "probability of transmission of

[35] In fact, COVID-19 is more deadly than diarrhea. The CDC states that 2195 children die each day from diarrhea while the WHO reported deaths from COVID-19 amount to >7,000/day. UNICEF data indicate that approximately 2000 children under age 5 die each year in Canada and that diarrhea accounts for 8% of global child mortality. Applying this to Ontario suggests an upper limit of 64 deaths annually from diarrhea. Over the 16 months of the COVID-19 pandemic, this would amount to approximately 85 deaths from diarrhea compared to 9101 from COVID-19. UNICEF data available online: <https://data.unicef.org/resources/data_explorer/unicef_f/?ag=UNICEF&df=CME&ver=1.0&dq=CAN.CME_TMM0+CME_TMY0T4..&startPeriod=2016&endPeriod=2021>.

COVID-19 in church services with attendees from with (sic) current rates of infections similar to that of the Niagara health region" (para 95).

54. Dr. Kettner begins by choosing a municipality that is not the one in which the Wellandport church is located; Wellandport is a hamlet located in West Lincoln, Ontario, not within the municipality of Welland. Data provided by Public Health Ontario indicate that this is slightly to the advantage of his analysis as the cumulative incidence for West Lincoln is 30/100,000 while that for Welland is 38.3/100,000. Regardless of the incidence rate chosen, Dr. Kettner provides no evidence that all attendees are drawn from a single municipality whose incidence can then be used for the calculations that follow.

55. Dr. Kettner's modeling approach appears to overlook the reality that many individuals attending religious gatherings will do so as members of household groups. COVID-19 secondary attack rates within households are reported to be higher for asymptomatic and presymptomatic cases than for symptomatic cases and these rise further for VOCs, such that VOCs were determined to have a household secondary attack rate 1.31 times higher than non-VOC for symptomatic cases, 1.91 times higher for asymptomatic VOC cases, and 3.41 times higher for presymptomatic cases.[36] The non-independence of COVID-19 infection risk among members of a household, coupled with high secondary attack rates in the time of VOCs' emergence, undermines Dr. Kettner's model as a basis for prudent decision making.

56. Furthermore, Dr. Kettner's model assumes a constant (i.e. the same number of new cases every day) incidence rate over a period when incidence varied substantially in Niagara region.

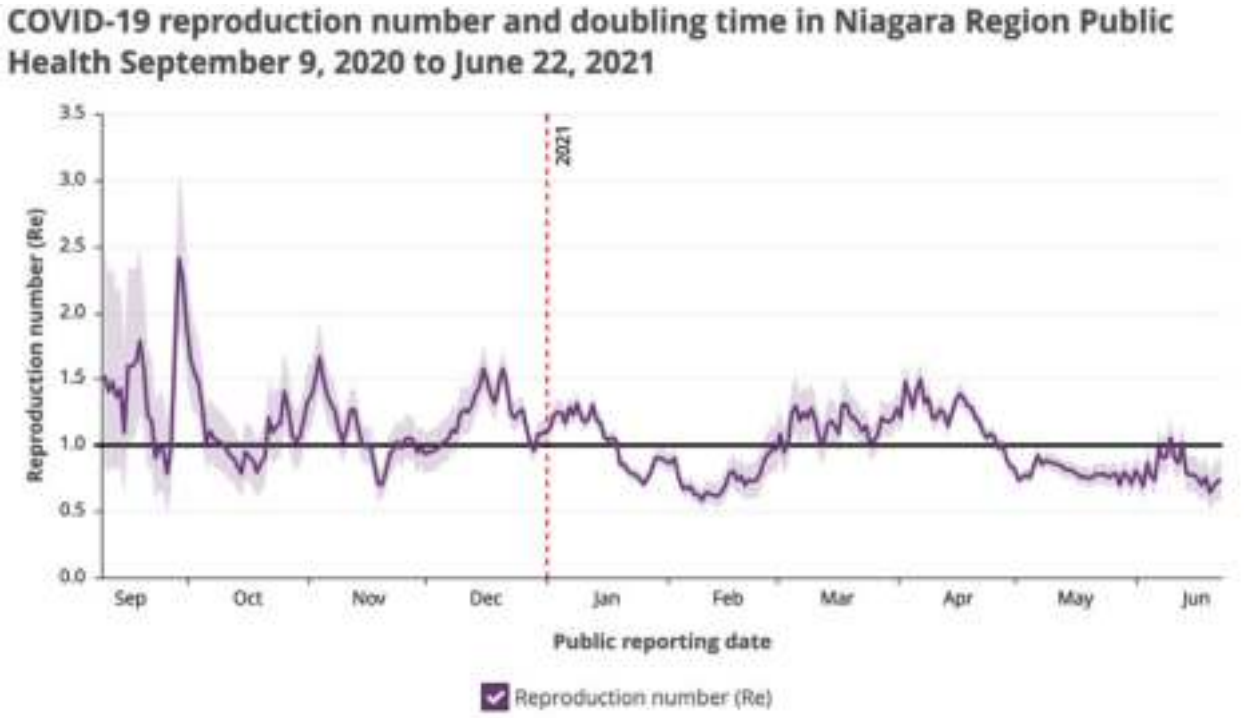
[36] See **Exhibit "N"**, *supra* note 28.

Using the day with the highest number of new cases, (200 cases, April 12, 2021), Kettner's 1/5000 estimate would more correctly be 1/1937, or 2.58 times greater.

57. Finally, Dr. Kettner's model fails to consider transmission dynamics over time. Using his rate of 1/5000 per day with the first infection on a Monday and services on Sunday, 7/5000 people will be infected by the first Sunday, 5 will be within Dr. Kettner's 10 days of infectiousness and 2 within Kettner's period of presymptomatic COVID (para 53). Using Dr. Kettner's 8% risk of transmission, the risk of infection from a symptomatic case on the first Sunday would be 5/5000*0.08 = 0.00008 (1 in 12500), but a week later the risk would have increased to 12/5000*0.08 = 0.000192 (1 in 5208), and that ignores the secondary cases, both within households and in the wider community. Dr. Kettner's model does not appear to account for the effective reproduction rate ("Re") during the period under consideration (March 14, 2020- April 29, 2021). Data provided by Public Health Ontario and shown in Figure 1 below indicate that the effective reproduction rate varied during this period and was greater than 1 for several weeks. Re greater than 1 means that exponential growth in the number of new cases is occurring yet Dr. Kettner's model picks 1/5000 as the constant correct rate and applies it across the entire time

period. This oversimplification fails to acknowledge the rapid growth rates of COVID-19 cases that occurred during the peaks of the second and third waves of COVID in Ontario.

FIGURE 1[37]



58. In summary, a model that uses the wrong geography, makes no account for household transmission dynamics, assumes a constant incidence over a period when incidence varied

[37] See **Exhibit "R":** Public Health Ontario, "Ontario COVID-19 Data Tool", online: <https://www.publichealthontario.ca/en/data-and-analysis/infectious-disease/covid-19-data-surveillance/covid-19-data-tool?tab=retd> (accessed 27 June 2021; configured to Niagara Region Public Health, 09 Sep 2020 – 22 Jun 2021).

significantly and included weeks with exponential growth (Re> 1), and which ignores the effects of time in transmission dynamics is not one to be recommended as a basis for policy decisions.

AFFIRMED by video conference by
MATTHEW HODGE of the [redacted]
in the Province of Ontario before me on this
2nd Day of July, 2021 in accordance with
O Reg 431/20, Administering Oath or
Declaration Remotely

Commissioner for the Taking of Affidavits

MATTHEW HODGE

This is "**Exhibit A**"
to the Affidavit of Matthew Hodge,
affirmed this 2nd day of July, 2021

A Commissioner, etc.

MATTHEW HODGE, MDCM, PhD, CCFP(EM), FRCPC

Informatics and metrics-savvy physician leader committed to quality improvement, developing people, value-for-money and reliable operational excellence supported by data and information systems. Results-focused physician executive with leadership experience in public health, health care delivery, and international health organizations; public health & preventive medicine specialist and practicing ER physician.

PROFESSIONAL EXPERIENCE & ACCOMPLISHMENTS

EMERGENCY DEPARTMENT PHYSICIAN, Toronto, ON **June 2011 - ongoing**
Providing clinical services in hospitals ranging from Rainy River to major academic centres in Toronto, currently at SRH, General & Birchmount sites and locum small hospital work in Grey-Bruce and NE Ontario.

CONSULTANT PHYSICIAN **June 2011 - ongoing**
Recent engagements include defining an analytic strategy to position a public health organization to focus its program efforts in early child development, redesigning public health inspection services, and ED operations consulting with Canadian startup Metricaid. Previous engagements have included LEAN-driven Emergency Department improvement projects, review and recommendations for restructuring and reorienting surveillance activities in a public health organization, and assessment of efficiency and provider mix in primary care. COVID work has included engagements with PHAC, PHO & Peel Region Public Health.

MEDICAL MANAGER, RMFCU. APFRB, MOHLTC, Toronto, ON **January 2016 – April 2017**
Providing clinical expertise to Risk Management & Fraud Control Unit (RMFCU) within the Corporate Services Division of the MOHLTC. Developed a strategic framework focused on deterrence, recovery and value to prioritize efforts and established analytic platform for post-payment review of expenditures.

CANCER CARE ONTARIO, Toronto, ON **March 2010 – June 2011**
Chief Medical Information Officer, & Director, Informatics
Led 140 informatics staff supporting cancer service management and Access-to-Care (Ontario-wide wait times for surgery, diagnostic imaging and Emergency Department care); represented CCO at provincial bodies including ER-ALC expert panel. Managed budget of CDN$16M.

Developed 'one informatics' plan to i) unify disparate informatics resources across the organization, ii) rationalize processes using LEAN and iii) engage and support hospitals and other health care delivery organizations directly in their performance improvement efforts; aligned enterprise architecture development, $2M electronic data warehouse project and business intelligence strategy around shared vision of the patient journey; led division with highest staff satisfaction scores.

UNITED NATIONS POPULATION FUND (UNFPA), New York, NY **January 2008 – February 2010**
Chief, Evaluation Branch, Division of Oversight Services
Led review and revision of evaluation program; subsequently promoted to Chief, Evaluation. Conducted or supervised 8 evaluations of country programmes with internal auditors; resulting tools established a shared audit & evaluation risk-based framework for evaluating relevance and strategic alignment of the Fund's country programmes, comprising $300M in annual expenditures. Reduced time from fieldwork to final report from over 360 days to 30 days. Led and participated in cross-functional audit/evaluation teams in the field in Africa and Asia. Contributed to the Fund's development of an evaluation policy.

CITY OF HAMILTON PUBLIC HEALTH SERVICES, Hamilton, ON **February 2005 – October 2007**
Associate Medical Officer of Health
Led epidemiology & evaluation within municipal public health department including responsibility for surveillance and emergency planning. Transformed $800K Public Health Research Education and Development (PHRED) program from unaccountable fund to competitive grants program; developed and implemented program evaluation cycle with self-assessment, epidemiologic best-evidence and peer review; led investigation, media and provincial liaison during legionella outbreak (2006) and provided ongoing medical expertise to communicable disease and environmental health investigations; represented Canada's

pubic health practitioners on Integration Working Group for Canada Health Infoway-funded communicable disease surveillance system (Panorama), 2006 - 2008

MCMASTER UNIVERSITY, Hamilton, ON **July 2005 - ongoing**

Associate Professor, Clinical Epidemiology & Biostatistics
Developed management education for Public Health & Preventive Medicine residents, course director 2012, 2013, 2014, 2016.

UNIVERSITY HEALTH NETWORK, Toronto, ON **January 2001 – April 2012**

Staff Physician, Emergency Department
Member, Practice Plan & Finance Committees

UNITED NATIONS CHILDREN'S EMERGENCY FUND (UNICEF) October 2003 – June 2004

Consultant, Evaluation Office
Completed thematic evaluations of midterm progress on Strategic Plan goals in immunization and HIV/AIDS; policy development for HIV/AIDS care and support and technical support to UNICEF-funded projects to prevent mother-to-child transmission of HIV infection in 11 countries.

MINISTRY OF HEALTH & LONG-TERM CARE, Toronto, ON **September 2002 – March 2003**

Senior Medical Consultant, Public Health Branch

Negotiated terms of MOHLTC pilot funding for colorectal cancer screening to be implemented by Cancer Care Ontario; SARS response.

UNITED NATIONS CHILDREN'S EMERGENCY FUND (UNICEF) September 2001 – September 2002

Senior Health Advisor, HIV/AIDS

WORLD HEALTH ORGANIZATION (WHO), Geneva, SUI **January 1999 – July 2001**

Medical Officer

EDUCATION AND PROFESSIONAL CERTIFICATIONS

MS, **Masters of Health Care Management, Harvard University**, 2011 (Mid-career physician management and leadership training program offered by Harvard School of Public Health)
MSIT, **Master of Science (Inf. Technology), Carnegie Mellon University,** 2008
MSc, **Development Finance, University of London**, 1999
MDCM, **McGill University**, 1996
PhD, **McGill University,** 1995 (MD-PhD Program, Thesis Title: Methods for Geographic Analyses of Health Services Use)
BA, **Economics, Yale University**, 1987
College of Physicians & Surgeons of Ontario (CPSO): Medical License #70425
Fellow, Royal College of Physicians and Surgeons of Canada, 2000
Public Health & Preventive Medicine
Diplomate, American Board of Preventive Medicine, 2007
Clinical Informatics Certification, American Board of Preventive Medicine, 2013
Certificate of Special Competence in Emergency Medicine, (CCFP(EM)), 2012

COMMUNITY CONTRIBUTIONS

Advisor, MARS Discovery District: providing advice to start-ups in the Health practice, 2014-ongoing
Public Health Physicians of Canada, formerly National Specialty Society for Community Medicine
President, 2009 – 2011; Treasurer, 2008 - 2009
Event Physician, Athletics Canada National Cross Country Championships, 2007 – 2010

Ontario Health Plan for an Influenza Pandemic

Chapter 1: Introduction

Audience

- health sector employers, health care providers and other health workers, emergency planners, health administrators and other provincial health system partners

Chapter objectives

- to introduce and orient readers to the 2013 Ontario Health Plan for an Influenza Pandemic (OHPIP)

Introduction

The Ministry of Health and Long-Term Care (MOHLTC) leads the development of the OHPIP to support the provincial health system to prepare for and respond to an influenza pandemic.

Since the release of the first iteration of the plan in 2004, the OHPIP has been regularly updated to reflect new knowledge, information and best practices. This process is supported by the OHPIP Steering Committee – which consists of representatives from health associations, unions, regulatory bodies and government organizations – and a variety of workgroups (See Appendix A – OHPIP Steering Committee and workgroup members).

The OHPIP supported the provincial health system's response to the 2009 H1N1 influenza pandemic (pH1N1). Although a number of simulated scenarios have been held over the years to exercise components of the OHPIP, pH1N1 was the first opportunity to use the plan to guide the response to a pandemic.

The 2013 version of the OHPIP was updated to incorporate the priority lessons learned and best practices from pH1N1. More information about Ontario's evaluation of the response to pH1N1 can be found in Pandemic (H1N1) 2009: A Review of Ontario's Response and The H1N1 Pandemic – How Ontario Fared: A Report by Ontario's Chief Medical Officer of Health.

Previous versions of the OHPIP have used World Health Organization (WHO) and Public Health Agency of Canada (PHAC) response plans as a conceptual foundation. These pandemic response plans are in the process of being revised based on the lessons learned and best practices from pH1N1. Some concepts that were previously incorporated in the OHPIP aren't in the 2013 iteration as they haven't yet been updated by the WHO and PHAC. For example, the WHO's six-phase description of a pandemic featured in previous versions of the OHPIP and Canadian Pandemic Influenza Plan for the Health Sector (CPIP). An evaluation by an external review committee on the functioning of the International Health Regulations (2005) in relation to pH1N1 recommended that the WHO simplify the pandemic phase structure. As the WHO has not released an updated plan since the evaluation was released, the phase structure is not included in this version of the OHPIP.

This is the final iteration of the OHPIP. The Ontario Influenza Response Plan *(*OIRP) will eventually replace it. Through this new plan, the provincial health system's focus will shift from preparing for an influenza pandemic to creating and building effective seasonal influenza responses and escalating those measures during a pandemic. The OIRP will link to updated pandemic response plans from the WHO and PHAC, and it will also address the next steps documented in this version of the OHPIP and outstanding lessons learned and best practices from pH1N1. The OIRP will outline influenza responses for the entire health system, including government, primary health care, community care, hospitals and public health.

Roles and responsibilities

All health system partners have a role to play during the response to an influenza pandemic, from the WHO at the international level to health sector employers and health workers at the community level.

The MOHLTC leads the Government of Ontario's response to an influenza pandemic through health system coordination and direction.[1] Within the MOHLTC's emergency response structure, there are many individuals and groups who provide operational and/ or strategic direction to guide the response. For example, the Chief Medical Officer of Health (CMOH) has legislated responsibilities under the Health Protection and Promotion Act (HPPA) and is the MOHLTC's Executive Lead during the response to an influenza pandemic. This means that the CMOH provides strategic leadership for the MOHLTC's response.

In the OHPIP, references to the MOHLTC include the Minister, CMOH and other individuals/ groups in the MOHLTC (e.g., Deputy Minister, Ministry Action Group). Please see the Ministry Emergency Response Plan for more detail on the MOHLTC's emergency response structure and decision-making process.

Table 1 outlines general roles and responsibilities of health system partners during an influenza pandemic. Each OHPIP chapter includes more detailed roles and responsibilities relevant to the chapter topic.

[1] As per the Emergency Management and Civil Protection Act, the MOHLTC assumes the role of primary ministry for emergencies, declared and undeclared, when the primary Government of Ontario response falls under the ministry's emergency responsibilities of "human health, disease and epidemics" or "health services during an emergency" as assigned by Order in Council (OIC) 1157/2009. The MOHLTC responds to the impacts on the health of Ontarians and on the health system.

TABLE 1. GENERAL INFLUENZA PANDEMIC RESPONSE ROLES AND RESPONSIBILITIES[2]

Party	Roles and responsibilities
WHO	Coordinate international response activities under the International Health Regulations Perform international surveillance and provide an early assessment of pandemic severity in order to help countries determine the level of intervention needed in the response Declare an influenza pandemic Select the pandemic vaccine strain and determine the time to begin production of the pandemic vaccine
PHAC	Coordinate national pandemic influenza response activities, including nation-wide surveillance, international liaison and coordination of the vaccine response, as outlined in the CPIP

[2] The information in this table is intended to provide general information about roles and responsibilities of different parties during an influenza pandemic. It is not a comprehensive listing of roles or obligations of a party. Roles, responsibilities and obligations of a party vary in specific circumstances.

Party	Roles and responsibilities
MOHLTC (through the Ministry Emergency Operations Centre (MEOC))	Liaise with PHAC and other provinces and territories Collaborate with Public Health Ontario (PHO) to use surveillance information to determine severity Develop recommendations[3] and provincial response strategies[4] for the provincial health system, as well as others affected by public health measures Communicate with provincial health system partners through situation reports, Important Health Notices (IHNs), the Health Care Provider Hotline, the Health Stakeholder Teleconference, the MOHLTC website and other methods Develop and issue directives[5], orders and requests as per the HPPA, Long-Term Care Homes Act and other relevant provincial legislation[6] Communicate with the public through media briefings, the MOHLTC website and other methods Solicit and respond to feedback and input from provincial health system partners Deploy supplies & equipment from the MOHLTC stockpile to health workers and health sector employers Deploy antivirals from the MOHLTC stockpile to community-based pharmacies and other dispensing sites

[3] This term refers to best practices as well as guidance on the risk posed by the pandemic. Recommendations related to occupational health and safety (OHS) may be considered by health sector employers to be reasonable precautions in the application of the Occupational Health and Safety Act (OHSA).

[4] Provincial response strategies include the surveillance strategy, public health measures strategy, outpatient care & treatment strategy, antiviral distribution strategy, immunization strategy and supplies & equipment strategy

[5] Directives are sent from the CMOH to health care providers or other health entities as per the HPPA.

[6] The OHSA continues to apply during an influenza pandemic and prevails when there is a conflict between that act and any other legislation.

Party	Roles and responsibilities
Public Health Ontario (PHO) (through the MEOC)	Support the MOHLTC to use surveillance information to determine severity Lead and coordinate the provincial surveillance strategy Coordinate and provide provincial influenza laboratory testing Provide scientific and technical advice to the MOHLTC (e.g., advice on infection prevention and control measures) Generate knowledge translation tools and offer training opportunities to supplement the MOHLTC's recommendations, directives and response strategies
Ministry of Labour (MOL)	Provide OHS advice to the MOHLTC (through the MEOC) Enforce the OHSA and its regulations
Emergency Management Ontario	Coordinate the provincial response to an influenza pandemic, with an emphasis on coordinating responses to non-health system impacts and consequences as outlined in the Provincial Coordination Plan for an Influenza Pandemic
Local Health Integration Networks (LHINs)[7]	Liaise between transfer payment (TP) organizations and the MOHLTC Participate in the coordination of local care & treatment
Public health units (PHUs)[8]	Follow MOHLTC recommendations, directives, orders and requests Develop and issue orders[9] Lead local implementation of the surveillance strategy Lead local implementation of immunization Participate in the coordination of local care & treatment Lead local implementation of public health measures Continue to provide other public health services

[7] Other LHIN roles during an influenza pandemic are currently under development.

[8] Throughout the OHPIP, PHU includes boards of health, medical officers of health (MOHs) and other PHU health workers (e.g., public health inspectors, epidemiologists, public health nurses, etc.). See the HPPA and Ontario Public Health Standards for more information on the roles and responsibilities of various PHU parties.

[9] This refers to orders made by MOHs and public health inspectors as per the HPPA.

Party	Roles and responsibilities
Health liaison organizations (provincial associations, unions and regulatory bodies)	Liaise between members and the MOHLTC (see Chapter 2: Health Sector Communications) Share best practices among sector/ membership
Health workers and health sector employers[10]	Follow MOHLTC recommendations, directives, orders and requests Follow PHU orders Continue to provide safe and effective care Participate in the coordination of local care & treatment Participate in research and surveillance activities Practice and role model appropriate behaviour to protect clients/ patients/ residents (C/P/Rs) and prevent further spread of influenza (e.g., get immunized; practise respiratory etiquette and hand hygiene; stay home when sick)
Other employers	Implement public health measures Follow MOHLTC orders and requests Follow PHU orders Encourage immunization among employees Be immunized as soon as possible
Public	Follow public health measures such as staying home when symptomatic, performing hand hygiene and keeping commonly touched surfaces clean Follow MOHLTC and PHU orders Be immunized as soon as possible

Ontario's approach to an influenza pandemic

The 2013 OHPIP is a response document. As opposed to providing detailed planning guidance for provincial health system partners, it outlines anticipated response activities

[10] See Chapter 5: Occupational Health & Safety and Infection Prevention & Control and Chapter 9: Primary Health Care.

based on the severity of the pandemic virus. The actual response activities will be confirmed by the MOHLTC at the time of a pandemic based on the epidemiology of the virus (see Chapter 3: Surveillance), impacts on the provincial health system and behavioural responses of the public. Before these things are known, the MOHLTC considers the precautionary principle in making decisions. During the planning phase, provincial health system partners are encouraged to review the response activities outlined in the OHPIP and take steps to ensure they are able to perform their role during an influenza pandemic. Health system partners are also encouraged to have continuity of operations plans in place that enable them to respond to any type of business disruption, including an influenza pandemic.

The MOHLTC recognizes that planning to respond to an influenza pandemic is not enough.

To ensure an effective pandemic response, health workers and health sector employers need to appropriately respond to seasonal influenza each year – including consistently applying appropriate OHS & infection prevention & control (IPAC) measures; effectively promoting and administering influenza immunization programs for C/P/Rs, health workers and members of the public; implementing timely epidemiological and laboratory surveillance; engaging and tailoring interventions to the needs of vulnerable populations; and promoting appropriate public health measures

Preparedness tip

Health organizations should develop a continuity of operations plan to support their ability to respond to emergencies, such as an influenza pandemic. PHUs can use the Ontario Public Health Standards' Public Health Emergency Preparedness Protocol to guide their planning.

Ontario's influenza pandemic response objectives

The objectives of the MOHLTC's response to an influenza pandemic are consistent with those in the CPIP:

- first, to minimize serious illness and overall deaths through appropriate management of Ontario's health system
- second, to minimize societal disruption in Ontario as a result of an influenza pandemic

Guiding principles

The actions of the MOHLTC during a pandemic response are based on the following guiding principles. Many of these principles are useful in guiding the decision making of

other parties, including health sector employers, health workers, emergency planners and other public health leaders.

Evidence

The MOHLTC uses scientific and technical evidence to inform decision-making, including evidence on the risk posed by the pandemic. The MOHLTC partners closely with PHO to obtain, understand and communicate the evidence.

Legislation

The MOHLTC responds based on provincial legislative requirements and responsibilities.

Precautionary principle

The MOHLTC does not await scientific certainty before taking action to protect health. For example, the MOHLTC considers the precautionary principle when developing recommendations and directives related to OHS & IPAC measures, especially during the early stages of an influenza pandemic when scientific evidence on the severity of the novel virus is limited.[11]

See Chapter 5: Occupational Health & Safety and Infection Prevention & Control for more information on the application of the precautionary principle to OHS.

Ontario Public Service values

The MOHLTC uses the Ontario Public Service values to inform decision making during an influenza pandemic.

Work is underway federally to develop an ethical framework for the CPIP. Future versions of the OIRP will include an ethical framework that aligns with that in the CPIP.

Health equity

The MOHLTC considers the needs of vulnerable populations[12] when developing response and recovery measures.

---

[11] As outlined in the HPPA, the CMOH must consider the precautionary principle when issuing a directive to a health care provider or health care entity related to health worker health and safety in the use of any protective clothing, equipment or device.

[12] The OHPIP defines vulnerable populations as a group of people who, because of the determinants of health, are more likely to be exposed to influenza, more likely to

To accomplish this, the MOHLTC may use the Health Equity Impact Assessment (HEIA), a decision support tool developed by the ministry to identify how a health program, service or policy impacts population groups in different ways. Work is underway at the MOHLTC to adapt the HEIA for a health emergency management context to ensure that provincial and local interventions do not exacerbate health disparities during an emergency.

Communication principles

The MOHLTC bases its communications with the provincial health system and the public on the following principles[13]:

- timeliness
- transparency
- accessibility
- credibility

Assumptions

The 2013 OHPIP is based on the following assumptions:

Origin and Timing

- The next pandemic could emerge anywhere in the world – including in Ontario.
- The next pandemic could emerge at any time of year.
- Ontario has little lead time between when a pandemic virus is first identified and when it arrives in the province.

Transmission

- The pandemic virus behaves like seasonal influenza viruses in significant ways, including the incubation period, period of communicability and methods of transmission.
- The pandemic strain is primarily community spread; that is, it is transmitted from person-to-person in the community as well as in institutional settings.

---

experience a serious impact because of exposure, less likely to benefit from response and recovery measures and/ or who may be negatively affected by response and recovery measures.

[13] See Chapter 2: Health Sector Communications for more information on the application of these principles to the MOHLTC's two-way communications with the health system.

Pandemic Epidemiology

- An influenza pandemic consists of two or more waves – or intense periods – of viral transmission.
- The novel influenza virus displaces other circulating seasonal strains during the pandemic.

Clinical Features

- As with seasonal influenza, the severity of the pandemic cannot be predicted, may be partially determined by the effectiveness of interventions such as treatment with antivirals and is not easily determinable at the start of an outbreak. (See Severity of an influenza pandemic for more information on the scenarios used to guide the development of the 2013 OHPIP).
- As with seasonal influenza, the clinical severity of the illness experienced by Ontarians who are infected by the pandemic virus varies considerably: some individuals who are infected do not display any clinical symptoms, while others become quite ill and may require hospitalization and may even die.
- The groups at increased risk for severe disease and complications during an influenza pandemic are similar to those for seasonal influenza; however, there may be additional high-risk groups because of specific features of the pandemic virus.
- Vulnerable populations that typically experience a disproportionate burden of negative health outcomes, or are more vulnerable to these outcomes, because of the effects of the social determinants of health are more severely affected by the pandemic than other members of the community. This includes Ontarians with low incomes, who face language barriers, and who are homeless.

Interventions

- Vaccine is available in time to have an impact on the overall pandemic; however, it is not available for the first wave.
- The MOHLTC maintains an antiviral stockpile to provide treatment for individuals that meet its clinical recommendations.
- The efficacy and dose requirements of antivirals are not known until the pandemic begins and may differ from that of seasonal influenza; therefore, recommendations may change.

Severity of an influenza pandemic

Given that the severity of a pandemic cannot be known in advance, the anticipated response activities outlined in the 2013 OHPIP are based on a number of severity scenarios adapted from draft work undertaken by the Centers for Disease Control and Prevention. In this model, severity is measured along two dimensions – transmissibility of the virus and clinical severity of illness. There are four severity scenarios – ranging from a mild scenario that is similar to seasonal influenza (low transmissibility and low

clinical severity) to the most severe scenario with high transmission and high clinical severity rates.

As well, the OHPIP severity model includes an initial stage before severity is known when the limited availability of surveillance data does not allow for confident identification of severity. The severity may not be clearly known until after an influenza pandemic is over. The MOHLTC uses surveillance data to estimate severity (see Chapter 3: Surveillance).

This model has been used to provide information on the types of responses that may be used during an influenza pandemic. As more information about the severity of an influenza pandemic is available, the MOHLTC will establish and communicate the provincial response strategies such as the outpatient care & treatment strategy, immunization strategy, public health measures strategy, antiviral distribution strategy and surveillance strategy.

Figure 1 outlines the four severity scenarios used in the OHPIP. Table 2 outlines how various influenza pandemics and seasonal epidemics are categorized in this model and the major health system impacts.

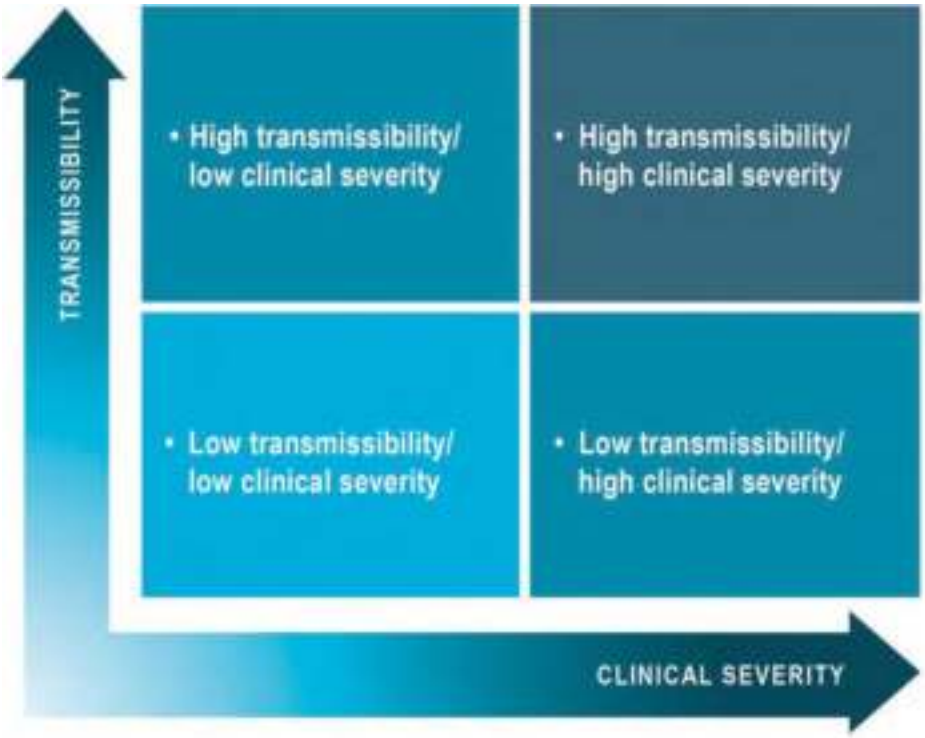

FIGURE 1. FOUR SEVERITY SCENARIOS USED IN THE OHPIP

TABLE 2. EXAMPLES AND IMPACT OF SEVERITY SCENARIOS

Overall severity	Characteristics	Examples	Impact on health system
Before severity is known	Limited surveillance data available	Either in the pre-pandemic phase or early in the pandemic, before there is enough information available to determine the severity of the pandemic	Unknown
Low transmissibility & low clinical severity	Cumulative attack rate[14]: < 21% R_0 (basic reproduction number)[15]: <1.6 Case Fatality Rate (CFR)[16]: <0.25%	Typical seasonal influenza epidemics 2009 influenza pandemic 1968 influenza pandemic	Comparable to seasonal influenza
High transmissibility & low clinical severity	Cumulative attack rate: ≥21% $R_0 \geq 1.6$ CFR: <0.25%	1927-28 seasonal influenza epidemic	Significant workplace absenteeism High burden on outpatient and acute services
Low transmissibility & high clinical severity	Cumulative attack rate: < 21% R_0: <1.6 CFR: ≥0.25%	1957 influenza pandemic	High burden on critical health care services

[14] The cumulative attack rate is the percentage of people who (are expected to) become symptomatic at some point during the influenza pandemic.

[15] The basic reproductive number is the number of secondary cases one case should produce in a completely susceptible population.

[16] The case fatality rate is the ratio of deaths within a designated population of cases over the course of a pandemic.

Overall severity	Characteristics	Examples	Impact on health system
High transmissibility & high clinical severity	Cumulative attack Rate: ≥21% R_0≥1.6 CFR: ≥0.25%	1918 influenza pandemic	Significant need for public health measures High burden on critical health care services

In addition to the characteristics of the virus, other factors – including the effectiveness of interventions, the behavioural response of Ontarians, the capacity of Ontario's health system and the social determinants of health – determine the impact of the pandemic.

Another consideration is that novel influenza viruses may differentially affect specific populations. For example, while the severity of a pandemic may be comparable to seasonal influenza (low transmissibility and low clinical severity), transmissibility or clinical severity could be significantly higher in specific population groups (e.g., children and youth). Therefore, the MOHLTC may need to develop recommendations and response strategies during an influenza pandemic to address specific population needs.

Next steps

In the development of the OIRP, the MOHLTC will work with its partners to:

- continue to clarify the role of LHINs in influenza pandemic response
- align the OIRP with the CPIP, including
  - the measurement of pandemic severity
  - ethical framework
- further develop strategies to support vulnerable populations, including adapting the HEIA for a health emergency management context

Appendix A – OHPIP Steering Committee and workgroup members

The MOHLTC is grateful to the following organizations and their members for their contributions to the 2012-13 OHPIP Steering Committee, workgroups and consultations:

- Aboriginal Affairs and Northern Development Canada
- Association of Family Health Teams of Ontario
- Association of Iroquois and Allied Indians
- Association of Local Public Health Agencies
- Association of Municipalities of Ontario
- Association of Ontario Health Centres
- Chiefs of Ontario
- Critical Care Services Ontario
- Emergency Management Ontario, Ministry of Community Safety and Correctional Services
- Emergency Nurses Association of Ontario
- Federation of Health Regulatory Colleges of Ontario
- First Nations and Inuit Health Branch, Ontario Region
- Independent First Nations
- Local Health Integration Networks
- Ministry of Children and Youth Services
- Ministry of Community and Social Services
- Ministry of Labour
- Nishnawbe Aski Nation
- Nurse Practitioners Association of Ontario
- Ontario Association for Non-Profit Homes and Services for Seniors
- Ontario Association of Community Care Access Centres
- Ontario Association of Medical Laboratories
- Ontario College of Family Physicians
- Ontario Community Support Association
- Ontario Home Care Association

- Ontario Hospital Association
- Ontario Long-Term Care Association
- Ontario Medical Association
- Ontario Nurses' Association
- Ontario Pharmacists' Association
- Ontario Public Services Employees Union
- Public Health Agency of Canada, Ontario and Nunavut Region
- Public Health Ontario
- Public Services Health & Safety Association
- Registered Nurses' Association of Ontario
- Union of Ontario Indians (Anishinabek Nation)

Appendix B – Glossary

Additional precautions

Additional precautions (i.e., contact precautions, droplet precautions and airborne precautions) that are necessary in addition to routine practices for certain pathogens or clinical presentations. These precautions are based on the method of transmission (e.g., contact, droplet, airborne). (Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in All Health Care Settings).

Adverse event

Adverse events are an unexpected and undesired incident directly associated with the care or services provided to the client/patient/resident (Source: Provincial Infectious Disease Advisory Committee's Best Practices for Infection Prevention and Control Programs in Ontario).

Aerosol-generating medical procedure

Aerosol-generating medical procedures are any procedure carried out on a client, patient or resident that can induce the production of aerosols as a result of manipulation of a person's airway. Examples of aerosol-generating medical procedures include intubation and related procedures (e.g., manual ventilation, open endotracheal suctioning); cardiopulmonary resuscitation; bronchoscopy; sputum induction; nebulized therapy; surgery and autopsy; and bi-level positive airway pressure (i.e., BiPAP) (Source: Canadian Pandemic Influenza Plan for the Health Sector).

Affiliated clients/ patients

Also known as rostered clients/ patients. Affiliated clients/ patients are formally enrolled with a primary health care organization, such as a family health team, community health centre or Aboriginal health access centre. Clients/ patients that are affiliated with a primary health care organization typically do not seek primary health care services in other locations.

Airborne precautions

Airborne precautions are used in addition to routine practices for clients/ patients/ residents known or suspected of having an illness transmitted by the airborne route (i.e., by small droplet nuclei that remain suspended in the air and may be inhaled by others)

(Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in all Health Care Settings).

Client/ patient/ resident

Any person receiving health care services within a health care setting (Source: Provincial Infectious Disease Advisory Committee's Best Practices for Infection Prevention and Control Programs in Ontario).

Client/ patient/ resident environment

The immediate space around a client/ patient/ resident that may be touched by the client/ patient/ resident and may also be touched by the health care provider when providing care. The client/ patient/ resident environment includes equipment, medical devices, furniture (e.g., bed, chair, bedside table), telephone, privacy curtains, personal belongings (e.g., clothes, books) and the bathroom that the client/ patient/ resident uses. In a multi-bed room, the client/ patient/ resident environment is the area inside the individual's curtain. In an ambulatory setting, the client/ patient/ resident environment is the area that may come into contact with the client/ patient/ resident within their cubicle. In a nursery/ neonatal setting, the patient environment is the isolette or bassinet and equipment outside the isolette/bassinet that is used for the infant. Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in all Health Care Settings).

Cohorting

The assignment of a geographic area such as a room or a care area to two or more clients/ patients/ residents who are either colonized or infected with the same microorganism, with staffing assignments restricted to the cohorted group of patients (Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in all Health Care Settings).

Contact tracing

The process of identifying relevant contacts of a person with an infectious disease and ensuring that they are aware of their exposure (Source: Provincial Infectious Disease Advisory Committee's Sexually Transmitted Infections Case Management and Contact Tracing Best Practice Recommendations).

Directives

Instructions that may be issued by the Chief Medical Officer of Health under the terms of the Health Protection and Promotion Act. A health care provider or health care entity that is served with a directive must comply with it.

Eye protection

A device that covers the eyes and is used by health care providers to protect the eyes when it is anticipated that a procedure or care activity is likely to generate splashes or sprays of blood, body fluids, secretions or excretions, or within two metres of a coughing client/patient/resident. Eye protection includes safety glasses, safety goggles, face shields and visors (Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in all Health Care Settings).

Fit-test

A qualitative or quantitative method to evaluate the fit of a specific make, model and size of respirator on an individual. Fit-testing is to be done periodically, at least every two years and whenever there is a change in respirator face piece or the user's physical condition that could affect the respirator fit (Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in all Health Care Settings).

Flu assessment centre

Temporary services during an influenza pandemic provided by primary health care organizations or emergency departments to provide influenza care & treatment services to community members who cannot rapidly access primary health care, with temporary financial and material support of the Ministry of Health and Long-Term Care.

Hand hygiene

A general term referring to any action of hand cleaning. Hand hygiene relates to the removal of visible soil and removal or killing of transient microorganisms from the hands. Hand hygiene may be accomplished using soap and running water or an alcohol-based hand rub. Hand hygiene also includes surgical hand antisepsis (Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in all Health Care Settings).

Health and safety representative

Workplaces with more than five workers and no joint health and safety committee must have a health and safety representative [section 8(1)]. Like joint health and safety committee members, the representative is committed to improving health and safety conditions in the workplace. (Source: Ministry of Labour's A Guide for Joint Health and Safety Committees and Representatives in the Workplace).

Health care-associated infection

A term relating to an infection that is acquired during the delivery of health care services (also known as '*nosocomial infection'*) (Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in all Health Care Settings).

Health care facility

A set of physical infrastructure elements supporting the delivery of health care services. A health care facility does not include a client's/ patient's home or physician offices where health care services may be provided (Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in all Health Care Settings).

Health care provider

Any person delivering health care services to a client/ patient/ resident. This includes, but is not limited to, the following: emergency service workers, physicians, dentists, nurses, respiratory therapists and other health professionals, personal support workers, clinical instructors, students and home health care workers. In some non-acute settings, volunteers might provide care and would be included as a health care provider. See also, *Staff* (Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in all Health Care Settings).

Health Care Provider Hotline

24/7 line for health care providers to contact the Ministry of Health and Long-Term Care's Emergency Management Branch (1-866-212-2272). This Hotline can be used by health system partners to reach the ministry during the response to an emergency. It is also operational during non-emergencies to enable health system partners to inform the ministry of a hazard or risk that has the potential to become an emergency.

Health care setting

Any location where health care services are provided, including settings where emergency care is provided, hospitals, complex continuing care, rehabilitation hospitals, long-term care homes, mental health facilities, outpatient clinics, community health centres and clinics, physician offices, dental offices, offices of allied health professionals and home health care (Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in all Health Care Settings).

Health care services

Direct client/ patient/ resident care, including diagnostic, treatment and care services.

Health Equity Impact Assessment

The Ministry of Health and Long-Term Care's Health Equity Impact Assessment is a decision support tool that walks users through the steps of identifying how a program, policy or similar initiative impacts population groups in different ways. The Health Equity Impact Assessment surfaces unintended potential impacts. The end goal is to maximize positive impacts and reduce negative impacts that could potentially widen health disparities between population groups — in short, more equitable delivery of the program, service or policy.

Health liaison organization

A provincial health association, union or regulatory body that liaises between its members and the Ministry of Health and Long-Term Care during an emergency. These organizations are a critical conduit for information collection, analysis and dissemination. Health liaison organizations typically participate in the Health Stakeholder Teleconference. See Chapter 2: Health Sector Communications for more information.

Health organization

An organization or agency that receive funding from the Ministry of Health and Long-Term Care to provide health services.

Health sector

Part of the economy dealing with health-related issues in society. (Source: WHO's Health System Performance Website)

Health sector employer

A person in a health setting who employs one of more workers or contracts for the services of one or more workers and includes a contractor or subcontractor who performs work or supplies services and a contractor or subcontractor who undertakes with an owner, constructor, contractor or subcontractor to perform work or supply services.(Source: Based on the Occupational Health and Safety Act)

Health services

Services delivered by the health system, including health promotion, disease prevention, diagnostic, treatment and care services.

Health setting

Organizations and agencies that receive funding through the Ministry of Health and Long-Term Care to provide health services.

Health system

The people, institutions and resources, arranged together in accordance with established policies, to improve the health of the population they serve, while responding to people's legitimate expectations and protecting them against the cost of ill-health through a variety of activities whose primary intent is to improve health. (Source: WHO's Health System Performance Website).

Health worker

A person who performs work or supplies services for monetary compensation in a health setting (Source: based on the Occupational Health and Safety Act)

High-risk group

Population with an increased likelihood of becoming ill and/ or suffering serious health outcomes as a consequence of pandemic influenza virus infection.

Infection

The entry and multiplication of an infectious agent in the tissues of the host. Asymptomatic or sub-clinical infection is an infectious process running a course similar to that of clinical disease but below the threshold of clinical symptoms. Symptomatic or clinical infection is on resulting in clinical signs and symptoms (disease) (Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in all Health Care Settings).

Infection prevention & control

Evidence-based practices and procedures that, when applied consistently in health care settings, can prevent or reduce the risk of transmission of microorganisms to health care providers, other clients/patients/residents and visitors (Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in all Health Care Settings).

Infection prevention & control professional(s)

Trained individuals responsible for a health care setting's infection prevention & control activities. In Ontario, an infection prevention & control professional must receive a minimum for 80 hours of instruction in a Community and Hospital Infection Control Association of Canada endorsed infection control program within six months of entering their role and must acquire and maintain Certification in Infection Control when eligible (Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in all Health Care Settings).

Infection prevention & control program

A health care facility or organization (e.g., hospital, long-term care, continuing complex care, home care) program responsible for meeting the recommended mandate to decrease infections in the client/ patient/ resident, health care providers and visitors. The program is coordinated by health care providers with expertise in infection prevention & control and epidemiology (Source: Provincial Infectious Disease Advisory Committee's Best Practices for Infection Prevention and Control Programs in Ontario).

Influenza

A highly contagious, febrile, acute respiratory infection of the nose, throat, bronchial tubes and lungs caused by the influenza virus. It is responsible for severe and potentially fatal clinical illness of epidemic and pandemic proportions (Source: Canadian Pandemic Influenza Plan for the Health Sector).

Influenza-like illness

A cluster of symptoms resembling and that could be caused by influenza, without laboratory confirmation. Case definitions for influenza-like illness vary, and are provided during an influenza pandemic by the Ministry of Health and Long-Term Care,

Integrated Public Health Information System

The information technology system used by public health units to report case information on all reportable communicable diseases that are outlined in the Health Protection and Promotion Act. Public health units are responsible for collecting case information on reportable communicable diseases occurring within their boundaries and entering this information into this system.

Isolation

Separation, for the period of communicability, of infected persons or animals from others in such places and under such conditions as to prevent or limit the direct or

indirect transmission or the infectious agent from those infected to those who are susceptible or who may spread the agent to others. (Source: Canadian Pandemic Influenza Plan for the Health Sector)

Joint health and safety committee

Committee composed of people who represent the workers and the employer, as described under the Occupational Health and Safety Act. Together, they are committed to improving health and safety conditions in the workplace. Committees identify potential health and safety problems and bring them to the employer's attention. As well, members must be kept informed of health and safety developments in the workplace. (Source: Ministry of Labour's A Guide for Joint Health and Safety Committees and Representatives in the Workplace).

Key population groups for immunization

The key population groups for immunization are those groups that are eligible to receive the pandemic vaccine. Given that vaccine availability will increase over time, the key population groups will expand during the course of the pandemic immunization program (i.e., additional population groups will be added as more vaccine becomes available).

Local Health Integration Network transfer payment agency

Also known as Local Health Integration Network Health Service Providers. Organizations that Local Health Integration Networks are responsible for, including hospitals, divested psychiatric hospitals, community care access centres, community support service organizations, community mental health and addictions agencies, community health centres and long-term care homes.

Long-term care

A broad range of personal care, support and health services provided to people who have limitations that prevention them from full participation in the activities of daily living. The people who use long-term care services are usually the elderly, people with disabilities and people who have a chronic or prolonged illness (Source: Provincial Infectious Disease Advisory Committee's Best Practices for Environmental Cleaning for Prevention and Control of Infections).

Mandatory public health measures

Extraordinary actions that are supported by the Health Protection and Promotion Act designed to address and counter specific public health threats.

Ministry Emergency Operations Centre

Site where the Ministry of Health and Long-Term Care coordinates its response to an emergency.

Ministry of Health and Long-Term Care

Throughout the Ontario Health Plan for an Influenza Pandemic, the Ministry of Health and Long-Term Care includes the Minister, Chief Medical Officer of Health and the rest of the Ministry of Health and Long-Term Care. For information on how emergency decisions are made in the MOHLTC, please see the Ministry Emergency Response Plan.

N95 respirator

A personal protective device that is worn on the face and covers the nose and mouth to reduce the wearer's risk of inhaling airborne particles. A National Institute for Occupational Safety and Health-certified N95 respirator filters particles one micron in size, has 95% filter efficiency and provides a tight facial seal with less than 10% leak (Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in All Health Care Settings).

Outpatient settings

Pertaining to a health care organization that provides influenza care & treatment services for clients/ patients who are not hospitalized or admitted to a long-term care home. It includes primary health care organizations, hospital emergency departments, community-based pharmacies and home care settings.

Pandemic

An epidemic disease of widespread prevalence around the globe (Source: Canadian Pandemic Influenza Plan for the Health Sector).

Pandemic Precautions

Occupational health & safety and infection prevention & control precautions recommended in health care settings during an influenza pandemic (e.g., use of N95 respirators for health workers at risk of exposure to a client/ patient/ resident with influenza-like illness or that client/ patient/ resident's environment)

Personal protective equipment

Clothing or equipment worn by health workers for protection against hazards (Source: Based on Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in All Health Care Settings).

Point of care

The place where three elements occur together: the client/ patient/ resident, the health care provider, and care or treatment involving client/ patient/ resident contact (Source: Provincial Infectious Disease Advisory Committee's Best Practices for Infection Prevention and Control Programs in Ontario).

Precautions

Interventions to reduce the risk of transmission of microorganisms (e.g., client/ patient/ resident-to-client/ patient/ resident, client/ patient/ resident-to-worker, contact with the environment, contact with contaminated equipment). (Source: PIDAC's Best Practices for Environmental Cleaning for Prevention and Control of Infections)

Precautionary principle

A principle used by the Ministry of Health and Long-Term Care and Chief Medical Officer of Health to guide decision-making during an emergency. According to this principle, reasonable steps to reduce risk should not await scientific certainty (Source: Spring of Fear, Justice Archie Campbell).

Primary health care

Primary care (the provision of integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with clients/ patients and practicing in the context of family and community), disease prevention, health promotion, population health and community development within a holistic framework, with the aim of providing essential community-focused health care (Sources: World Health Organization, Institute of Medicine). Primary health care organizations include family health teams, community health centres, Aboriginal health access centres, departments of family medicine, nurse practitioner-led clinics and solo practitioners such as family physicians, general practitioners and pediatricians.

Provincial Infectious Disease Advisory Committee

A multidisciplinary scientific advisory body that provides to the Chief Medical Officer of Health evidence-based advice regarding multiple aspects of infectious disease identification, prevention and control (Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in all Health Care Settings).

Public Health Agency of Canada

A national agency that promotes improvement in the health status of Canadians through public health action and the development of national guidelines (Source: Provincial Infectious Disease Advisory Committee's Best Practices for Environmental Cleaning for Prevention and Control of Infections).

Public health measures

Non-pharmaceutical interventions that help to slow the spread of disease in the community.

Public Health Ontario

Formerly known as the Ontario Agency for Health Protection and Promotion. An arm's-length government agency dedicated to protecting and promoting the health of all Ontarians and reducing inequities in health. Public Health Ontario was created by legislation in 2007 and began operations in July 2008 with a mandate to provide scientific and technical advice to those working to protect and promote the health of Ontarians. Its vision is to be an internationally recognized centre of expertise dedicated to protecting and promoting the health of all Ontarians through the application and advancement of science and knowledge (Source: Provincial Infectious Disease Advisory Committee's Best Practices for Infection Prevention and Control in Perinatology).

Recommendations from the Ministry of Health and Long-Term Care

This term refers clinical, occupational health & safety and infection prevention & control guidance. Recommendations related to occupational health & safety may be considered reasonable precautions in the application of the Occupational Health and Safety Act.

Regional Infection Control Networks

Networks that coordinate and integrate resources related to the prevention, surveillance and control of infectious diseases across all health care sectors and for all health care providers, promoting a common approach to infection prevention & control and utilization of best-practices within the region (Source: Provincial Infectious Disease Advisory Committee's Best Practices for Environmental Cleaning for Prevention and Control of Infections).

Respiratory etiquette

Personal practices that help prevent the spread of bacteria and viruses that cause acute respiratory infections (e.g., covering the mouth when coughing, care when disposing of tissues) (Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in all Health Care Settings).

Routine practices

The system of infection prevention & control practices recommended by the Public Health Agency of Canada to be used with all clients/ patients/ residents during all care activities to prevent and control transmission of microorganisms in all health care settings (Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in all Health Care Settings).

Seal-check

A procedure that the health care provider must perform each time an N95 respirator is worn to ensure it fits the wearer's face correctly to provide adequate respiratory protection (Source: Provincial Infectious Disease Advisory Committee's Routine Practices and Additional Precautions in all Health Care Settings).

Sentinel health care provider

A health care provider that participates in a sentinel surveillance system. In Ontario, sentinel health care providers participate in Public Health Agency of Canada's FluWatch Program or the national Sentinel Vaccine Effectiveness Study. Ideally, Ontario would have adequate numbers of sentinel health care providers, representative of the population of the province, so that the information gathered from FluWatch and the Sentinel Vaccine Effectiveness Study could be applied to the population as a whole.

Seroprevalance

The proportion of a population that is seropositive – i.e., has been exposed to the influenza virus.

Surgical mask

Also known as procedure mask. Surgical masks are used as physical barriers to protect users from hazards, such as splashes of large droplets of blood or body fluids. Surgical masks are used for several different purposes, including being placed on sick people to limit the spread of infectious respiratory secretions to others. (Source: Based on United States Department of Labor Occupational Safety and Health Administration Fact Sheet: Respiratory Infection Control).

Surveillance

The systematic ongoing collection, collation and analysis of data with timely dissemination of information to those who require it in order to take action (Source: Provincial Infectious Disease Advisory Committee's Best Practices for Infection Prevention and Control Programs in Ontario).

Syndromic surveillance

The detection of individual and population health indicators of illness (i.e., signs and symptoms of infectious disease) that are discernible before confirmed laboratory diagnoses are made (Source: Provincial Infectious Disease Advisory Committee's Best Practices for Infection Prevention and Control Programs in Ontario).

Vaccine delivery agent

Health care providers who administer immunization outside of a public health unit.

Visitor

An individual who does not have an established relationship with a health organization. Visitors may be household contacts and friends that accompany clients/ patients to outpatient settings or visit clients/ patients/ residents in inpatient settings.

Voluntary public health measures

The behaviours and the environmental supports that create the conditions that support good public health practices.

Vulnerable population

A group of people who, because of the determinants of health, are more likely to be exposed to influenza, more likely to experience a serious impact because of exposure,

less likely to benefit from response and recovery measures and/ or who may be negatively affected by response and recovery measures.

Appendix C – Acronyms

AHAC	Aboriginal health access centre
BAL	bronchoalveolar lavage
CAEFISS	Canadian Adverse Events Following Immunization Surveillance System
CCIS	Critical Care Information System
CDC	Centers for Disease Control and Prevention
CFR	case fatality rate
CHC	community health centre
CMOH	Chief Medical Officer of Health
C/P/R	client/ patient/ resident
CPIP	Canadian Pandemic Influenza Plan for the Health Sector
EDSS	Emergency Department Syndromic Surveillance
EMCPA	Emergency Management and Civil Protection Act
ETT	endotracheal tube
FAC	flu assessment centre
F/P/T	federal - provincial - territorial
FF100	first few hundred
FHT	family health team
HCRF	Health Care and Residential Facilities regulation
HEIA	Health Equity Impact Assessment
HNS	Health Network System
HPPA	Health Protection and Promotion Act
HSR	health and safety representative
IHN	Important Health Notice
ILI	influenza-like illness
IMPACT	Immunization Monitoring Program ACTive
IPAC	infection prevention & control
iPHIS	Integrated Public Health Information System
IRS	internal responsibility system
JHSC	joint health and safety committee
LHIN	Local Health Integration Network

LTCHA	Long-Term Care Homes Act
MEOC	Ministry Emergency Operations Centre
MOH	medical officer of health
MOHLTC	Ministry of Health and Long-Term Care
MOL	Ministry of Labour
MRSA	methicillin-resistant *S. aureus*
NACI	National Advisory Committee on Immunization
NML	National Microbiology Laboratory
NP	nasopharyngeal
OHIP	Ontario Health Insurance Plan
OHPIP	Ontario Health Plan for an Influenza Pandemic
OHS	occupational health & safety
OHSA	Occupational Health and Safety Act
PEOC	Provincial Emergency Operations Centre
PHAC	Public Health Agency of Canada
PHO	Public Health Ontario
PHOL	Public Health Ontario Laboratories
PHU	public health unit
PICB	Performance Improvement and Compliance Branch
PIDAC	Provincial Infectious Disease Advisory Committee
PPE	personal protective equipment
R_0	basic reproduction number
RACE	recognize the hazard, assess the risk, control the risk and evaluate the controls
RICN	Regional Infection Control Network
RIDT	rapid influenza diagnostic testing
RP/AP	routine practices and additional precautions (i.e., PIDAC's Routine Practices and Additional Precautions in All Health Care Settings)
SARS	Severe Acute Respiratory Syndrome
TP	transfer payment
UIIP	Universal Influenza Immunization Program
VDA	vaccine delivery agent
WHO	World Health Organization

Coronavirus disease (COVID-19)

12 October 2020 | Q&A

Latest update 13 May 2021 - WHO is continuously monitoring and responding to this pandemic. This Q&A will be updated as more is known about COVID-19, how it spreads and how it is affecting people worldwide. For more information, regularly check the WHO coronavirus pages. https://www.who.int/covid-19

What is COVID-19?

What are the symptoms of COVID-19?

What happens to people who get COVID-19?

Among those who develop symptoms, most (about 80%) recover from the disease without needing hospital treatment. About 15% become seriously ill and require oxygen and 5% become critically ill and need intensive care.

Complications leading to death may include respiratory failure, acute respiratory distress syndrome (ARDS), sepsis and septic shock, thromboembolism, and/or multiorgan failure, including injury of the heart, liver or kidneys.

In rare situations, children can develop a severe inflammatory syndrome a few weeks after infection.

Who is most at risk of severe illness from COVID-19?

Are there long-term effects of COVID-19?

How can we protect others and ourselves if we don't know who is infected?

When should I get a test for COVID-19?

What test should I get to see if I have COVID-19?

What about rapid tests?

I want to find out if I had COVID-19 in the past, what test could I take?

What is the difference between isolation and quarantine?

What should I do if I have been exposed to someone who has COVID-19?

How long does it take to develop symptoms?

Is there a vaccine for COVID-19?

What should I do if I have COVID-19 symptoms?

Are there treatments for COVID-19?

Are antibiotics effective in preventing or treating COVID-19?

Ontario COVID-19 Data Tool

The Ontario COVID-19 Data Tool provides epidemiological information on COVID-19 activity in Ontario to-date. Explore the most recent COVID-19 data including: daily case counts, hospitalizations and deaths (Case trends), total or recent cases counts by age and sex, map by public health unit, source of COVID-19 infection (acquisition), outbreaks and laboratory testing.

Additions to the Ontario COVID-19 Data Tool as of May 28th, 2021:

- Vaccine uptake data on the Summary, Map and Vaccines sections
- COVID-19 reproduction number and doubling time

The COVID-19 Data Tool is updated Monday to Fridays at 11:30 a.m. except on statutory holidays. For weekend case counts see the **Daily Epidemiological Summary.**

For questions about the data, please contact **EPIR@oahpp.ca**.

Summary | Case trends | Age and sex | Map | Acquisition | Reproduction | Outbreaks | Lab tests | Vaccines | Technical notes | Glossary

Summary +

Date

24 Jun 2021

Confirmed COVID-19 cases in Ontario

As of June 24, 2021

Daily cases, rates, hospitalizations and deaths by public health unit can be found in **Case trends**.

Change in cases

256

Recent cases

5,469

reported in last 14 days
1.0% of cases

Total cases

543,571

3,656.9 per 100,000

Total hospitalized

27,643

186.0 per 100,000
5.1% of cases

Total deaths

9,101

61.2 per 100,000
1.7% of cases

COVID-19 cases in Ontario with a variant of concern detected

As of June 24, 2021

Find daily case counts of COVID-19 variants of concern by public health unit in **Case trends**.

Total case counts for B.1.1.7 include all confirmed COVID-19 cases where lineage B.1.1.7 was identified by genomic analysis and those presumed to be B.1.1.7 based on a positive N501Y and negative E484K mutation.

Total cases

B.1.1.7	**143,035**
B.1.351	**1,161**
P.1	**4,270**

Laboratory tests for COVID-19 in Ontario

As of June 24, 2021

See daily historical data in **Lab tests**.

New tests

26,561

178.7 tests per 100,000

Daily % positive

1.3

Total tests

15,805,892

106,333.7 tests per 100,000

COVID-19 vaccine uptake in Ontario

As of June 23, 2021 Vaccine data are updated weekly on Thursdays.

See the **Vaccine** and **Map** tabs for more vaccination data.

At least one dose

9,753,684

65.6% of population

Fully vaccinated

3,348,673

22.5% of population

Change in cases reflects new cases reported since the previous day.

Recent cases include cases reported within the past 14 days with a three day lag from the time of data extraction.

Rate is per 100,000 population.

Hospitalizations include all cases reported as ever being hospitalized during their infection.

Percent positive refers to the percentage of tests performed that were positive for COVID-19 and does not translate to the number of specimens or persons testing positive.

New tests refer to the number of tests performed and do not reflect the number of specimens or persons tested.

COVID-19 variants of concern (VOC) cases are confirmed COVID-19 cases where a designated VOC was identified by genomic analysis of their SARS-CoV-2 positive specimen. Lineage B.1.1.7 includes cases where lineage B.1.1.7 was identified by genomic analysis and those presumed to be B.1.1.7 based on positive N501Y and negative E484K mutation

- **PANGO lineage B.1.1.7** first detected in England.
- **PANGO lineage B.1.351** first detected in South Africa.
- **PANGO lineage P.1** first detected in Brazil.

Interpret the VOC and mutation case counts with caution. Daily counts may change due to the varying time required to complete VOC testing and/or genomic analysis following the initial positive test for SARS-CoV-2 and may result in totals differing from past publicly reported case counts. Additionally, changes to the VOC testing algorithm may occur over time. Refer to the Technical Notes for more information.

Vaccine series: the number of vaccine doses within a schedule that has been approved by Health Canada. COVID-19 vaccine

products available in Ontario have either a one-dose (i.e. Janssen) or two-dose (i.e. Moderna, Pfizer-BioNTech, AstraZeneca or COVISHIELD) schedule. Note: Janssen vaccines have not yet been distributed in Ontario.

At least one dose: refers to individuals that have received at least one dose of a COVID-19 vaccine. Reflects individuals that have received the first dose of a two-dose series, as well as those that have completed a COVID-19 vaccine series.

At least one dose coverage: the proportion of the total population of Ontario, or a public health unit, that has received at least one dose of a COVID-19 vaccine. Reflects individuals that have received the first dose of a two-dose series, as well as those that have completed a COVID-19 vaccine series

Fully vaccinated: refers to individuals that have received both doses of a two-dose COVID-19 vaccine series (i.e. dose two of two) or one dose of a one-dose COVID-19 vaccine series (i.e. dose one of one). Reflects individuals that have completed a COVID-19 vaccine series.

Fully vaccinated coverage: the proportion of the total population of Ontario, or a public health unit, that has received both doses of a two-dose COVID-19 vaccine series (i.e. dose two of two) or one dose of a one-dose COVID-19 vaccine series (i.e. dose one of one). Reflects individuals that have completed a COVID-19 vaccine series.

COVID-19 daily epidemiology update

Updated: June 29, 2021, 7 pm EST

Summary of COVID-19 cases across Canada and over time. Contains detailed data about the spread of the virus over time and in different regions of the country. Includes breakdowns by age and sex or gender. Provides an overview of hospitalizations and deaths, testing, variants of concern and exposures.

Key updates as of June 29, 2021, 7 pm EST

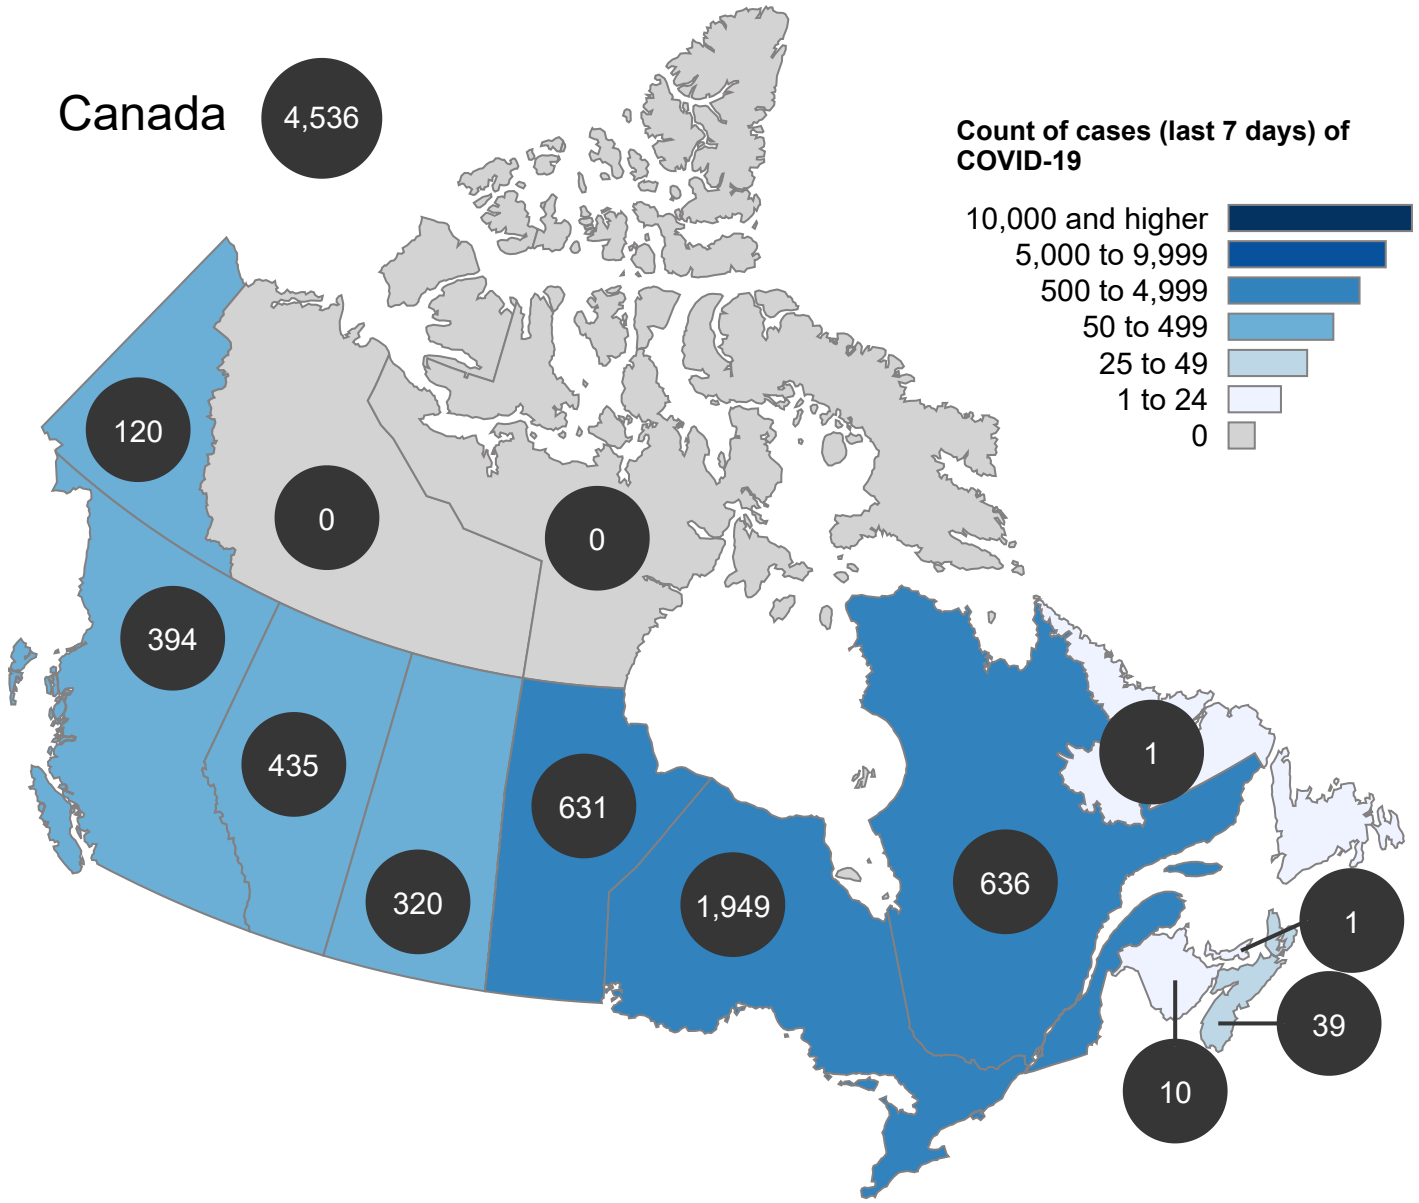
Cases today	Total cases	Active cases	Total resolved	Deaths today	Total deaths
602	1,414,736	7,447	1,381,016	35	26,273

Total tests performed	Daily percent positive (last 7 days)	Daily tests per 100,000 population (last 7 days)
36,705,571	1.2%	156

- We update these sections daily at 7:00 PM EST: Key updates, Current situation and National overview. Laboratory data represents specimens received by labs up to June 27, 2021 to allow time to process results.
- We update these sections every Friday: Epidemic curve, Demographics, How people were exposed, and Severe illness and outcomes.
- Most cases (65.0%) and deaths (77.5%) were reported by Ontario and Quebec.
- Of the 13 jurisdictions reporting updates, no new cases were reported in 3 provinces or territories in the past 24 hours.
- Of the 13 jurisdictions reporting updates, no new deaths were reported in 9 provinces or territories in the past 24 hours.

Current situation

Figure 1a. Count of cases (last 7 days) of COVID-19, by province/territory as of June 29, 2021



The count of cases (last 7 days) of COVID-19 in **Canada** was **4,536** as of June 29, 2021.

This information is based on data our provincial and territorial partners published on cases, deaths, and testing daily, and are current as of the day they are published. Today's numbers are current as of June 29, 2021. For the most up to date data for any province, territory or city, please visit their website. The number of cases or deaths reported on previous days may differ slightly from those on the provincial and territorial websites as these websites may update historic case and death counts as new information becomes available.

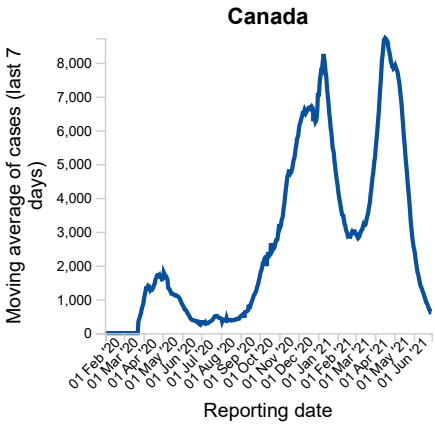
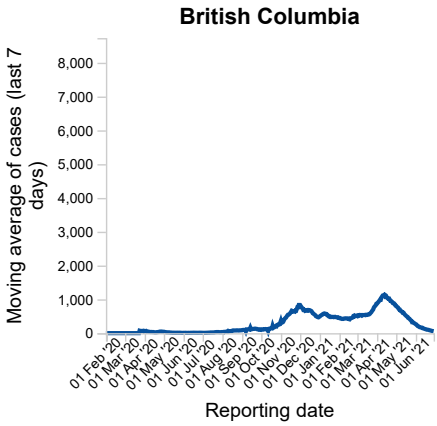
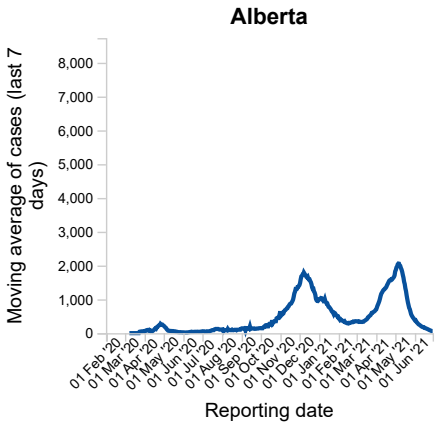
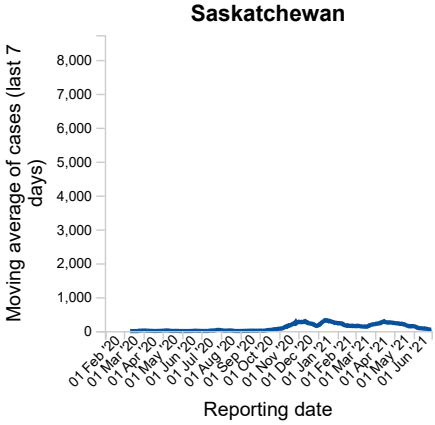
Figure 1b. Moving average of cases (last 7 days) of COVID-19 in Canada as of June 29, 2021, 7 pm EST

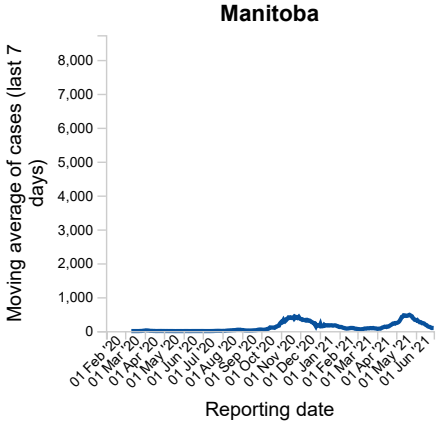
The figures below show cases over time. The range of dates (January 31st, 2020 - present date) is the same for each figure. This allows you to compare the provinces and territories on the same timescale.

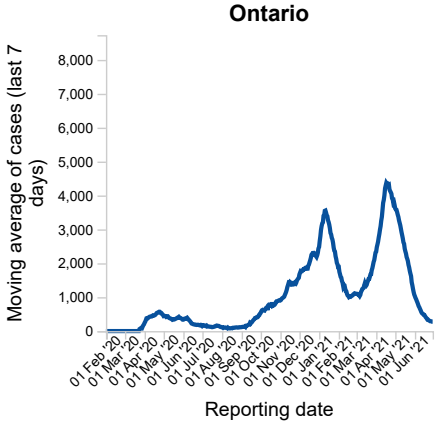


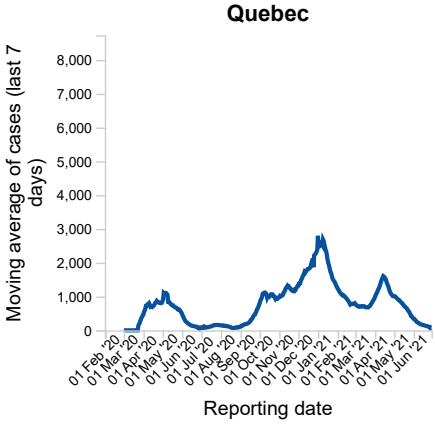


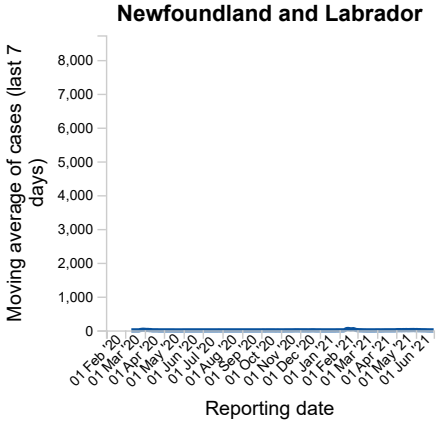


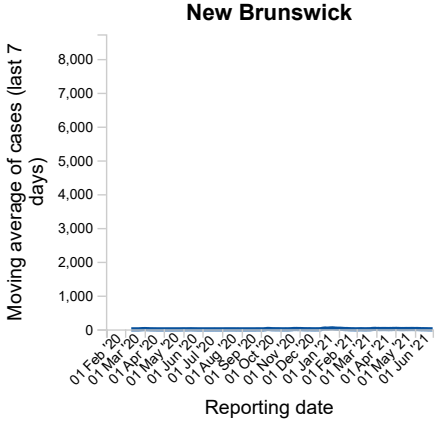


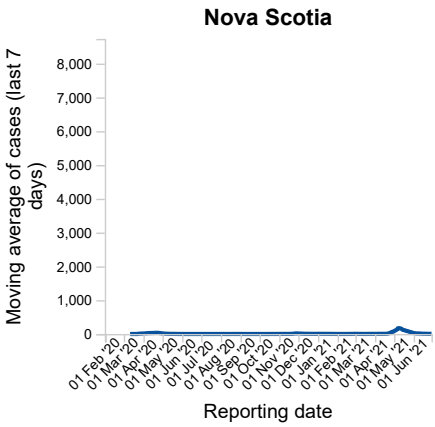


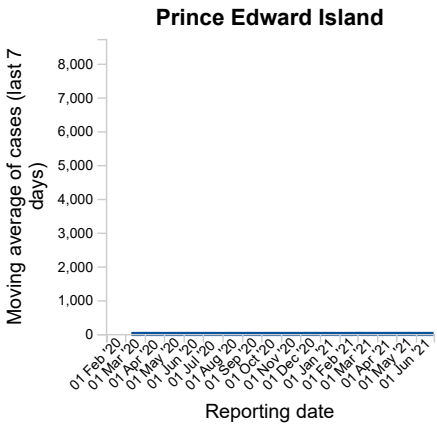


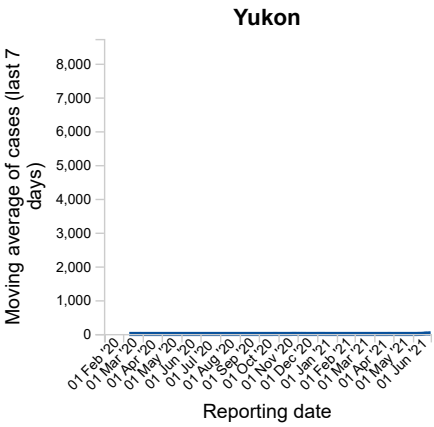


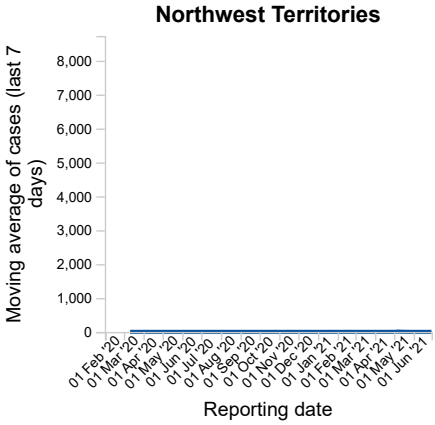


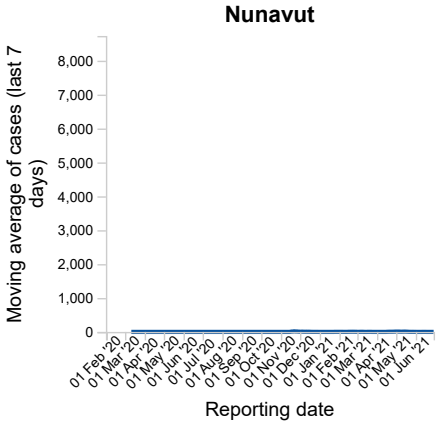












This information is based on data our provincial and territorial partners published on cases, deaths, and testing daily, and are current as of the day they are published. Today's numbers are current as of June 29, 2021. For the most up to date data for any province, territory or city, please visit their website. The number of cases or deaths reported on previous days may differ slightly from those on the provincial and territorial websites as these websites may update historic case and death counts as new information becomes available.

Downloadable data (in .csv format).

Note: Out of the total number of people tested, 76 were repatriated travellers, of which 13 were cases.

National overview

There have been over **36,705,571** COVID-19 tests performed in Canada or **965,803 tests per 1 million people**. Of these, **4.0%** were positive. For information about testing trends, please see the Detailed weekly epidemiological report (PDF).

Table 1. Daily* change in the number of cases, deaths and tests performed, by province or territory, as of June 29, 2021, 7 pm EST

Location	New cases	New deaths	Tests performed
Canada	**602**	**35**	**61,585**
British Columbia	29	0	3,664
Alberta	61	4	22,232
Saskatchewan	52	2	1,425
Manitoba	61	0	1,575
Ontario	299	25	13,071
Quebec	71	4	15,365
Newfoundland and Labrador	0	0	561

Nova Scotia	1	0	3,077
Prince Edward Island	1	0	138
Yukon	24	0	N/A
Northwest Territories	0	0	13
Nunavut	0	0	63

* The new cases, deaths and tests reflect the difference between a province or territory's current report and their last report. Some provinces and territories do not update daily.

N/A means that no daily update was provided by the province or territory.

Variants of concern (VOC) in Canada

All viruses, including COVID-19, change or mutate over time. Not all mutations are of concern. However, some changes result in variants of concern (VOC). A VOC (Variants of concern) has changes that are significant to public health.

For example, they might:

- spread more easily
- cause more severe illness
- require different treatments, or
- not respond the same to current vaccines

The Public Health Agency of Canada (PHAC) updates VOC (Variants of concern) information from Sunday to Thursday at 7:00 PM EDT, using publicly reported information from the provinces and territories.

Table 2. Cumulative number of cases involving variants of concern (VOC) publicly reported, as of June 29, 2021

Location	B.1.1.7 variant	B.1.351 variant	P.1 variant
Canada	**221,763**	**2,149**	**17,974**
British Columbia	12,054	151	9,709
Alberta	45,508	159	2,752
Saskatchewan	6,634	10	322
Manitoba	6,630	72	205
Ontario	143,381	1,315	4,439
Quebec	6,989	420	511
Newfoundland and Labrador	187	6	1
New Brunswick	180	4	1
Nova Scotia	73	12	1
Prince Edward Island	26	0	0
Yukon	3	0	31
Northwest Territories	77	0	2
Nunavut	21	0	0

Note:

- The table reports publicly available information from the provinces and territories. In case of discrepancies, the provincial or territorial data should be considered current and correct.

- PHAC is in the process of replacing this table with a graphical view that is more representative of the mix of variants present in Canada in the coming weeks. This new graphical view will include all variants of concern including B.1.617 and variants of interest.

There are many variants being tracked internationally and across Canada. Most of these are similar to the original variants that emerged in 2020. VOCs (Variants of concern) now represent a majority of COVID-19 cases in Canada.

Four VOCs (Variants of concern) have been detected in most provinces and territories:

- B.1.1.7
- B.1.351
- P.1
- B.1.617

The **B.1.1.7 variant** continues to account for most VOCs (Variants of concern) classified to date in Canada.

The **B.1.617 variant** has only been recently identified and thus is less understood. Its 3 sub-lineages may have different properties. Early data from the U.K. indicate that the B.1.617.2 sub-lineage may be more transmissible overall, either similar to or perhaps more transmissible than the B.1.1.7 variant. However, laboratory data suggest that currently authorized vaccines are also effective against this sub-lineage. The B.1.617.1 and B.1.617.3 sub-lineages are less well-known, but may be less affected by vaccines. There are many variants being tracked internationally and across Canada, most of which are similar to the original variants that emerged in 2020.

The impact of the B.1.617 variant and its sub-lineages is still being assessed in Canada, where the variant has been identified in all 10 provinces and 1 territory. Genomic surveillance has also identified all 3 sub-lineages (B.1.617.1, B.1.617.2 and B.1.617.3).

Of these 3:

- B.1.617.1 accounted for most of the identified cases in March and April 2021
- B.1.617.2 accounted for most of the identified cases detected at the border
- B.1.617.3 accounts for a very small proportion (1%) of identified cases

Canada is collecting evidence to determine if each of these sub-lineages meets the definition for a variant of concern or a variant of interest.

New variants will continue to appear. It is crucial to remain vigilant and take all available measures to limit spread.

Detailed case information

The tables and figures below reflect detailed case information provided to the Public Health Agency of Canada (PHAC) by health authorities in the provinces and territories. This data is updated every week. It may change as we get more information about cases.

Updated: June 25, 2021, 7 pm EST

Epidemic curve

As of June 25, 2021, 7 pm EST, PHAC has received detailed case report data on 1,410,946 cases. Both exposure and symptom onset date were available for 1,254,652 (88.9%) cases [1].

The shaded area on the far right of Figure 2 represents lag time. This is the period of time (1 to 2 weeks) before the latest cases are reported to PHAC. This delay is a result of the time required to seek health care, get tested and receive results. It also takes time for public health authorities to gather information on cases. We update this information as it becomes available.

Figure 2. COVID-19 cases (n=1,411,021 [1]) in Canada by date of illness onset [2] as of June 25, 2021, 7 pm EST (total cases)

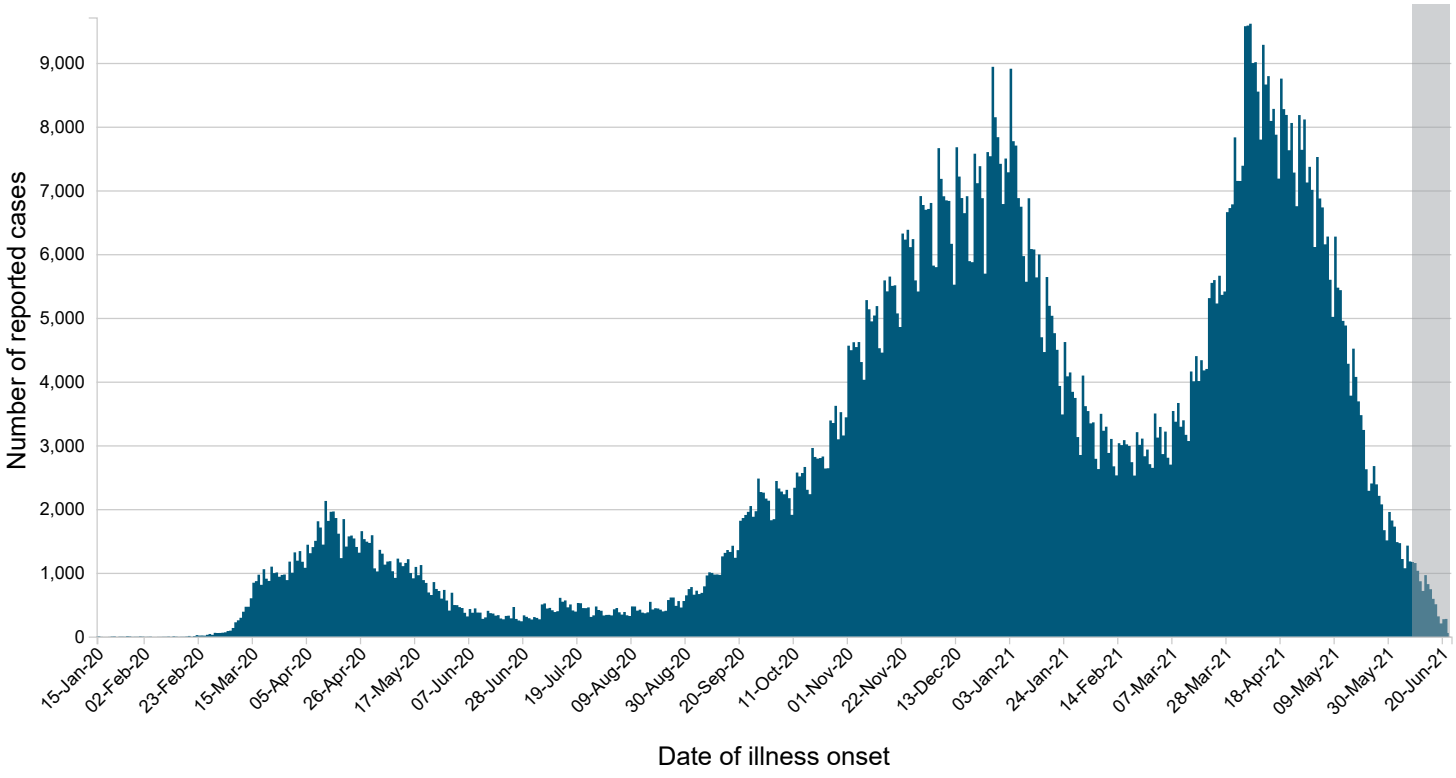

Figure 2. COVID-19 cases (n=1,254,652 [1]) in Canada by date of illness onset [2] as of June 25, 2021, 7 pm EST (by exposure)

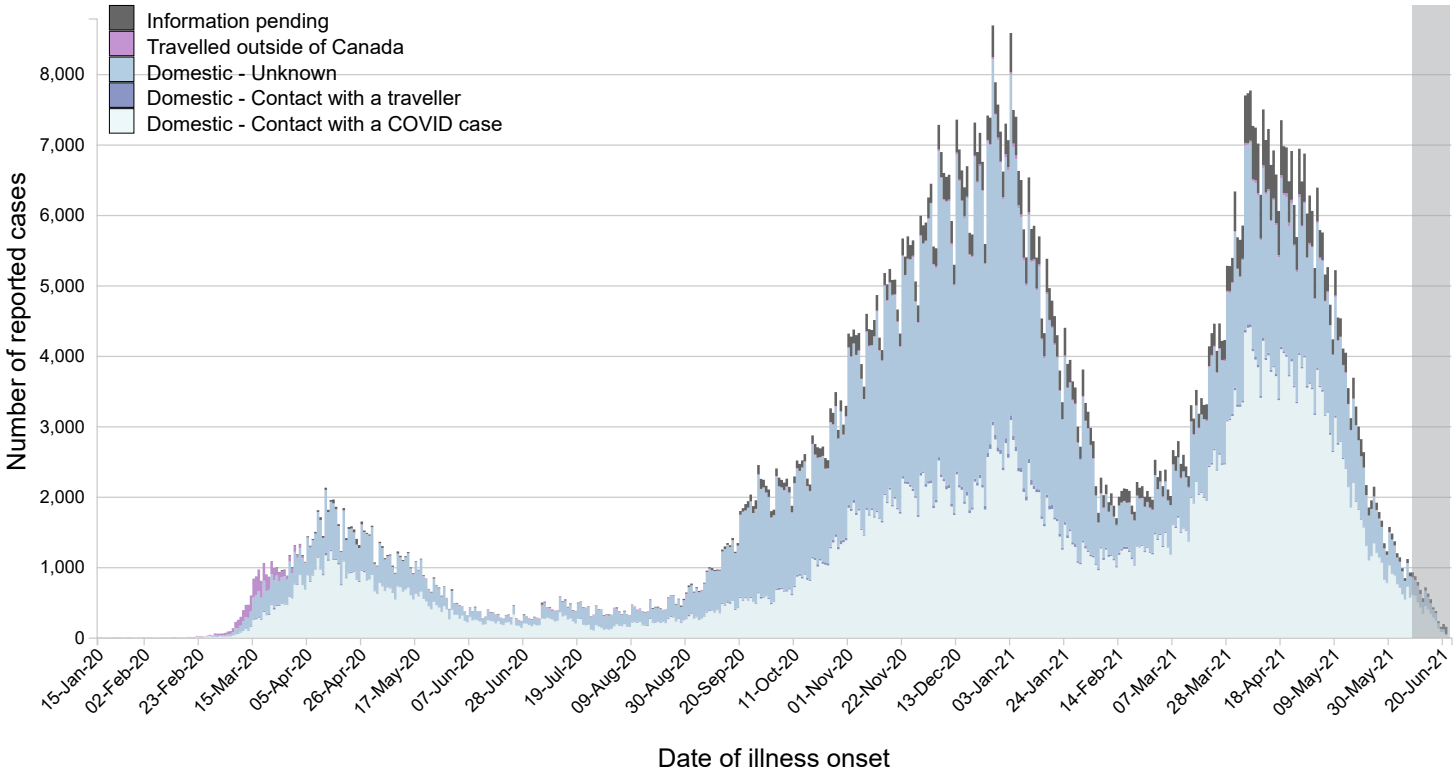

Figure 2. COVID-19 cases (n=1,410,571 [1]) in Canada by date of illness onset [2] as of June 25, 2021, 7 pm EST (by age - 10 year groups)

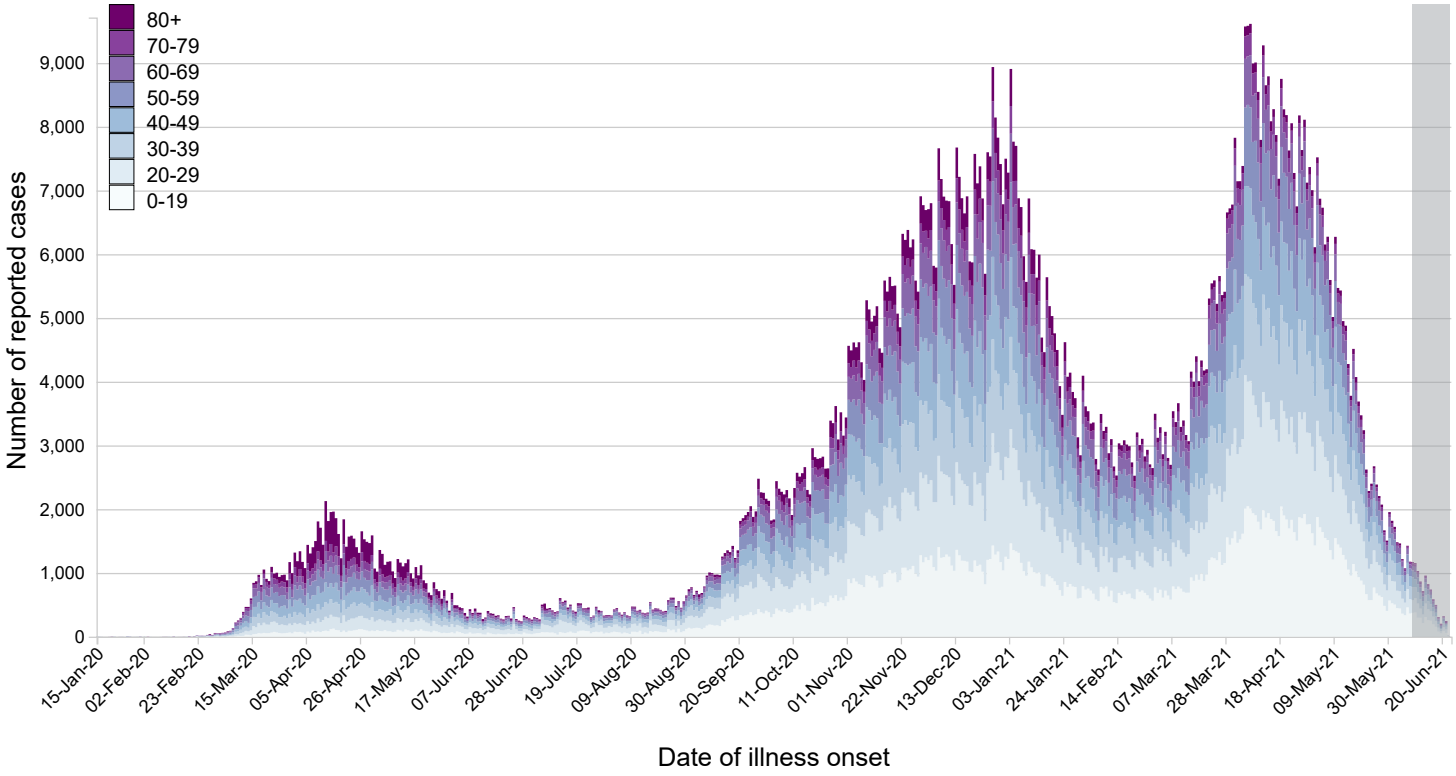

Figure 2. COVID-19 cases (n=1,410,571 [1]) in Canada by date of illness onset [2] as of June 25, 2021, 7 pm EST (by age - 20 year groups)

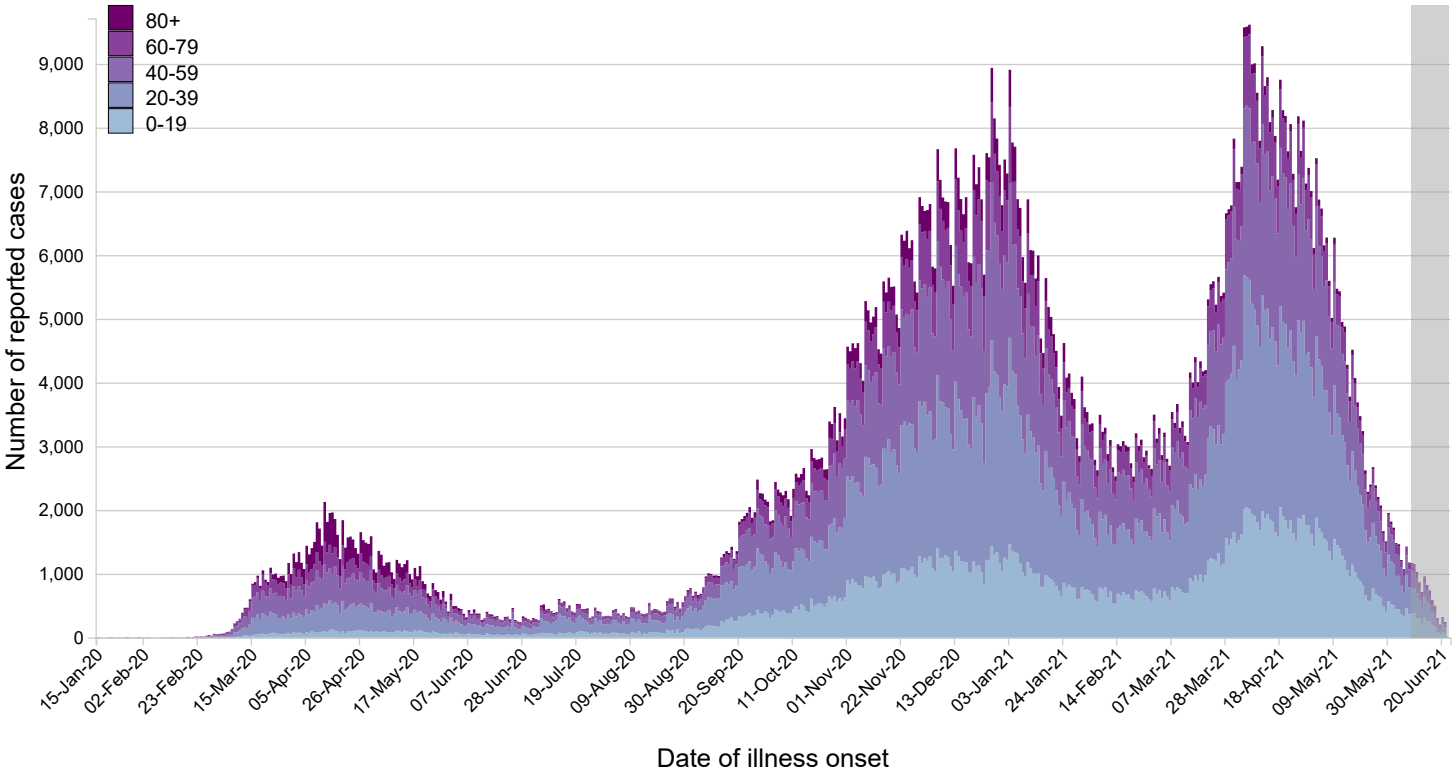


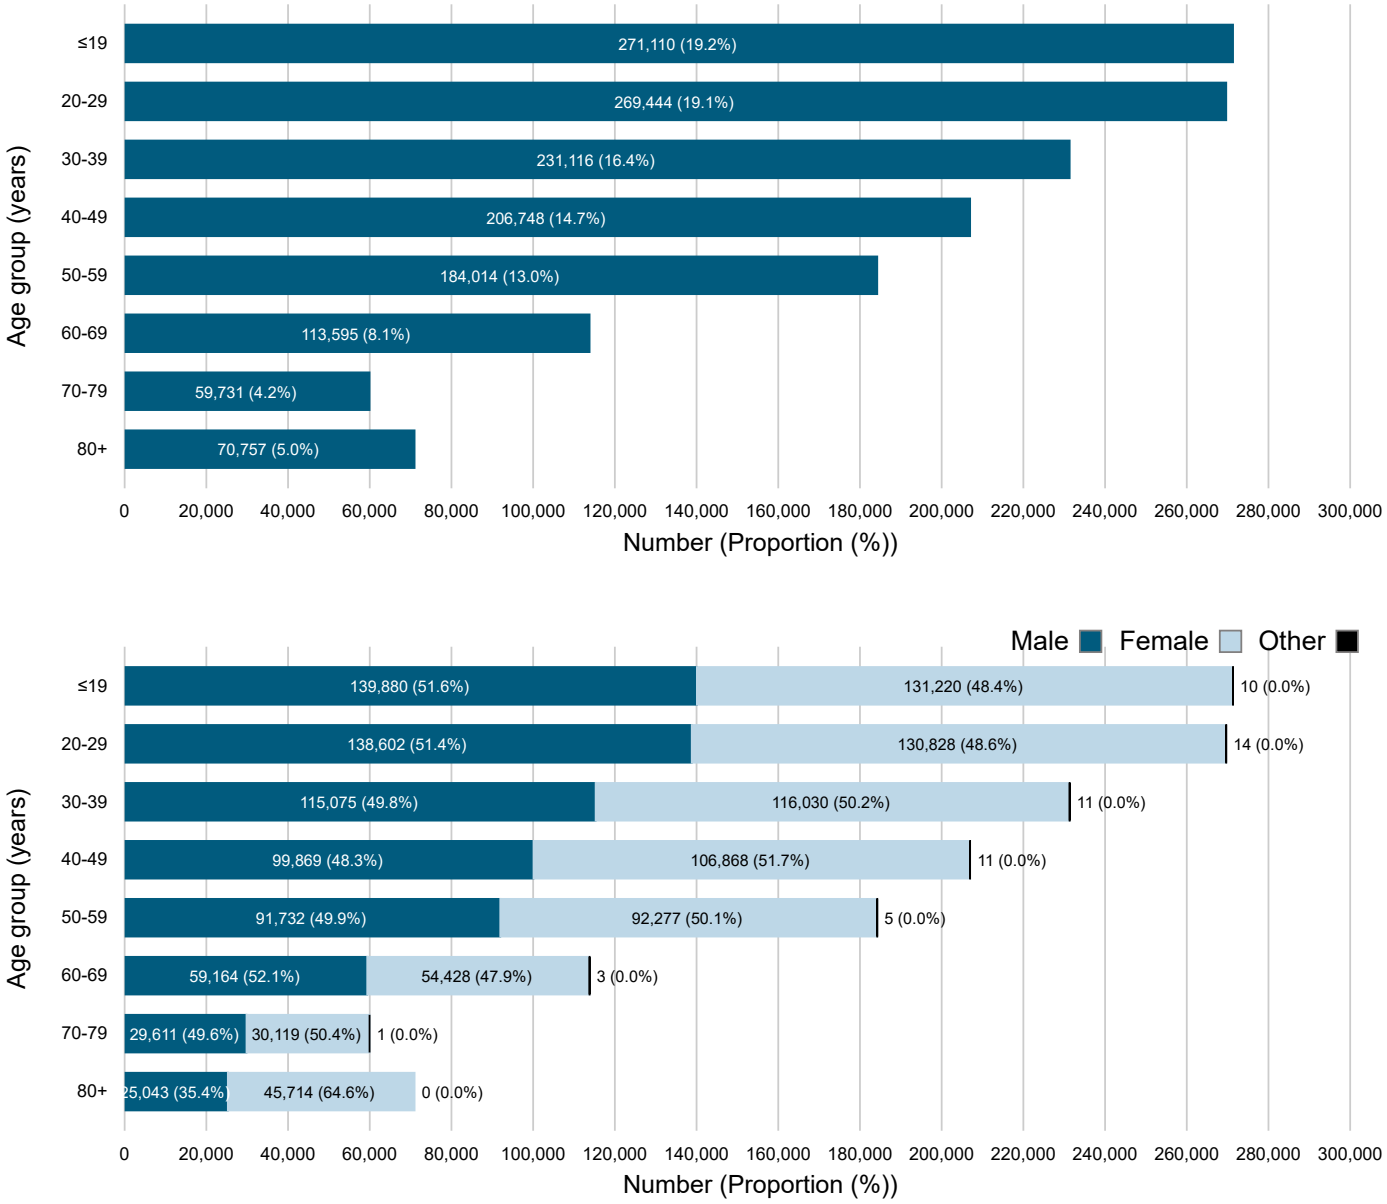
This figure may underestimate the total number of cases among returning travelers. Exposure history is not available for all cases and jurisdictions have not all consistently reported exposure history to PHAC throughout the pandemic.

Demographics

We have detailed case report data from 1,410,946 cases. We know the age of patients in 100.00% of cases, and both age and gender in 99.69% of cases.

Of the cases reported in Canada so far, 50.3% were female and 35.6% were between 20 and 39 years old (Figure 3).

Figure 3. Age distribution of COVID-19 cases (n=1,410,946 [1]) in Canada as of June 25, 2021, 7 pm EST [4]



Age by gender [4] distribution of COVID-19 cases (n=1,410,946 [1]) in Canada, June 25, 2021, 7 pm EST

Age group (years)	Number of cases with case reports (percentage)	Number of male cases (percentage)	Number of female cases (percentage)	Number of other cases (percentage)
≤19	271,110 (19.2%)	139,880 (20.0%)	131,220 (18.5%)	10 (18.2%)
20-29	269,444 (19.1%)	138,602 (19.8%)	130,828 (18.5%)	14 (25.5%)
30-39	231,116 (16.4%)	115,075 (16.5%)	116,030 (16.4%)	11 (20.0%)
40-49	206,748 (14.7%)	99,869 (14.3%)	106,868 (15.1%)	11 (20.0%)

60-69	113,595 (8.1%)	59,164 (8.5%)	54,428 (7.7%)	3 (5.5%)
70-79	59,731 (4.2%)	29,611 (4.2%)	30,119 (4.3%)	1 (1.8%)
80+	70,757 (5.0%)	25,043 (3.6%)	45,714 (6.5%)	0 (0.0%)
Total	1,406,515 (100%)	698,976 (100%)	707,484 (100%)	55 (100%)

How people were exposed [3]

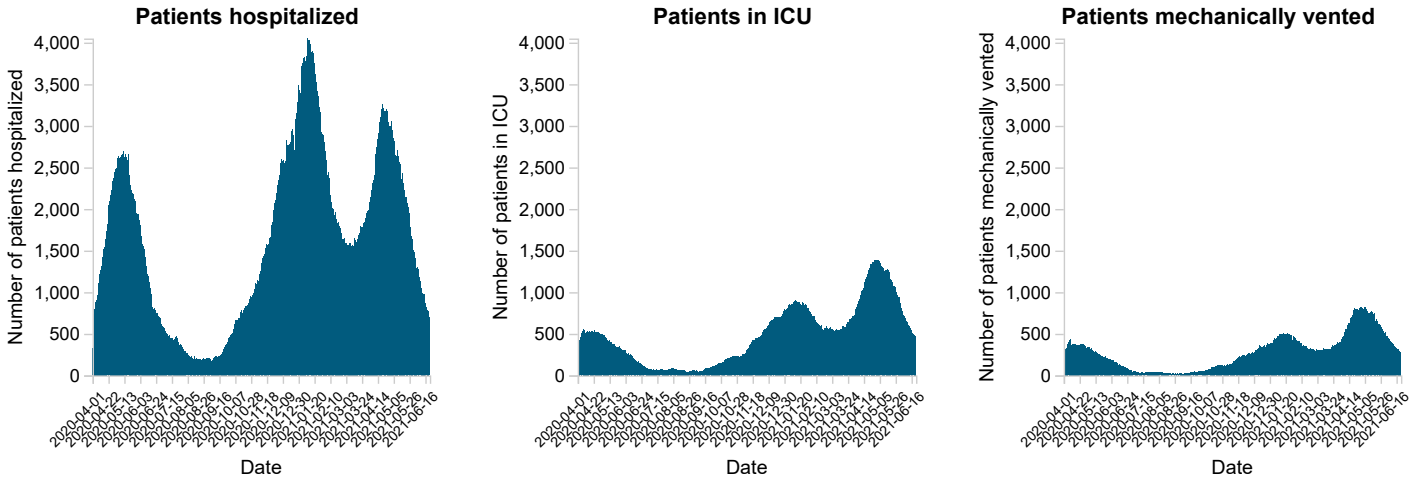
In Canada, detailed case report data were provided for 1,410,946 cases. We have exposure history for 1,254,652 (88.9%) cases. The probable exposure setting of these cases [1] are:

- any exposure that occurred in Canada: **1,167,909 (93.1%)**, including
  - from contact with a known COVID case: **583,505 (46.5%)**
  - from contact with a traveller: **8,451 (0.7%)**
  - from an unknown source: **575,953 (45.9%)**
- currently unknown (information pending): **77,135 (6.1%)**
- travelled outside of Canada: **9,608 (0.8%)**

Severe illness and outcomes

Hospital use

Figure 4. Daily number of hospital beds and ICU beds occupied by COVID-19 patients as of June 21, 2021



Between June 14, 2021 and June 21, 2021:

- the number of **hospital beds** occupied by COVID-19 patients **decreased** from **981** to **696** beds.
- the number of **ICU beds** occupied by COVID-19 patients **decreased** from **563** to **471** beds.
- the number of **COVID-19 patients who were mechanically vented decreased** from **337** to **282**.

Hospitalizations and deaths to date

We have detailed case report data on 1,410,946 cases, and hospitalization status for 988,451 (70.1%) of them:

- **74,044** cases **(7.5%)** were hospitalized, of whom:
  - **13,789 (18.6%)** were admitted to the ICU
  - **1,919 (2.6%)** needed mechanical ventilation

The provinces and territories provided detailed case report forms for **26,172** deaths related to COVID-19.

Figure 5a. Age and gender [4] distribution of COVID-19 cases hospitalized in Canada as of June 25, 2021, 7 pm EST (n=73,902 [1])

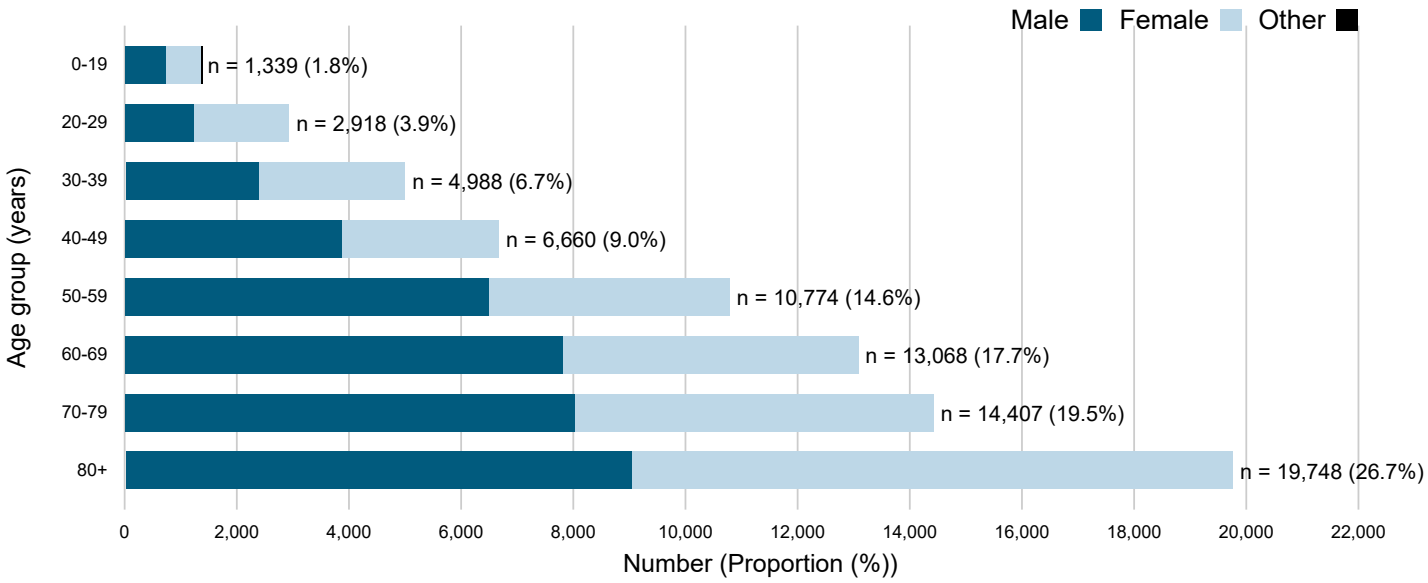


Figure 5b. Age and gender [4] distribution of COVID-19 cases admitted to ICU in Canada as of June 25, 2021, 7 pm EST (n=13,754 [1])

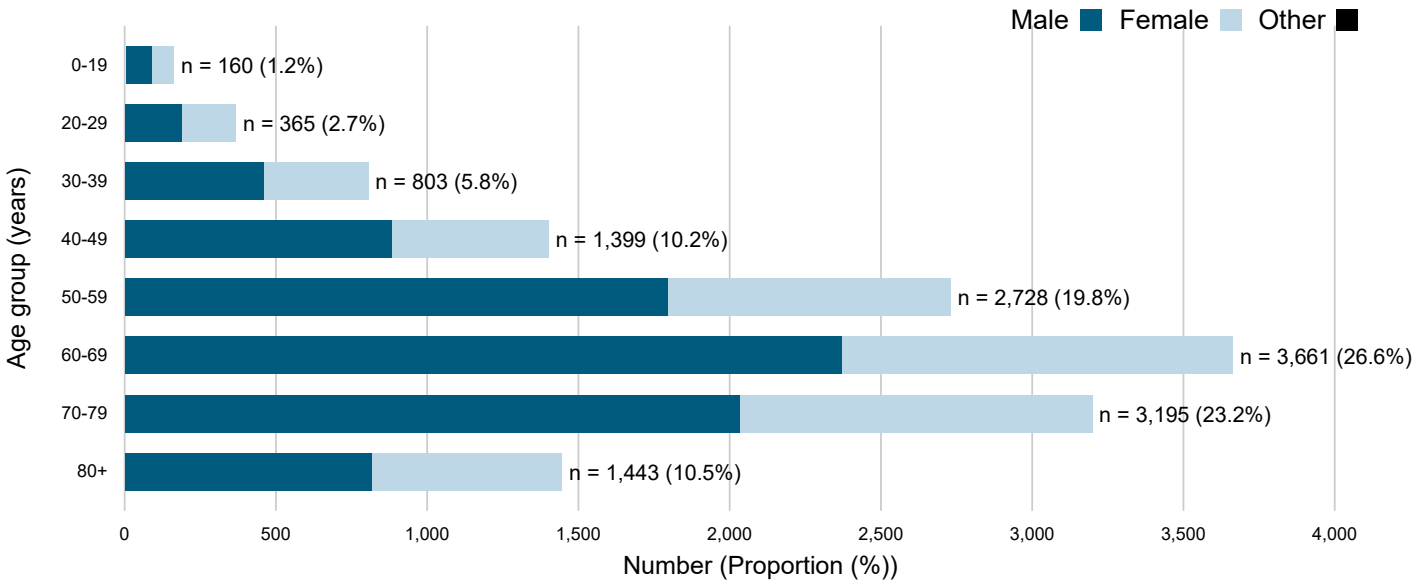

Figure 5c. Age and gender [4] distribution of COVID-19 cases deceased in Canada as of June 25, 2021, 7 pm EST (n=26,117 [1])

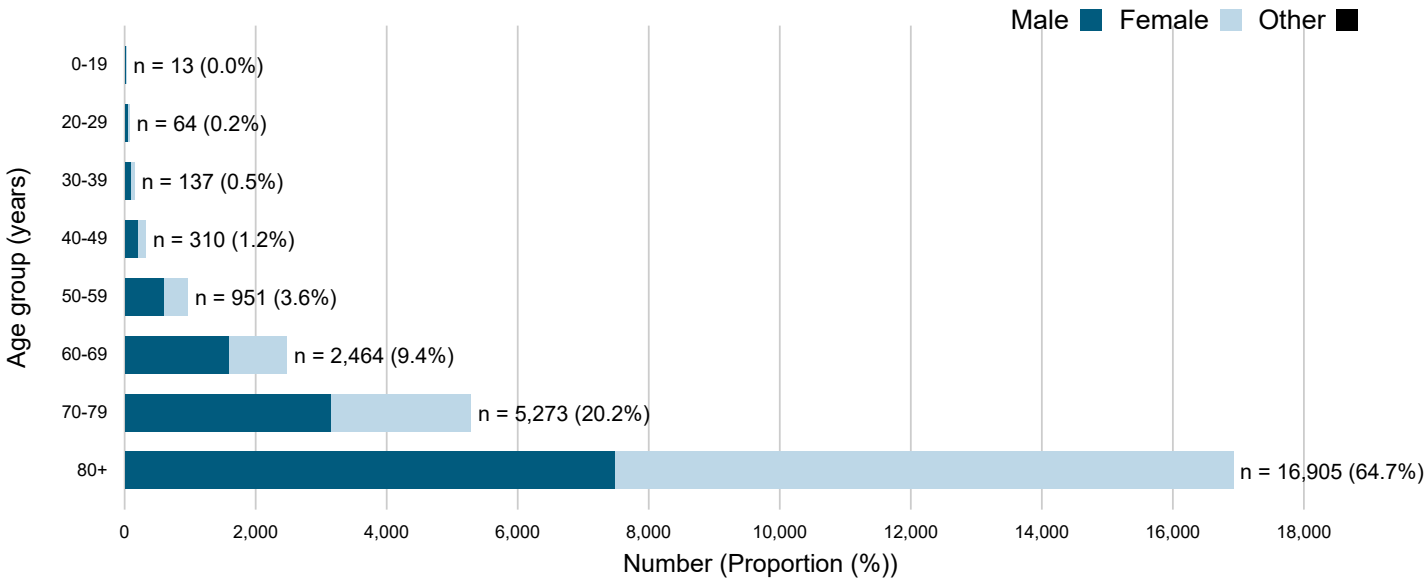

Data note: Figure 5 includes COVID-19 cases hospitalized, admitted to ICU, and deceased for which age and gender information were available. Therefore, some COVID-19 hospitalizations, ICU admissions, and deaths may not be included in Figure 5.

Age and gender [4] distribution of COVID-19 cases hospitalized in Canada as of June 25, 2021, 7 pm EST (n=73,902 [1])

Age group (years)	Number of cases with case reports (percentage)	Number of male cases (percentage)	Number of female cases (percentage)	Number of other cases (percentage)
0-19	1,339 (1.8%)	714 (1.0%)	624 (0.8%)	1 (0.0%)
20-29	2,918 (3.9%)	1,231 (1.7%)	1,687 (2.3%)	0 (0.0%)

---

1 This figure is based on cases for which a case report form was received by the Public Health Agency of Canada from provincial or territorial partners.

2 The shaded area represents a period of time (lag time) where it is expected that cases have occurred but have not yet been reported nationally. The earliest of the following dates were used as an estimate: Onset date, Specimen Collection Date, Laboratory Testing Date, Date Reported to Province or Territory, or Date Reported to PHAC.

3 Exposure information may not be available for all cases. Some jurisdictions haven't consistently reported to PHAC how people were exposed throughout the pandemic. As a result, this may underestimate the total number of cases by different exposures, especially among returning travelers.

4 Where available, gender data was used; when gender data was unavailable, sex data was used. Reliable data on gender diverse respondents are unavailable due to small counts.

About Us: The Ontario COVID-19 Science Advisory Table is a group of scientific experts and health system leaders who evaluate and report on emerging evidence relevant to the COVID-19 pandemic, to inform Ontario's response. Our mandate is to provide weekly summaries of relevant scientific evidence for the COVID-19 Health Coordination Table of the Province of Ontario, integrating information from existing scientific tables, Ontario's universities and agencies, and the best global evidence. The Science Table summarizes its findings for the Health Coordination Table and the public in Science Briefs.

Key Message

New variants of concern (VOCs) now account for 67% of all Ontario SARS-CoV-2 infections. Compared with early variants of SARS-CoV-2, VOCs are associated with a 63% increased risk of hospitalization, a 103% increased risk of intensive care unit (ICU) admission and a 56% increased risk of death due to COVID-19.

VOCs are having a substantial impact on Ontario's healthcare system. On March 28, 2021, the daily number of new SARS-CoV-2 infections in Ontario reached the daily number of cases observed near the height of the second wave, at the start of the province-wide lockdown, on December 26, 2020.

The number of people hospitalized with COVID-19 is now 21% higher than at the start of the province-wide lockdown, while ICU occupancy is 28% higher (Figure 1). The percentage of COVID-19 patients in ICUs who are younger than 60 years is about 50% higher now than it was prior to the start of the province-wide lockdown.

Because the increased risk of COVID-19 hospitalization, ICU admission and death with VOCs is most pronounced 14 to 28 days after diagnosis, there will be significant delays until the full burden to the health care system becomes apparent.

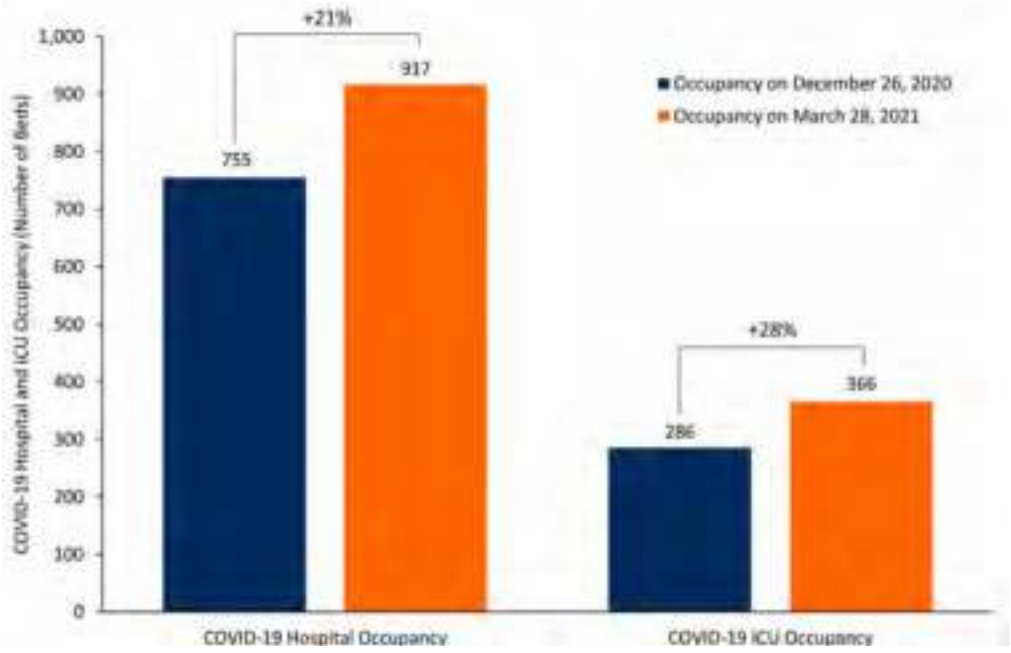

Figure 1. COVID-19 Hospital and ICU Occupancy on March 28, 2021 Compared with December 26, 2020
Bar graphs showing the COVID-19 hospital and ICU occupancy in Ontario. The relative increase between March 28,

2021 and December 26, 2020 is indicated above the corresponding bars for hospital and ICU occupancy. ICU, intensive care unit.

Summary

Background

As of March 28, 2021 new variants of concern (VOCs) account for 67% of all Ontario SARS-CoV-2 infections. The B.1.1.7 variant originally detected in Kent, United Kingdom accounts for more than 90% of all VOCs in Ontario, with emerging evidence that it is both more transmissible and virulent.

Questions

What are the risks of COVID-19 hospitalization, ICU admission and death caused by VOCs as compared with the early variants of SARS-CoV-2?

What is the early impact of new VOCs on Ontario's healthcare system?

Findings

A retrospective cohort study of 26,314 people in Ontario testing positive for SARS-CoV-2 between February 7 and March 11, 2021, showed that 9,395 people (35.7%) infected with VOCs had a 62% relative increase in COVID-19 hospitalizations (odds ratio [OR] 1.62, 95% confidence interval [CI] 1.41 to 1.87), a 114% relative increase in ICU admissions (OR 2.14, 95% CI 1.52 to 3.02), and a 40% relative increase in COVID-19 deaths (OR 1.40, 95% CI 1.01 to 1.94), after adjusting for age, sex and comorbidities.

A meta-analysis including the Ontario cohort study and additional cohort studies in the United Kingdom and Denmark showed that people infected with VOCs had a 63% higher risk of hospitalization (RR 1.63, 95% CI 1.44 to 1.83), a doubling of the risk of ICU admission (RR 2.03, 95% CI 1.69 to 2.45), and a 56% higher risk of all-cause death (RR 1.56, 95% CI 1.30 to 1.87). Estimates observed in different studies and regions were completely consistent, and the B.1.1.7 variant was dominant in all three jurisdictions over the study periods.

The number of people hospitalized with COVID-19 on March 28, 2021, is 21% higher than at the start of the province-wide lockdown during the second wave on December 26, 2020, while ICU occupancy is 28% higher.

Between December 14 to 20, 2020, there were 149 new admissions to ICU; people aged 59 years and younger accounted for 30% of admissions. Between March 15, 2021 and March 21, 2021, there were 157 new admissions to ICU; people aged 59 years and younger accounted for 46% of admissions.

Interpretation

The new VOCs will result in a considerably higher burden to Ontario's health care system during the third wave compared to the impact of early SARS-CoV-2 variants during Ontario's second wave.

Since the start of the third wave on March 1, 2021, the number of new cases of SARS-CoV-2 infection, and the COVID-19 hospital and ICU occupancies have surpassed prior thresholds at the start of the province-wide lockdown on December 26, 2020.

Background

Around March 1, 2021, Ontario entered the third wave of the COVID-19 pandemic, with the slope of the epidemic curve driven by the increasing number of VOCs since March 3, 2021 (Figure 2).[1] As of March 28, 2021, there were an estimated total of

107.1 new SARS-CoV-2 infections per 100,000 persons per week, with 35.7 new SARS-CoV-2 infections per 100,000 Ontarians per week caused by early variants of SARS-CoV-2 (non-VOCs), and 71.4 new SARS-CoV-2 infections per 100,000 Ontarians per week caused by new VOCs. The VOCs accounted for an estimated 67% of new cases of SARS-CoV-2 infections.[1] VOCs are now the dominant source of SARS-CoV-2 infection in Ontario.

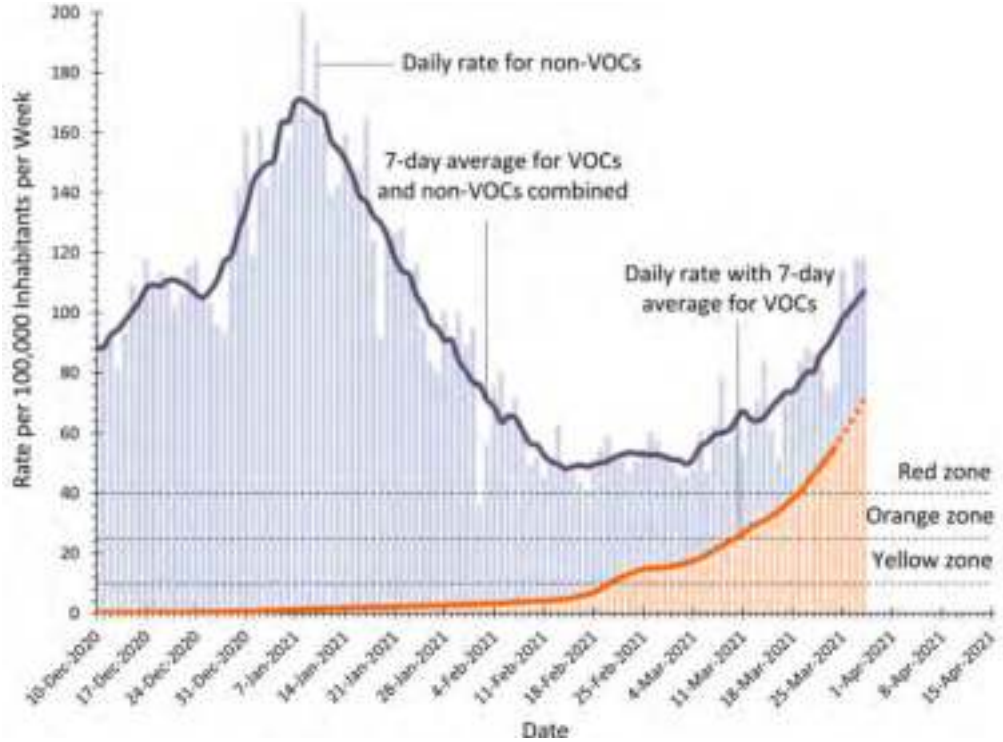

Figure 2. Rate of New SARS-CoV-2 Infections in Ontario

Seven-day moving averages of confirmed new SARS-CoV-2 infections overall in Ontario per 100,000 inhabitants per week (purple line), and infections caused by new VOCs in Ontario per 100,000 inhabitants per week (orange line). The daily rate per 100,000 inhabitants per week is represented by blue and orange bars. The incidence of new infections related to VOCs from March 24th 2021 and onwards is predicted (dashed orange line). The color-coded zones are the zones of public health measures established by Ontario's COVID-19 response framework: grey/red zone = weekly SARS-CoV-2 incidence of ≥40 per 100,000; orange zone = weekly incidence 25 to 39.9 per 100,000; and yellow zone = weekly incidence of 10 to 24.9 per 100,000. VOC, variant of concern. Graph adapted from Ontario COVID-19 Science Advisory Table.[1]

The B.1.1.7 variant, which was originally detected in Kent, United Kingdom, currently accounts for more than 90% of all VOCs in Ontario. The B.1.351 and P.1 variants originally detected in South Africa and Brazil, respectively, account for the remaining VOCs.[2] The B.1.1.7 variant which is dominant in Ontario, is at least 40% more transmissible than early variants of SARS-CoV-2,[3] and emerging evidence suggests it may be more virulent.[4]

Questions

What are the risks of COVID-19 hospitalization, ICU admission and death caused by VOCs as compared with the early variants of SARS-CoV-2?

What is the early impact of new VOCs on Ontario's healthcare system?

Findings

Table 1 presents the results of a retrospective cohort study of 26,314 people in Ontario who were PCR-positive for SARS-CoV-2 between February 7 and March 11, 2021, with 9,395 people (35.7%) having an infection caused by a VOC. After adjusting for age, sex and comorbidities, infections due to VOCs were associated

with a 62% relative increase in COVID-19 hospitalizations (odds ratio [OR] 1.62, 95% confidence interval [CI] 1.41 to 1.87), a 114% relative increase in ICU admissions (OR 2.14, 95% CI 1.52 to 3.02), and a 40% relative increase in COVID-19 deaths (OR 1.40, 95% CI 1.01 to 1.94). These risk elevations for COVID-19 hospitalization, ICU admission and death were consistent across all age groups.

	Adjusted odds ratio (95% CI)
COVID-19 Hospitalizations	1.62 (1.41 to 1.87)
COVID-19 ICU admissions	2.14 (1.52 to 3.02)
COVID-19 Deaths	1.40 (1.01 to 1.94)

Table 1. Risk of COVID-19 Hospitalization, Intensive Care Unit Admission and Death Associated with VOCs Compared to Early Variants in Ontario, Canada

Adjusted odds ratios and 95% confidence intervals for the risk of COVID-19 hospitalizations, intensive care unit admissions and deaths associated with new VOCs compared to early variants. VOC, variant of concern; CI, confidence interval; ICU, intensive care unit.

Figure 3 presents the results a meta-analysis of cohort studies in Ontario (Table 1, above), the United Kingdom[5,6] and Denmark[7] comparing new VOCs with early variants, again with the dominant VOC being B.1.1.7 in all three jurisdictions over the study periods.[3] Pooling adjusted estimates of relative risks (RRs), people infected with VOCs had a 63% higher risk of hospitalization (RR 1.63, 95% CI 1.44 to 1.83), a doubling of the risk of ICU admission (RR 2.03, 95% CI 1.69 to 2.45), and a 56% higher risk of all-cause death (RR 1.56, 95% CI 1.30 to 1.87). Estimates observed in different studies and regions were completely consistent.

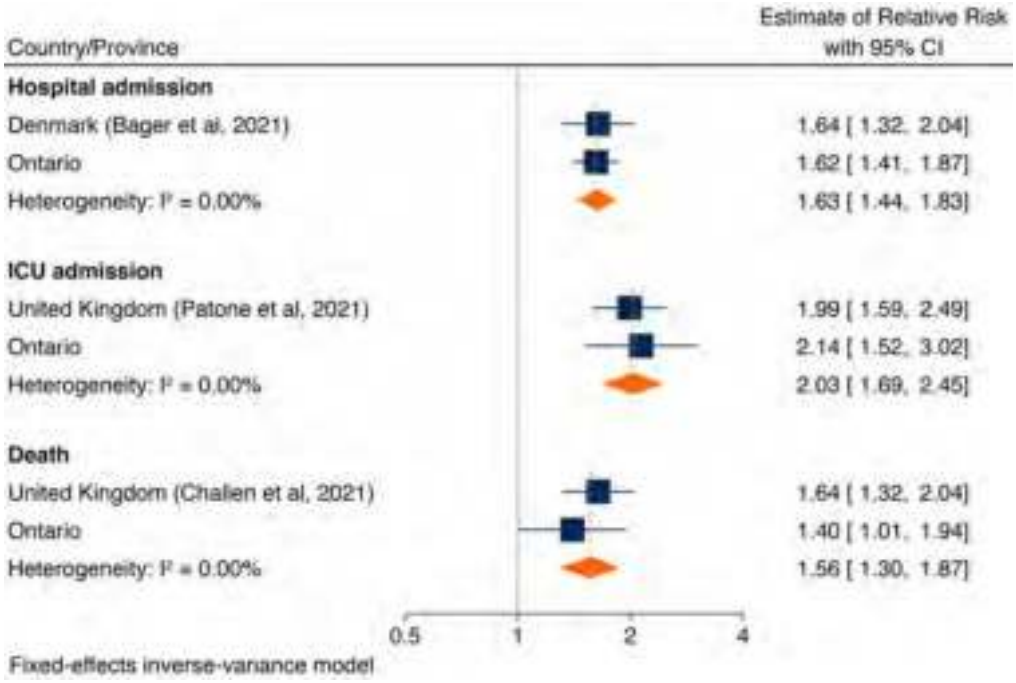

Figure 3. Meta-Analysis of the Risk of COVID-19 Hospitalization, Intensive Care Unit Admission and Death Associated with new VOCs Compared to Early Variants

Each square presents the results of an individual cohort study, with the size of the square being proportional to the weights used in the meta-analysis and the horizontal lines indicating the 95% confidence intervals. The solid vertical line at 1 indicates that there is no difference in prognosis between new VOCs and early variants. The diamond indicates the pooled estimate of the relative risk combining individual studies from different regions. Estimates for Ontario and Denmark are odds ratios; estimates for the United Kingdom are hazard ratios. The retrospective cohort study in Ontario included 26,314 participants in Ontario with PCR confirmed SARS-CoV-2 infection between February 7 and March 11, 2021, of whom 9,395 were infected with new VOCs. The retrospective cohort study by Bager et al. included 18,449 participants in Denmark with PCR confirmed SARS-CoV-2 infection between January 1 and February 9, 2021 with 2,155 infected with new VOCs.[7] Estimates were adjusted for age, sex, calendar period, region, and number of comorbidities during the past 5 years. The retrospective cohort study by Patone et al. included 198,420 individuals in the United Kingdom with PCR confirmed SARS-CoV-2 infection between November 1, 2020 and January 27, 2021, of whom 80,494 were infected with new VOCs. Relative risk estimates were adjusted for age, sex, region, socio-demographic factors and comorbidities, including asthma, chronic obstructive pulmonary disease, diabetes

and hypertension.[5] The retrospective cohort study by Challen et al. included 109,812 individuals in the United Kingdom with PCR confirmed SARS-CoV-2 infection between October 1, 2020 and January 29, 2021, with 54,906 participants with new VOCs matched to 54,906 participants with early variants.[6] Participants were matched on age, sex, date of specimen collection, ethnicity, geographical location, and index of multiple deprivation, which is a marker for socioeconomic status; estimates were subsequently adjusted for age. VOC, variant of concern; CI, confidence interval; ICU, intensive care unit.

Figure 4 shows the time to death observed in a retrospective cohort study by Challen et al. in the United Kingdom involving 109,812 participants with positive PCR tests for SARS-CoV-2 between October 1, 2020, to January 29, 2021, with 54,906 participants infected with new VOCs matched to 54,906 participants infected with the early variant.[6] The curves overlap until day 12 after diagnosis, at which point the curves start to separate, with a higher risk of death among participants infected with new VOCs compared with participants infected with early variants.

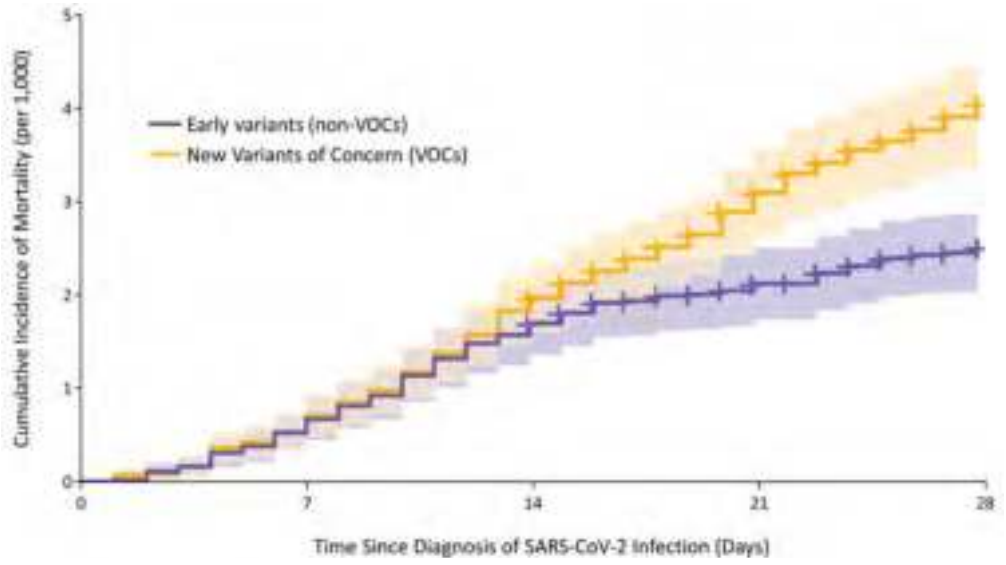

Figure 4. Time to Death Following SARS-CoV-2 Infection with New VOCs Compared with Early Variants
Curves describing the time to death from first PCR confirmation of SARS-CoV-2 infection among individuals in the United Kingdom infected with new VOCs versus early SARS-CoV-2 variants. Participants were matched on age, sex, date of specimen collection, ethnicity, geographical location, and index of multiple deprivation, which is a marker for socioeconomic status, and estimates were subsequently adjusted for age. Data from Challen et al.[6] VOC, variant of concern.

Figure 5 shows the risk of death associated with new VOCs compared with early SARS-CoV-2 variants from days 0 to 14 and days 15 to 28 after diagnosis of SARS-CoV-2 infection. Results are adapted from the aforementioned retrospective cohort study of people with PCR confirmed SARS-CoV-2 infection in the United Kingdom by Challen et al.[6] Between days 0 and 14 after diagnosis, there was only a minimal difference in the risk of death (RR 1.23, 95% CI 0.92 to 1.64) associated with the new VOCs compared with early variants. However, between days 15 and 28, the risk of death was more than doubled (RR 2.40, 95% CI 1.66 to 3.47).

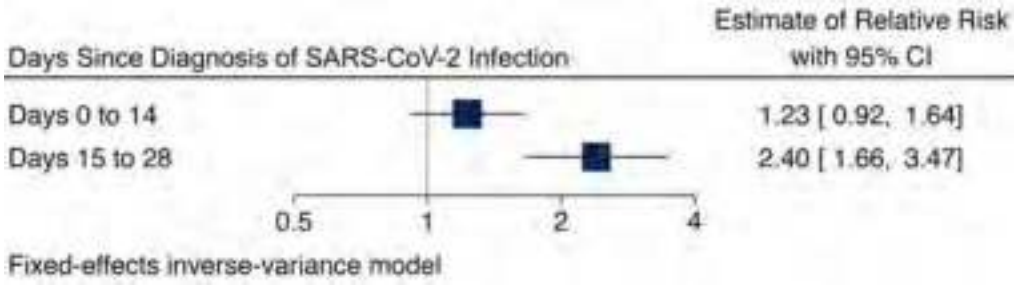

Figure 5. Risk of COVID-19 Death Associated with new VOCs Compared with Early Variants by Time Since Diagnosis of SARS-CoV-2 Infection
Adapted from a retrospective cohort study by Challen et al. which included 109,812 individuals in the United Kingdom with PCR-confirmed SARS-CoV-2 infection between October 2020 to 29 January 2021, with 54,906 individuals with new VOCs matched to 54,906 individuals with the early variant.[6] Individuals were matched on age, sex, date of specimen

collection, ethnicity, geographical location, and index of multiple deprivation, which is a marker for socioeconomic status. Each square presents the relative risk for death with the new VOCs versus early variants. The horizontal lines indicate the 95% confidence intervals. The solid vertical line at 1 indicates that there is no difference in prognosis between new VOCs and early SARS-CoV-2 variants. VOC, variant of concern; CI, confidence interval.

Figure 6 shows the risk of ICU admission associated with new VOCs versus early SARS-CoV-2 variants at days 1, 5, 10 and 15 after diagnosis of SARS-CoV-2 infection in a retrospective cohort study by Patone et al. The study involved 198,420 individuals in the United Kingdom with PCR-confirmed SARS-CoV-2 infection, of whom 80,494 were infected with new VOCs.[5] On day 1, there was a minimal difference in the risk of ICU admission between people infected with new VOCs and those infected with early variants (RR 1.20, 95% CI 0.58 to 2.48). Subsequently, there was a progressive, lagged increase in the risk of ICU admission associated with new VOCs, with a 58% increase at day 5 and a near fourfold increase at day 10.

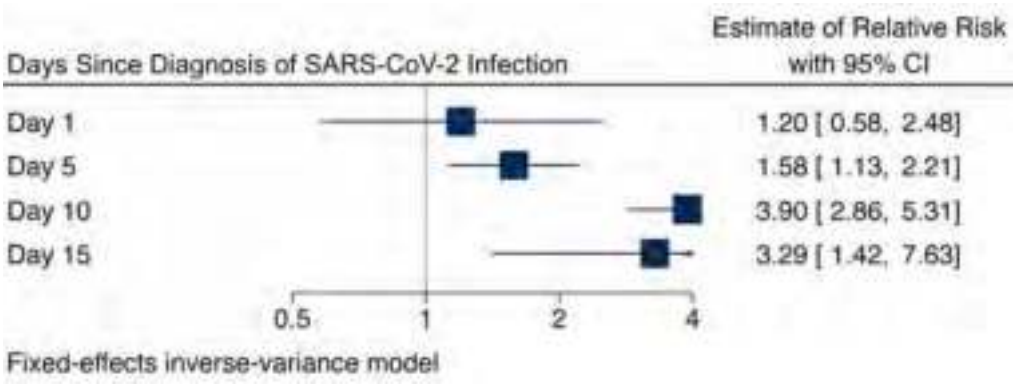

Figure 6. Risk of COVID-19 ICU Admission Associated with New VOCs Compared with Early Variants by Time Since Diagnosis of SARS-CoV-2 Infection

Adapted from a retrospective cohort study by Patone et al.[5] The study involved 198,420 individuals in the United Kingdom with PCR-confirmed SARS-CoV-2 infection, of whom 80,494 were infected with new VOCs. Relative risk estimated were adjusted for age, sex, region, socio-demographic factors and comorbidities including asthma, chronic obstructive pulmonary disease, diabetes and hypertension. Each square represents the relative risk for ICU admission with the new VOCs versus early variants. The horizontal lines indicate the 95% confidence intervals. The solid vertical line at 1 indicates that there is no difference in prognosis between new VOCs and early variants. VOC, variant of concern; CI, confidence interval.

Figure 7 shows the 7-day moving average of daily SARS-CoV-2 infections, and daily COVID-19 hospital and ICU occupancy in Ontario. At the time of the province-wide lockdown near the height of Ontario's second wave on December 26, 2020, there were 2,236 new infections per day, 755 people were hospitalized due to COVID-19, and 286 in ICU due to COVID-19.

Since the start of the third wave around March 1, 2021, the number of new cases, as well as hospital and ICU occupancy have surpassed prior thresholds seen at the start of the province-wide lockdown on December 26, 2020. The threshold of 286 COVID-19 cases in ICUs at the time of the lockdown on December 26, 2020, was reached on March 9, 2021. Likewise, COVID-19 hospital occupancy of 755 people was reached on March 16, 2021. Finally, the threshold of 2,236 new SARS-CoV-2 infections per day was reached on March 28, 2021.

We project a 2 to 4 week time lag between daily SARS-CoV-2 cases and COVID-19 hospitalizations and ICU admissions, with lagging risk increases due to the new VOCs (see Figures 3 to 5). Therefore, hospital and ICU occupancies due to COVID-19 will continue to increase considerably over time, and would so even if SARS-CoV-2 case numbers were to remain at the current level seen on March 28, 2021.

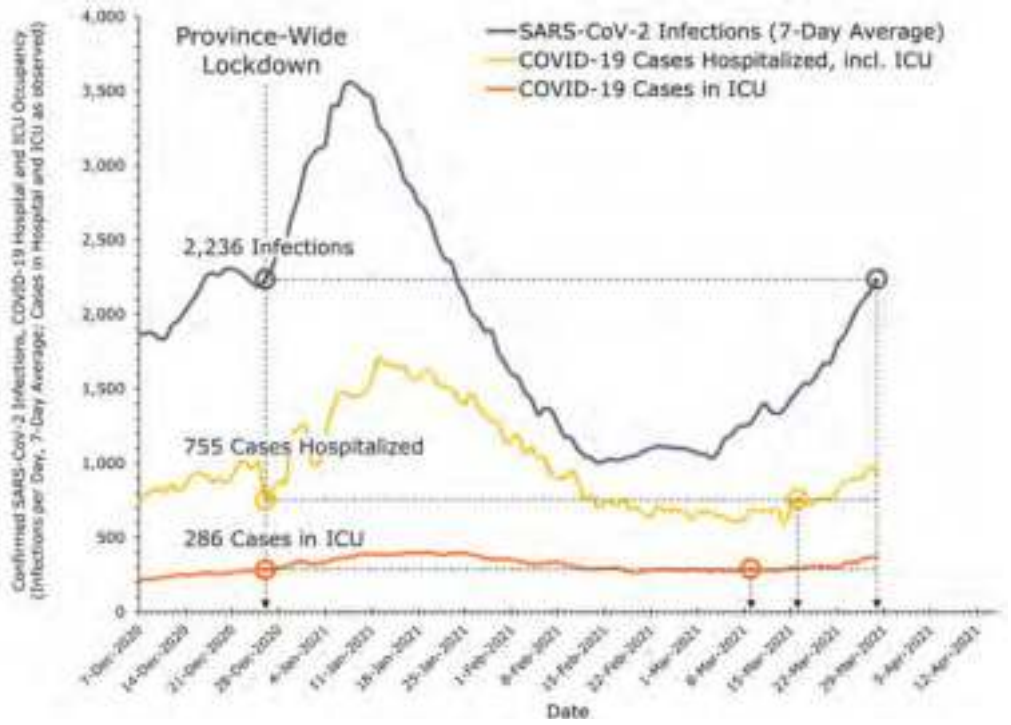

Figure 7. Number of New SARS-CoV-2 Infections, COVID-19 Hospital, and ICU Occupancy in Ontario
7-day moving averages of confirmed new SARS-CoV-2 infections in Ontario per week, number of people hospitalized with COVID-19, and number of ICU beds in Ontario occupied by COVID-19 patients. VOC, variant of concern; ICU, intensive care unit.

Table 2 presents a comparison of the number of new SARS-CoV-2 infections and COVID-19 hospital and ICU occupancy for key dates during the third wave compared with the start of the province-wide lockdown on December 26, 2020 during the second wave. As of March 28, 2021, the predicted 7-day average of SARS-CoV-2 infections during the third wave reached the 7-day midpoint average seen at the start of the province-wide lockdown on December 26, 2020.

Key	Date	SARS-CoV-2 Infections	Hospital Occupancy	ICU Occupancy
A	26-Dec-20	**2,236**	**755**	**286**
B	9-Mar-21	1,269	689	**290**
C	16-Mar-21	1,480	**761**	292
D	28-Mar-21	**2,236**	917	366

Table 2. Comparison of Key Dates During the Third Wave in Ontario with the Start of the Province-Wide Lockdown During the Second Wave on December 26, 2020
A, December 26, 2020, was the start date of the province-wide lockdown during the second wave; B, March 9, 2021 is the date when the COVID-19 ICU occupancy during the third wave reached COVID-19 ICU occupancy seen on December 26, 2020; C, March 16, 2021 is the date when COVID-19 hospital occupancy during the third wave reached COVID-19 hospital occupancy seen on December 26, 2020; D, March 28, 2021 is the date when the predicted 7-day average of SARS-CoV-2 infections during the third wave reached the 7-day midpoint average seen on December 26, 2020. ICU, intensive care unit. Second wave, September 1, 2020 to February 28, 2021. Third wave, March 1, 2020 to ongoing.

Figure 1 above presents a comparison of COVID-19 hospital occupancy and ICU occupancy in Ontario on March 28, 2021, compared with the start of the province-wide lockdown on December 26, 2020. The number of people hospitalized with COVID-19 on March 28, 2021, is 21% higher than on December 26, 2020, while ICU occupancy is 28% higher.

Figure 8 presents the percentage of COVID-19 ICU admissions in Ontario by age group in the week prior to the lockdown during the second wave (December 14 to 20, 2020) with the last available week of ICU admission data during the third wave (March 15 to 21, 2021). Between December 14 to 20, 2020, there were 149 new admissions to ICU; people aged 59 years and younger accounted for 30% of admissions. Between March 15, 2021 and March 21, 2021, there were 157 new admissions to ICU; people aged 59 years and younger accounted for 46% of admissions.

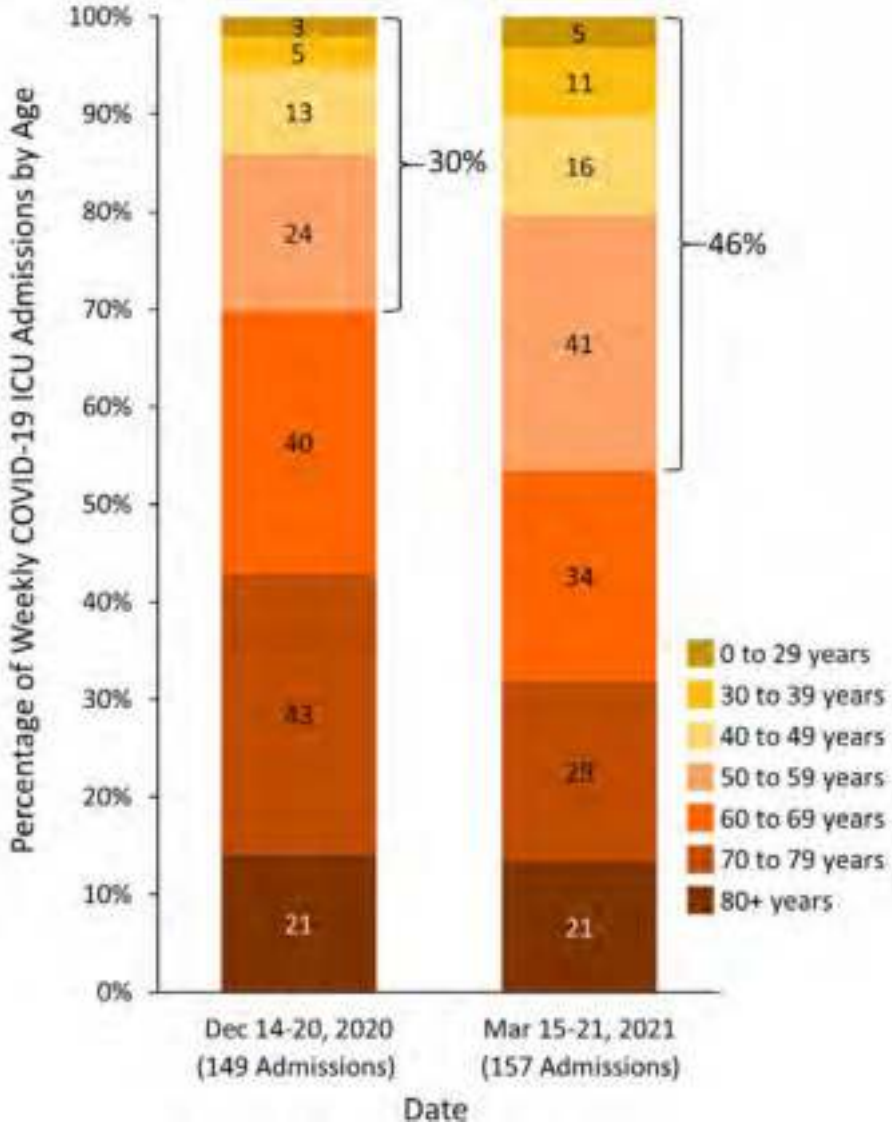

Figure 8. Weekly COVID-19 ICU Admissions in Ontario by Age
December 14 to 20, 2020 corresponds to the week prior to lockdown during the second wave, March 15 to 21, 2021 corresponds to the last available week of ICU admission data during the third wave. Data sourced from the Critical Care Information System (CCIS).

Interpretation

Compared with early variants of SARS-CoV-2, new VOCs are associated with a 103% increase in the risk of hospitalization, a 63% increase in the risk of ICU admission and a 56% increase in the risk of death due to COVID-19, which will result in a considerably higher burden to the health care system than observed with early variants during the second wave. The risk increase is particularly pronounced 14 to 28 days after a diagnosis of SARS-CoV-2 infection, which in turn will result in delays until the full burden to the health care system becomes apparent.

Since the start of the third wave around March 1, 2021, the number of new cases of SARS-CoV-2 infection, and the COVID-19 hospital and ICU occupancies have surpassed prior thresholds at the start of the province-wide lockdown on December 26, 2020. As of March 28, 2020, hospital occupancy was 21% higher and ICU occupancy 28% higher than at the start of the province-wide lockdown.

Currently, patients aged 59 years and younger make up 46% of new COVID-19 admissions to ICUs, compared with 30% in the week prior to the start of the province-wide lockdown on December 26, 2020.

Methods Used for This Science Brief

We conducted a retrospective cohort study using cases of SARS-CoV-2 infection reported in CCM/iPHIS with a case report date between Feb 7 and March 11, 2021. We restricted the analysis to cases that were tested for variants of concern. As Ontario's long-term care population was highly vaccinated with SARS-CoV-2 vaccines as of February 2021, and were unlikely to become critically ill and require intensive care, long term care residents were excluded from the analysis. A total of 26,314 individuals were included in the analysis, of whom 9,395 had a detected SARS-CoV-2 infection with a VOC. Associations between VOC SARS-CoV-2 infection and COVID-19 outcomes were evaluated by constructing logistic regression models with the following prespecified covariates: age (by 10-year age categories), sex, obesity, and any of the following medical comorbidities: asthma, immunocompromise, COPD, hematological disease, renal disease, neurological condition, diabetes, or liver disease. Time (date of case report) was included as a linear trend term. To account for geographic variability in the fraction of infections caused by VOCs, public health units were included as indicator variables. The analysis of the age distribution in Figure 8 is based on all cases, without exclusion of long-term care residents.

We searched PubMed, Google Scholar, the COVID-19 Rapid Evidence Reviews, the Joanna Briggs Institute's COVID-19 Special Collection, LitCovid in PubMed, the Oxford COVID-19 Evidence Service, the World Health Organization's Global Literature on Coronavirus Disease, and other COVID-19 specific resources listed by the Guidelines International Network and the McMaster Health Forum for studies on the prognosis associated with new VOCs compared with early variants. In addition, we retrieved reports citing relevant articles through Google Scholar and reviewed references from identified articles for additional studies. The search was last updated on March 26, 2021. For the United Kingdom, the analysis by Challen et al[6] was selected for extraction of mortality data rather than the analysis by Davies et al[4] since Challen et al.'s analysis was considered to have a lower risk of confounding.

We used an inverse-variance fixed-effects meta-analysis to combine adjusted estimates from individual studies. Analyses were done in R (R Foundation, Vienna, Austria) and STATA (StataCorp LLC, College Station, TX).

Author Contributions

PJ conceived the Science Brief. ART, AO and PJ wrote the first draft. ART, DNF, PB and PJ performed analyses. All authors revised the Science Brief critically for important intellectual content and approved the final version.

WEEKLY EPIDEMIOLOGICAL SUMMARY

SARS-CoV-2 Whole Genome Sequencing in Ontario, June 23, 2021

This report summarizes the results of SARS-CoV-2 whole genome sequencing completed by Public Health Ontario (PHO) as of June 17, 2021 and partner laboratories in the Ontario COVID-19 Genomics Network as of June 16, 2021. Not all data from the network laboratories were available to be included in this report. Results included in this report represent the number of samples tested and not the number of cases. More than one sample may be sequenced per person.

Background

The continued monitoring of global SARS-CoV-2 genomic data has identified changes in the genome as it spreads through populations. These random changes or mutations arise as a virus evolves over time. The accumulation of these mutations can result in a new lineage of the virus, which is a common occurrence. These new lineages will differ slightly in genome sequence and are termed variants. Although many variants will have no difference in the ability to spread or cause disease, some variants have mutations which may enhance virulence, transmissibility, and/or allow the virus to escape natural or vaccine-induced immunity.

The identification of variants and mutations occurs through whole genome sequencing (WGS) of select samples. Through global surveillance of SARS-CoV-2 genomes, a number of variants have been identified with evidence of clinical and/or public health significance, termed variants of concern (VOC). Current VOCs include B.1.1.7 (Alpha), B.1.351 (Beta), P.1 (Gamma) and B.1.617.2 (Delta). WGS has also identified a number of variants of interest (VOI), which may share one or more mutations in common with a VOC, but do not have sufficient evidence at this time to be categorized as a VOC (i.e. evidence of increased transmissibility, disease severity, or immune escape). These variants are also characterized and monitored through genomic surveillance. A VOI may be re-classified as a VOC where there is sufficient scientific evidence to support this designation. Full definitions of VOC/VOI can be found on the Public Health Agency of Canada's SARS-CoV-2 Variants webpage.[1]

The Ontario COVID-19 Genomics Network performs WGS on select samples received for SARS-CoV-2 diagnostic testing or VOC PCR testing. Sequences are processed using bioinformatics analysis and assigned a Pango lineage[2] using the pangolin tool[3], allowing for the identification of VOC, VOI and other lineages.

Highlights

- From May 9 to June 5, 2021, there were 2,342 samples sequenced by the Ontario COVID-19 Genomics Network for representative surveillance. The majority were Pango lineage B.1.1.7 (Alpha; 71.6%), followed by B.1.617.2 (Delta; 17.1%), and P.1 (Gamma; 4.0%).
- The proportion that were B.1.617.2 (Delta) increased from 14.1% (May 23 to 29) to 22.2% (May 30 to June 5).
- The public health units with the highest proportion of B.1.617.2 (Delta) from May 30 to June 5, 2021 were: Peel Public Health (38.2%), Region of Waterloo Public Health and Emergency Services (34.9%), Porcupine Health Unit (29.4%), and Halton Region Public Health (26.7%); excluding public health units with fewer than 25 samples sequenced.
- From January 1 to June 5, 2021, the most commonly identified VOI was B.1.1.318, with a total of 1,513 samples.

The data in this report should be interpreted with caution. For representative surveillance, PHO began sequencing eligible samples prior to other laboratories. For cumulative whole genome sequencing (WGS) results, the selection of samples for WGS historically has been influenced by laboratory testing algorithms. This has created a sampling bias reflected in the distribution of lineage results.

The Ontario COVID-19 Genomics Network is in the process of implementing a representative surveillance strategy. This will allow for provincial estimates of the prevalence of VOC, VOI, and other lineages. On June 14, the network moved to sequencing 100% of eligible samples.

Representative Surveillance

Table 1. Number and percentage of samples by VOC/VOI Pango lineage and week, representative surveillance, Ontario, May 9, 2021 to June 5, 2021

Pango lineage (WHO label)	Week 19 (May 9-15)	Week 20 (May 16-22)	Week 21 (May 23-29)	Week 22 (May 30-June 5)	Total (May 9-June 5)
Variant of concern (VOC)					
B.1.1.7 (Alpha)	337 (77.3%)	252 (68.9%)	483 (75.6%)	605 (67.1%)	1,677 (71.6%)
B.1.351 (Beta)	1 (0.2%)	3 (0.8%)	4 (0.6%)	5 (0.6%)	13 (0.6%)
P.1 (Gamma)	25 (5.7%)	14 (3.8%)	18 (2.8%)	36 (4.0%)	93 (4.0%)
B.1.617.2 (Delta)	47 (10.8%)	64 (17.5%)	90 (14.1%)	200 (22.2%)	401 (17.1%)
Variant of interest (VOI)					
A.23.1	0 (0.0%)	1 (0.3%)	0 (0.0%)	0 (0.0%)	1 (0.0%)
B.1.1.318	10 (2.3%)	8 (2.2%)	21 (3.3%)	19 (2.1%)	58 (2.5%)
B.1.427/B.1.429 (Epsilon)	0 (0.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)
B.1.525 (Eta)	3 (0.7%)	4 (1.1%)	4 (0.6%)	14 (1.6%)	25 (1.1%)
B.1.526 (Iota)	0 (0.0%)	0 (0.0%)	1 (0.2%)	0 (0.0%)	1 (0.0%)
B.1.526.1	0 (0.0%)	1 (0.3%)	3 (0.5%)	1 (0.1%)	5 (0.2%)
B.1.526.2	0 (0.0%)	0 (0.0%)	0 (0.0%)	1 (0.1%)	1 (0.0%)
B.1.526.3	0 (0.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)
B.1.616	0 (0.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)

B.1.617.3	0 (0.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)
P.2 (Zeta)	0 (0.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)
P.3 (Theta)	0 (0.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)
Non-VOC/VOI	12 (2.8%)	19 (5.2%)	14 (2.2%)	20 (2.2%)	65 (2.8%)
Total sequenced	**436 (100%)**	**366 (100%)**	**639 (100%)**	**901 (100%)**	**2,342 (100%)**

Note: Results may not be representative of Ontario overall. PHO began sequencing 10% of eligible samples on May 2 and 50% on May 30. Other VOC PCR testing laboratories were asked to submit 10% of eligible samples to the Ontario COVID-19 Genomics Network (OCGN) on May 26 and 50% on June 2. Results are included for four (of five) OCGN laboratories. Week was assigned based on earliest date available for the sample. Results for recent weeks are incomplete as not all sequencing and bioinformatics analysis were complete at the time of data extraction and will be included in subsequent reports.

Total sequenced	**6 (100%)**	**3 (100%)**	**15 (100%)**	**0 (0.0%)**	**47 (100%)**	**2 (100%)**	**73 (100%)**

Note: Results may not be representative of public health units overall. PHO began sequencing 10% of eligible samples on May 2 and 50% on May 30. Other VOC PCR testing laboratories were asked to submit 10% of eligible samples to the Ontario COVID-19 Genomics Network (OCGN) on May 26 and 50% on June 2. Results are included for four (of five) OCGN laboratories. Sample date is the earliest date available for the sample. Results for recent weeks are incomplete as not all sequencing and bioinformatics analysis were complete at the time of data extraction and will be included in subsequent reports. Public health unit was assigned based on patient postal code. If unavailable, ordering provider postal code was used.

Cumulative Whole Genome Sequencing Results

Table 4. Number of samples by VOC/VOI Pango lineage, cumulative counts, Ontario, January 1, 2021 to June 5, 2021

Pango lineage (WHO label)	January 1 - May 8	May 9 - June 5	Total
Variant of concern (VOC)			
B.1.1.7 (Alpha)	6,767	2,107	8,874
B.1.351 (Beta)	1,093	39	1,132
P.1 (Gamma)	3,324	365	3,689
B.1.617.2 (Delta)	269	684	953
Variant of interest (VOI)			
A.23.1	83	1	84
B.1.1.318	1,187	326	1,513
B.1.427/B.1.429 (Epsilon)	16	0	16
B.1.525 (Eta)	306	50	356
B.1.526 (Iota)	95	3	98
B.1.526.1	2	5	7
B.1.526.2	4	1	5
B.1.526.3	7	0	7
B.1.616	0	0	0
B.1.617.1 (Kappa)	72	5	77
B.1.617.3	2	0	2
P.2 (Zeta)	46	0	46
P.3 (Theta)	1	0	1
Non-VOC/VOI	3,390	126	3,516
Total sequenced	**16,664**	**3,712**	**20,376**

Note: Includes results from PHO since January 1, 2021, The Hospital for Sick Children since April 21, 2021, Kingston Health Sciences Centre since January 1, 2021, Shared Hospital Laboratory since March 26, 2021, and Hamilton Regional Laboratory Medicine Program since April 11, 2021. Past testing algorithms have led to preferential sequencing of samples with N501Y and/or E484K mutations detected by PCR, which has biased the results toward lineages with these mutations. Results should be interpreted with caution as frequencies do not reflect prevalence. Sample date is the earliest date available for the sample.
Data source: PHO, The Hospital for Sick Children, Kingston Health Sciences Centre, Shared Hospital Laboratory, Hamilton Regional Laboratory Medicine Program

Technical Notes

Data Sources

- Public Health Ontario (PHO)
    - Data were extracted from the PHO Laboratory Information Management System on June 17 at approximately 5:00 a.m.
    - Data were extracted from the PHO SARS-CoV-2 Whole Genome Sequencing Database on June 17 at approximately 9:00 a.m.
- The Hospital for Sick Children (HSC)
    - Data were received by PHO on June 16, 2021 at approximately 11:45 a.m.
- Kingston Health Sciences Centre (KHSC)
    - Data were received by PHO on June 16, 2021 at approximately 4:00 p.m.
- Shared Hospital Laboratory (SHL)
    - Data were received by PHO on June 16, 2021 at approximately 5:45 p.m.
- Hamilton Regional Laboratory Medicine Program (HRLMP)
    - Data were received by PHO on June 17, 2021 at approximately 6:45 a.m.

Ontario SARS-CoV-2 Whole Genome Sequencing Strategy

- At the beginning of 2021, Ontario's whole genome sequencing strategy was to sequence samples with specific mutations identified from VOC PCR testing to confirm they were variants of concern. From February 3, 2021 this included sequencing samples with the N501Y mutation detected (initially associated with the B.1.1.7 [Alpha] lineage) and from March 22, 2021, samples with the E484K mutation detected (initially associated with the P.1 [Gamma] and B.1.351 [Beta] lineages).
- Ontario's strategy has recently shifted to representative surveillance with VOC PCR testing laboratories being asked to send 10% of eligible samples (Ct ≤ 30 and sufficient volume remaining) to Ontario COVID-19 Genomics Network (OCGN) sequencing laboratories. PHO began sequencing a 10% systematic sample of eligible samples on May 2; 50% on May 30; and 100% on June 14. Other VOC PCR testing laboratories were asked to begin submitting a 10% systematic or random sample of eligible samples to OCGN laboratories on May 26; 50% on June 2; and 100% on June 14.

Data Caveats and Methods

- Whole genome sequencing sample logistics are complex and require samples to be transferred across a large network of laboratories. Samples are initially sent to one of 73 diagnostic testing laboratories. If the diagnostic PCR cycle threshold is ≤ 35 and there is sufficient volume remaining, samples are submitted for testing at one of 11 VOC PCR testing laboratories. If the VOC PCR cycle threshold is ≤ 30 and there is sufficient volume remaining, VOC PCR testing laboratories have been asked to submit a proportion of their eligible samples to one of five OCGN laboratories for sequencing according to the surveillance strategy.

- Results included in this report are sample-based and not person-based. As such, it is possible that more than one sample was sequenced per individual.

- The dates associated with samples submitted by network laboratories vary due to sample logistics and different laboratory information systems. Dates associated with WGS samples were assigned based on a hierarchy: sample collection date > SARS-CoV-2 diagnostic received date > SARS-CoV-2 diagnostic reported date > VOC PCR received date > VOC PCR reported date > WGS received date > WGS reported date. Weeks were created to align with surveillance weeks used by the Public Health Agency of Canada for influenza reporting.

- Lineage nomenclature is dynamic. Pango lineage naming and assignment may change as more samples are sequenced and analyzed globally. Similarly, VOC and VOI classifications may change.

Data Caveats and Methods: Representative Surveillance

- Results may not be representative of Ontario overall. Samples selected include a proportion of eligible samples received by OCGN laboratories according to the whole genome sequencing strategy. Individual VOC PCR laboratories may have implemented the strategy and/or increased the proportion of samples selected from 10% to 50% on different dates.

- PHO is unable to confirm whether VOC PCR testing laboratories have submitted eligible samples.

- Results for recent weeks are incomplete as not all sequencing and bioinformatics analysis were complete at the time of data extraction.

- Public health unit was assigned based on patient postal code. If unavailable, ordering provider postal code was used (13.8% of samples).

Data Caveats and Methods: Whole Genome Sequencing Results

- The data included do not reflect all whole genome sequencing conducted in Ontario. Data from the OCGN laboratories cover different time periods: PHO since January 1, 2021, HSC since April 21, 2021, KHSC since January 1, 2021, SHL since March 26, 2021, and HRLMP since April 11, 2021.

- Past testing algorithms have led to preferential sequencing of samples with N501Y and/or E484K mutations detected by VOC PCR. This has created a sampling bias reflected in the distribution of lineage results. Data submitted to PHO from other laboratories in the OCGN have not been independently verified.

COVID-19 Transmission Through Large Respiratory Droplets and Aerosols… What We Know So Far

Introduction

Public Health Ontario (PHO) is actively monitoring, reviewing and assessing relevant information related to Coronavirus Disease 2019 (COVID-19). "What We Know So Far" documents provide a rapid review of the evidence on a specific aspect or emerging issue related to COVID-19. Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is transmitted in different ways; however, this document will focus on transmission by respiratory droplets and aerosols.

Key Findings

- The historical dichotomy of droplet versus airborne transmission, while useful in implementing infection prevention and control (IPAC) strategies, does not accurately recognize the complexity of viral respiratory transmission, including for SARS-CoV-2.
- SARS-CoV-2 is transmitted most frequently and easily at short range through exposure to respiratory particles that range in size from large droplets which fall quickly to the ground to smaller droplets, known as aerosols, which can remain suspended in the air.
- There is evidence to suggest long-range transmission can occur under the right set of favourable conditions, implicating aerosols in transmission.
- The relative role of large respiratory droplets versus smaller droplet particles in short-range transmission is challenging to quantify. Their contributions to a specific case-contact interaction vary based on contextual factors including source/receptor characteristics (e.g., forceful expulsions such as singing, coughing, sneezing; viral load) and pathway characteristics (e.g., duration of exposure; environmental conditions such as ventilation, temperature, humidity, ultraviolet light; source control; and use of personal protective equipment).
- Translation of this summary into control measures needs to take into consideration other information, such as evidence around the effectiveness of control measures to date. Several control measures applied together in a layered approach are likely to be effective irrespective of the relative contribution of droplets or aerosols, including achieving high vaccination coverage and avoiding the "3 C's" (closed spaces, crowded places and close contact).

Background

The diameter of microorganism-containing respiratory particles relevant for respiratory infections ranges from approximately 0.01 micrometres (µm) to greater than 100 µm.[1] Particles larger than about 100 µm play a role in respiratory infection transmission by impacting on mucosal surfaces, such as the nostrils, mouth and eyes. Particles smaller than 100 µm can be inhaled or impact on mucosal surfaces. Some particles are small enough that they can be suspended in the air for various periods of time (known as aerosols).[2] Environmental factors such as local air currents and humidity affect these particles, e.g., how they move, evaporate, and how long they remain in air.[3] Therefore, the mode of transmission is influenced by three key elements: the source, the pathway, and the receptor. Depending on the unique characteristics of each element, certain modes may be more likely than others.

Traditionally, respiratory particles >5 or 10 µm have been termed droplets and were thought to impact directly on mucous membranes, while smaller particles were thought to be inhaled. This dichotomy of transmission routes has been applied to infection prevention controls within health care settings worldwide. However, these transmission routes are not mutually exclusive as droplets well over 5 µm are capable of remaining suspended in air for some time and can be inhaled. At short range within about 2 metres (m), infection can occur from inhaled aerosols as well as droplets landing on mucous membranes (short-range transmission). Herein, we refer to what was traditionally called airborne transmission via inhalation of aerosols that have remained suspended over long distances and periods of time[4,5] as long-range transmission.

We describe transmission through epidemiological studies, experimental or simulation of transmission studies, and statistical or mathematical modelling. Modelling shows what is possible, experimental studies what is plausible, and epidemiologic studies observe what is actually occurring, and each type of evidence is subject to limitations. However, exact routes of SARS-CoV-2 transmission in real-life scenarios can only be inferred based on the available data.

The purpose of this rapid review is to outline the evidence for droplets and aerosols in SARS-CoV-2 transmission. We have summarized the evidence as either short-range transmission from large respiratory droplets and small droplets or aerosols, or long-range transmission from aerosols.

Methods and Scope

In considering feasibility, scope and timelines, we undertook a rapid review to update our summary of SARS-CoV-2 transmission from large respiratory droplets and aerosols. A rapid review is a knowledge synthesis where certain steps of the systematic review process are omitted in order to be timely (e.g., duplicate screening).[6]

We conducted literature searches in MEDLINE (April 22, 2021) and National Institutes of Health COVID-19 Portfolio (Preprints) (April 27, 2021), search strategies are available upon request. We searched PubMed and Google Scholar on April 28, 2021 for additional articles of interest.

English-language peer-reviewed and non-peer-reviewed records that described large respiratory droplet and aerosol routes of transmission of COVID-19 were included. We restricted the search to articles published after January 1, 2020. This rapid review concentrated on evidence from systematic reviews and meta-analyses, supplemented by primary literature where appropriate. We reviewed citations from included articles to identify additional research.

Prior to publishing, PHO subject-matter experts review all What We Know So Far documents. As the scientific evidence is expanding rapidly, the information provided in this document is only current as of the date of respective literature searches.

Out-of-scope for this document was a review of IPAC practices appropriate for individual transmission scenarios and settings. Application of a hierarchy of control measures for non-health care settings is briefly discussed in the conclusions. For additional information related to IPAC in health care settings, please see PHO's technical briefing *IPAC Recommendations for Use of Personal Protective Equipment for Care of Individuals with Suspect or Confirmed COVID-19* and *Interim Guidance for Infection Prevention and Control of SARS-CoV-2 Variants of Concern for Health Care Settings*.[7,8] Please note that the *Ministry of Health's Directive 1* is the provincial baseline standard for provision of personal protective equipment for hospitals, long-term care homes and retirement homes and that the *Ministry of Health's Directive 5* provides agency to health care workers to make professional decisions regarding the appropriate personal protective equipment when dealing with suspected, probable or confirmed COVID-19 patients or residents.[9,10] Evidence for contact/fomite transmission, and virus and host (source/receptor) factors were not reviewed in this document, but are acknowledged as contributors to short- and long-range transmission. Other routes of transmission are reviewed in PHO's synthesis *COVID-19 Routes of Transmission – What We Know So Far*.[11]

Short-range Transmission

Main Findings

SARS-CoV-2 is transmitted most frequently and easily at short range. Short-range transmission generally occurs within 2 m of an infectious individual (e.g., during a conversation with inadequate distancing, no barriers, no personal protective equipment). Theoretically, short-range transmission may occur due to droplets or aerosols, but the relative contribution of either is specific to each case-contact interaction which varies based on contextual factors including source/receptor and pathway characteristics.

Environmental Factors Affecting Short-range Droplets and Aerosols

In addition to virus and host factors, environmental factors are associated with short-range viral transmission. The distance travelled by large respiratory droplets is generally <2 m, although it can reach up to 8 m in certain circumstances. In a study by Guo et al. (2020), SARS-CoV-2 virus was detected on the floor up to 4 m away from a patient.[12] In a systematic review of studies assessing the horizontal distance travelled by respiratory droplets, Bahl et al. (2020) reported that droplets could travel up to 8 m.[13] In a mathematical model, Chen et al. (2021) reported that respiratory droplets >100 µm in diameter are only important in transmission at a distance of less than 0.2 m when the infector is talking, or within 0.5 m when the infector is coughing.[14] Modelling by Wang et al. (2021) (preprint) suggested droplets >100 µm would most often not travel past 1.75 m (most droplets >100 µm diameter settle before 1.25 m).[15]

In a review of respiratory virus transmission, Leung (2021) reported that environmental factors affecting transmission include temperature, relative humidity, ventilation, airflow and ultraviolet (UV) light.[16] Ventilation, airflow and forceful expulsion (sneezing or coughing) can make respiratory particles travel further than 2 m through momentum.[14,17] High temperature and low humidity contributes to shrinking of droplets such that they may remain suspended in air for longer periods of time.[18]

Even at short-range distances, ventilation may affect transmission. De Oliveira et al. (2021) modelled infection risk in ventilated (10 air changes per hour [ACH]) and unventilated spaces without respiratory protection during a 1-hour exposure at 2-m distance.[19] The impact of decreasing concentration of virus in the air through ventilation was notable. Estimates of infection risk were reduced by at least three times based on the parameters and assumptions of their model. The authors also commented that the direction of airflow can have a significant impact – upward air streams can maintain aerosols at face height significantly increasing infectious risk.

Indoor settings are a predominant risk factor for transmission. In a systematic review of 5 studies, Bulfone et al. (2020) reported that the odds of indoor transmission were 18.7 times (95% confidence interval [CI]: 6.0–57.9) higher than outdoor settings, and less than 10% of infections occurred outdoors.[20] Very few superspreading events have been described from exclusively outdoor exposures. The explanation for this observation is likely multifactorial which includes important differences in ventilation, UV light, humidity, as well as possible differences in behaviour.

Epidemiological and Modelling Studies Describing Short-range Transmission

The following section reviews the epidemiologic and modelling evidence supporting short-range transmission of COVID-19. It reviews the reproductive number and summarizes the epidemiological and modelling studies by setting, including transportation, health care and sports.

The reproductive number (R_0) of SARS-CoV-2 is less suggestive of long-range transmission commonly occurring, as viruses where long-range transmission commonly occurs tend to have a higher R_0.[16] For example, in a systematic review by Guerra et al. (2017), the R_0 for the measles virus in the pre-vaccine era was 6.1–27.0,[21] compared to the median range of R_0 (2.7–3.3) reported for SARS-CoV-2.[22] It is important to note that R_0 is not a direct measure or indication of transmission route, as R_0 can be setting and population-specific, and be impacted by factors such human behaviours. The R_0 for SARS-CoV-2 also displays overdispersion, where the overall R_0 is lower than pathogens that commonly transmit through aerosols at long-range, but a small proportion of cases are associated with reproductive numbers in the range typical of viruses that commonly transmit through aerosols at long-range (i.e., superspreader events).[23] Such cases illustrate the potential variability in COVID-19 transmission, depending on differences in source/receptor characteristics and environment.

Short-range transmission was favoured in a retrospective cohort study of 18 short-to-medium haul flights (median flight time 115 minutes) to England from the beginning of the pandemic.[24] The attack rate was 0.2% (95% confidence interval [CI]: 0.1–0.5) for all aircraft-acquired cases, and was higher at 3.8% (95% CI: 1.3–10.6) if a subgroup analysis was performed only on contacts within a two-seat radius. It was assumed that no masks were worn given that it was early in the pandemic.

Family gatherings for meals are high-risk scenarios for transmission. Lo Menzo et al. (2021) reported transmission of lineage B.1.1.7 variant of concern to 8 of 9 family members during a dinner gathering.[25] The only uninfected family member was presumed to have immunity acquired from a previous infection (high antibody titres and polymerase chain reaction (PCR) negative result). Contact and fomite transmission cannot be excluded from this type of event.

In a case-control study of 154 patients 18 years and older in the United States (US), Fisher et al. (2020) reported that close contact with a person with COVID-19 was reported more often among cases (42.2%) than controls (14.5%) ($p<0.01$).[26]

Short-range transmission has been documented in school settings. Four student-to-student and one student-to-teacher transmission events were reported in Salt Lake County, Utah.[27] For four transmission events, unprotected, short-range exposures were noted. There was a lack of transmission to other students that were a median of 1 m away during class, but adhered to control measures implemented in the school. However, when household transmission associated with the secondary cases was evaluated, transmission was high for 3 of the 5 households of secondary patients. In these three households, 6 of 8 household members were also infected and may be related to challenges with physical distancing, masking, and shared surfaces in the household.

Using whole genome sequencing of SARS-CoV-2 clinical samples (n=50) in Dublin, Ireland, Lucey et al. (2020) investigated cases of hospital-acquired COVID-19 and reported that the majority of infections were among patients who required extensive and prolonged care by health care providers.[28] The authors concluded that the likely mode of transmission from health care workers to patients was through short-range transmission and close contact, rather than long-range transmission. Notably, the use of masks by health care providers was not universal and patients were not wearing masks either.

Three short-range health care-associated transmission events have been reported where large respiratory droplet transmission was less likely because masks were worn by either the source or the contact and in two of three events, the contact was also wearing eye protection.[29] In case 1, an asymptomatic, unmasked patient transmitted infection to two health care workers who wore medical masks and face shields, following multiple hours of exposure in a room with 6 ACH. A second case occurred where a presymptomatic masked health care worker transmitted infection to an unmasked patient in a room with 6 ACH. A third case involved a presymptomatic masked patient transmitting infection to a health care worker who was wearing a mask and goggles during a 45 minute face-to-face discussion at 1 m. Notably in the third case, the patient's mask was removed temporarily for oropharynx inspection. While each case was verified by whole genome sequencing, there was a lack of detail about the specific encounters (e.g., distance, duration, if direct contact occurred, if doffing errors occurred), and no airflow studies were conducted.

An analysis of SARS-CoV-2 infections in an outdoor rugby league, including video evaluation of close contact due to tackling inherent in the game, indicated that no cases among players in the league could be linked to close-contact during the outdoor rugby games.[30] Instead, transmissions were linked to other indoor short-range transmission events. While this study demonstrates examples where outdoor close-contact transmission did not occur, there were not enough close-contacts documented to provide evidence that close-contact transmission could not have occurred in the context of outdoor rugby.

In a modelling study, Zhang and Wang (2020) reported that the median infection risk via long-range aerosol transmission (10^{-6}–10^{-4}) was significantly lower than the risk via close contact (10^{-1}).[31] The model was based on a 1-hour exposure in a room with an area of 10–400 m^2, with one infected individual and a ventilation rate of 0.1–2.0 ACH. In a modelling study by Hu et al. (2020), the transmission risk from epidemiological data among train passengers as 0%–10.3% (95% CI: 5.3%–19.0%).[32] Travellers directly adjacent to the index patient had a much higher infection risk (relative risk [RR]: 18.0; 95% CI: 13.9–23.4), and the attack rate decreased with increasing distance.

Household and Non-Household Secondary Attack Rates

The consensus among systematic reviews is that household settings, where physical distancing, consistent source control mask-wearing, and disinfection of shared surfaces are potentially not feasible, are associated with a higher risk of infection compared to casual-contact settings (17%–27% compared

to 0%–7%). However, the secondary household attack rates are not as high as would be expected if SARS-CoV-2 easily spread through long-range transmission (e.g., >90% in measles).[16,33]

In a systematic review and meta-analysis of 54 studies and 77,758 patients, Madewell et al. (2020) reported that the household secondary attack rate was 16.6% (95% CI: 14.0–19.3).[34] In a systematic review and meta-analysis of 45 studies, Thompson et al. (2021) estimated the household secondary attack rate as 21.1% (95% CI: 17.4–24.8; 29 studies).[35] Non-household settings had lower secondary attack rates: 1) social settings with family and friends (5.9%; 95% CI: 0.3–9.8; 7 studies); 2) travel (5.0%; 95% CI: 0.3–9.8; 5 studies); 3) health care facilities (3.6%; 95% CI: 1.0–6.9; 10 studies); workplaces (1.9%; 95% CI: 0.0–3.9; 7 studies); and casual social contacts with strangers (1.2%; 95% CI: 0.3–2.1; 7 studies). Koh et al. (2020), in a meta-analysis of 43 studies, reported that the household secondary attack rate was 18.1% (95% CI: 15.7–20.6; 43 studies), much higher than the secondary attack rate in health care settings (0.7%; 95% CI: 0.4–1.0; 18 studies).[36] In a systematic review and meta-analysis of 24 studies, Lei et al. (2020) reported that the secondary attack rate in households was 27% (95% CI: 21−32); the risk of secondary infection was 10 times higher in households compared to non-household settings (odds ratio [OR]: 10.7; 95% CI: 5.7–20.2; p<0.001).[37] Tian and Huo (2020), in a meta-analysis of 18 studies, reported that the household secondary attack rate was 20% (95% CI: 15–28; 15 studies; n=3,861 patients), followed by social gatherings at 6% (95% CI: 3–10; 5 studies; n=2,154 patients) and health care settings at 1% (95% CI: 1–2; 4 studies; n=1,320 patients).[38]

Long-range Transmission

Main Findings

Transmission of SARS-CoV-2 over longer distances (generally >2 m) and time occurs through inhalation of aerosols under favourable circumstances, such as prolonged exposure in an inadequately ventilated space. Current evidence supports long-range transmission of SARS-CoV-2 occurring “opportunistically”, in that long-range transmission can occur under some circumstances, but inconsistently, and is not the predominant situation in which transmission occurs. Epidemiological and modelling studies support that long-range transmission via aerosols occurs. All of these examples include combinations of favourable source/receptor and pathway conditions such as inadequate ventilation, prolonged exposure time, high viral load, with certain activities (singing, exercising, yelling, etc.), and lack of masking for source control by the index case.

Environmental Factors Affecting Long-range Aerosols

In experimental models, researchers have demonstrated the potential for long-range transmission. In a series of experiments, simulations and modelling, Wang et al. (2021) (preprint) reported that aerosols could remain suspended for a longer period than historically predicted.[15] In general, viral copies/millilitre (ml) or concentration decreased as distance from source increased. The work showed that the evaporation time for large respiratory droplets is longer than predicted, especially at higher relative humidity (90%). In a sneeze plume, the largest respiratory droplets (>100 µm) are centrally located within the plume, with smaller respiratory droplets and aerosols at the periphery. The largest droplets contain more virus copies but are less abundant as they settle quickly to the ground, while smaller droplets carry fewer virus copies but are more abundant and remain in the air. The authors conclude that while aerosol transmission is important past 1 m from the source, aerosol transmission is likely even more important at shorter ranges.

Modelling studies have also highlighted the potential for aerosol transmission at varying distances. Xu et al. (2021) analysed the data of 197 symptomatic COVID-19 cases in the Diamond Princess cruise ship outbreak and concluded that long-range transmission did not occur between cabins based on the random distribution of symptomatic cases on all decks and the lack of spatial clusters of close contact (within cabin) infection.[39] The authors inferred that most transmission had occurred in public areas before the quarantine, possibly due to crowding and insufficient ventilation in those spaces. The authors also inferred that there was no transmission between passenger rooms during the quarantine period, and suggested that the ship's central heating, ventilation, and air conditioning (HVAC) system did not play a role in SARS-CoV-2 transmission. However, the authors noted that the lack of data on 109 of the 306 symptomatic individuals and on the 328 asymptomatic individuals may alter their estimation. In addition, their estimation did not take into consideration possible transmission between crew and passengers. Another model of the same outbreak estimated that the contribution of short-range transmission (from large droplets or aerosols) accounted for a median of 36% (mean: 35%) of transmission events, fomite (median: 21%; mean: 30%) and long-range (median: 41%; mean: 35%) contributing to the remainder.[40]

A study of aerosol particles (<5 μm diameter) by Dobramysl et al. (2021) (preprint) reported that time to infection increases approximately linearly as distance from source increases, the most important parameter for time to infection.[41] Exposure to a person breathing normally (simulating an asymptomatic individual) at a distance of 1 m led to infection after 90 minutes; however, coughing every 5 minutes led to infection in 15 minutes. Mask use and even minimal ventilation increased time to infection at a given distance. The importance of ventilation is also described in a modelling study by Jones (2020) which suggested that exposure to inhalable particles mostly (80%) occurs within close proximity to the patient.[42] In still air, aerosols will rise above head-level; however, turbulent air can change the trajectory of virus-laden aerosols, bringing aerosols closer to the head.[43-45] A modelling study by Sen (2021) found that when the ceiling-mounted elevator fan was off, about 11% of the droplets expelled by coughing fell to the ground while 89% evaporated and became smaller.[46] After travelling downward in cough-induced turbulence for approximately 6 seconds, droplets about 50 μm tended to move up and spread in the upper part of the elevator. If the cough happened at 30° to another rider, up to 40% of the droplets may fall on the face of another elevator rider. However, when the fan is operating, up to 50% of the droplets were dragged down to the floor in less than 3 seconds.

The basement of a large wholesale market was investigated as the source of a major outbreak in Beijing, China.[47] Many factors contributed to spread across multiple possible modes of transmission including long-range transmission. A field study of the area using fluorescent powders and microspheres as tracers allowed authors to conclude that while air was circulated, the air was unfiltered and there was very little fresh air, there was high humidity, low temperature, inadequate hand sanitization supplies in washrooms, and significant contamination of surfaces possibly due in part to resuspension of droplets from wet floors.

Given that persistence of aerosols over time is a factor in long-range transmission, the viability of SARS-CoV-2 in aerosols is important to consider. The half-life of SARS-CoV-2 in aerosols is approximately 1 hour.[48,49] Humidity seems to have less of an effect on SARS-CoV-2 viability in aerosols compared to the effect of sunlight or temperature.[50,51] Increasing temperature is associated with a reduction in the half-life of SARS-CoV-2 in aerosols.[52-54] Using a rotating drum experiment similar to other studies for viability of SARS-CoV-2, simulated sunlight (UVA/UVB) was applied to aerosolized virus through a window on the drum.[51] Results indicated 90% inactivation of virus within 20 minutes.

Inadequate ventilation can contribute to spread of aerosols, where the buildup of infectious aerosols is inversely proportional to the number of air exchanges.[55-57] In a modelling study, Schijven et al. (2021) assessed the risk of aerosol transmission of SARS-CoV-2 at a distance beyond 1.5 m from continuous breathing, speaking, or singing, or from one cough or one sneeze, in an indoor environment of 100 m^3.[58] Where there was no ventilation, the mean risk of transmission (derived from dose-response data for human coronavirus 229E) after 20 minutes of exposure to a person with 10^7 RNA copies/ml of mucous was estimated at 0.1%, except for sneezing with high aerosol volume (40,000 picolitres/sneeze). The mean risk of transmission increased to above 30% for sneezing with high aerosol volume and above 10% for singing after an exposure of 2 hours to a person with mucous RNA concentration above 10^8 copies/ml. Ventilation at 1 ACH reduced the risk by approximately half and at 6 ACH, the risk of transmission was reduced by a factor of 8–13 for sneezing and coughing, and by a factor of 4–9 for singing, speaking and breathing.

Estimates for minimum infectious dose, amount of viable virus in aerosols and quantified exposure rates are lacking. One preprint study assessed superspreading events related to long-range transmission in order to determine a minimum infectious dose for transmission.[59] The model used rate of aerosolized virion shedding based on data from other coronaviruses and a destabilization rate measured for SARS-CoV-2. They reported a critical exposure threshold for aerosol transmission of 50 virions. A computational characterization of inhaled droplets by Basu (2021) reported an estimated inhaled infectious dose around 300 virions, which was similar to estimates of 500 virions for ferrets.[60] The author acknowledged that this estimate could vary widely depending on environmental and individual biological factors.

Epidemiological and Modelling Studies Describing Long-range Transmission

Epidemiological case studies have reported long-range transmission of SARS-CoV-2, exclusively in indoor settings (e.g., bus, church, restaurant, concert halls, apartment building, office building).[61-67] In most of these case studies, long-range transmission was inferred as the dominant route of transmission, given that infectees were usually further than 2 m away from index cases. In addition, in these case studies, susceptible people were exposed to index cases for prolonged periods (>50 minutes) in indoor environments with inadequate ventilation and, in some instances, with increased respirations (e.g., singing, yelling, or exercising) and/or no face mask use (by case and/or contact). As with most epidemiological studies on transmission events, it was difficult to exclude other contributing routes of transmission. We summarize a few of these case studies, highlighting settings and contributing contextual factors to long-range transmission.

Stagnant indoor conditions can contribute to aerosol transmission. One example is a series of transmissions linked to an individual who developed symptoms around the time they were playing squash in an unventilated squash court.[68] Players who arrived hours after the index case and played in the same squash court were later identified as positive cases, though the role of other potential routes (e.g. unidentified staff contacts, shared surfaces) may have contributed as well and the source of transmission could not be confirmed. In contrast, a post-operative analysis of susceptible patients (no previous SARS-CoV-2 infection or vaccination) in a surgical suite within 48 hours following the use of the suite by SARS-CoV-2 positive patients indicated that there were no transmission events. The event rate was lower than the number of events in a control group (0% vs. 1.9%).[69] Ventilation was likely a significant factor that prevented transmission in the surgical suite.

In a study of six indoor singing events (five with transmission) in the Netherlands, Shah et al. (2021) (preprint) reported that long-range transmission was the likely route of transmission (short-range transmission possibly contributing to transmission at three of these events and indirect contact transmission possibly contributing to transmission at one of the events).[62] The authors assigned transmission likelihood as either less likely or possible; however, the authors do not state how these were defined. Attack rates at these events ranged from 25%–74% (9–21 people aged 20–79 years attended the events) and authors hypothesize that singing led to transmission. The authors note that they cannot quantify the contribution of each route of transmission. Genomic sequencing was not performed to help rule out other sources of SARS-CoV-2.

In a choir group (Washington, US), 53 of 60 individuals (excluding the index patient) were confirmed or strongly suspected to have been infected during a 2.5 hour rehearsal in a main hall.[64] Individuals who moved to another area of the building from the index case to practice for 45 minutes were less likely to become infected than those who remained in the main hall for the full duration of the rehearsal.

Twelve secondary cases of SARS-CoV-2 were linked to an index case, an 18-year-old chorister with high viral load who sang at four 1-hour services.[70] The index case was seated at a piano raised approximately 3 m from the ground floor and facing away from the secondary cases. Secondary cases sat between 1–15 m (horizontal distance) from the index case. Use of masks was not in place and there was minimal ventilation during the service (ventilation system was off, fans were off and doors and windows were largely closed). Interestingly, no new cases were linked to exposure that occurred the day of respiratory symptom-onset, and no explanation could be provided for why only a certain section near the chorister was affected and other sections (including those directly in front of the index case) were not.

In a case study by Shen et al. (2020), passengers who were not wearing masks were exposed to a presymptomatic index patient for 100 minutes while on a bus in eastern China.[61] Twenty-four of 67 passengers became infected, including several passengers seated beyond 2 m distance. The bus containing the index patient was heated and air was recirculated without filtration. Infections occurred in individuals at either end of the bus and the index case was located roughly in the middle. Risk of infection was only moderately higher for individuals sitting closer to the index patient. In contrast, seven of 172 other people attending the same religious event were positive for SARS-CoV-2. Some of the cases became positive after 14 days from exposure; thus, transmission likely did not occur on the bus for these case. The authors of this study postulate that the poor ventilation in the bus supports aerosol transmission in this cluster; however, other routes of transmission such as close contact from movement within the bus or fomites could not be excluded.

Vehicles are also potential environments for short-range and long-range transmission. A patient transport van was implicated in long-range aerosol transmission despite physical distancing observed by the infected drivers in two distinct transmission events.[71] One driver did not wear a mask, but all passengers wore a single-layer mask. The passengers were exposed for 2 hours during both events. Transmission was confirmed by whole genome sequencing. Fans were on medium speed and windows were closed. Airflow experiments were conducted with different size aerosols demonstrating plausibility of spread from the driver.

An epidemiological investigation of a chain of transmissions was reported beginning with a flight from India to New Zealand, a bus ride to a quarantine facility, a stay at a quarantine facility, a bus ride to the airport, and subsequent household transmissions.[72] Based on positivity test dates, genome sequencing, flight positions and hotel room placement the transmission events were ascribed to both short-range and long-range transmission on flights, within the quarantine facility, and within households. Masks

were required on flights and bus rides. One of the transmission events occurred between two adjacent hotel rooms in the quarantine facility. The authors used recorded video and observed >20 hours between any shared items and no direct contact. The authors concluded that fomite transmission was unlikely and attributed transmission to aerosols in the corridor outside of the hotel rooms wherein the space was enclosed and unventilated. Notably, the hotel rooms themselves, based on a review of the ventilation system, exerted positive pressure relative to the corridor.

An investigation by Lin et al. (2021) into an outbreak of nine COVID-19 cases from three families living in vertically-aligned units of an apartment building in Wuhan, China supported the possibility of long-range transmission.[66] Phylogenetic analysis of respiratory samples showed that all cases were infected by the same strain of SARS-CoV-2. Epidemiological investigation revealed that 4/5 cases of the index family in apartment 15-b had a travelling history to Wuhan, while the other four cases in apartments 25-b and 27-b had neither a travelling history to Wuhan nor close contact with any COVID-19 cases prior to their infection. Transmission through close contact in the elevators was considered unlikely as video records in the elevator did not show any close contact between the index family and the cases from units 25-b and 27-b. However, there was an incident where one unmasked occupant of unit 27-b took the elevator 8 minutes after two unmasked occupants from the index family had left the elevator. Epidemiologically, the infection rate for residents in units b was significantly higher ($p<0.05$) than that in units a and c. Testing of wind speed at the bathtub drain and floor drain found that the airflow produced by toilet flushing on one storey can influence the entire building as the drain pipes for toilets and the sewage pipes connected with floor drains were connected with the exhaust pipe. An experiment with a tracer gas indicated that gas could spread from one storey to another via the drainage and vent systems, especially as the seals in U-shaped traps in the floor drains were dried out in some units and the use of exhaust fans could create a negative pressure in the pipeline system. A similar situation was reported involving air ducts in a naturally ventilated apartment complex in Seoul, South Korea.[67] There were no valves blocking air from entering the bathrooms from the shared natural ventilation shafts (not for building or apartment unit ventilation). Limitations of this outbreak investigation included no genome sequencing or air sampling. Direct applicability to Canadian contexts may be limited by different building construction standards and practices.

Independent of ventilation, movement of air from an infected individual to others nearby can be an important factor in long-range transmission. Direct airflow was deemed responsible for a long-range transmission event in a restaurant in Korea.[73] The suspected index case sat 4.8 m and 6.5 m away and directly upwind of the airflow from two secondary cases at different tables. Nine other visitors in the restaurant did not test positive for SARS-CoV-2 even though at least two were closer to the index case for longer but not in the direct path of airflow originating from the index case. Notably the transmission in one case was suspected to have occurred from an exposure as short as five minutes, and three patrons sitting with the secondary cases but facing away from the index cases were not infected.

An investigation by Lu et al. (2020) into a COVID-19 outbreak in a restaurant in Guangzhou, China involving three families sitting at three tables in close proximity for about 1 hour concluded that the air conditioning (AC) system likely contributed to transmission.[63] In this scenario, a presymptomatic index case and secondary cases were present in the same area for 53–73 minutes. The location of a consistently running AC unit was in the airflow path of the secondary cases and was in an enclosed environment. No secondary cases occurred in staff or at adjacent tables that were outside of the likely "air column". The furthest distance between index and secondary cases was approximately 3 m. Additional investigation indicated that the exhaust fans had been closed due to cold outside temperatures.[74] The airflow assessment indicated that air was recirculating in a defined area, which exposed the three families.

A report involving group exercise at three facilities in Hawaii, US calculated attack rates of 25%–100%.[75] There was no fresh air ventilation and exposure occurred over a duration of 1 hour. Extended close contact and lack of masks in some cases were concluded as contributing to the transmission.

An outbreak in a multi-bed hospital room occurred wherein three patients and six health care workers became infected despite the use of masks and presence of ventilation of 3–4 ACH.[76] The presymptomatic index case was a parent located in a chair beside their child's bed who constantly wore a surgical mask, near the entrance to the room. Notably the air conditioning unit appeared to be located on the ceiling and no details were given about how it operated (e.g., constant versus timed/triggered) and what amount of fresh air circulation it provided. There were no exhaust vents indicated on the room diagram. Exposures for health care workers were in the range of 10–15 minutes, most at distances further than 2 m from the index patient. The report noted that masks were worn as personal protective equipment by health care workers. Transmission was based on the epidemiology of the outbreak without corroboration by genomic analysis of infections.

Detection of SARS-CoV-2 in Air Samples

Air sampling for virus refers to the process of collecting volumes of air by a device to determine if aerosols may contain virus. Collection can vary by aerodynamic size captured, duration of collection, volume per second collected, and media on which samples deposit. Air samples can then be tested by molecular methods such as reverse transcription PCR (RT-PCR) to amplify viral nucleic acids and/or viral culture. RT-PCR cannot determine whether the microorganisms detected are viable. Viral culture is used to determine whether a sample containing the virus is capable of replication. While there are several factors that contribute to the probability of infection, replication is a surrogate measure for inducing infection. To detect viability, researchers apply a sample to a susceptible cell culture and incubate up to a few weeks to detect morphological changes.

Detection of SARS-CoV-2 RNA in air samples has been inconsistent.[77] Multiple air sampling studies performed in proximity to confirmed COVID-19 cases were unable to detect any virus by RT-PCR.[78-86] Kenarkoohi et al. detected SARS-CoV-2 RNA by RT-PCR in 1/5 samples from a ward containing intubated, severely ill patients, but did not find any positive air samples in other areas of the hospital such as wards with suspected, confirmed and mild patients (culturing of virus was not attempted in this study).[87] Chia et al. (2020), in an extended study of Ong et al. (2020), detected SARS-CoV-2 RNA by RT-PCR in air samples collected within 1 m of patients in two of three airborne infection isolation rooms (AIIRs) (no culture of virus attempted).[88] Lei et al. (2020) reported limited detection of SARS-CoV-2 RNA virus by air sampling in open wards, private isolation rooms and bathrooms.[85] One PCR-positive air sample was obtained during an endotracheal intubation within 10 cm of the patient's head in a naturally ventilated room (window open with fan attached), eleven other air samples near patients and 17 samples outside patient rooms and at nursing stations were PCR-negative.[89] The stage of infection and level of infectiousness of the patient populations sampled were not reported.

In a study of SARS-CoV-2 RNA in air samples collected from a variety of settings, Liu et al. (2020) reported that the highest concentration of viral RNA was reported from patient and staff areas of hospitals, compared to public areas.[90] Gharehchahi et al. (2021) (preprint) found SARS-CoV-2 RNA in 7/17 (41.2%) of air samples in a hospital for COVID-19 patients, including a mechanically-ventilated temporary waste storage area, two naturally-ventilated offices (one in the admission and discharge area, the other in an administrative department), and within 2 m of patients' beds in two intensive care units (ICUs), a negative pressure room, and an accident and emergency ward that are mechanically-ventilated with or without natural ventilation.[91] SARS-CoV-2 RNA was not detected from the four

samples at nursing stations 2–5 m from patients' beds. The authors speculated that the detection of RNA in non-clinical areas could be due to inadequate ventilation and the occasional presence of infected health care workers.

Stern et al. (2021) sampled air in locations outside of patient care areas in an acute care hospital and found 8/90 (9%) of the samples positive for SARS-CoV-2 RNA, with concentrations ranging from 5–51 copies/m^3.[92] The size of the RNA-positive samples ranged from ≤2.5 to ≥10 μm. Locations adjacent to negative-pressured wards designated for COVID-19 patients did not appear to increase the likelihood of detecting viral RNA, having higher viral concentration, or finding particles of specific sizes in air samples. However, a significant positive association was observed between the average number of COVID-19 patients staying in the hospital during each sampling period, and the likelihood of an air sample testing positive for SARS-CoV-2 RNA. Furthermore, areas where staff congregated during times of high community rates of COVID-19 were associated with positive air samples. Of note, one RNA-positive air sample was taken when the unit was closed for cleaning and not under negative pressure, and the unit doors were left open for cleaning staff who had to pass by the air sampler to access the area for cleaning.

When air samples were RT-PCR-positive, culturing attempts were infrequently successful. In a systematic review and meta-analysis of 24 studies, Birgand et al. (2020) reported that 17.4% (82/471) of air samples from patient environments were RNA-positive (there was no difference in positivity at ≤1 m [2.5%] or 1–5 m [5.5%]; p=0.22), while culturing produced viable virus in 8.6% (7/81; 2 out of 5 studies) of samples.[93] A study by Guo et al. (2020) detected SARS-CoV-2 by RT-PCR in 35% (14/40) of air samples in an ICU and 12.5% (2/16) of air samples in the general ward that managed patients with COVID-19. Fifteen of 16 RT-PCR-positive air samples were from within 2 m of patients, with 1/8 samples positive at 4 m away.[12] Ben-Shmuel et al. (2020) conducted limited sampling (generally one air sample per area) in rooms with ventilated and non-ventilated patients, at a nursing station, and in private and public areas of a quarantine hotel.[94] RT-PCR-positive air samples were detected in a room with a ventilated patient (distance from patient was not reported) (n=1/1), at a nursing station (n=1/1), and in a quarantine hotel room (n=1/1). However, there were no positive air samples in rooms of non-ventilated patients (n=0/3), a doffing area (n=0/1), and a public area of a quarantine hotel (n=0/1). The authors attempted viral culturing; however, no samples were positive.

At this time, only three studies, two from the same research group and one preprint from July 2020, have successfully cultured viable virus from the air. The preprint and one published study were already referred to above in the summary of Birgand et al. (2020). Sampling techniques and equipment may have caused the lack of culture viability despite RT-PCR detection in other studies. Future studies should aim to replicate the use of equipment and culture methods as these studies.

Lednicky et al. (2021) used a prototype and commercial version of an air sampler and custom RT-PCR probes for detection of SARS-CoV-2 in a patient room with two patients. One patient was discharged soon after sampling periods began and after receiving a negative RT-PCR test.[95] The remaining patient began experiencing respiratory illness two days prior to admission to the room. The study detected RT-PCR-positive air samples following 3 hours of sampling as well as positive viral cultures. Researchers positioned samplers 2–4.8 m from the recently symptomatic patient's head. The ventilation unit provided 6 ACH, filtering air and treating air with UV irradiation before recycling the air. Estimates of virus per volume of air ranged from 6–74 tissue culture infective dose $(TCID)_{50}$ units/L of air. Recently, a second study by Lednicky et al. was performed to detect viable SARS-CoV-2 virus from the front passenger seat area of a car driven by a SARS-CoV-2-positive patient without cough symptoms.[96] This study involved a sampler affixed to the sun visor in the passenger seat collecting particles sizes in ranges

of <0.25 µm, 0.25–0.50 µm, 0.50–1.0 µm, 1.0–2.5 µm and >2.5 µm. The patient drove for 15 minutes with the windows up and air conditioner on. The sampler was turned off 2 hour after the patient completed the 15 minute drive. Viable virus was cultured only from the 0.25–0.5 µm fraction, which also had the highest quantity of detectable copies of viral RNA.

Further research is needed to reconcile differences in viral RNA detection and virus viability in air samples, despite RT-PCR-positive samples found on the surfaces of ventilation units.[97] Differences may be due to several factors, including: 1) air sampling devices are potentially not capable of maintaining viability of captured virus; 2) timing of air sampling varies by time since onset of symptoms, severity of disease or viral load; and 3) the conditions of ventilation (engineering controls) reducing concentrations of viral aerosols to undetectable levels. Even in rooms with high air exchanges, Tang et al.'s review of SARS-CoV-2 aerosols indicates that viral RNA copies can still be detected in air samples from patient rooms (1.8–3.4 viral RNA copies/m^3), toilet rooms (19 copies/m^3), and personal protective equipment doffing rooms (18–42 copies/m^3).[98] In a series of distinct room types (two AIIR with 15+ ACH, an isolation room without negative pressure and a shared cohort room) for patients admitted within 7 days of symptom-onset, Kim et al. reported that 32 air samples were negative and 20 air samples from anterooms were also negative.[86] Culturing viruses is technically challenging; therefore, the lack of positive cultures does not necessarily indicate an absence of infectious virus. On the other hand, the detection of SARS-CoV-2 viral RNA on surfaces that are rarely touched suggests that the virus may be transported through the air to those no-touch surfaces.[99]

Conclusions

Respiratory virus transmission occurs on a spectrum, from larger droplets that spread at short range, to aerosols that are present at short ranges but may also contribute to long-range transmission. As a result, categorizing SARS-CoV-2 transmission as either droplet or airborne does not accurately reflect this spectrum. Other respiratory viruses, like influenza, have similarly been described to demonstrate a spectrum of droplet sizes contributing to transmission.[100,101]

The highest risk of SARS-CoV-2 transmission likely occurs via close (<2 m), unprotected exposure (lacking multiple prevention measures) to an infectious individual. While there is a lower risk of transmission at longer distances with unprotected exposure, this kind of transmission has only been documented to occur under certain conditions, usually involving inadequate ventilation or with recirculation of unfiltered or untreated air in combination with activities involving increased exhalation/expulsion (e.g., shouting, singing, exercising), and often with a lack of source control masking.[102] Defining measures or cutoffs for inadequate ventilation was not possible based on the available descriptions of the contexts in which inadequate ventilation was reported to contribute to transmission. However, they included situations where air is circulated without filtration or exchange with fresh air, where there is no ventilation (e.g., windowless rooms without a ventilation system), and where the size of the room and ventilation rate relative to the quantity of infectious aerosols generated exceeds an unknown threshold of risk for infection. VOCs may be more effectively transmitted across all modes of transmission; however, there is no evidence that any VOCs transmit by fundamentally different routes.[103-105]

The delineation of relative contributions of short-range large respiratory droplets and aerosols and long-range aerosols to overall transmission patterns is complicated by the variable confluence of dynamic source/receptor factors and pathway factors. For example, each infector/infectee interaction is affected by source activities and amount of source viral load (e.g., forceful expulsion of droplets during coughing or singing, and timing in the course of illness), source/receptor adherence to preventative measures in place (e.g., hand hygiene, physical distancing, surface disinfection, mask-wearing and ventilation), and

pathway factors that include airflow, UV, temperature, and humidity in indoor or outdoor environments.[16] It is likely that the relative contribution of respiratory particle size to transmission will depend on these combination of factors.

A large body of evidence is emerging related to SARS-CoV-2. Studies related to identification of a specific mode of transmission are generally low quality. Moreover, data from different fields (e.g., epidemiology versus modelling) can be at odds with respect to conclusions drawn about the role of different sized droplets in short-range transmission and relative importance of long-range transmission events. Ongoing study is needed for further evidence regarding the quantity of viral particles required to cause infection. Additional assessment of SARS-CoV-2 viability in aerosols is needed. Lastly, elucidation of setting-specific risk factors for transmission (e.g., differences between source/receptor and pathway factors in health care settings, residential buildings, schools, warehouses, transportation) may provide further insight into mechanisms for transmission.

The COVID-19 pandemic has identified the importance of interdisciplinary collaboration towards understanding and having a common lexicon for describing virus transmission. When the analysis and interpretation of data is challenged by variable terminology used between and within public health, clinicians, aerosol scientists and the public, this can limit progress towards identification and application of appropriate mitigation measures.[106]

Implications for Practice

This document summarizes the evolving evidence on transmission through respiratory particles and acknowledges the role for both larger droplets and aerosols in transmission. While our understanding of how transmission occurs has evolved and the relative contribution of droplets and aerosols continues to be studied, this may not necessitate a change in infection control measures, but highlights the importance of incorporating multiple infection control layers to mitigate transmission. Translation of this information into recommendations for control measures also needs to take into consideration evidence not reviewed in this document on the overall effectiveness of control measures to date: 1) effectiveness of measures in isolation and in combination as layered mitigation; 2) effectiveness in the community vs. health care settings; and 3) effectiveness and the impact of implementation fidelity.

A detailed assessment of the evidence for infection prevention and control measures was out of scope for this document and thus limits discussion of recommendations for specific measures in different contexts. Of note, vaccination against SARS-CoV-2 is a relatively recent measure that is very effective at reducing transmission regardless of the mode of transmission and should be the priority control measure both in health care and community settings.[107]

In health care settings, recommendations for IPAC measures are described in *IPAC Recommendations for Use of Personal Protective Equipment for Care of Individuals with Suspect or Confirmed COVID-19* and *Interim Guidance for Infection Prevention and Control of SARS-CoV-2 Variants of Concern for Health Care Settings*.[7,8] These documents integrate the existing evidence around droplet, aerosol and contact transmission with jurisdictional experience with control measures and outbreak management to date, and recommends the use of the hierarchy of hazard controls to reduce the risk of transmission.

The bulk of disease transmission occurs in the community and in workplaces, not in health care settings. As SARS-CoV-2 transmits early in the course of infection, most commonly in the asymptomatic or presymptomatic period[108-111] and within the first two days of symptom-onset, cases may not seek health care during their most transmissible phase. In all settings it is necessary to utilize multiple control

measures to mitigate the dynamic transmission factors and address potential routes of transmission. Infection prevention controls should also be context-dependent and take into account vaccination status/coverage, the ability to physically distance and avoid crowding, the feasibility of proper wearing of appropriate personal protective and source control equipment, training and education on the appropriate use of personal protective equipment, hand hygiene, surface disinfection, indoor ventilation, and early identification and isolation of infectious persons. Finally, application of measures should also be in the context of overall rates of community transmission and risk of exposure.

Several resources exist for community guidance (e.g., non-health care workplaces, public and private spaces) on how to reduce the risk of SARS-CoV-2 transmission through a layered approach of multiple public health measures designed to mitigate short-range and long-range transmission.[112-114] In general these involve avoiding the "3 C's": closed spaces, crowded places, and close contact. The degree to which various mitigation layers are necessary or possible will depend on the setting and risk context. Transmission can be mitigated through:

- Getting vaccinated[115,116] (higher vaccine coverage in the population can reduce risk for individuals unable to receive a vaccine)
- Staying home when sick[117,118] (e.g., active and passive screening prior to entry into public settings)
- Limiting the number and duration of contacts with individuals outside your household
- Physical distancing[114] and avoiding crowded spaces
- Consistently and appropriately using a well-fitted, well-constructed (2-3-layer) mask for source control and personal protective equipment.[119-122]
- Ensuring that ventilation systems[123] are well-maintained and optimized with the support of professionals according to relevant recommendations (e.g., from American Society of Heating, Refrigerating and Air-Conditioning Engineers) and/or using outdoor environments whenever possible.
- Performing hand hygiene, respiratory etiquette, and environmental cleaning[124]

The above measures are effective means of reducing risk of transmission irrespective of the relative contribution of larger droplets or aerosols to transmission. Some controls will be more effective than others and it is the combination and consistent application of these controls that is most effective for reducing disease spread.

Coronavirus disease (COVID-19): How is it transmitted?

13 December 2020 | Q&A

The English version was updated on 30 April 2021.

How does COVID-19 spread between people?

We know that the disease is caused by the SARS-CoV-2 virus, which spreads between people in several different ways.

The virus can spread from an infected person's mouth or nose in small liquid particles when they cough, sneeze, speak, sing or breathe. These particles range from larger respiratory droplets to smaller aerosols.

- **Current evidence suggests that the virus spreads mainly between people who are in close contact with each other, typically within 1 metre (short-range). A person can be infected when aerosols or droplets containing the virus are inhaled or come directly into contact with the eyes, nose, or mouth.**
- **The virus can also spread in poorly ventilated and/or crowded indoor settings, where people tend to spend longer periods of time. This is because aerosols remain suspended in the air or travel farther than 1 metre (long-range).**

People may also become infected by touching surfaces that have been contaminated by the virus when touching their eyes, nose or mouth without cleaning their hands.

Further research is ongoing to better understand the spread of the virus and which settings are most risky and why. Research is also under way to study virus variants that are emerging and why some are more transmissible. For updated information on SARS-CoV-2 variants, please read the weekly epidemiologic updates.

When do infected people transmit the virus?

What is the difference between people who are asymptomatic or pre-symptomatic? Don't they both mean someone without symptoms?

Are there certain settings where COVID-19 can spread more easily?

How can I reduce my risk of getting COVID-19?

13 December 2020 | Q&A

The English version was updated on 30 April 2021.

How does COVID-19 spread between people?

When do infected people transmit the virus?

Whether or not they have symptoms, infected people can be contagious and the virus can spread from them to other people.

Laboratory data suggests that infected people appear to be most infectious just before they develop symptoms (namely 2 days before they develop symptoms) and early in their illness. People who develop severe disease can be infectious for longer.

While someone who never develops symptoms can pass the virus to others, it is still not clear how frequently this occurs and more research is needed in this area.

What is the difference between people who are asymptomatic or pre-symptomatic? Don't they both

A Commissioner, etc.

Avoid the Three Cs

World Health Organization
Western Pacific Region

Be aware of different levels of risk in different settings.

There are certain places where COVID-19 spreads more easily:

1

Crowded places

with many people nearby

2

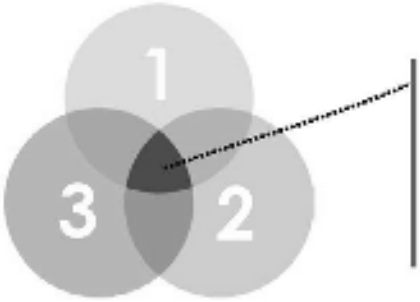
Close-contact settings

Especially where people have close-range conversations

3

Confined and enclosed spaces

with poor ventilation

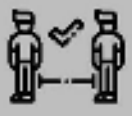


The risk is higher in places where these factors overlap.

Even as restrictions are lifted, consider where you are going and #StaySafe by avoiding the Three Cs.

WHAT SHOULD YOU DO?

Avoid crowded places and limit time in enclosed spaces



Maintain at least 1m distance from others

When possible, open windows and doors for ventilation

Keep hands clean and cover coughs and sneezes

Wear a mask if requested or if physical distancing is not possible

If you are unwell, stay home unless to seek urgent medical care.

The airborne lifetime of small speech droplets and their potential importance in SARS-CoV-2 transmission

Valentyn Stadnytskyi[a], Christina E. Bax[b], Adriaan Bax[a,1], and Philip Anfinrud[a,1]

[a]Laboratory of Chemical Physics, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD 20892-0520; and [b]Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA 19104

Edited by Axel T. Brunger, Stanford University, Stanford, CA, and approved May 4, 2020 (received for review April 10, 2020)

Speech droplets generated by asymptomatic carriers of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) are increasingly considered to be a likely mode of disease transmission. Highly sensitive laser light scattering observations have revealed that loud speech can emit thousands of oral fluid droplets per second. In a closed, stagnant air environment, they disappear from the window of view with time constants in the range of 8 to 14 min, which corresponds to droplet nuclei of *ca.* 4 μm diameter, or 12- to 21-μm droplets prior to dehydration. These observations confirm that there is a substantial probability that normal speaking causes airborne virus transmission in confined environments.

COVID-19 | speech droplet | independent action hypothesis | respiratory disease | disease transmission

It has long been recognized that respiratory viruses can be transmitted via droplets that are generated by coughing or sneezing. It is less widely known that normal speaking also produces thousands of oral fluid droplets with a broad size distribution (*ca.* 1 μm to 500 μm) (1, 2). Droplets can harbor a variety of respiratory pathogens, including measles (3) and influenza virus (4) as well as *Mycobacterium tuberculosis* (5). High viral loads of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) have been detected in oral fluids of coronavirus disease 2019 (COVID-19)–positive patients (6), including asymptomatic ones (7). However, the possible role of small speech droplet nuclei with diameters of less than 30 μm, which potentially could remain airborne for extended periods of time (1, 2, 8, 9), has not been widely appreciated.

In a recent report (10), we used an intense sheet of laser light to visualize bursts of speech droplets produced during repeated spoken phrases. This method revealed average droplet emission rates of *ca.* 1,000 s^{-1} with peak emission rates as high as 10,000 s^{-1}, with a total integrated volume far higher than in previous reports (1, 2, 8, 9). The high sensitivity of the light scattering method in observing medium-sized (10 μm to 100 μm) droplets, a fraction of which remain airborne for at least 30 s, likely accounts for the large increase in the number of observed droplets. Here, we derive quantitative estimates for both the number and size of the droplets that remain airborne. Larger droplets, which are also abundant but associated with close-proximity direct virus transfer or fomite transmission (11), or which can become resuspended in air at a later point in time (12), are not considered here.

According to Stokes' law, the terminal velocity of a falling droplet scales as the square of its diameter. Once airborne, speech-generated droplets rapidly dehydrate due to evaporation, thereby decreasing in size (13) and slowing their fall. The probability that a droplet contains one or more virions scales with its initial hydrated volume, that is, as the cube of its diameter, d. Therefore, the probability that speech droplets pass on an infection when emitted by a virus carrier must take into account how long droplet nuclei remain airborne (proportional to d^{-2}) and the probability that droplets encapsulate at least one virion (proportional to d^3), the product of which is proportional to d.

The amount by which a droplet shrinks upon dehydration depends on the fraction of nonvolatile matter in the oral fluid, which includes electrolytes, sugars, enzymes, DNA, and remnants of dehydrated epithelial and white blood cells. Whereas pure saliva contains 99.5% water when exiting the salivary glands, the weight fraction of nonvolatile matter in oral fluid falls in the 1 to 5% range. Presumably, this wide range results from differential degrees of dehydration of the oral cavity during normal breathing and speaking and from decreased salivary gland activity with age. Given a nonvolatile weight fraction in the 1 to 5% range and an assumed density of 1.3 $g{\cdot}mL^{-1}$ for that fraction, dehydration causes the diameter of an emitted droplet to shrink to about 20 to 34% of its original size, thereby slowing down the speed at which it falls (1, 13). For example, if a droplet with an initial diameter of 50 μm shrinks to 10 μm, the speed at which it falls decreases from 6.8 $cm{\cdot}s^{-1}$ to about 0.35 $cm{\cdot}s^{-1}$. The distance over which droplets travel laterally from the speaker's mouth during their downward trajectory is dominated by the total volume and flow velocity of exhaled air (8). The flow velocity varies with phonation (14), while the total volume and droplet count increase with loudness (9). Therefore, in an environment of stagnant air, droplet nuclei generated by speaking will persist as a slowly descending cloud emanating from the speaker's mouth, with the rate of descent determined by the diameter of the dehydrated speech droplet nuclei.

The independent action hypothesis (IAH) states that each virion has an equal, nonzero probability of causing an infection. Validity of IAH was demonstrated for infection of insect larvae by baculovirus (15), and of plants by Tobacco etch virus variants that carried green fluorescent protein markers (16). IAH applies to systems where the host is highly susceptible, but the extent to which IAH is valid for humans and SARS-CoV-2 has not yet been firmly established. For COVID-19, with an oral fluid average virus RNA load of 7×10^6 copies per milliliter (maximum of 2.35×10^9 copies per milliliter) (7), the probability that a 50-μm-diameter droplet, prior to dehydration, contains at least one virion is ∼37%. For a 10-μm droplet, this probability drops to 0.37%, and the probability that it contains more than one virion, if generated from a homogeneous distribution of oral fluid, is negligible. Therefore, airborne droplets pose a significant risk only if IAH applies to human virus transmission. Considering that frequent person-to-person transmission has been reported in community and health care settings, it appears likely that IAH

applies to COVID-19 and other highly contagious airborne respiratory diseases, such as influenza and measles.

Results and Discussion

The output from a green (532 nm) Coherent Verdi laser operating at 4-W optical power was transformed with spherical and cylindrical optics into a light sheet that is ~1 mm thick and 150 mm tall. This light sheet passed through slits centered on opposite sides of a cubic 226-L enclosure. When activated, a 40-mm, 12-V muffin fan inside the enclosure spatially homogenizes the distribution of particles in the enclosure. A movie showing the arrangement is available (17). Movie clips of speech droplet nuclei were recorded at a frame rate of 24 Hz with high-definition resolution (1,920 × 1,080 pixels). The camera lens provided a horizontal field of view of ~20 cm. Therefore, the volume intercepted by the light sheet and viewed by the camera is ~30 cm^3. The total number of particles in the enclosure can be approximated by multiplying the average number of particles detected in a single movie frame by the volume ratio of the enclosure to the visualized sheet, which is ~7,300. Slow convection currents, at speeds of a few centimeters per second, remained for the duration of the recording. These convection currents are attributed to a 0.5 °C temperature gradient in the enclosure (bottom to top) that presumably is due to heat dissipated by the iPhone11 camera, which was attached to the front side of the enclosure. Since the net air flux across any horizontal plane of the enclosure is zero, this convection does not impact the average rate at which droplet nuclei fall to the bottom of the enclosure.

With the internal circulation fan turned on, the enclosure was purged with HEPA-filtered air for several minutes. Then, the purge shutter was closed, the movie clip was started, the speaker port was opened, and the enclosure was "filled" with speech droplets by someone repeating the phrase "stay healthy" for 25 s. This phrase was chosen because the "th" phonation in the word "healthy" was found to be an efficient generator of oral fluid speech droplets. The internal fan was turned off 10 s after speech was terminated, and the camera continued recording for 80 min. The movie clip was analyzed frame by frame to determine the number of spots/streaks whose maximum single-pixel intensity exceeded a threshold value of 30. Fig. 1 charts the time-dependent decrease in the number of scattering particles detected. We are not yet able to quantitatively link the observed scattered light intensity to the size of the scattering particle because the light intensity varies across the sheet. However, the brightest 25% were found to decay more quickly than the dimmer fraction, with the two curves reasonably well described by exponential decay times of 8 and 14 min, respectively (Fig. 1*A*). These fits indicate that, near time 0, there were, on average, approximately nine droplet nuclei in the 30-cm^3 observation window, with the larger and brighter nuclei (on average) falling to the bottom of the enclosure at faster speeds than the smaller and dimmer ones.

With the assumption that the contents of the box are homogenized by the muffin fan at time 0, the average number of droplets found in a single frame near time 0 corresponds to *ca.* 66,000 small droplets emitted into the 226-L enclosure, or *ca.* 2,600 small droplet nuclei per second of speaking. If the particle size distribution were a delta function and the particles were uniformly distributed in the enclosure, the particle count would be expected to remain constant until particles from the top of the enclosure descend to the top of the light sheet, after which the particle count would decay linearly to background level. The observation that the decay profiles are approximately exponential points to a substantial heterogeneity in particle sizes, even after binning them into two separate groups.

The weighted average decay rate (0.085 min^{-1}) of the bright and dim fractions of particles (Fig. 1*A*) translates into a half-life in the enclosure of *ca.* 8 min. Assuming this half-life corresponds to the time required for a particle to fall 30 cm (half the height of the box), its terminal velocity is only 0.06 $cm{\cdot}s^{-1}$, which corresponds to a droplet nucleus diameter of ~4 μm. At the relative humidity (27%) and temperature (23 °C) of our experiment, we expect the droplets to dehydrate within a few seconds. A dehydrated particle of 4 μm corresponds to a hydrated droplet of *ca.* 12- to 21-μm diameter, or a total hydrated volume of ~60 nL to 320 nL for 25 s of loud speaking. At an average viral load of 7×10^6 per milliliter (7), we estimate that 1 min of loud speaking generates at least 1,000 virion-containing droplet nuclei that remain airborne for more than 8 min. These therefore could be inhaled by others and, according to IAH, trigger a new SARS-CoV-2 infection.

The longest decay constant observed by us corresponds to droplets with a hydrated diameter of ≥12 μm when exiting the mouth. The existence of even smaller droplets has been

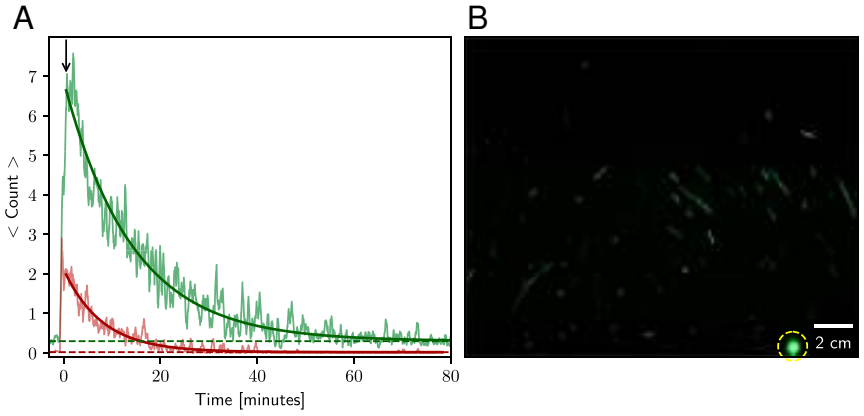

Fig. 1. Light scattering observation of airborne speech droplet nuclei, generated by a 25-s burst of repeatedly speaking the phrase "stay healthy" in a loud voice (maximum 85 dB_B at a distance of 30 cm; average 59 dB_B). (*A*) Chart of particle count per frame versus time (smoothed with a 24-s moving average), with the red curve representing the top 25% in scattering brightness and the green curve representing the rest. The bright fraction (red) decays with a time constant of 8 min, and the dimmer fraction (green) decays with a time constant of 14 min. Both exponential decay curves return to their respective background level of *ca.* 0 (red horizontal dashed line) and 0.4 (green dashed line) counts per frame. Time "0" corresponds to the time the stirring fan was turned off. The 25-s burst of speaking started 36 s before time 0. The black arrow (at 0.5 min) marks the start of the exponential fits. (*B*) Image of the sum of 144 consecutive frames (spanning 6 s) extracted shortly after the end of the 25-s burst of speaking. The dashed circle marks the needle tip used for focusing the camera. The full movie recording is available in ref. 17, with time "0" in the graph at time point 3:38 in the movie.

established by aerodynamic particle sizer (APS) measurements (2). APS is widely used for detecting aerosol particulates and is best suited for particles in the 0.5- to 5-μm range. Morawska et al. (2) detected as many as 330 particles per second in the 0.8- to 5.5-μm range upon sustained "aah" vocalization. Considering the short travel time (0.7 s) between exiting the mouth and the APS detector, and the high relative humidity (59%) used in that study, droplet dehydration may have been incomplete. If it were 75% dehydrated at the detector, an observed 5.5-μm particle would have started as an 8.7-μm droplet when exiting the mouth, well outside the 12- to 21-μm range observed above by light scattering. This result suggests that APS and light scattering measurements form a perfect complement. However, we also note that, even while the smallest droplet nuclei effectively remain airborne indefinitely and have half-lives that are dominated by the ventilation rate, at a saliva viral load of 7×10^6 copies per milliliter, the probability that a 1-μm droplet nucleus (scaled back to its originally hydrated 3-μm size) contains a virion is only 0.01%.

Our current setup does not detect every small particle in each frame of the movie, and our reported values are therefore conservative lower limit estimates. We also note that the saliva viral load shows large patient-to-patient variation. Some patients have viral titers that exceed the average titer of Wölfel et al. by more than two orders of magnitude (7, 18), thereby increasing the number of virions in the emitted droplets to well over 100,000 per minute of speaking. The droplet nuclei observed in our present study and previously by APS (2, 9) are sufficiently small to reach the lower respiratory tract, which is associated with an increased adverse disease outcome (19, 20).

Our laser light scattering method not only provides real-time visual evidence for speech droplet emission, but also assesses their airborne lifetime. This direct visualization demonstrates how normal speech generates airborne droplets that can remain suspended for tens of minutes or longer and are eminently capable of transmitting disease in confined spaces.

Data Availability Statement. All raw data used for analysis are available in ref. 17.

Abstract

IMPORTANCE: Higher secondary attack rates related to variant of concern (VOC) index cases have been reported, but have not been explored within households, which continue to be an important source of coronavirus disease 2019 (COVID-19) transmission

OBJECTIVE: To compare secondary attack rates in households with VOC versus non-VOC index cases.

DESIGN: A retrospective cohort study of household index cases reported from February 7 – 27, 2021. A propensity-score matched cohort was derived to calculate adjusted estimates.

SETTING: Ontario, Canada.

PARTICIPANTS: A population-based cohort of all private households with index cases. We excluded cases in congregate settings, as well as households with one individual or with >1 case with the same earliest symptom onset date.

EXPOSURE: VOC status, defined as either individuals confirmed as B.1.1.7 using whole genome sequencing or those that screened positive for the N501Y mutation using real-time PCR.

MAIN OUTCOME AND MEASURE: Household secondary attack rate, defined as the number of household secondary cases that occurred 1-14 days after the index case divided by the total number of household secondary contacts.

RESULTS: We included 1,259 index VOC and non-VOC cases in the propensity score-matched analysis. The secondary attack rate for VOC index cases in this matched cohort was 1.31 times higher than non-VOC index cases (RR=1.31, 95%CI 1.14-1.49), similar to the unadjusted estimate. In stratified analyses, the higher secondary attack rate for VOC compared to non-VOC index cases was accentuated for asymptomatic index cases (RR=1.91, 95% CI 0.96-3.80) and presymptomatic cases (RR=3.41, 95%CI 1.13-10.26)

CONCLUSIONS AND RELEVANCE: This study provides strong evidence of increased transmissibility in households due to VOCs and suggests that asymptomatic and pre-symptomatic transmission may be of particular importance for VOCs. Our study suggests that more aggressive public health measures will be needed to control VOCs and that ongoing research is needed to understand mechanisms of VOC transmissibility to curb their associated morbidity and mortality.

Introduction

The prevalence of variants having the N501Y mutation have rapidly increased globally,[1] including in Ontario, Canada, where this prevalence increased dramatically in February, 2021. These patterns of rapid strain replacement suggest increased transmissibility of variants with the N501Y mutation, which is present across variants of concern (VOC), including B.1.1.7, B.1.351, and P.1 lineages.[2] However the exact degree of increased transmissibility, and specific settings when increased transmissibility occurs, remains unclear. [1, 3,4,5] Higher secondary attack rates related to VOC index cases have been reported, [6] but have not been explored within households, which continue to be an important source of coronavirus disease 2019 (COVID-19) transmission.[7] The objective of this study was to compare secondary attack rates in households with VOC versus non-VOC index cases in Ontario, Canada.

Methods

We identified individuals with laboratory-confirmed COVID-19 reported in the Public Health Case and Contact Management Solution (CCM), Ontario's COVID-19 reporting system, and included households with index cases reported from February 7 to 27, 2021. VOC cases included either individuals confirmed as B.1.1.7 using whole genome sequencing or those that screened positive for the N501Y mutation using real-time PCR. B.1.1.7 accounted for 94% of confirmed VOC cases reported in Ontario until February 27, 2021.[8] All PCR-positive specimens in Ontario with cycle threshold ≤35 underwent screening for the N501Y mutation during the study period using real-time PCR. Non-VOC cases were those that screened negative for the N501Y mutation.

We grouped cases living in the same household based on residential address.[9] Index cases were defined as the first case in the household based on symptom onset date (or specimen collection date, if symptom onset date was not available) and secondary cases were included if they occurred 1-14 days after the index case. We excluded cases in congregate settings, as well as households with one individual or with >1 case with the same earliest symptom onset date. We used reported household size to calculate

medRxiv preprint doi: https://doi.org/10.1101/2021.03.31.21254502; this version posted April 5, 2021. secondary attack rates by dividing the number of secondary cases by the total number of household secondary contacts (i.e., household size minus one). Cases with and without symptoms were classified based on symptom information and onset date reported in CCM.

Poisson regression was performed for the unadjusted and adjusted analyses, overall and by strata. The models were specified with the count of household secondary cases as the outcome, the logarithm of household size as the offset and VOC status as a binary exposure covariate. Clustering was accounted for with a random intercept for household to account for known overdispersion.

Our unadjusted risk ratios (RR) included the entire cohort of households with a VOC or non-VOC index case in Ontario. Adjusted RRs were based on a propensity score matched analysis. VOC index cases were 1:1 matched to non-VOC index cases based on gender and age group, and matched on the logit of the propensity score, using a caliper width of 0.2 times the standard deviation.[10] The propensity score was based on a logistic regression model of VOC status as a function of five covariates: reported date, time between symptom onset and testing, association with a reported outbreak, as well as the neighbourhood proportion of visible minority residents (non-white and non-Indigenous population) and household crowding as determined using 2016 Canadian Census data.[11] Regression estimates were reported using RRs and 95% confidence intervals (CI). Statistical analysis was performed in R version 4.0.4.[12]

This study was approved by Public Health Ontario's Research Ethics Board.

Results

We identified 5,617 index cases and 3,397 secondary cases across the study period. Amongst index cases, 1,318 were classified as VOC (151 B.1.1.7 and 1,167 N501Y) and 4,299 were classified as non-VOC. The overall secondary attack rate was higher for VOC index cases (25.9%) compared to non-VOC (20.5%, $p<0.01$) with consistently higher secondary attack rates for VOCs across individual characteristics of the index cases (Table 1). The secondary attack rate of VOC index cases was 1.28 times

medRxiv preprint doi: https://doi.org/10.1101/2021.03.31.21254502; this version posted April 5, 2021. higher than that of non-VOC index cases (RR=1.28, 95% CI 1.16-1.42); a similar trend of increased secondary attack rate was observed across subgroups (Figure 1).

We included 1,259 index VOC and non-VOC cases in the propensity score-matched analysis. The secondary attack rate for VOC index cases in this matched cohort was 1.31 times higher than non-VOC index cases (RR=1.31, 95%CI 1.14-1.49), similar to the unadjusted estimate. In stratified analyses, the higher secondary attack rate for VOC compared to non-VOC index cases was accentuated for asymptomatic index cases (RR=1.91, 95% CI 0.96-3.80) and presymptomatic cases (RR=3.41, 95%CI 1.13-10.26)

Discussion

In our cohort, we estimated that the household secondary attack rate of VOC index cases was 31% higher than non-VOC index cases, providing evidence of increased transmissibility. This is consistent with previous VOC (i.e., B.1.1.7) secondary attack rate estimates from the United Kingdom (relative secondary attack rate (32%, 12.9% vs 9.7% among all contacts);[6] however, households are an important contributor to COVID-19 and provide a valuable setting in which to examine transmission.[7] Our estimates of increased transmission from asymptomatic and pre-symptomatic VOC index cases has not previously been reported and suggests an increased importance of prevention measures when individuals are not aware of their infection. The biological mechanism responsible for increased transmissibility has not been identified, but hypotheses include higher viral loads (i.e. increased transmission potential per contact), and prolonged viral shedding (i.e., longer infectious period).[3] The N501Y mutation has also been associated with enhanced binding affinity of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) to angiotensin-converting enzyme 2 (ACE2) receptors.[13,14]

Limitations of this study include potential misclassification of secondary cases as index cases and small sample sizes in some subgroups. We may have underestimated secondary attack rates as we only captured diagnosed secondary cases and we lacked testing data on all household contacts; however, we do not

medRxiv preprint doi: https://doi.org/10.1101/2021.03.31.21254502; this version posted April 5, 2021. believe this would be differential by VOC status of the index case. Ontario implemented more stringent measures for close contacts of all cases (not just VOC cases) in early February in response to VOC introductions, including increased frequency of testing during quarantine and outbreaks.[15] If household contacts were more likely to test once VOC status was known, a similar increase in the risk ratio would be expected across symptom status, suggesting an independent effect of asymptomatic and presymptomatic VOC cases on transmission.

This study provides strong evidence of increased transmissibility in households due to VOCs and suggests that asymptomatic and pre-symptomatic transmission may be of particular importance for VOCs. Our study suggests that more aggressive public health measures will be needed to control VOCs. While measures effective for persons with unknown disease status such as physical distancing and masking may continue to be highly effective, measures focused on symptomatic individuals, such as public health contact tracing, may be increasingly ineffective unless extremely rapid. Ongoing research is needed to understand mechanisms of VOC transmissibility to curb their associated morbidity and mortality.

Aerosol emission and superemission during human speech increase with voice loudness

Received: 14 June 2018

Sima Asadi[1], Anthony S. Wexler[2,3,4,5], Christopher D. Cappa[4], Santiago Barreda[6], Nicole M. Bouvier[7,8] & William D. Ristenpart[1]

Mechanistic hypotheses about airborne infectious disease transmission have traditionally emphasized the role of coughing and sneezing, which are dramatic expiratory events that yield both easily visible droplets and large quantities of particles too small to see by eye. Nonetheless, it has long been known that normal speech also yields large quantities of particles that are too small to see by eye, but are large enough to carry a variety of communicable respiratory pathogens. Here we show that the rate of particle emission during normal human speech is positively correlated with the loudness (amplitude) of vocalization, ranging from approximately 1 to 50 particles per second (0.06 to 3 particles per cm^3) for low to high amplitudes, regardless of the language spoken (English, Spanish, Mandarin, or Arabic). Furthermore, a small fraction of individuals behaves as "speech superemitters," consistently releasing an order of magnitude more particles than their peers. Our data demonstrate that the phenomenon of speech superemission cannot be fully explained either by the phonic structures or the amplitude of the speech. These results suggest that other unknown physiological factors, varying dramatically among individuals, could affect the probability of respiratory infectious disease transmission, and also help explain the existence of superspreaders who are disproportionately responsible for outbreaks of airborne infectious disease.

It has long been recognized that particles expelled during human expiratory events, such as sneezing, coughing, talking, and breathing, serve as vehicles for respiratory pathogen transmission[1–6]. The relative contribution of each expiratory activity in transmitting infectious microorganisms, however, remains unclear[4]. Much previous research has focused on coughing[7–12] and sneezing[11,13,14] activities that yield relatively large droplets (approximately 50 μm or larger) easily visible to the naked eye. Less noticeable, but arguably more infectious for some diseases, are the smaller particles emitted during sneezing and coughing as well as during breathing[15–17] and talking[16,18,19]. These small particles are believed to be generated during breathing and talking from the mucosal layers coating the respiratory tract via a combination of a "fluid-film burst" mechanism within the bronchioles and from vocal folds adduction and vibration within the larynx[6,20,21]. The particles emitted during breathing and typical speech predominantly average only 1 μm in diameter[15–17] and are thus too small to see without specialized equipment; most people outside of the community of bioaerosol researchers are less aware of them.

Despite their small size, however, these micron-scale particles are sufficiently large to carry a variety of respiratory pathogens such as measles virus (50–500 nm)[22], influenza virus (100 nm–1 μm)[23], and *Mycobacterium tuberculosis* (1–3 μm)[24]. Indeed, recent work by Yan *et al.* has confirmed that significant amounts of influenza viral RNA are present in small particles (<5 μm) emitted by influenza-infected individuals during natural breathing, without coughing or sneezing[25]. These small particles are potentially more infectious than larger sneeze- or

cough-generated droplets for several reasons. First, smaller particles persist in the air for longer time periods before setting by gravity, thus increasing the probability of inhalation by susceptible individuals[26]. Second, smaller particles have a larger probability of penetrating further into the respiratory tract of a susceptible individual to initiate a lower respiratory tract infection[4]. Third, and perhaps most importantly, speech can release dramatically larger numbers of particles compared to coughing. Early work by Papineni and Rosenthal[16] and Loudon and Roberts[19] reported that speaking (as exemplified by counting aloud) releases about 2–10 times as many total particles as a single cough. Similarly, Loudon and Roberts investigated the role of singing in the spread of tuberculosis and showed that the percentage of airborne droplet nuclei generated by singing is 6 times more than that emitted during normal talking and approximately equivalent to that released by coughing[27]. More recent work using advanced particle characterization techniques have yielded similar results[21,28–30]. Chao *et al.*[28] used an interferometric imaging technique to obtain the size distribution of particles larger than 2 μm and found that counting aloud from 1 to 100 releases at least 6 times as many particles as an individual cough. Likewise, Morawska and coworkers[21,29] reported that counting aloud for 10 seconds followed by 10 seconds of breathing, repeated over two minutes, releases half as many particles as 30 seconds of continual coughing, which in turn releases half as many particles as saying "aah" for 30 seconds. They also reported that more particles are released when speech is voiced, which involves vocal folds vibration, rather than whispered, which does not.

Despite the clear evidence that speech emits large quantities of potentially infectious particles, to date little is known about how particle emission is modulated by different types of speech. Notably, the above work measured neither the total duration nor the loudness of the vocalizations; it is also unclear whether counting aloud will have a distribution of phones (phonemes) that is representative of typical conversational speech. Many important questions remain unanswered. For example, does raising your voice cause an increase in particle emission, or alter the particle size distribution? Does it matter what language you speak? Do all individuals emit particles at similar rates?

To address these questions, we used an aerodynamic particle sizer (APS) placed in a laminar flow hood to characterize the number and size distribution of particles emitted by individual human volunteers while they performed various vocalizations and breathing activities. Using this approach, we find three key results:

(1) The particle emission rate during speech is linearly correlated with the amplitude (loudness) of vocalization, for four different languages tested.
(2) The particle size distribution is independent of vocalization loudness or language spoken.
(3) Some individuals emit particles at a rate more than an order of magnitude larger than their peers, i.e., they behave as "speech superemitters."

Taken together, the results strongly suggest that individual human speech patterns and speech-associated particle emissions are highly heterogeneous and thus might play a role in the transmission of some respiratory pathogens. Furthermore, the results suggest a new hypothesis: that speech superemitters might contribute to the phenomenon of superspreading, in which a relative few contagious individuals infect a disproportionately large number of secondary cases during infectious disease outbreaks[31].

Results

Four separate types of experiments were performed. In the first experiment, participants said /ɑ/ (the vowel sound in 'saw') for five seconds, followed by 15 seconds of nose breathing, repeated six times in succession. This procedure mimics previous experimental measurements of particle emission during vocalization[21], but here the participants also systematically repeated the experiment at different voice amplitudes. Representative raw data for a single participant performing a series of six successive /ɑ/ vocalizations, at approximately the same loudness, are shown in Fig. 1. The simultaneous microphone recording (Fig. 1A) and APS measurements (Fig. 1B) demonstrate that the dynamics of particle release are highly correlated with the vocalization. Prior to and between vocalizations, during nose breathing in which exhaled air is directed away from the APS, the particle count is negligible, as is expected for the HEPA filtered air inside the laminar flow hood. Shortly after the vocalization commences, the number of particles rapidly increases and peaks, then decreases back to zero as the participant resumes nose breathing; the process then repeats at the next five-second vocalization. The approximately two-second lag between onset of vocalization and the observed increase in particle count is due to the time necessary for the released particles to reach the sensor in the APS. We emphasize that by design an APS does not measure 100% of the particles drawn into it, so the particle emission rates reported here do not represent the absolute number of particles emitted by the participant; the emission rates are best understood in relative terms, or in terms of the equivalent instantaneous concentrations of particles sampled from the funnel. As shown in the secondary axis of Fig. 1B, the instantaneous concentration of particles for this particular experiment was approximately 2 per cm^3 of sampled air.

The six vocalizations shown in Fig. 1A were made, to the best of the participant's ability, at the same loudness. Each participant then repeated a similar series of /ɑ/ vocalizations at different self-regulated voice amplitudes. Representative results for a single participant (F4) show that the particle emission rate (N), defined as the total number of particles emitted during a single vocalization divided by the measured duration (in seconds) of that vocalization, also correlates with the root mean square amplitude (A_{rms}) of the vocalization (Fig. 2A). In our set-up $A_{rms} = 0.45$ corresponds to an extremely loud conversational voice, as loud as comfortable without yelling (~98 decibels measured 6.5 cm from the participant's mouth, measured over background noise of approximately 65 decibels), while $A_{rms} = 0.02$ corresponds to a quiet vocalization just above whispering (~70 decibels; cf. Supplementary Fig. S1). As shown in Fig. 2A, the particle emission rate is linearly correlated with A_{rms} over this entire range of vocalization amplitudes, with the particle emission rate increasing from 6 to 53 particles per second at the quietest and loudest vocalizations respectively.

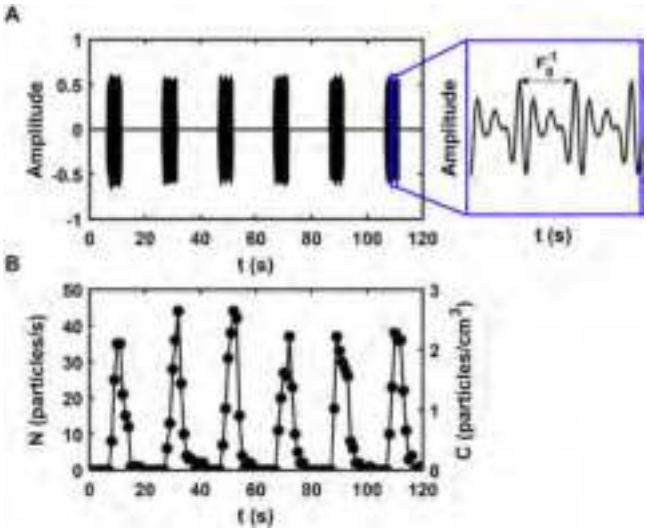

Figure 1. Representative raw data in which a participant (F4) said /ɑ/ for 5 seconds, followed by 15 seconds of nose breathing, repeated 6 times at approximately the same loudness. (**A**) The amplitude (arb. units) recorded by the microphone versus time. Magnification shows 13 ms of the waveform with fundamental frequency of F_0. (**B**) The corresponding number/concentration of particles measured by the APS versus time.

Although the particle emission rate increased with amplitude, the size distribution of the particles was not affected significantly (Fig. 2B), with the geometric mean particle diameter remaining near 1 μm regardless of voice amplitude (Supplementary Fig. S2A). Because the particle size remains similar regardless of amplitude, the increased particle counts shown in Fig. 2 indicate that the total volume of emitted respiratory fluid (i.e., the proteinaceous liquid droplets aerosolized from the serous and mucoid layers lining the respiratory tract) increases considerably with the vocalization loudness. Note that the characteristic time scale for evaporative drying of 1-micron diameter droplets is on the order of 100 milliseconds[26], which is much less than the time required for the particles to move from the participant's mouth into the detection module within the APS, suggesting that the particles measured here had fully dried into droplet nuclei prior to measurement (see methods and Supplementary Fig. S3).

Experiments with multiple participants indicated that these trends are conserved over a larger sample size (Fig. 2C). The particle emission rate increased approximately linearly with A_{rms} for each of the study participants, although the absolute magnitude varied between individuals. One participant (F3) released as many as 200 particles per second at higher amplitudes; another (F2) released as few as 1 particle per second at lower amplitudes. Notably, the data with this cohort of non-elderly adults reveal no obvious trends with gender or age (Supplementary Figs S4A, B). Similarly, no clear correlation was observed with the body mass index (BMI) of the participants (Supplementary Figs S4C, D).

To more closely represent normal conversational speech, the participants read aloud a short passage of text in English at varied loudness (quiet, intermediate, or loud). Representative raw data for a single participant (F4) indicate that the particle emission rate also correlates with voice amplitude for normal speech (Fig. 3A,B). To quantify the loudness, we take A_{rms} here as the average over the entire approximately two-minute duration of the vocalization, excluding pauses between words. Aggregated data for 10 participants confirms that the particle emission rate for normal English speech correlates linearly with A_{rms} (Fig. 3C); speaking loudly yielded on average a 10-fold increase in the emission rate compared to speaking the same series of words quietly. Again, the size distributions (Fig. 3D) and geometric mean diameter of particles (Supplementary Fig. S2B) were insensitive to voice amplitude. The reading experiment also was repeated in different languages to test whether choice of language matters; the results (Supplementary Fig. S5) confirmed the increasing trend between particle emission rate and amplitude, but exhibited no significant difference in the particle emission rate among the languages tested (Supplementary Fig. S6). Likewise, we measured the temperature and humidity during the experiments, and found no significant impact of temperature or humidity on either the particle emission rate or the mean particle size (Supplementary Figs S7 and S8).

A key recurring feature of the data is that some individual participants emitted many more particles than others. Because all participants spoke at slightly different amplitudes, we used linear regressions of the particle emission rate versus amplitude for each individual (cf. Fig. 2A) to calculate a normalized particle emission rate at the loudness amplitude of 0.1 (approximately 85 dB). Using this approach, the results for 40 people show that the particle emission rate for different individuals follows a long-tailed distribution for both vocalization of /ɑ/ (Fig. 4A) and reading of English text aloud (Fig. 4B). At this loudness, the normalized particle emission rates ranged from approximately 1 to 14 particles per second between different individuals, with an average of approximately 4 particles per second. Notably, the rates have a sizeable standard deviation well approximated by a lognormal fit (red curves in Fig. 4). In other words, although half of the participants emitted fewer than 3 particles per second, a small fraction of individuals (8 out of 40) emitted considerably more. These "speech superemitters,"

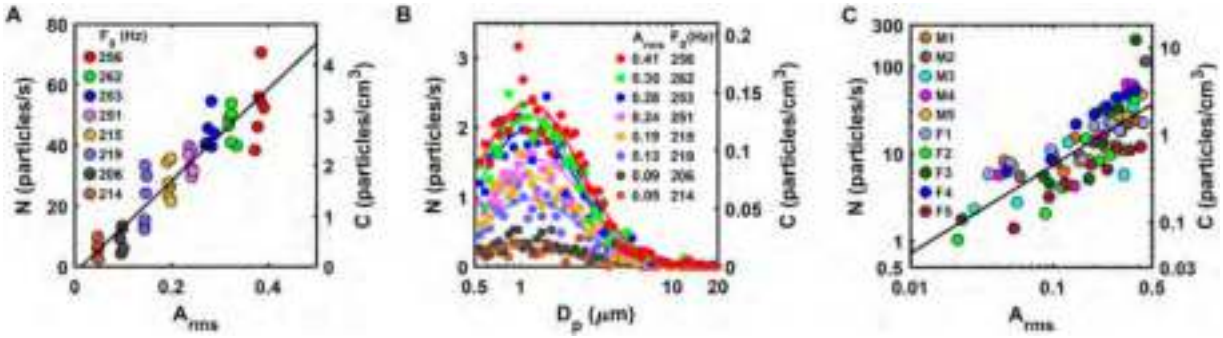

Figure 2. Particle emission rate/concentration while saying /ɑ/ at 8 different amplitudes, repeated 6 times at each amplitude. (**A**) Particle emission rate/concentration versus root mean square amplitude, A_{rms} (arb. units) for a representative participant (F4). Solid line is the best linear fit, with correlation coefficient $\rho = 0.932$ and Pearson's p value $= 5.9 \times 10^{-22}$. (**B**) Corresponding particle size distribution for the data presented in (**A**). (**C**) Aggregated particle emission rate/concentration versus root mean square amplitude, A_{rms} (arb. units) for 10 participants, 5 males (denoted as M1 to M5) and 5 females (denoted as F1 to F5). There are 8 data points for each participant, each representing the average of repeating /ɑ/ six times at approximately the same voice amplitude (cf. Fig. 1). Solid line is a power law fit with exponent 1.004, correlation coefficient $\rho = 0.774$ and Pearson's p value $= 3.8 \times 10^{-17}$.

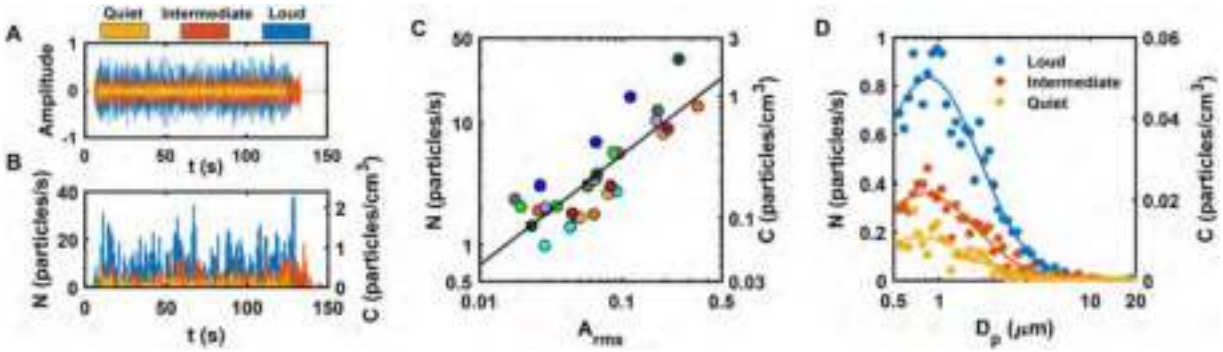

Figure 3. Particle emission rate/concentration while reading a passage of text aloud (the "Rainbow" passage), at three different loudness levels. (**A**) Superimposed representative recordings of amplitude (arb. units) for an individual (F4) reading the passage at three different voice amplitudes, and (**B**) the corresponding number/concentration of particles measured by the APS versus time. Color code same as in (**A**). (**C**) Particle emission rate/concentration as a function of root mean square amplitude, A_{rms}, for 10 participants. There are 3 points for each person, representing 3 voice amplitudes, color code same as Fig. 2C. Solid line is a power law fit with exponent 0.96, correlation coefficient $\rho = 0.865$ and Pearson's p value $= 6.8 \times 10^{-10}$. (**D**) Representative particle size distribution for the one individual (F4).

whose individual particle emission rate exceeded the group mean by one standard deviation or more, consistently released an order of magnitude more particles than their peers. For vocalizing /ɑ/, Fig. 4A shows that 15% of the participants emitted 32% of the total particles, while Fig. 4B shows that, for reading aloud in English, 12.5% of the participants emitted 40% of the total particles. Supplementary Fig. S9A shows that 4 out of these 8 individuals are superemitters for both saying /ɑ/ and passage reading activities, while 2 of them are only superemitters while saying /ɑ/, and 2 of them are superemitters while reading a text passage. We repeated the passage reading experiment for two of the participants (M5 and F4) on three different days separated by several months (Supplementary Fig. S9B), and the results show that the particle emission rates remained almost unchanged for at least these two individuals (F4, a superemitter, and M5, a non-superemitter) despite the long time period between measurements.

To help interpret our findings we also compared the particle emission rates of four different types of breathing with speech at three levels of loudness using the same experimental set-up. The breathing experiments included nose breathing, mouth breathing, a "deep-fast" mode, and a "fast-deep" mode (see methods for details). The results show that the particle emission rate for speech is significantly higher than all types of breathing tested here (Fig. 5A). Furthermore, the corresponding geometric mean diameters of the particles generated during speech are slightly larger on average than those generated during breathing (Fig. 5B), consistent with prior work and the hypothesis that vocalization activates laryngeal particle generation[21]. Note that in Fig. 5A the speech outliers correspond to a single participant who is a speech superemitter (F4), but this individual was not also responsible

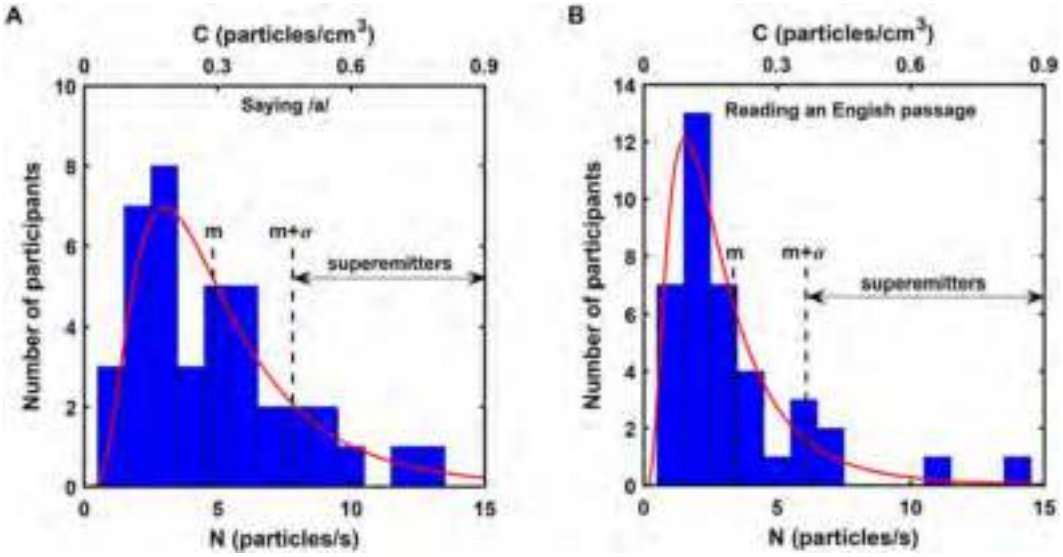

Figure 4. Histogram of particle emission rate/concentration at voice amplitude of 0.1 (approximately 85 dB). (**A**) For saying /ɑ/, with median of M = 4.3 particles/s, mean of m = 4.8 particles/s and standard deviation of σ = 3.0 particles/s. (**B**) For reading an English passage (10 people read the "Rainbow" passage and 30 people read chapter 24 of "The Little Prince") with median of M = 2.5 particles/s, mean of m = 3.4 particles/s and standard deviation of σ = 2.7 particles/s. Particle emission rates larger than m + σ are labeled superemitters. Red curves are lognormal fits found via nonlinear regression.

for the observed outliers of "fast-deep" and "nose" breathing activities. In other words, the "breathing high producers" as defined by Edwards *et al.*[15] are not necessarily also speech superemitters.

Discussion

Given that the results clearly indicate that particle emission rate is correlated with vocalization amplitude, a natural question is: why? The particles emitted during breathing and speech are hypothesized to be formed primarily by a "fluid-film burst" mechanism inside the small airways of the lungs and/or via vocal folds vibration and adduction at the larynx[6,20,21]. During exhalation the elastic walls of the respiratory bronchioles contract, and the mucosal fluid on the lumen surface forms a continuous film that can completely fill the airway. During the subsequent inhalation, the bronchioles expand and the film ruptures, yielding particles that are drawn into the alveoli and subsequently exhaled. A similar mechanism is believed to occur in the larynx, as the vocal folds repeatedly close and open during vocalization[21]; when the vocal folds come into contact during adduction, fluid films that form between them can then rupture during their subsequent abduction. Our direct comparison of particles emitted during various types of breathing versus speech demonstrates that even quiet speech yields significantly more particles than normal breathing (Fig. 5A). Coupled with the observation that the particles generated during speech on average are slightly larger (Fig. 5B), the results suggest that laryngeal particle generation, which presumably does not occur during normal breathing, is at least partially responsible for the observed larger rates of particle emission. Indeed, the fundamental frequency or "pitch" of vocalization (i.e., the frequency at which the vocal folds open and close) increases slightly with amplitude (cf. Supplementary Fig. S11 and Gramming *et al.*[32]), so the increased amplitude could reflect an increased opportunity for particles to form at the larynx.

Complicating matters, however, vocalization at a larger voice amplitude requires a larger exhalation flow rate[33,34]. A possible interpretation of our observations is that the underlying physical mechanism of particle release hinges on the combination of laryngeal particle generation rate and the time integral of the exhalation flow rate during vocalization[35]. If the volume of exhaled air is larger when the voice amplitude is higher, a larger fraction of particles formed in bronchiolar film rupture may escape from the lungs, with consequently more emitted particles, thus increasing the particle concentration in the exhaled air. Since our measurements only gauge the particle emission rate (and equivalent concentration), it is difficult to decouple the relative contributions of these two mechanisms. Fitting our particle size distributions to constrained bimodal lognormal distributions provides some evidence consistent with the interpretation presented by Johnson *et al.*[21] that there are two modes, presumably due to bronchiolar versus laryngeal generation, but we do not find any significant difference in particle emission rates for the two modes as a function of vocalization amplitude (Supplementary Fig. S10 and cf. Fig. 5B). Furthermore, it is less understood how particles originating in the respiratory tract might deposit in more proximal regions instead of being emitted during exhalation. Particle deposition efficiency during nasal exhalation is known to depend on exhalation flow rate in a convoluted fashion, with Brownian diffusion, sedimentation, and inertial impaction all playing roles at different length and time scales within the respiratory tract[36]. Nonetheless, our results strongly suggest that, in general, more particles escape the respiratory tract if the vocalization is louder.

Our results also clearly show that some participants release many more particles than others, for as-yet unclear reasons. It is known that the Rayleigh-Plateau instability that gives rise to small droplets during the "film burst" is

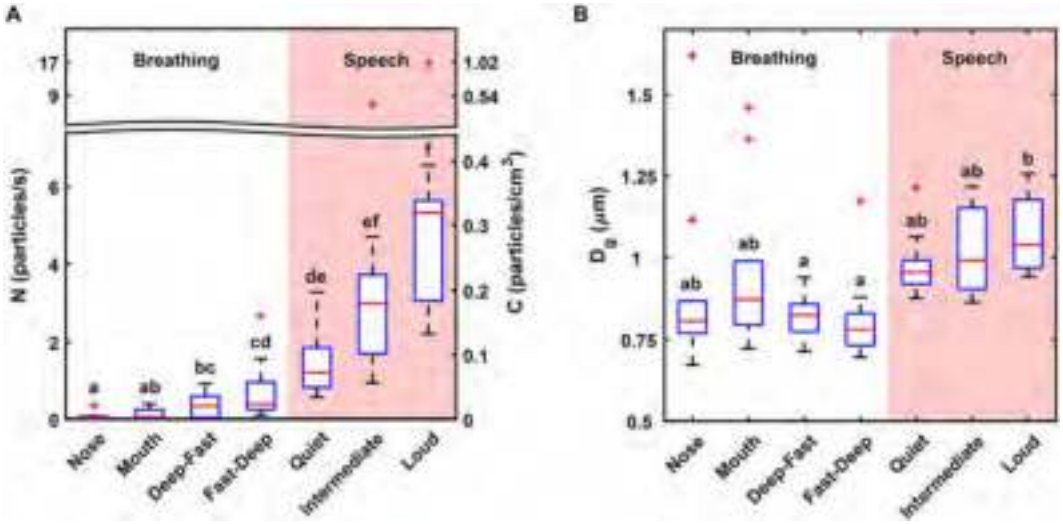

Figure 5. Comparison of (**A**) emission rate/concentration and (**B**) corresponding geometric mean diameters of particles emitted during various modes of breathing versus speech at different loudness levels. "Nose" denotes normal nasal breathing; "Mouth" denotes normal mouth breathing; "Deep-Fast" denotes deep, slow nasal inhalation followed by fast mouth exhalation; "Fast-Deep" denotes fast nasal inhalation followed by deep (i.e., slow and prolonged) mouth exhalation. "Quiet", "Intermediate", and "Loud" denote loudness levels while reading aloud a passage of text ("Rainbow" passage) at respective amplitudes. Red lines indicate medians, while bottom and top of blue boxes indicate the 25th and 75th percentiles respectively; sample size is n = 10. Outliers (defined as values that exceed 2.7 standard deviations) are indicated with red plus signs. Note that the 2 outliers for speech in (**A**) are a different individual (F4) than the two outliers observed for nose and fast-deep breathing (M24 and M5 respectively). Scheffe groups are indicated with letters; groups with no common letter are considered significantly different with $p < 0.05$, cf. Supplementary Table S1. Note that (**A**) has different scales above and below the break.

sensitive to the interfacial tension, density, and viscosity of the fluid[37], so one possible explanation is that the mucosal fluids in different people have different material properties and correspondingly generate more or fewer drops. Notably, different disease states are known to alter the physicochemical properties of the mucosal fluid lining the respiratory tract[38], so it is possible that infected individuals might generate markedly different quantities of particles than those emitted by the healthy individuals tested here. Intriguingly, Edwards *et al.*[15] found that delivering nebulized isotonic saline to individuals decreased the number of particles exhaled during normal breathing for a few hours after inhalation of the saline; further tests are warranted with speech. Alternatively, it is possible that individual manners of articulation affect the amount of internal deposition of the particles before they manage to escape the mouth. Our tests of different languages yielded no significant differences, at odds with previous speculation that language spoken might have played a role in the epidemiology of SARS coronavirus transmission[39], and suggesting that some as yet unknown physiological factor causes the dramatic variation among individuals.

Regardless of the underlying physical mechanism, from an epidemiological perspective the existence of speech superemitters motivates consideration of a new hypothesis: that speech superemitters contribute to "superspreading" of infectious diseases transmitted by emitted airborne particles. A superspreader is a contagious individual who infects a disproportionately large number of susceptible contacts[31,40,41]. To date, several airborne superspreading events have been documented, such as the MERS-CoV outbreak in South Korea in 2015 and the SARS-CoV outbreak in 2003, the latter being initiated in Hong Kong and spreading to Canada, Vietnam, and Singapore through travel[40–43]. In the case of respiratory infectious diseases in particular, the underlying physiological and immunological factors that contribute to heterogeneity in individual infectiousness remain poorly understood, despite the epidemiological importance of respiratory superspreaders. Quantifying infectious pathogen loads in exhaled air is technically challenging, relative to other contagious substances like blood, urine, and feces. Many factors presumably affect the secondary attack rate attributable to any infectious individual, including the herd immunity status of others in proximity. Nonetheless, our results suggest that, for respiratory infections transmitted from person to person via airborne particles, the existence of speech superemitters might help explain the existence of superspreaders. A similar hypothesis was advanced by Edwards *et al.*[15] in response to their observation of variability between individuals in the number of particles emitted during mouth breathing. Interestingly, our data show that speech superemitters are not necessarily breathing superemitters as well (Fig. 5A), suggesting that respiratory superemission during vocalized speech has a different underlying physiology than superemission during tidal breathing.

Our results indicate that speech is potentially of much greater concern than breathing for two reasons: the particles on average are larger, and thus could potentially carry a larger number of pathogens, and much greater quantities of particles are emitted compared to breathing, thus increasing the odds of infecting nearby susceptible individuals. Laryngeal particle generation during speech is also potentially important since some studies suggest that human influenza viruses attach more abundantly to the large airways of the upper respiratory tract than to

the bronchiolar and alveolar cells in the lower respiratory tract, while MERS-CoV and avian influenza viruses mainly cause lower respiratory tract infections due to the greater presence of these virus receptors deeper within the lung[44–47]; likewise there is evidence that laryngeal tuberculosis is potentially more contagious than typical pulmonary tuberculosis[48].

A second key epidemiological implication of our results is that simply talking in a loud voice would increase the rate at which an infected individual releases pathogen-laden particles into the air, which in turn would increase the probability of transmission to susceptible individuals nearby[49]. For example, an airborne infectious disease might spread more efficiently in a school cafeteria than a library, or in a noisy hospital waiting room than a quiet ward. Moreover, our data suggest a related hypothesis, that infected individuals could be transmitting significant numbers of respiratory pathogens via speech in the absence of overt clinical signs of illness like coughing or sneezing. More research is needed; however, the presence of asymptomatic or paucisymptomatic superspreaders would have important public health implications in the surveillance for and mitigation of infectious disease epidemics that are spread by airborne respiratory particles. The data presented here strongly suggest that further efforts to test these hypotheses are warranted.

Methods

Human subjects. The University of California Davis Institutional Review Board approved this study and all research was performed in accordance with relevant guidelines and regulations of the Institutional Review Board. We recruited 48 healthy volunteers (26 males and 22 females, ranging in age from 18 to 45 years old) by posting flyers at the University of California Davis campus over the time period May 2016 to March 2018. Informed consent was obtained from all participants prior to study participation. All participants completed a brief questionnaire including age, gender, weight, height, general health status, and smoking history. Only participants who self-reported as healthy non-smokers were included in the study. The subject in Supplementary Fig. S12 provided her written informed consent for the publication of identifying information/images in an online open-access publication.

Experimental set-up. A photograph of the experimental set-up is provided as Supplementary Fig. S12. An aerodynamic particle sizer (APS, TSI model 3321) operating at a total flow rate of 5 L/min (sheath flow rate $\cong$ 4 L/min, sample flow rate $\cong$ 1 L/min) was placed inside a HEPA filtered laminar flow hood that provided class 10 air. A plastic funnel (diameter = 10 cm) was connected to the APS sampling inlet via a conductive silicon tube (distance between funnel hole to APS inlet = 7.5 cm, tube inner diameter = 1.2 cm). During each experiment, participants sat at the laminar flow hood, in front of the APS, and spoke into the funnel. For the majority of speaking and breathing experiments, a nose rest across the funnel opening was used to position participants' mouths approximately 7.5 cm away from the funnel inlet (hole) and also to divert nasal exhalations away from the APS. During "nose-breathing" experiments, the nose rest was removed to allow nasal exhalations to be drawn into the APS. Note that participants' faces did not touch the funnel, so that air was free to move around the side of their faces; in this sense the cone was a semi-confined environment and not all expired particles were necessarily sampled by the APS. Also note that the sheath flow inside of an APS is filtered, so the particle emission rates sampled by the APS automatically remove 80% of the particles sampled from the funnel. Equivalent concentrations reported on the secondary axes in Figs 1 through 5 are determined from the raw particle counts using the sample flow rate, i.e., $C = \frac{\text{particles}}{\text{s}} \times \frac{\text{s}}{\text{cm}^3} = \frac{\text{particles}}{\text{cm}^3}$. Also note that the APS measures the size distribution of particles larger than 0.5 µm, but only detects the presence of particles between 0.37 µm and 0.5 µm without providing precise size measurements. For this reason Figs 1–5 exclude the counts of particles smaller than 0.5 µm; including them has little impact on the results since the vast majority of particles were larger than 0.5 microns.

A microphone (audio-technica PRO 37) and a decibel meter (Extech, 407760) were placed immediately on either side of the funnel to record the vocalizations. A computer screen with word prompts and a timer was placed behind the APS to guide participants in making requested vocalizations for the specified duration. The timing, duration, repetition, and order of vocalization and breathing experiments were coordinated by customized code written in LabVIEW (National Instruments). A digital hygrometer was used to measure the ambient temperature and relative humidity inside the laminar flow hood during all experiments. The participants were not allowed to drink or eat during the experiment, but they were free to rest between experiments for a few minutes as needed; data from each individual participant was gathered over an approximately 1-hour time period. We performed the experiments in an indoor (controlled) environment, so the ambient temperature varied only from approximately 20 to 25 °C, while the ambient relative humidity measured inside the laminar flow hood varied from a low of approximately 45% to a high of 80%. Control experiments indicate that the particle size distribution was independent of whether the particles were expired early or late during a sustained vocalization (Supplementary Fig. S3), indicating that transient fluctuations in the humidity inside the funnel due to exhalation had no impact on the final measured size distribution. Particles with initial diameter of less than 20 µm dry to approximately half of their initial diameter in less than 1 second[49,50]. Different correction factors have been suggested in the literature that one can use to estimate the initial size of the particles[49,51]; here we focus on the final size distribution because epidemiologically it is the final size distribution governs the deposition efficiency of the particles in the respiratory tract of nearby susceptible individuals[52].

Vocalization experiments. *"/ɑ/" experiments.* Participants (n = 10, 5 males, M1 to M5, and 5 females, F1 to F5) voiced /ɑ/ (the vowel sound in 'saw') for five seconds, followed by 15 seconds of nose breathing, repeated six times in succession. The participant repeated the series of six /ɑ/ vocalizations, to the best of the participant's ability, at the same amplitude. Each participant completed eight sets of /ɑ/ experiments, each set performed at different, self-regulated voice amplitude. Timed prompts with directions for the requested vocalization appeared on the computer screen, which displayed a timer and an amplitude (loudness) gauge to help the participants regulate their voice amplitude. The requested amplitudes were presented to participants in a random order.

"Rainbow passage" experiments. Participants (n = 10, 5 males, M1 to M5, and 5 females, F1 to F5) read aloud a 330-word excerpt of text in English, known in linguistics research as the Rainbow passage[53]. Participants were asked to read the Rainbow passage aloud three times, at a comfortable pace, over approximately 2 minutes per reading. Each of the three readings was performed at a different self-regulated amplitude: quiet, intermediate, and loud. Quiet was defined for participants as "just louder than a whisper," intermediate as a "normal conversational voice," and loud as "giving a loud lecture".

"The Little Prince" experiments. Bilingual participants (n = 30) fluent in both English and either Spanish (n = 10, 5 males, M6 to M10, and 5 females, F6 to F10), Mandarin (n = 10, 5 males, M11 to M15, and 5 females, F11 to F15), or Arabic (n = 10, 6 males, M16 to M21, and 4 females, F16 to F19) read Chapter 24 of "The Little Prince[54]" aloud six times, three times in English translation, each time at a different amplitude (quiet, intermediate, and loud) and three times in their respective language, again at three loudness levels.

Breathing/speaking experiments. Participants (n = 10, 6 males, M5 and M22 to M26, and 4 females, F4 and F20 to F22) alternated four silent breathing patterns with vocalized speech at three amplitudes. For breathing measurements, the breathing patterns were designated as "nose" (both inhalation and exhalation through the nose), "mouth" (both inhalation and exhalation through the mouth), "deep-fast" (deep, slow inhalation for ~3 seconds through the nose, holding it for ~1 second, followed by fast exhalation through the mouth (~1 second)), and "fast-deep" (rapid inhalation through the nose (~1 second), holding it for ~1 second, followed by slow exhalation through the mouth for ~3 seconds). Each breathing experiment was performed over 2 minutes, and at a comfortable pace for the participants. Between performing different breathing patterns, participants were asked to read the Rainbow passage in a "quiet," "intermediate," or "loud" voice, as prompted by the computer in random order.

Statistical analysis. Data analysis was performed in MATLAB (MathWorks), with data fits performed as noted in figure legends. Pearson's linear correlation coefficients and p values were calculated for linear fits. Lognormal fits were made via nonlinear regression, and median, mean, and standard deviation were calculated. Box-and-whisker plots show the median (red line), interquartile range (blue box), and range (black whiskers). To analyze the breathing/speaking experiments data presented in Fig. 5, Stata/SE 15.1 was used to perform general linear mixed model (GLMM) analysis to account for person-level correlations, and post hoc pairwise comparisons were performed and adjusted for multiple comparisons using Scheffe's method.

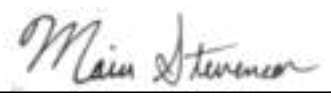
affirmed this 2nd day of July, 2021



A Commissioner, etc.

Ontario is now in Step 2 of the Roadmap to Reopen. Follow the restrictions and public health measures.

Ontario

Reopening Ontario

Learn about the Roadmap to Reopen, the province's three-step plan to safely and gradually lift public health measures based on ongoing progress of provincewide vaccination rates and improvements of key public health and health care indicators.

Ontario is in Step 2 of the Roadmap to Reopen as of **June 30 at 12:01 a.m.**

Overview

The Roadmap to Reopen is a three-step plan to safely and cautiously reopen the province and gradually lift public health measures.

The plan is based on:

- the provincewide vaccination rate
- improvements in key public health and health care indicators

In Step 2 of the roadmap, we must all continue to follow the public health measures, advice and restrictions (https://covid-19.ontario.ca/public-health-measures) .

Guiding principles

Step 1: An initial focus on resuming outdoor activities with smaller crowds where the risk of transmission is lower, and permitting limited indoor settings with restrictions.

Step 2: Further expanding outdoor activities and resuming limited indoor services with small numbers of people and with face coverings being worn.

Step 3: Expanding access to indoor settings, with restrictions, including where there are larger numbers of people and where face coverings can't always be worn.

Moving through the steps

The province will remain at each step for **at least 21 days** to evaluate any impacts on key public health and health system indicators. It can take up to two weeks for COVID-19 vaccinations to offer protection against the virus.

The province will remain in Step 1 for at least 21 days to evaluate any impacts on key public health and health system indicators.

If at the end of the 21 days the province has met the following vaccination thresholds, and there are continued improvements in other key public health and health system indicators, the province may move to the next step of the

roadmap:

- **Step 1:** 60% of adults vaccinated with one dose
- **Step 2:** 70% of adults vaccinated with one dose and 20% vaccinated with two doses
- **Step 3:** 70 to 80% of adults vaccinated with one dose and 25% vaccinated with two doses

Roadmap to reopen – key highlights

Vaccination rate
plus key public health and health care indicators

Step 1

60%

Adults with one dose

Permit with restrictions

Outdoor spaces begin reopening, limited indoor settings with restrictions

- Outdoor social gatherings and organized public events for up to 10 people
- Outdoor dining for up to 4 people per table
- Essential retail capacity at 25%
- Non-essential retail capacity at 15%
- Religious services, rites and ceremonies indoors at 15% capacity and outdoors with capacity limited to permit physical distancing of 2 metres
- Outdoor sports training (no games or practices), fitness classes and personal training up to 10 people
- Day camps
- Overnight camping at campgrounds and campsites, including Ontario Parks and short-term rentals
- Outdoor horse racing and motor speedways without spectators
- Outdoor pools and wading pools

+21 days before next stage

Vaccination rate
plus key public health and health care indicators

Step 2

70%

Adults with one dose
20% Fully vaccinated

Permit with restrictions

Open indoors with small numbers and face coverings and expand outdoors

- Outdoor social gatherings and organized public events for up to 25 people
- Indoor social gatherings and organized public events for up to 5 people
- Outdoor dining for up to 6 people per table
- Essential and other select retail permitted at 50% capacity
- Non-essential retail capacity at 25%
- Stores in shopping malls open, with restrictions
- Larger indoor religious services, rites, or ceremonies, including wedding services and funeral services at 25% capacity
- Outdoor religious services, rites, or ceremonies, including wedding services and funeral services, capped at the number of people that can maintain a physical distance of two metres
- Overnight camps
- Personal care services where face coverings can be worn at all times at 25% capacity
- Outdoor fitness classes are capped at the number of people who can maintain 3 metres of distance
- Public libraries permitted at 25% capacity
- Outdoor meeting and event spaces at 25% capacity
- Outdoor amusement and water parks at 25% capacity
- Outdoor sports games, leagues and events at 25% capacity
- Outdoor cinemas, performing arts, live music events and attractions at 25% capacity
- Outdoor horse racing and motor speedways at 25% capacity

+21 days before next stage
Vaccination rate
plus key public health and health care indicators

Step 3

70-80%

Adults with one dose
25% Fully vaccinated

Permit with restrictions

Expand indoors where face coverings can’t always be worn

- Larger indoor and outdoor social gatherings and organized public events
- Indoor dining
- Essential and non-essential retail with limited capacity
- Larger indoor religious services, rites or ceremonies, including wedding services and funeral services with capacity limits
- Indoor meeting and event spaces
- Indoor sports and recreational facilities

- Indoor seated events
- Indoor attractions and cultural amenities
- Casino and bingo halls
- Other outdoor activities from Step 2 permitted to operate indoors

Roadmap to reopen at a glance

This is a high-level overview of what can reopen in each step.

Read our public health measures, advice and restrictions (https://covid-19.ontario.ca/public-health-measures) for a more detailed summary or refer to *O. Reg. 263/20 (https://www.ontario.ca/laws/regulation/200263)* for a complete list of public health and workplace safety measures and restrictions for Step 2.

Gatherings

Step 1

Maximum 10 people for outdoor gatherings

Outdoor end-of-school-year celebration ceremonies held by a school or private school are exempt from outdoor gathering limits, with restrictions

Retirement homes are exempt from gathering limits

Step 2

Maximum 25 people for outdoor gatherings

Maximum 5 people for indoor gatherings

Step 3

Larger indoor and outdoor gatherings with size limits

Religious services, rites or ceremonies, including wedding services and funeral services (does not apply to receptions)

Step 1

15% capacity indoors of the room

Outdoor permitted with capacity limited to permit physical distancing of 2 metres

Step 2

Indoor permitted at 25% capacity of the room

Outdoor permitted with capacity limited to permit physical distancing of 2 metres

Step 3

Larger indoor religious services, rites and ceremonies

Outdoor permitted with capacity limited to permit physical distancing of 2 metres

---

Retail

Step 1

Essential and select retail at 25% capacity and can sell all goods (including discount and big box)

Non-essential retail at 15% capacity

Retail stores in malls closed unless the stores have a street facing entrance

Restrictions on shopping malls

Step 2

Essential retail at 50% capacity

Non-essential retail at 25% capacity

Stores in shopping malls open

Step 3

Essential and non-essential retail open with capacity limited to permit physical distancing of 2 metres

---

Liquor stores

Step 1

Open at 25% capacity

Step 2

Open at 50% capacity

Step 3

Open with capacity limited to permit physical distancing of 2 metres

---

Restaurants and bars

Step 1

Outdoor dining with 4 people per table from different households and other restrictions

Step 2

Outdoor dining with 6 people per table and other restrictions

Karaoke permitted with restrictions (outdoor only)

Step 3

Indoor dining with capacity and other restrictions

Outdoor dining with capacity limited to permit physical distancing of 2 metres

Buffets permitted

Karaoke permitted with restrictions

Personal care services

Step 1

Closed

Sensory deprivation pods permitted when prescribed or administered by a regulated health professional, with restrictions

Step 2

Open at 25% capacity

Appointment required

Services that require the removal of a face covering not permitted

Step 3

Open with capacity limited to permit physical distancing of 2 metres and other restrictions

---

Sports and recreational fitness facilities

Step 1

Outdoor fitness classes, outdoor sports training (no games or practices) and outdoor personal training, with 10 patrons maximum

Closed for indoor use except for high-performance athletes and day camps

Step 2

Outdoor sports leagues open

Training for professional or amateur athletes and/or competitions

Closed for indoor use except for high-performance athletes and day or overnight camps

Step 3

Indoor open, with restrictions

Outdoor open, with restrictions

Personal fitness and training

Step 1

Outdoor fitness classes – 10 people maximum, 3 metres distance

Outdoor personal training – 10 people maximum, 3 metres distance

Outdoor sports training only – 10 people maximum, 3 metres distance (no games or practices)

Step 2

Outdoor fitness classes and personal training – with limit on the number of patrons, 3 metres distance

Step 3

Outdoor and indoor fitness classes and personal training permitted, with restrictions

---

Outdoor recreational amenities

Step 1

Open with restrictions

Step 2

Open with restrictions

Step 3

Open

Water features

Step 1

Outdoor pools, splash pads, spray pads, whirlpools, wading pools and water slides open

Step 2

Outdoor pools, splash pads, spray pads, whirlpools, wading pools and water slides open

Step 3

Indoor and outdoor pools, splash pads, spray pads, whirlpools, wading pools and water slides open

---

Meeting and event spaces

Step 1

Closed with exceptions for certain purposes including social services, government operations, court services, in-person examinations for select professions (subject to conditions)

Step 2

Outdoor spaces open at 25% capacity and other restrictions

Indoor meeting and event spaces closed, with exceptions for certain purposes, including for viewing for potential booking of a future event

Step 3

Indoor spaces open with capacity and other restrictions, including for tradeshows, conferences and exhibitions

---

Day camps

Step 1

Open based on guidance from the Chief Medical Officer of Health (PDF) (https://www.health.gov.on.ca/en/pro/programs/publichealth/coronavirus/docs/2019_summer_day_camps_guidance.pdf)

Step 2

Open based on guidance from the Chief Medical Officer of Health (PDF) (https://www.health.gov.on.ca/en/pro/programs/publichealth/coronavirus/docs/2019_summer_day_camps_guidance.pdf)

Step 3

Open based on guidance from the Chief Medical Officer of Health (PDF) (https://www.health.gov.on.ca/en/pro/programs/publichealth/coronavirus/docs/2019_summer_day_camps_guidance.pdf)

Overnight camps

Step 1

Closed

Step 2

Open based on guidance from the Chief Medical Officer of Health

Step 3

Open based on guidance from the Chief Medical Officer of Health

---

Commercial film and TV production

Step 1

Open with no audience, no more than 50 performers on set, and other restrictions

Step 2

Open with no audience, and other restrictions

Step 3

Open with capacity restrictions for studio audiences, and other restrictions

---

Performing arts

Step 1

Outdoor open for rehearsing or performing a recorded or broadcasted event – 10 people maximum, spectators not permitted

Step 2

Indoor closed, permitted only for the purpose of rehearsing or performing a recorded or broadcasted event – spectators not permitted

Outdoor open, including live music, with spectator capacity at 25% and other restrictions

Step 3

Indoor open, including live music, with spectator capacity and other restrictions

Outdoor open, including live music, with spectator capacity and other restrictions

---

Cinemas

Step 1

Drive-in open

Step 2

Indoor closed

Outdoor open with spectator capacity at 25% and other restrictions

Step 3

Indoor open with spectator capacity and other restrictions

Outdoor open with spectator capacity and other restrictions

Casino, bingo halls and gaming establishments

Step 1

Closed

Step 2

Closed

Step 3

Open with capacity and other restrictions

Horse racing

Step 1

Outdoor with capacity and crew restrictions

No spectators

Step 2

Outdoor open with spectator capacity at 25% and other restrictions

Step 3

Open with spectator capacity and other restrictions

Motorsports and speedways

Step 1

Outdoor with capacity and crew restrictions

No spectators

Step 2

Outdoor open with spectator capacity at 25% and other restrictions

Step 3

Open with spectator capacity and other restrictions

Short-term rentals (does not include hotels, motels, lodges or resorts, but does apply to cabins and cottages)

Step 1

Open

Indoor pools, communal steam rooms, saunas or indoor whirlpools, indoor fitness centres, or other indoor recreational facilities closed

Step 2

Open

Indoor pools, communal steam rooms, saunas or indoor whirlpools, indoor fitness centres, or other indoor recreational facilities closed

Step 3

Open

Indoor pools, communal steam rooms, saunas or indoor whirlpools, indoor fitness centres, or other indoor recreational facilities open with some restrictions

---

Hotels, motels, lodges, resorts and other shared rental accommodation

Step 1

Open. Indoor pools, communal steam rooms, saunas or indoor whirlpools, indoor fitness centres, or other indoor recreational facilities closed

Step 2

Open. Indoor pools, communal steam rooms, saunas or indoor whirlpools, indoor fitness centres, or other indoor recreational facilities closed

Step 3

Open. Indoor pools, communal steam rooms, saunas or whirlpools, indoor fitness centres, or other indoor recreational facilities open with some restrictions

---

Public libraries

Step 1

Curbside pickup for materials

Access to computers, photocopiers, and similar services permitted

Step 2

Open with 25% capacity and other restrictions

Step 3

Open, with capacity limited to permit physical distancing of 2 metres and other restrictions

---

Museums and attractions

Step 1

Outdoor zoos, landmarks, historic sites, botanical gardens, and similar outdoor attractions open with capacity limited to 15% for ticketed areas and other restrictions

Step 2

Outdoor waterparks open with 25% capacity and other restrictions

Outdoor amusement parks open with 25% capacity and other restrictions, including on rides

Step 3

Indoor museums and art galleries, Zoos and aquariums, waterparks, and amusement parks open with capacity restrictions

---

Fairs and rural exhibitions

Step 1

Closed

Step 2

Outdoor open at 25% capacity and other restrictions

Step 3

Indoor and outdoor open at reduced capacity and other restrictions

---

Teaching and instruction (for example, recreational classes and lessons)

Step 1

Outdoor open, 10 patrons maximum, 2 metres physical distancing and other restrictions

Step 2

Outdoor open, with distancing and other restrictions

Step 3

Indoor and outdoor open with distancing and other restrictions

---

Tour and guide services

Step 1

Outdoor open, 10 patrons maximum, 2 metres physical distancing and other restrictions

Boat tours and motor vehicle tours not permitted

Step 2

Outdoor open, with capacity at 25% and other restrictions

Step 3

Indoor and outdoor open with capacity and other restrictions

Construction

Step 1

All construction open

Step 2

All construction open

Step 3

All construction open

Driving instruction

Step 1

Not permitted, except for drivers of commercial vehicles

Step 2

Driving instruction permitted with restrictions

Step 3

Driving instruction permitted with restrictions

Ontario Parks and campgrounds

Step 1

Open

Step 2

Open

Step 3

Open

Marinas and boating clubs

Step 1

Permitted with clubhouses, and other indoor amenities closed

Recreational boating permitted but only members of a household can gather on a boat

Step 2

Permitted with clubhouses, and other indoor amenities closed

Step 3

Open with restrictions

Strip clubs

Step 1

Permitted to operate as a restaurant in alignment with restaurant restrictions

Step 2

Permitted to operate as a restaurant in alignment with restaurant restrictions

Step 3

Permitted to operate as a strip club in alignment with restaurant and performance restrictions

---

Domestic services

Step 1

Open to support children, seniors or vulnerable persons

Step 2

Open

Step 3

Open

Photography studios and services

Step 1

Outdoor open and by appointment only, with restrictions

Step 2

Outdoor and limited indoor open with restrictions

Step 3

Outdoor and indoor open with restrictions

Community centres and multi-purpose facilities

Step 1

Open for social services, child care and day camps, mental health support services or addictions support services, and permitted indoor and outdoors activities and services, with restrictions

Step 2

Open for social services, child care and day and overnight camps, mental health support services or addictions support services, and permitted indoor activities and services, with restrictions

Step 3

Open with restrictions

Real estate open houses

Step 1

Showings by appointment only

Step 2

Showings by appointment only

Step 3

Open

Drive-in and drive through events

Step 1

Open with restrictions

Step 2

Open with restrictions

Step 3

Open with restrictions

Health and safety training

Step 1

Indoor: 10 person limit

Outdoor: 10 person limit

Physical distance of at least two metres from every other person in the instructional space, except where necessary for teaching and instruction that cannot be effectively provided if physical distancing is maintained

Step 2

Indoor: 10 person limit

Outdoor open, with capacity and other restrictions

Step 3

Indoor and outdoor open with capacity and other restrictions

TORONTO

COVID-19

Toronto is in Step Two of the Province's Roadmap to Reopen. Get health updates and information about COVID-19 vaccines at toronto.ca/covid19 (https://www.toronto.ca/home/covid-19).

Programs & Services for Tuberculosis (TB)

It is estimated that one in three people worldwide is infected with the TB bacteria. In Toronto, about 300 people become sick with **tuberculosis (https://www.toronto.ca/?page_id=28540)** every year. Treatment for TB disease involves taking medication every day for six months or longer. Although treatment can take a long time, a person can be cured of TB once treatment is complete.

Different specialty teams in the TB program work together to provide support for individuals with TB as well as their families and to help prevent the spread of TB in Toronto.

Expand All | Collapse All

Case Management Teams

- Provide case management services for people with active TB
- Ensure adequate TB treatment is received and completed
- Follow-up of individuals exposed to TB
- Educate clients and contacts
- Order TB medication for clients with TB disease and contacts with TB infection

Directly Observed Therapy

Directly Observed Therapy (https://www.toronto.ca/community-people/health-wellness-care/health-programs-advice/tuberculosis-tb/programs-services-for-tuberculosis-tb/directly-observed-therapy-dot-in-tuberculosis-tb/)

- Ensure clients take medication correctly
- Monitor for side effects
- Prevent/Reduce drug resistance caused by interrupted drug therapy
- Collaborates with Case Management Teams regarding client care

Homeless and Corrections Team

- Manage TB disease and infection in the **homeless/underhoused and corrections populations (https://www.toronto.ca/community-people/health-wellness-care/health-programs-advice/tuberculosis-tb/tuberculosis-tb-and-homeless-service-settings/)**
- Ensure adequate TB treatment is received and completed
- Follow-up of individuals exposed to TB
- Educate shelters, drop-in centers, clients, contacts and within correctional facilities
- Coordinate TB follow-up upon discharge from correctional facilities
- Liaise with Ministry of Community Safety and Correctional Services and other Toronto Public Health programs

Medical Surveillance and Drug Order Team

Medical Surveillance (https://www.toronto.ca/community-people/health-wellness-care/health-programs-advice/tuberculosis-tb/programs-services-for-tuberculosis-tb/tuberculosis-tb-medical-surveillance/) and Drug Order Team

- Immigrants, refugees, visitors, visa students/workers identified through immigration surveillance are monitored for TB disease
- Monitor clients with TB infection identified through routine surveillance
- Order TB medication for clients with TB infection on immigration and routine surveillance
- Order TB medication for Toronto clinicians whose clients live outside of Toronto

Prevention Team

Provide free educational materials, presentations, and consultation to clients, community agencies and health professionals

- Health promotion and community development
- Outreach to populations at higher risk for TB disease and health professionals
- Create and develop multi-language resource materials for clients and health professionals
- Partner with community agencies to increase TB awareness

Social Work for TB Clients

- .Provide assessment, counselling and referral
- Focus on income and housing
- Provide internal and external consultation

TB STOP Drop-in

TB STOP (https://www.toronto.ca/community-people/health-wellness-care/health-programs-advice/tuberculosis-tb/tuberculosis-tb-and-homeless-service-settings/?accordion=tb-stop-drop-in) provides drop-in services for people who are homeless and under-housed as well as for service providers to the homeless in Toronto:

- Symptom screening
- Sputum collection
- Referrals to other health professionals as appropriate
- TB skin testing

Ontario COVID-19 Data Tool

The Ontario COVID-19 Data Tool provides epidemiological information on COVID-19 activity in Ontario to-date. Explore the most recent COVID-19 data including: daily case counts, hospitalizations and deaths (Case trends), total or recent cases counts by age and sex, map by public health unit, source of COVID-19 infection (acquisition), outbreaks and laboratory testing.

Additions to the Ontario COVID-19 Data Tool as of May 28th, 2021:

- Vaccine uptake data on the Summary, Map and Vaccines sections
- COVID-19 reproduction number and doubling time

The COVID-19 Data Tool is updated Monday to Fridays at 11:30 a.m. except on statutory holidays. For weekend case counts see the **Daily Epidemiological Summary.**

For questions about the data, please contact **EPIR@oahpp.ca**.

Public health unit

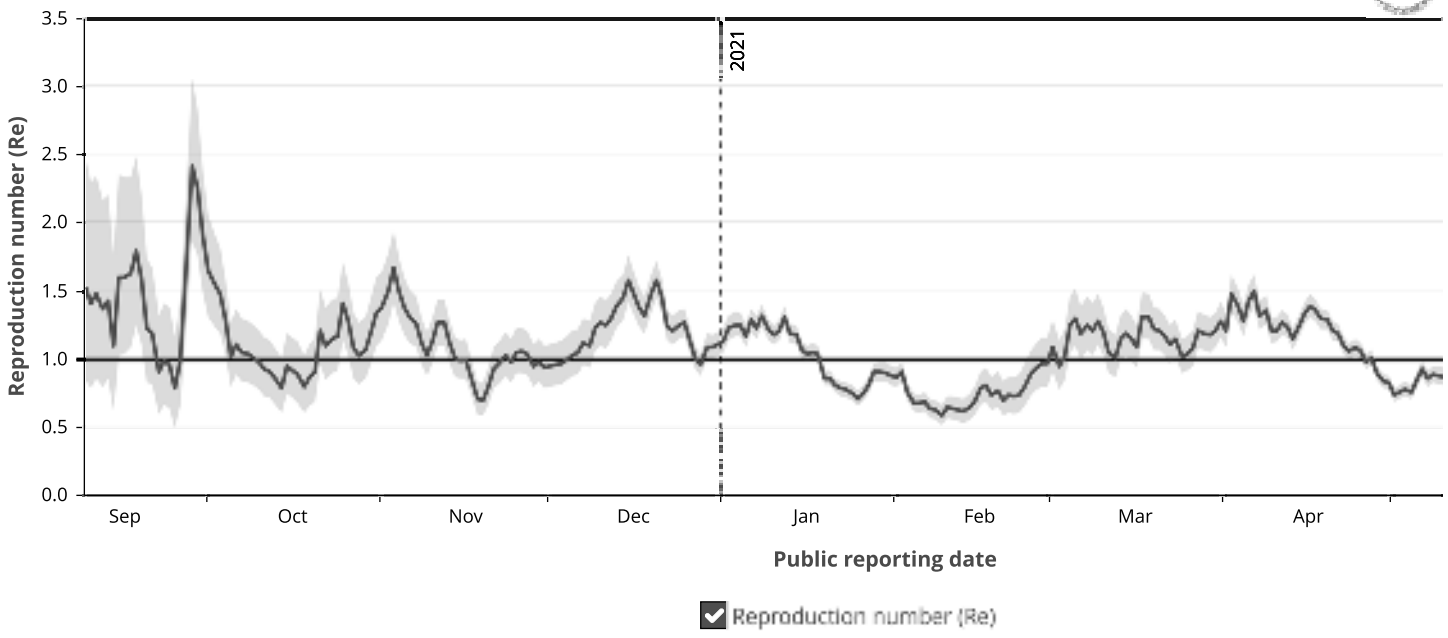
Niagara Region Public Health

09 Sep 2020 — 22 Jun 2021

doubling time in Niagara Region Public Health

September 9, 2020 to June 22, 2021

Reproduction data are updated weekly on Tuesdays. Scroll over the data line to view doubling time estimates. An Re greater than 1 means that the overall number of new cases is increasing, while an Re less than 1 means the overall number of new cases is decreasing. An Re equal to 1 means the overall number of new cases will remain stable.



The Re is not shown when there are fewer than 12 cases in the last 7 days for a local public health unit.

95% Credible Interval (CI): There is a 95% probability that the true estimate lies within this interval based on the observed data. This interval is highlighted in light purple on the graph.

Doubling time (Td) is an estimate of the number of days it will take for the number of daily COVID-19 cases to double given the current trends in incidence. When this estimate is greater than 100 days, it is reported as >100.

Public reporting date is the date the public health unit reported the case to Public Health Ontario plus one day to account for the delay in public reporting.

Reproduction number (Re) is the average number of secondary cases of infection generated by each person infected with COVID-19. An Re greater than 1 means that the overall number of new cases is growing in a region. An Re equal to 1 means the overall number of new cases will remain stable. An Re less than 1 means the overall number of new cases is decreasing and suggests that COVID-19 is coming under control in a region.

AFFIDAVIT OF DRS. KARIM ALI and ZAIN CHAGLA
(Affirmed July 5, 2021)

I, DR. KARIM ALI of the [redacted] in the Province of Ontario, and I, DR. ZAIN CHAGLA of the [redacted] in the Province of Ontario, **AFFIRM**:

1. Dr. Ali's work address is 1200, Fourth Ave, St Catharines, ON L2S 0A9.
2. Dr. Chagla's work address is 300-25 Charlton Ave. East, Hamilton ON, L5G 3l2.
3. At the request of counsel for the Attorney General of Ontario, we have provided an expert report regarding COVID-19 risk factors, transmission and public health measures. Our expert report is attached to this affidavit as **Exhibit "A".** It details the specific questions counsel for the Respondent asked us to address within the report, our relevant expertise and the sources of our information.
4. We make this affidavit to provide our expert opinion and for no improper purpose. To this end, attached as **Exhibits "B"** and **"C"** are signed copies of our Acknowledgement of Expert's Duty. Attached as **Exhibits "D"** and **"E"** are the CVs of Drs. Ali and Chagla, respectively.

AFFIRMED by video conference by DR. KARIM ALI of the [redacted] in [redacted] before me at the City of Toronto on this 5th Day of July, 2021 in accordance with O Reg 431/20, Administering Oath or Declaration Remotely

A Commissioner for the Taking of Affidavits

This is "**Exhibit A**"
to the Affidavit of Drs. Karim Ali and Zain Chagla,
affirmed this 5th day of July, 2021

_____

A Commissioner, etc.

1) Generation of Report

a) The following report was generated by Dr. Karim Ali and Dr. Zain Chagla and represent the opinions of the authors alone, and clinical evidence to support these.

b) Both Dr. Ali and Dr. Chagla have experience in COVID-19 first hand, in the prevention and management of COVID-19 transmission, both from a patient and staff standpoint in their respective healthcare systems, as well as assisting with outbreak management in other congregate settings.

c) The questions asked of this report are:
   i) What is your background and expertise related to COVID-19 and its transmission?
   ii) What are the dangers of COVID-19, including dangers of variants?
   iii) What are the modes of transmission of COVID-19 and the risk factors for COVID-19 transmission?
   iv) How does the public health risk of permitting places of worship to open compare to the public health risks of permitting other indoor establishments or activities like retail, stores, bars, and film/TV production to open?

d) Materials reviewed include the submissions by Dr. Schabas, Dr. Kettner, and Dr. Warren.

2.1) Your background and expertise related to COVID-19 and its transmission - Dr. Zain Chagla

a) Dr. Chagla did his B.Sc and MD at Queen's University in Kingston. He completed a residency in Internal Medicine at Western University. He completed a fellowship in Infectious Diseases at McMaster University.

b) Dr. Chagla also completed a M.Sc in Infectious Diseases through the London School of Hygiene and Tropical Medicine. He also completed a diploma in Tropical medicine through the same institute, which was done in East Africa.

c) Dr. Chagla has tenure at McMaster University as an Associate Professor.

d) Dr. Chagla practices as an Infectious Diseases Physician at St. Joseph's Healthcare in Hamilton, with interests in General Infectious Diseases, Renal Transplantation, and Complex Respiratory Infections.

e) Dr. Chagla serves as Co-Medical Director of Infection Control at St. Joseph's Healthcare, Niagara Health System.

f) Dr. Chagla is a Consultant Infection Control physician at Woodstock General Hospital.

g) Dr. Chagla is Section Chair for Infectious Diseases for the Ontario Medical Association.

h) During the pandemic, Dr. Chagla has provided pandemic planning, contact tracing, outbreak management, data modelling, clinical care and support, and advisory services for St. Joseph's Healthcare Hamilton, Hamilton Public Health, Niagara Health Systems, and Woodstock General Hospital.

i) This included a significant amount of work around the transmission and management of COVID-19 in congregate settings, which provided experience on the spread of COVID-19 in indoor settings, and the management of transmission events from both staff and patients. There was also experience preventing transmission across healthcare institutions with over 4000 employees.

j) Dr. Chagla has worked on provincial guidelines for COVID-19 through Ontario Health on personal protective equipment, procedures and surgical guidelines, and operating assessment clinics.

k) Dr. Chagla has served on federal committees with relation to foreign travel, as well as ventilation.

l) Dr. Chagla has co-authored 16 peer reviewed papers on COVID-19 over the past 16 months, including epidemiology, testing, serological analysis, therapeutics, infection control, and vaccine efficacy.

m) Dr. Chagla has co-authored 12 editorials in national newspapers, and had over 100 media interviews over Canadian, American, and global networks relating to COVID-19.

n) Dr. Chagla has also served as a mentor for global COVID-19 responses in India, Afghanistan, and Nepal.

2.2) Your background and expertise related to COVID-19 and its transmission - Dr. Karim Ali

a) Dr Ali completed his MBBS from Ziauddin Medical University in Karachi, Pakistan.

b) Dr. Ali completed his Internal Medicine Residency at Hennepin County Medical Center in Minneapolis, MN. He completed his Infectious Diseases fellowship at Creighton University Medical Center and University of Nebraska Medical Center.

c) Dr. Ali joined Niagara Health in 2012.

d) Dr. Ali established the Division of Infectious Diseases at Niagara Health.

e) Dr.Ali was instrumental in establishing a system wide Antimicrobial Stewardship program at Niagara Health.

f) Dr Ali currently serves as the Director, Division of Infectious Diseases and Antimicrobial Stewardship Program at Niagara Health.

g) Dr. Ali is also the pandemic preparedness lead for Niagara Health at this time. In this role, he has been advising Niagara Health on COVID-19 since January 2020.

h) Dr. Ali has provided support with contact tracing, management of outbreaks, pandemic planning and clinical care of COVID 19 patients.

i) Together with Dr Chagla, Dr. Ali has been part of the outbreak management and response team at Niagara Health.

j) Dr. Ali is an Assistant Clinical Professor (Adjunct) at McMaster University.

k) Dr. Ali is involved in multiple national and international clinical trials for COVID-19 therapeutics.

l) Dr. Ali has done numerous local and national media interviews with regards to COVID transmission, treatment, epidemiology and vaccines.

3) Background information on COVID-19 and the dangers it poses, including dangers of variants

a) SARS-CoV-2 is a novel coronavirus that was first identified in the human population in Dec. 2019. This virus is responsible for the disease COVID-19. There are numerous other coronaviruses that circulate in the human population. After initial spread in 2019, SARS-CoV-2 rapidly spread across the globe and led to sustained human to human transmission. This led to the World Health Organization declaring it a pandemic in March 2020. Thus far this is the only known pandemic due to a coronavirus in human history.

b) A novel virus poses a significant threat, as there is no immunity to this virus at the population level. Time and again we saw health care systems being overwhelmed by a large number of people becoming sick with COVID-19 in a short period of time, overrunning the health care systems. This was seen in New York, Los Angeles, Italy, Brazil and is currently unfolding in India and other parts of the world.

c) While other coronaviruses do show a seasonal pattern, given the novel nature of SARS-CoV-2, it is too early to make sound inferences about seasonality. For example, the Middle East Respiratory Syndrome Coronavirus (MERS CoV), does not show a clear seasonality pattern (16).

d) Like other respiratory viruses, SARS-CoV-2 undergoes genetic mutations as it replicates. We saw this in March 2020 with the D614G variant which likely arose in the People's Republic of China and then spread throughout the world. With a significant amount of disease burden across the world, it was expected that other variants would emerge. This is due to the fact that genetic mutations do occur with every individual infected, and any mutation that gives the virus an advantage to infect large populations would cause that variant to predominate as more people became infected. Furthermore, as there is an increase in spread, infections in immunocompromised individuals, who have chronic infections, may then lead to the generation of further variants.

e) The first such variant of concern (VOC) was identified in Kent, UK around Sept. 2020. This VOC was known as B.1.1.7 and has recently been renamed SARS-CoV-2

variant Alpha. It is not only approximately 60% more transmissible, it also carries a higher likelihood of hospitalization, ICU admission and death (1).

f) SARS-CoV-2 variant Alpha rapidly spread across the globe and became the predominant strain.

g) By February 2021, SARS-CoV-2 variant Alpha had become the predominant strain in Ontario and has been largely responsible for the third wave in Ontario. Although, one must acknowledge that vaccinations would have mitigated much of this, unfortunately the federal government was unable to secure a sufficient supply of vaccines at the time.

h) A study of 26,314 people in Ontario testing positive for SARS-CoV-2 between February 7 and March 11, 2021 showed that 9,395 people (35.7%) infected with VOCs had a 62% relative increase in COVID-19 hospitalizations, a 114% relative increase in ICU admissions and a 40% relative increase in COVID-19 deaths compared to prior circulating COVID-19 strains (2, 15).

i) In recent weeks, another VOC, SARS-CoV-2 variant Delta, was identified in India and has now spread to over 80 countries across the globe. SARS-CoV-2 variant Delta is relatively more transmissible, with some estimates at a 40-60% increase in infectivity over the Alpha variant (3).

j) SARS-CoV-2 variant Delta also has an increased risk of hospitalizations especially amongst people who are not vaccinated, or have been vaccinated with just one dose at this time (3). It is projected that SARS-Cov-2 variant Delta will be the predominant strain in Ontario by July 2021. The best defence against this is to have our populations fully vaccinated. Until that objective can be achieved, the next-best defence is to drive down transmission by Non-Pharmaceutical Interventions ("NPI") (e.g, limiting the number of people who can attend indoor gatherings or religious services etc.)

4) Modes of transmission of COVID-19 and risk factors

a) Respiratory viruses in general are transmitted by inhalation of respiratory particles, or contamination of surfaces and subsequent inoculation by contact with mucous membranes. Viruses can enter through either the respiratory tract (nasal and oral cavities), or through direct contact with mucous membranes such as the eye.

b) The fomite (contact) based transmission route of SARS-COV-2 has likely not played a large role in ongoing transmission globally. Although studies have suggested initial viability of SARS-COV-2 on surfaces (4), more recent analysis of high burden areas such as intensive care units show very little viral seeding of the environment (5). Based on this, the CDC has updated guidance identifying this as low risk (6).

c) With regards to respiratory transmission, SARS-COV-2 is generally transmitted by small respiratory droplets[1], leading to transmission typically within close contacts of an infected case (7). In most settings, transmission occurs within close contacts, particularly in close proximity (<2 meters). This has led to many of the precautions

[1] In limited circumstances, SARS-COV-2 is transmitted by aerosols. See para d) *infra*.

we see in day to day life including physical distancing, which is used to mitigate that risk. The use of masking, particularly in indoor settings, is meant to block the flow of respiratory droplets from the source, particularly in the context of individuals who are infectious prior to their symptom onset (presymptomatic) or people without symptoms.

d) In poorly ventilated spaces, particularly with long interactions, and with behaviours that generate increasing respiratory particles such as coughing, singing, talking, yelling, or breathing heavily, there has been aerosol based transmission of the virus. Such events have led to spread over increased distance over 2 meters, as well as to large degrees of people becoming infected in one setting.

e) The initial Skagit choir in Washington was a noted occurrence where 50-80% of individuals at the event were infected in a single event, likely worsened by high aerosol generation and ventilation (8).

f) A choir singer in an Australian church likely infected 12 individuals as far as 15 meters away from the source (9).

g) Other long range occurrences have been noted in a restaurant (10) and a bus (11), supporting longer range transmission in particular settings, with higher than normal attack rates.

h) Dr. Shabas notes in his materials that large indoor gatherings can contribute to the spread of COVID-19, but then also notes that evidence-based policies are lacking, and the larger impact of COVID-19 transmission is unknown. This would be contrary to the wealth of experience of superspreading events, such as the Skagit choir (8).

i) While mitigation measures such as masking and physical distancing do offer a pathway to minimize risk, they are fallible, and can still lead to transmission. In Ontario to date, there have been 213 outbreaks occurring in settings categorized as "other recreational" which includes religious congregations, each one involving several cases. With secondary transmission of the variants of concern being up to 12% for household members (3), and increasing social nodes of contact due to loosening restrictions, there likely have been further secondary cases generated from each of these known cases.

j) On top of the risks of transmission within a facility due to masking and physical distancing, the amount of COVID cases in the community also affect the risk of transmission. If there are increasing cases in the community, there is an increased risk of an individual entering a facility while asymptomatic or presymptomatic.

k) Even with this case data in mind, we also recognize that these numbers vastly underestimate risk, as many cases are not diagnosed due to minimal symptoms or a lack of access to testing, and appropriate contact tracing is not initiated unless outbreaks are recognized. Finally, even the mitigation measures such as masks and physical distancing are not perfect, as individuals may not wear well-fitting masks, ventilation may be suboptimal, and screening for active COVID-19 symptoms may miss people who are still infectious or who minimize their symptoms.

l) Dr. Warren's report notes that Canadian and Ontario COVID-19 data shows a small absolute number of cases associated with religious services. However, that data was collected during periods when there were regional controls in place to minimize the spread of COVID-19 in many provinces, many of which included restrictions on the size of religious gatherings. The paradox in public health is as cases are controlled and reduced through public health interventions, they are not accounted for as they are effectively prevented, and data is drawn from the "tip of the iceberg" of the cases that broke through. It is difficult to model the impact of not having public health measures against mechanisms of transmission.

m) Dr. Warren points to a paper on a randomized clinical trial of mask use for example (18) but this study was not used to assess the use of universal masking as a source control (i.e. as a method to reduce the user's shedding of aerosols and droplets to the environment), rather, the study only looked at the use of masking as personal protective equipment (i.e as a method to block aerosols and droplets from being inhaled by the user), which significantly underestimates the effect of masking on the overall reduction of transmission.

n) A randomized control trial would be ideal in this setting as Dr. Warren recognizes, however, the practicality of this within the context of a global pandemic is difficult. However, larger natural history studies comparing non-pharmaceutical interventions in the first wave showed cancellation of large and small gatherings, and minimization of gatherings to < 10 had significant impacts on reproductive rates (12, 13), which likely did have larger effects in pandemic prevention.

o) Dr. Kettner tries to approximate risk of infectivity by describing the local context of COVID-19, and approximating that to the risk of an individual being asymptomatic or presymptomatic on the day of attending a congregation. However, this approach underestimates the fact that a) many cases are undiagnosed, b) individuals are not truthful with screening, and c) presymptomatic transmission is a significant risk factor for spread. Finally, Dr. Kettner approximates his numbers from outbreaks in Ontario at the time, but only recognizes outbreaks where multiple cases acquired COVID-19 from a common link. There are still a significant number of cases in Ontario where no link is identified, and it is highly variable if contact tracing would identify these links in the community. This is due to the fact that contact tracing relies on self-reported data, and overwhelmed public health units may not trace individuals outside of very high risk facilities (eg hospitals, long term care, and workplaces), and the pattern of a common link between a number of cases is not easily recognized. In these circumstances, one could have acquired COVID-19 at a congregate facility like a church, but not attributed transmission to the church given the lack of contact tracing.

p) Adding to this underestimation of risk is the impact of overdispersed transmission. In large contact tracing studies, 20% of cases account for the bulk of transmission, particularly in superspreader events. This is magnified by the variants of concern. In the right environment with poor physical distancing, and high aerosol production, superspreader events can occur. The Skagat choir example had a 50-80% attack rate with a single exposure including deaths (8). Cumulatively these cases can also go back and infect community members, thereby worsening an outbreak.

5) How does the public health risk of permitting places of worship to open compare to other indoor establishments or activities like retail, stores, bars, and film/TV protection to open?

a) Prior to assessing risk, the major component of what can remain open relates to the ability to care for patients in acute care. When hospitals are overwhelmed with COVID-19, the ability to care for patients, both with COVID-19 and with other medical issues becomes compromised.

b) For example, at the peak of the 3rd wave in Ontario there were 891 people in Intensive care units. This required the halting of elective surgery, redeployment of healthcare staff into critical care units, transferring patients throughout the province to balance out hospitals dealing with surges, and the potential invocation of a triage protocol to limit access to intensive care units for those with the best prognosis.

c) During this interval, any pressures on the community leading to further transmission would have been devastating for providing healthcare to the community.

d) More generally, assessing risk in an individual setting requires an examination of the hierarchy of controls, which is a core principle of infection prevention and control (14).

e) Elimination is the most important element, and in the context of high transmission, may include closure of higher risk settings. While screening may offer the ability to eliminate symptomatic cases, presymptomatic cases often present the highest viral loads, and hence, may not be eliminated by a symptom screen.

f) Substitution Controls involve replacing the hazard. Engineering Controls involve isolating people from the hazard, and Administrative Controls involve changing the way people work. These types of control broadly encompass measures to prevent the spread of COVID-19 in environments, such as physical distancing, ventilation, prioritizing outdoor settings, minimizing capacity limits, cleaning and hand hygiene. These are important but less effective than Elimination in preventing the spread of infectious pathogens.

g) Personal protective equipment, such as the use of well fitted masks, may decrease the acquisition of COVID-19, as well as reduce the shedding of the user if they are unknowingly infected. While this has been an important measure, the effectiveness may be less than the measures above. For example, a meta-analysis showed masked use reduced the odds of infection by 85% with mask use, but 90-95% lower with physical distancing (17).

h) The decision to close or keep open across the province varied, but did have commonalities amongst settings with risk. For example, outdoor settings were considered much safer than indoors due to better ventilation. Capacity limits were used to mitigate transmission in retail settings.

i) Indoor settings often had a gradient of risk based on capacity, ventilation, controls, the ability to mask, and the production of aerosols through singing, talking, or heavy breathing.

j) In periods of harder "lockdowns", measures were put in place to limit the spread of COVID-19, using the risk profile above, and evaluating the essentialness of particular environments. It is outside of the scope of this report to determine what is considered essential, recognizing that the provision of food, essential goods, and medical care are very high on the list.

k) Ultimately, safety in settings opened during periods of high case transmission was related to the hierarchy of controls, particularly in the ability to operate safely while physical distancing, masking, having appropriate ventilation, screening, provide case and contact management, and the essential nature of work. These were the factors used by public health units, along with the health systems capacity, and the ability to contact trace cases effectively to determine what restrictions to impose.

l) Ultimately, settings such as restaurants and bars, had to either mitigate risk (such as by the use of patios, curbside pickup, and delivery), implement significant capacity restrictions or face closure during the highest periods of transmission.

m) Some businesses, such as film and TV used personal protective measures and serial testing in order to operate workplaces effectively. I have read the affidavit of Justin Cutler. As a result of COVID-19 health and safety measures in the last four months of 2020, 25 major MPA productions in Ontario administered more than 132, 938 PCR tests, with an overall positivity rate of 0.06%. This positivity rate was significantly less than the test positivity rate of between 0.6 and 9.7% for the general population at that time. Every positive test has been identified through testing without any further spread in the workplace.

n) While Dr. Warren asserts that there is no evidence for lockdown measures prior to COVID-19, a number of studies comparing non-pharmaceutical interventions do show differences between lockdowns, business closures, and low capacity limits for reductions of the community reproductive rate.

o) While Dr. Schabas compares the ability to keep a liquor store open and a church closed, it is important to remember that members of the public face lower risk in a liquor store or other retail setting given the transient nature of the gathering in those locations compared to religious gatherings.

6. Conclusion

a) Thank you for the opportunity to provide this report.

DR. DAVID McKEOWN, affirmed

CROSS-EXAMINATION BY MR. KITTREDGE:

1. Q. Good morning, Dr. McKeown.

A. Good morning.

2. Q. I represent the moving parties on this motion and I will be asking you a series of questions today. I understand you provided some evidence in this matter by way of an affidavit you affirmed on July 5th, 2021; is that correct?

A. Yes.

3. Q. Do you have a copy of your affidavit in front of you?

A. I do.

4. Q. At the time you affirmed your affidavit, you were the associate chief medical officer of health for Ontario; is that correct?

A. Correct.

5. Q. You say in paragraph 1 of your affidavit that you have held that position since early 2020. Can you be a little more precise about your start date?

A. March 30th, 2020.

6. Q. March 30, right. I understand that you have held the post of associate chief medical officer of health in the past, and, unless I specify otherwise, when I refer to your term as associate chief medical officer of health in my questioning, I mean your current term which began in 2020. Were you appointed associate chief medical officer of health permanently or temporarily?

A. I'm not sure what the human resources term would be for it for the government, but it was intended to be temporary.

7. Q. Right. Was it for a specified length of time?

A. Yes, it was, and that time has been extended several times.

8. Q. Right. In your role as associate chief medical officer of health, you were part of the office of the chief medical officer of health; is that correct?

A. Correct.

9. Q. And you reported directly to the chief medical officer of health?

A. Yes.

10. Q. And the chief medical officer of

health reports directly to the deputy minister of health?

A. Yes.

11. Q. Are you the only associate chief medical officer of health?

A. No.

12. Q. How many are there?

A. At the time that I joined in 2020, there were two others.

13. Q. And currently?

A. Currently, there are one, two, three, four, five others.

14. Q. And that increase, is that due to the...is that in response to the COVID-19 pandemic?

A. I believe those positions existed, but were vacant prior to the pandemic.

15. Q. And were you brought in as associate chief medical officer of health primarily in response to the COVID-19 pandemic?

A. Yes.

16. Q. Is it fair to say that since early 2020, your primary focus, and the primary focus of your office, has been on COVID-19 and the threat it may pose to public health?

A. Yes.

17. Q. At paragraph 2 of your affidavit, you say that your responsibilities in your role included monitoring the spread of COVID-19 in Ontario and advising on the Ontario government's policy response to the pandemic. Were these your primary responsibilities?

A. Yes.

18. Q. Apparently...approximately what percentage of your time was spent on COVID-related work?

A. It would be close to 100 percent.

19. Q. I understand that during your term, you were also a member of the Ontario COVID-19 Science Advisory Table?

A. For part of that term, yes.

20. Q. Okay, and you are no longer a member of that Table; is that correct?

A. Correct.

21. Q. And the Science Advisory Table is an independent group of scientific experts and health system leaders tasked with evaluating and reporting on emerging scientific evidence relevant to the COVID-19 pandemic. Is that an accurate description?

A. I think so.

22. Q. The Science Table provides weekly summary reports to Ontario's Health Coordination Table, formerly known as the Health Command Table; is that correct?

A. I don't think the reports were necessarily weekly throughout the full pandemic, but they were...

23. Q. No?

A. ...frequent.

24. Q. All right, thank you. Is the chief medical officer of health a member of the Health Coordination Table?

A. Yes, I believe so.

25. Q. And were you?

A. No.

26. Q. Among other things, the office of the chief medical officer of health set public policy and provincial public health control measures, communicates health guidance to Ontarians, and determines how the province will respond to urgent emergency public health situations?

MR. HUNTER: Can we just break... there's a number of items there,

Counsel. Can we just go one by one?

27. MR. KITTREDGE: Sure, I'm, essentially, reading off the description from the Public Health Ontario website, but I suppose...I can just move right on to my next question, then. I'll pass on that one.

BY MR. KITTREDGE:

28. Q. The office of the chief medical officer of health has the authority to direct local jurisdictions within Ontario to implement public health measures, when necessary, in response to a public health risk or emergency; correct?

A. Yes, that authority exists, but usually local public health officials act without needing to refer to that authority.

29. Q. Okay. In the context of the COVID-19 pandemic, the office of the CMOH...I'll just say "CMOH" rather than chief medical officer of health, because it's getting a little repetitive. In response to the...in the context of the COVID-19 pandemic, the office of the CMOH sets directives and guidelines around screening,

testing, triage, precautions and reporting; correct?

A. Yes.

30. Q. During the pandemic, the office of the CMOH has determined which businesses, services, products, and events are considered to be essential; is that correct?

A. No, the chief medical officer of health would provide advice to government. The government would make those decisions.

31. Q. Right, and has the government typically followed the advice of the chief medical officer of health?

MR. HUNTER: Don't answer that. The question what cabinet has or hasn't done, and what advice was given, is public-interest immunity. /R

BY MR. KITTREDGE:

32. Q. The office of the CMOH determines the definition used by the province for COVID probable cases and COVID confirmed cases; is that correct?

A. I have to confirm that. Certainly advice is provided on that. I'm not

sure what the final decision is.

33. Q. All right, can we get an undertaking to provide an answer to that question?

MR. HUNTER: I just want to clarify your question. You're asking about the definitions used by the province, not necessarily other public health units; correct?

34. MR. KITTREDGE: Yes.

MR. HUNTER: Okay, we'll make an undertaking to make inquiries to determine who sets that definition, if there is a standardized definition. U/T

BY MR. KITTREDGE:

35. Q. All right. In your affidavit, Dr. McKeown, where you use the term "case" without any additional qualifier, are you referring to a "probable case" or a "confirmed case"?

A. It might depend on the context, but, in general, when I use the word "case", I would mean a confirmed case.

36. Q. All right. The province's

definition of “probable case” may capture some instances where a person is not actually infected with COVID-19; is that correct?

A. I believe that’s why it’s called a “probable case”, yes.

37. Q. Right, and is it also true that the province’s definition of “confirmed case” may capture some instances where a person is not actually infected with COVID-19?

A. The “case” definition is intended to not have that happen.

38. Q. Right, but...all right, I understand that a person who has received a positive PCR test result would meet the province’s definition of a “confirmed case”; is that correct?

A. That is correct.

39. Q. A PCR test is typically done by taking a sample from a patient with a nasal swab; is that correct?

A. Well, it depends. Earlier on, the samples were usually taken with a much higher nasopharyngeal swab, but there are some tests, now, that can be done with a nasal swab.

40. Q. All right, but either way, you

are taking a sample of material from inside of the nose of a patient, in layman's term?

A. Correct.

41. Q. All right, and the result of the PCR test will be positive if any fragment of the SARS-CoV-2 virus is found in the sample; is that correct?

A. This is outside my expertise in terms of the details of the laboratory tests and how they work. So I...

42. Q. Okay.

A. ...can't speak to that.

43. Q. All right. SARS-CoV-2 is the virus that causes the disease COVID-19; is that correct?

A. Yes.

44. Q. So I may have to rephrase this based on the last one. A positive PCR test result indicates whether the SARS-CoV-2 virus was found in a sample taken from a patient; is that correct?

A. Yes.

45. Q. But it does not indicate, with certainty, whether that patient is infected with the disease COVID-19; is that correct?

A. I'm not sure I understand the distinction. Can you clarify the question?

46. Q. So the PCR test will return positive if some amount of the SARS-CoV-2 virus is found in a sample taken from a patient; that is correct, right?

A. Yes.

47. Q. All right, but it may or may not be that that patient has an active COVID-19 infection, as in he has the disease that's...he or she has the disease that is referred to as "COVID-19"; is that correct?

A. My understanding is that the presence of the virus does indicate an active infection. Whether or not the person is symptomatic is a different question.

48. Q. Could a positive PCR test indicate that a fragment of inactive or dead SARS-CoV-2 virus was found in a sample taken from an uninfected patient?

A. Again, you would have to consult someone who is more familiar with the technology of the test as to what its sensitivity for detecting different fragments of virus. I'm not a microbiologist, so I can't speak to that.

49. Q. Okay. All right, so you are not aware of whether a positive PCR test result could be a false positive in the sense that it detected inactive SARS-CoV-2 virus in a patient who was not infected with COVID-19?

A. No, I can't speak to that.

50. Q. Okay, would it be reasonable to assume that some of the PCR tests performed in Ontario produced false positive results?

A. I believe all tests can have false positive results.

51. Q. Okay, and that would include the PCR tests performed to detect SARS-CoV-2 virus?

A. Yes.

52. Q. All right. Have there been any known instances, or are you aware of any known instances, of false positive PCR test results in Ontario?

A. I'm not aware of specific false positive tests, but I'm aware that there have been false positive tests.

53. Q. Okay, so you agree that not everybody who tests positive on a PCR test is infectious or has the disease COVID-19?

A. Yes, to the extent that there are

false positives, that would be a true statement.

54. Q. Okay. Do you agree that, therefore, the province's counts of confirmed cases include at least some instances where a PCR test was a false positive?

A. Yes, unless there is an investigation to determine whether or not a positive test is a false positive, then, yes, there would be instances like that.

55. Q. And in the public health context, PCR tests are used for other viruses, as well; is that correct?

A. Yes.

56. Q. I understand that the idea that someone can test positive on a PCR test for a virus, but not become infected, or contract the disease that is associated with that virus, I understand that this occurs with other viruses, as well, as with the SARS-CoV-2 virus?

A. Could you repeat that, please?

57. Q. Sure, I'm a little confused myself. And I understand that the idea that someone can test positive on a PCR test for a virus, but not be infected by the disease associated with that virus, occurs with viruses

other than SARS-CoV-2 and COVID-19?

A. Okay, well, if you find the virus in an individual, whether they are...that implies that there is an infection. The infection is the presence of the virus in the individual's body. Whether or not they have a disease, depends on whether the virus produces any symptoms, and we do know that the COVID-19 can infect people without producing symptoms.

58. Q. Is it possible for a fragment of a virus, or a single virus, if that's the proper term, to be found in the nose of an individual where that fragment of virus, or individual virus, whatever the proper term is, was inactive at the time that it came into contact with the individual?

A. I don't know the answer to that.

59. Q. Okay, so you can't speak to whether it's possible that a positive finding on a PCR test might have happened because an inactive fragment of virus was...sorry, I'll just skip that. I think I have the answer to the question, and I'm having trouble rephrasing it myself.

When you use the term "testing" or

"test" in your affidavit, you are referring to PCR testing; correct?

A. In most cases, yes, because that was the dominant form of testing for most of the pandemic.

60. Q. All right, well, you just answered my next question. Of the people who do become infected with COVID-19, would you agree that the majority experienced mild or no symptoms, and go onto a full recovery?

A. Taken as a whole population, including all ages and all states of health, yes, the majority would recover. But there's a potential minority that experience severe illness.

61. Q. Those who do experience severe illness and severe outcomes, including hospitalization and death, have been primarily among those people over the age of 60; is that correct?

A. There's certainly a higher rate of hospitalization and severe illness amongst those who are older, but it also affects people who have other medical conditions which make them more vulnerable to disease.

62. Q. Right, but, by far, the majority of severe outcomes are in individuals over the age of 60; is that correct?

A. There are more severe outcomes in older people, yes.

63. Q. And higher numbers of severe outcomes in older people?

A. Well, you have...in order to say, you have to look at the number of older people there are. There's a higher rate, a higher likelihood of severe illness in people who are older. How they contribute to the overall numbers of cases in the population depends on the underlying denominator; how many older people are there, how many middle age, how many young people, and so forth.

64. Q. Right. All right, well, fair enough. And I understand that the overwhelming majority of COVID-19 deaths have occurred among persons over 60 years of age?

A. That's true.

65. Q. And the cohorts who are most at risk of severe outcomes or death have been relatively well understood since quite early in the pandemic; is that correct?

A. Yes, it's particularly the age distribution of severity...

66. Q. Right.

A. ...that has been understood since early on.

67. Q. And a higher likelihood of severe outcomes in people who comorbidities, or chronic illnesses, has been understood since early on, as well?

A. Yes, although I think our understanding of that has evolved. But, yes, the fundamentals were understood early on.

68. Q. Sure. Okay, thank you. The office of the chief medical officer of health designed the public health measures that the province has taken during the COVID pandemic; is that correct?

A. The chief medical officer of health made recommendations to the government about public health measures, yes.

69. Q. Right. Generally speaking, has the office of the chief medical officer of health been satisfied with the public health measures that the province has actually taken during the COVID-19 pandemic after receiving advice from the

CMOH; is that correct?

A. I'm not sure I know what you mean by "satisfy".

70. Q. The office of the chief medical officer of health felt that the public health measures taken by the province were effective in combating the COVID-19 pandemic; is that correct?

A. I can't speak for the chief MOH, himself...

71. Q. Oh, sorry, the office there.

A. ...but I would say that the measures taken were effective in reducing transmission of COVID-19.

72. Q. And when giving advice to the province on which public health measures should be taken, the office of the CMOH has provided advice...I'm backing myself into a corner here. I'll pass onto the next question.

The regulations that you reference in paragraphs 4 to 45 of your affidavit, in the second section, it's titled "Ontario's Policy Response to the COVID-19 Pandemic", are, in essence, embodiments of the recommendations of the office of the chief medical officer of health; is that correct?

A. Well, they reflect decisions made by the government following receiving advice from the chief MOH, yes.

73. Q. Right. In section number 3 of your affidavit, titled “The Impact of Ontario’s Public Health Measures”, which begins at paragraph 55, on page 23 of your affidavit, when you say “Public Health Measures” in the title of this section, you mean the regulations, legislation, and frameworks that you described in section 2 of your affidavit?

A. Yes, but it would also include actions that are advised by the chief MOH and the government, to the public, which are not framed in regulation. So there have been times when the government and the chief MOH have advised the public to, for example, wear a mask, where that is not required by regulation. The combination of regulatory interventions and public advice.

74. Q. All right, could you please read paragraph 55 of your affidavit for the record?

A. "...The public health measures implemented by Ontario had a significant impact on decreasing the transmission of COVID-19 across the province and

reducing the strain on the healthcare system. Among other things, the implementation of public health measures during the second and third states of emergency were shortly followed by a substantial decrease in the number of COVID-19 cases and hospitalizations..."

75. Q. On the following page, you provide two graphs showing the number of COVID daily case counts over time, from September 1st, 2020 to June 17th, 2021, as well as the daily hospitalization counts for the same time period; is that correct?

A. Yes.

76. Q. Are you aware of the maxim, "...Correlation does not imply causation..."

A. I'm familiar with it.

77. Q. What do you understand that phrase to mean?

A. That means that things that happen at the same time are not necessarily causally related.

78. Q. The charts you provided and your comments in paragraphs 55 to 57 of your affidavit

show a correlation between the timing of the second and third states of emergency and a drop in case counts and hospitalizations; would you agree?

A. Yes, they do.

79. Q. Does that correlation demonstrate with certainty that the restrictive public health measures in place during the second and third states of emergency caused those drops in case counts and hospitalizations?

A. I think, based on my experience with epidemics of different kinds, tracking this kind of data, I would say it’s very likely that there is a causal relationship.

80. Q. But it doesn’t demonstrate with certainty that there is a causal relationship?

A. No, I don’t think we can say “certainty”, but I think there’s a...

81. Q. Right.

A. ...high degree of likelihood.

82. Q. At paragraph 58 of your affidavit, you quote a statement from the Science Table’s May 20th, 2021 public update, to whit,

"...Control of the pandemic is improving due to current public health

measures..."

Is that correct?

A. Yes.

83. Q. Would you agree that this statement is, essentially, a restatement of your assertion at paragraph 55 that the public health measures implemented by Ontario had a significant impact on decreasing the transmission of COVID-19 across the province and reducing the strain on the healthcare system?

A. Yes, I think the members of the Science Table drew the same conclusion.

84. Q. Right, but it's, essentially, another way of saying the same thing?

A. I think...yes, I think the Science Table was in agreement with the statement that was made in the earlier paragraph, that's right.

85. Q. Did the Science Table read your affidavit before it made this statement that you quote in paragraph 55?

A. No...well, if I'm not mistaken, the statement preceded my comment.

86. Q. Yes. So the Science Table couldn't have been in agreement with a statement

that they had never read; is that correct?

A. Oh, I see what you are saying. I'm saying that they agreed with the content of the statement. I wasn't suggesting that they had reviewed the statement and evaluated it for their agreement.

87. Q. Right, so it is, essentially, another way of making the same statement that you made in paragraph 55?

A. I think it's more accurate to say that I and the Science Table came to the same conclusion looking at the data.

88. Q. And the data that you and the Science Table were looking at was a correlation between the timing of the second and third states of emergency and the decreases in COVID-19 case counts and hospitalizations that are shown on the charts in the following...in the paragraphs following paragraph 55?

A. I think that's part of it. I'm sure that the Science Table, as we did, was aware of similar relationships in other jurisdiction, which had implemented public health measures, was aware of the most current knowledge that we have about how COVID-19 is transmitted, and what

measures would be likely to interrupt that transmission, based on that understanding. So I can't speak for the Science Table, but I'm assuming that they would have been aware of all of that information when they made their statement.

89. Q. So is it fair to say that the section of the affidavit that we are reading right now, which is titled "The Impact of Ontario's Public Health Measures", is a statement of the...a summary of the evidence that is available to support your claim that the public health measures had a significant impact on decreasing the transmission of COVID-19 and lowering case counts and hospitalizations?

A. As I mentioned, there were other bits of evidence I think that underpin that conclusion rather than just the epidemiologic trends in Ontario, but yes.

90. Q. Are you aware that the motion you are speaking to today involves a challenge to the constitutionality of the public health measures taken by the province?

A. I'm not a lawyer, so I'm not sure that I understand that in the way that you would.

91. Q. Right, but have...but you are aware that this is a challenge of some kind to the public health measures taken by the province?

A. Yes.

92. Q. And that one of the consequences, if our challenge is successful, may be that certain of the public health measures taken would be struck down or deemed invalid?

A. Yes, I'm not familiar with the remedies that are available to the court, but I do understand that this is about the public health measures.

93. Q. So without asking you to draw any conclusions about what remedies are available to the court, you at least understand that it's important for the government to prevail in this matter?

MR. HUNTER: Mr. Kittredge, what's the relevance of the impact of a legal challenge on the evidence the witness has given?

94. MR. KITTREDGE: Well, I'm just trying to understand...

MR. HUNTER: I'm sure your clients also feel strongly that their

evidence...they would like to prevail on their case.

95. MR. KITTREDGE: It's true, it's true, but...

BY MR. KITTREDGE:

96. ...well, I could just move on to where I'm going with it, basically, which is that, did you put...in your affidavit, and particularly in this section of your affidavit, did you put forward the best evidence available to support your claim that the public health measures implemented by Ontario had a significant impact on decreasing the transmission of COVID-19 across the province?

A. The evidence that is in the affidavit, I think, does support that conclusion. There could have been a much more extensive body of evidence included...

97. Q. Right, so let's...

A. ...but this is the most appropriate and relevant to Ontario.

98. Q. Right, so reviewing what is contained in this section of the affidavit, you make, at paragraph 55, a statement to the effect

that the public health measures were effective, and that...in support of that statement, you offer that,

> "...among other things, the implementation of public health measures during the second and third states of emergency were shortly followed by a substantial decrease in the number of COVID-19 cases and hospitalizations..."

A. Yes, that's correct.

99. Q. You didn't specify what these "other things" were.

A. No, they are not specified in this part of the affidavit, that's correct.

100. Q. And at paragraph 56, you describe the chart that is attached at that paragraph, and provide further support for your claim that the public health measures were effective. That support constitutes nothing more than a statement to the effect that the case counts dropped after the states of emergency were implemented; is that correct?

A. Yes, that's what the graphs show.

101. Q. Right, so at paragraph 55, you offer that statement, in other words. At

paragraph 56, you offer pretty much the identical statement in a description of the graph below; is that correct?

A. No, I don't think it's an identical statement. The fact that there was a relationship between the trends, the epidemiologic trends, and the implementation of public health measures does support the statement in paragraph 55. It's not a restatement of it...

102. Q. I'm sorry...

A. ...it's evidence in support of, I would say.

103. Q. Sorry, can you repeat that? I missed what the additional evidence was.

A. I think you were asking me if paragraphs 55 and 56, basically, said the same thing, and I was pointing out that paragraph 56 summarizes the evidence of the statement in 55, or, at least, some of the evidence.

104. Q. And that "evidence" being the drops...the leveling off and drop in case counts that are shown in the chart below that paragraph; is that correct?

A. Yes, I'm pointing to that as evidence that supports the statement about the

effectiveness of public health measures, along with other things.

105. Q. Pardon me, I didn’t catch the last bit of that.

A. I just said...

106. Q. “Along with other”...

A. ...along with other evidence, but what is in the affidavit...

107. Q. But you’re not referring to the other evidence in paragraph 56; are you?

A. No, it’s not listed in paragraph 56, that’s correct.

108. Q. All right. And in paragraph 57, you describe the chart that appears below paragraph 57, a chart showing numbers of daily new hospitalizations for the same time period as the chart above?

A. Correct.

109. Q. And you note that it follows a similar trend as in the hospitalization counts drop at around the same time that the state of emergencies were implemented; is that correct?

A. Yes.

110. Q. And you don’t provide any further evidence in support of the effectiveness of the

public health measures in this paragraph; do you?

A. No, that's correct.

111. Q. And in paragraph 58, you describe the statement of the COVID-19 Science Table taken from its May 20th, 2021 update, and that statement, once again, was,

"...Control of the pandemic is improving due to current public health measures..."

Is that correct?

A. Yes.

112. Q. And you follow that up by pointing out that the Science Table noted that,

"...The percentage of individuals testing positive for COVID-19 decreased following the implementation of the province-wide lockdown and provincial emergency brake..."

In other words, the measures taken around the time of the state of emergency; is that correct?

A. Yes.

113. Q. And you could describe the chart that you have attached at paragraph 56 above as showing that the percentage of individuals testing positive for COVID-19 decreased around

the time of the two states of emergency; is that correct?

A. I'm sorry, could you repeat that?

114. Q. The Science Table's description of the evidence supporting its...sorry, your description of the Science Table's evidence, in support of the Science Table's statement to the effect that the public health measures caused the improvement in control of the pandemic...the evidence that you...that they offered was that the percentage of individuals testing positive for COVID-19 decreased following the implementation of the lockdowns and the emergency brake, in other words, the two states of emergency?

A. Yes, that's what the Science Table said, or noted, at that time.

115. Q. And you could just as easily have used that exact same phrasing to describe your chart at paragraph 56; is that true?

A. Well, they're two different types of data. They happen to support the same conclusion, but one of them is a track of daily case counts, that's reported cases. The percentage positivity is a different measure. We

use both to track...

116. Q. Oh, right.

A. ...the progress of the outbreak.

117. Q. So the percentage of individuals testing positive for COVID-19 might decrease if more tests were administered; is that the case?

A. Yes, it might.

118. Q. Does the fact that the percentage of individuals testing positive for COVID-19 decrease following the states of emergency, does that prove, with certainty, that the states of emergency caused that decrease?

A. No, once again, it’s a supportive piece of data, which supports the same conclusion, but, like all the other data, in and of itself, isn’t sufficient. You’re looking a number of different measures that allow you to draw a conclusion about what is happening.

119. Q. Right, and so far, the...

A. So what...the measures that we have typically looked at throughout the pandemic include case incidence reports, percent positivity of testing, hospitalization rates, the R-effective measure of transmissibility, all of these things are looked at together to help build

an accurate picture of what is happening in the pandemic.

120. Q. But you don't mention any of these things in this section of your affidavit; do you?

A. Not specifically. I mean, we'll see the Science Table statement is preceded by the words "Among other things". So it acknowledges that there are other factors that the Science Table is looking at in reaching its conclusion. But you are right, they are not enumerated in this affidavit.

121. Q. So, in short, there is nothing in paragraph 58 that proves a causal link between the public health measures and a decrease in COVID case counts, or hospitalizations, or percentage of people testing positive?

A. In my view, those facts all support the conclusion that the introduction of public health measures did cause a reduction in transmission of COVID-19, and the Science Table came to the same conclusion looking at the same information.

122. Q. Right, but it seems that what has been outlined in this section of your affidavit

is simply a correlation and not a causal relationship. Is that correct?

A. The conclusion that I draw from looking at this information based on my experience and expertise is that there is, in fact, a causal correlation...sorry, a causal relationship.

123. Q. And you put forward your best evidence for that in your affidavit; is that correct?

A. I put forward some of the evidence for it, yes.

124. Q. And what we have here is evidence of a correlation; is that correct?

A. There is a correlation, but some correlations reflect a causal relationship, and I would conclude that that's what is happening here.

125. Q. All right, and you would conclude that based on the correlation between the drop in case counts and the drop in hospitalizations, and the drop in percentage of individuals testing positive, the correlation between those measures and the timing of the two states of emergency?

A. Yes, I think the states of

emergency reflect the implementation of public health measures. So, yes, those things all factor into the conclusion that I draw, along with...and this is...remember, this is all Ontario data. There are a number of other jurisdictions around the world in which similar relationships have been seen as public health measures have been introduced and withdrawn, and it also entirely consistent with what we understand about the way in which COVID-19 is transmitted.

126. Q. All right. In paragraph 59, you acknowledge that there are many factors that contribute to the transmission of COVID-19; is that correct?

A. Yes.

127. Q. And rather than saying that the data, meaning the key public health indicators that you just mentioned, the drops in case counts, the drops in hospitalization, and the drops in percentage of individuals testing positive, you say that those suggest that the public health measures decrease the spread of COVID-19 in this paragraph; don't you?

A. Yes, that's the language that is

used here...that I've used.

128. Q. You didn't use the word "show" or the word "prove", or even that you "conclude" that Ontario's public health measures decreased the spread of COVID-19; is that correct?

A. Yes, I think...I think I could have just as easily used some of those words. I wouldn't have used the word "prove", but I could easily have used the word "I conclude" or "in my opinion, this is"...

129. Q. Do you think the word "suggests" has, essentially, the same meaning as "leads to the conclusion"?

A. I'm just saying that the choice of that word doesn't reflect on the strength of my view on this matter.

130. Q. But, nonetheless, you chose that word?

A. M'hmm.

131. Q. Isn't it possible that these decreases in case counts, hospitalizations, and percentage of individuals testing positive, could have been caused by factors other than the province's restrictive public health measures?

A. Well, as I say in that paragraph

of the affidavit that said, “there are many factors that contribute”...so, yes, there...undoubtedly, there are some other factors which have a bearing on the trends in transmission rates of COVID-19 in the population.

However, I think the evidence can fairly be interpreted as saying that the public health measures were responsible...one of the main factors responsible for these changes. As I said, I haven’t claimed that they are the only factors.

132. Q. Is it conceivable that the correlation is a coincidence?

A. In my opinion, I don’t believe that’s a reasonable conclusion to draw, no.

133. Q. So you believe that the correlation between the drops and the key public health measures is valid evidence to support the conclusion that the public health measures caused those drops?

A. Yes, taken together with other pieces of evidence that we’ve spoken about in the past few minutes.

134. Q. Could vaccination have contributed to these drops in case counts and

hospitalizations in Ontario?

A. Well, the timing of significant numbers of Ontarians becoming vaccinated came quite late in terms of these graphs, so I think the trends that are represented here can't reasonably be explained by vaccination.

If you were to follow the same indicators forward in time to the present day, then, yes, we currently have high levels of vaccination which are making a difference in the occurrence of COVID-19, but over the period covered by these graphs, that's not a factor.

135. Q. Would you agree that May 20th, 2021 falls within the time period covered by these graphs?

A. It's towards the very end, as I read it.

136. Q. Right...

A. It's after...

137. Q. ...can I take you to Exhibit Y of your affidavit? And we'll be coming back to these charts in a moment, so don't lose that spot, either. Exhibit Y is the May 20th, 2021 update on COVID-19 projections from Science Advisory Table.

A. Yes, hang on, I think I might have it. Sorry, you said the May 20th, 2021 update?

138. Q. Yes, it's at page...I have it marked as page 177...

A. Okay, well, my figure doesn't have any page numbers, unfortunately.

139. Q. ...if that helps. Okay, I'm...

A. I think I've got the one you mean.

140. Q. Okay, so this is...so the first page of it, after the Exhibit Y marking, is titled "Update on COVID-19 projections, dated May 20th, 2021"; is that correct?

A. That's what I've got.

141. Q. All right, so if we go one, two, three, four, five, six, seven, eight, nine, ten pages to a page marked page 11 in this exhibit, it's titled "Vaccination coverage continues to increase".

A. Got it.

142. Q. What does this tell you about the percentage of the populations who has received at least one dose of the COVID-19 vaccine?

A. It's not very well marked, this

particular page. I'm not sure. The only percentages I see are the ones at the top, as listed as "Provincial Progress", but it's not labeled in terms of what those numbers represent.

143. Q. As of May 20th, 2021, what is your understanding of the vaccination status in the province? What percentage of individuals in the province had received at least one dose of the vaccine?

A. I'm sorry, I don't have that in front of me, although this graph may show that. But, as I say, it's not labeled properly. What I recall, without reference to documents, is that vaccination was starting to ramp up at that point, and significant numbers were starting to occur towards the end of that third wave.

144. Q. And so if we look back at this page 11, once again, titled "Vaccination coverage continues to increase"...

A. Right.

145. Q. ...we have several charts divided up by age, at the bottom of the...or in the lower ...in the centre of the page. Is that correct?

A. I'm looking at the same page as you are, yes.

146. Q. Right, and the blue portion of the bars that appear on that chart on the left-hand side...

A. Right.

147. Q. ...represent the number of individuals with at least one dose completed?

A. Yes, the dark blue?

148. Q. Yes.

A. Yes.

149. Q. And then there is a much smaller number of individuals, marked in a lighter blue, who have made an appointment for a vaccination?

A. Right.

150. Q. And at the top of the bar, there’s yellow marking that represents the remaining population has not yet received a vaccine; is that correct?

A. That’s what it looks like.

151. Q. All right, and if you were to assume that that was true, would this reflect your understanding of the vaccination status of Ontarians aged 40 and up, at this time?

A. That’s what it looks like, yes.

152. Q. Right. So you were the associate chief medical officer of health, at this time,

dealing with COVID matters, primarily, and you have no...you don't have a sufficient recollection of the vaccination status of Ontarians, especially older Ontarians, at the end of this wave, a very significant moment in the pandemic? You don't have the recollection to go any further than to say "That's what this chart looks like"?

A. I'm trying to be accurate in my responses to your questions. What I recall is that the vaccination program, as I said, was ramping up and we were starting to get significant numbers of people vaccinated towards the end of that wave.

Where we started this question was about how the trend changed at the time public health measures were implemented. For most of that decline, I believe public health measures were responsible, rather than vaccination, for the decline that was happening.

The decline certainly happened before there was significant number of people vaccinated. Towards the end of that curve as it was coming down, undoubtedly vaccination was playing a role, particularly amongst the elderly

because they were given priority in terms of access to vaccines.

153. Q. Right, and we agreed earlier on that the vast majority of hospitalizations were among elderly people?

A. Yes, the hospitalization rates were much higher among elderly people.

154. Q. Right, and from looking at this chart, it appears that the vast majority of people, let’s say, older than 70 years old, had received at least one vaccination shot; is that correct?

A. Yes, I think that’s what this data looks like, yes.

155. Q. Right, and quite a large majority of individuals, aged 60 to 69, had also received one dose of the vaccine; is that correct...or does that look accurate to you?

A. Yes. Yes, it looks...again, these are not percentages, but it does look like it, yes.

156. Q. Sure. And perhaps about two-thirds to three-quarters of individuals, 50 to 59, had received one dose of the vaccine; does that look like a fair description to you?

A. Yes, I would say it does.

157. Q. And about half of the individuals, 40 to 49, had received at least once dose of the vaccine?

A. It does look that way.

158. Q. So the age groups we have covered here would include certainly the people most at risk of severe...or with the exception of younger people with comorbidities or chronic health conditions, what we see in this chart represents most of the people who are at risk of severe outcomes and hospitalization; is that true?

A. Yes, deliberately so, because they were given priority in vaccination.

159. Q. Right.

A. Also, I think I should point out that interpretation of this data...the blue, the dark blue, is one dose, which doesn't...

160. Q. Yes.

A. ...give us much protection. So these are people who are not considered fully immunized.

161. Q. True, but one dose of the vaccine does give...

A. Does give some protection.

162. Q. ...some protection?

A. Yes, yes.

163. Q. All right, and it would be expected that when a population that is most likely to become hospitalized receives a vaccination, hospitalizations will drop; would you agree with that?

A. Yes, and that fact is what has happened if you were to project the data forward, beyond this point.

164. Q. Right. So would you say that vaccination may have had an impact on the decrease in hospitalization rates as shown in the charts at your...on your page 24?

A. I would say, as I said before, just towards the end when...after the rates of both hospitalization and case numbers had already come down, I'm sure that the vaccination that was ramping up, at that point, to significant levels, did have some impact on pushing that curve lower.

165. Q. When did Ontario begin vaccinating people over 80 years old?

A. I don't have that date.

166. Q. Approximate.

A. I don't have that date in my

head, I'm afraid.

167. Q. Do you have an approximate date in your head?

A. I wouldn't want to...it's an easy enough number to find, but I wouldn't want to get it wrong. I don't have it in my head, though.

168. Q. Do you know what month the province started vaccinating 80-year-old people and older?

A. Yes, I'm afraid I don't have that in my head. Just to explain, I was not involved with the vaccination program very closely, so...

169. Q. Right.

A. But we could easily find out.

170. Q. Sure. Okay, well, I think we can move back up to your page 24, again.

A. M'hmm.

171. Q. You mentioned earlier that in your monitoring of the COVID-19 pandemic situation, you kept an eye on jurisdictions around the world, and that you had noticed that some of the...you had noticed that some jurisdictions saw drops in hospitalizations and drops in case counts at around the same time that the drops...or that the two...the second and

third states of emergency were imposed and in effect in Ontario; is that correct?

A. I don't think so. Could you repeat the question?

172. Q. You said that...well, correct me if I'm understanding you incorrectly, but I thought you said that one of the pieces of evidence that you had relied on in support of your conclusion, or the suggestion, that public health measures in Ontario had been effective in dropping case counts and hospitalizations, was seeing similar drops in other jurisdictions at around the same time; is that correct?

A. Okay, no, let me correct you. It wasn't that they were happening at the same time. It was that other jurisdictions saw reductions in hospitalization and case counts at the time that they implemented their public health measures.

So, in other words, we were seeing, in other jurisdictions, a similar relationship between the implementation of public health measures and the epidemiologic trends as were seen in Ontario; not that jurisdictions were experiencing at the same time as each other.

173. Q. Are you aware of any other

jurisdictions that experienced peaks and drops at around the same time that the Province of Ontario implemented its second and third states of emergency?

A. Again, I think the way you've stated it doesn't reflect what I said. It wasn't those...

174. Q. No, I'm just...I'm asking if you are aware of any, not...

A. It's not something we would have looked at. What we were looking for was the relationship between the implementation of measures and the outcomes, in terms of trends in the pandemic, not whether other jurisdictions were experiencing things at the same time as we were. I'm sure there were some, but that wasn't, primarily, what we were looking at.

175. Q. Did you follow the progress of the COVID-19 pandemic in Florida?

A. Yes, over the course of the pandemic, we looked at many other jurisdictions, many times. So Florida was, certainly, something that we looked at at different times.

176. Q. And what was remarkable or of note about...or, sorry, I'll rephrase that.

Florida was well known to have not imposed lockdowns, or public health measures, anywhere near as stringent as those imposed in Ontario; is that correct?

A. From memory, I believe that's correct.

177. Q. Were you following the progress of the COVID-19 pandemic in Sweden?

A. I think we did look at it at one point. I wouldn't be able to tell you much about it at this stage, but I think it was one of the jurisdictions we may have looked at.

178. Q. And Sweden was another jurisdiction that was well known for not having imposed public health measures anywhere near as strict as those imposed in Ontario, as well; is that correct?

A. I don't recall that. I can't comment on it.

179. Q. You don't recall hearing anything about Sweden taking a more laissez-faire approach to the COVID-19 pandemic than other jurisdictions?

A. No, I don't recall that.

180. Q. You don't recall hearing anything

about Sweden's approach to the COVID-19 pandemic?

A. I remember Sweden was one of many jurisdictions we looked at. I don't remember the specifics of what we saw in Sweden.

181. Q. So you have no recollection...

MR. HUNTER: Counsel, you have asked the question three times.

182. MR. KITTREDGE: Okay, sure, fair enough. All right, I would like to show you a couple of images or webpages. And I'll apologize at the outset of this because we may be heading for a minute or two of me figuring out exactly how to do this, but...so I have a second Zoom connection here that is called "Rob Kittredge Chat" and something else. So let me just open up this document. I hope I don't share something mortifying instead of the document I'm hoping to share.

All right, and what I suppose I will do here, Counsel, is I will share a screen capture that I have taken of the webpage that I would like to show your client, or your witness, and in the

event that you would prefer, I could share a live view of the webpage, itself. So, I suppose, just because of the nature of the proceedings, I'll take whichever approach you prefer, or both. So I'll leave it up to you. But why don't we start with the image and then if you have any preferences, just make them known and I'll behave accordingly.

MR. HUNTER: That's fine.

BY MR. KITTREDGE:

183. Q. So, Dr. McKeown...it strikes me that there's a risk of sharing some privileged documents at this point, so I'll be careful, and I'll apologize for the time it's going to take here, but I believe I'm not doing something terrible. All right, Dr. McKeown, can you see the document that I've just shared?

A. Yes, I'm seeing something.

184. Q. Sure. Does that document look familiar to you at all? It's a screen capture from a website.

A. I don't recognize it, but that doesn't mean I haven't seen it at some point.

185. Q. Right. Do you recognize the logo in the top-left corner?

A. Yes, WHO.

186. Q. Right. Do you recognize this as a screen capture from the WHO website?

A. I wouldn't be able to...apart from the logo, I wouldn't be able to comment on that...

187. Q. Would it be of any assistance if I shared a live view of the page where I captured this image? Or, alternately, would it be of any assistance if I sent you a link to the page where I captured this image?

A. "Of assistance" in what way? Are you asking me to...

188. Q. In recognizing this...

A. ...validate the source of the page?

189. Q. ...yes, and recognizing this document.

A. I don't think it would make a difference to my recognition. I mean, if you tell me that this came from the WHO website, I have no reason to doubt you.

190. Q. Right. Well, are you willing to

accept that this is a screen capture from the WHO website?

A. Sure. As I say, I have no reason to think it's not.

191. Q. All right.

A. If that's where you say you got it.

192. Q. Sure. All right, would you agree that this chart shows confirmed cases, over the course of time, from the beginning of the COVID pandemic to somewhere around the present day?

A. It does look that way. It looks like it's a bar graph for weekly case counts is the way I'm interpreting it.

193. Q. Right. Do you notice two peaks in this weekly bar graph of weekly case counts?

A. Yes. Well, two large peaks, anyway. There are other peaks, as well, but two large ones.

194. Q. Right, two prominent peaks...

A. Yes.

195. Q. ...the two most prominent peaks. And when would you estimate that those two most prominent peaks occurred?

A. Well, looking...

196. Q. I'm sorry, I'll rephrase that. When would you estimate that the first of the two most prominent peaks occurred?

A. I would only be able to estimate based on the x-axis, which is a time axis.

197. Q. Right.

A. It looks like late December.

198. Q. Right, and would you agree that the peaks that are shown on your charts, on page 24 of your affidavit, the first of the two prominent peaks on your charts also occurred around late December?

A. If you are referring to the third wave, yes, that's approximately right. I'm assuming this is 2021, but...

199. Q. The second state of emergency is the date that I'm looking at, the peak that I'm looking at.

A. Yes.

200. Q. So you would agree that that peak, the second state of emergency peak, in your chart corresponds, roughly, to the same time period as the first peak on this chart of weekly case counts in Sweden?

A. Yes, it looks roughly.

201. Q. And turning to the second peak, when would you estimate that took place? I'm sorry, the second peak in the Sweden chart.

A. In the Sweden...yes, well, again, you have to eyeball it, so it may not be accurate, but sometime early May/late April.

202. Q. Right. I mean, don't you see...do you see the date "April 1st" directly below two prominent...two of the highest weekly case counts?

A. I'm sorry, I misspoke. Yes, so early April.

203. Q. Right.

A. Yes.

204. Q. And would you agree that that corresponds, approximately, to the time of the third state of emergency...that the third state of emergency was imposed in Ontario?

A. Roughly, yes. Very roughly.

205. Q. And this peak corresponds to the peak...this peak, timewise, corresponds to the timing of the peak in the charts that...of the second peak in the charts that you provided at your page 24; is that correct?

A. Yes, very roughly, yes.

206. Q. Right, and after these two peaks on the Sweden chart, the cases dropped off and became lower?

A. That's correct.

207. Q. I mean, there's a substantial similarity in the shape of these two peaks and the timing of these two peaks and the two peaks and the timing of the two peaks in the charts that you provide at page 24; do you agree?

A. Yes, the timing of the highest level, yes.

208. MR. KITTREDGE: Sure. All right, well, I would like to mark this as Exhibit A to this cross-examination.

MR. HUNTER: I'm fine with marking it as an exhibit. Of course, we're not admitting the truth of any of the contents of it.

209. MR. KITTREDGE: Absolutely, okay. Thank you.

--- EXHIBIT A: Chart of Swedish weekly COVID cases

BY MR. KITTREDGE:

210. Q. And I would like to show you one other document, and I will probably...a strong possibility I'm going to accidentally close this window. I apologize for the delay here. Okay, all right, do you see the second document that I'm showing you now on my shared screen?

A. Yes.

211. Q. And do you recognize this? It's another captured webpage from the internet.

A. From the CDC website, I assume?

212. Q. Yes. Are you willing to accept that this is a capture from the CDC website, subject, of course, to not admitting the truth of its contents?

A. Yes, it appears to be that way from what I can see.

213. Q. All right, and can you describe the chart that you see in the centre of this or towards the bottom part of this image, right here?

A. Yes, it's labeled as "Daily Trends in Cases and Cumulative Incidence Rates in Florida as reported to CDC, per 100,000". It's a graph of cases over time with a number of peaks.

214. Q. And do you note that...and this

is a chart for the state of Florida, a chart of cases and cumulative incidence rates of cases in Florida?

A. Yes.

215. Q. Do you note that there's a peak around late December of 2020?

A. Yes, I can see that.

216. Q. And it's quite a prominent peak?

A. Yes.

217. Q. And would you say that the timing of that peak corresponds, roughly, to the timing of the imposition of the second state of emergency in Ontario, in late December?

A. Yes, very roughly, yes.

218. Q. Right, and after that peak, on the Florida chart, the cases drop off?

A. Yes.

219. Q. And do you notice another smaller peak around April of 2021 on this Florida chart?

A. Yes.

220. Q. And does that peak correspond, roughly, to the timing of the imposition of the third state of emergency in Ontario?

A. Again, very roughly.

221. Q. And after that peak, the case

counts drop off, as well; don't they?

A. Yes. Although interestingly, they...the thing that really strikes me about these curves is the high, high rates of case incidence that they have with...and the peak you've just been talking about, 15,000 cases a day, and even...

222. Q. Right.

A. ...at the low point, you're seeing, you know, not many fewer cases than Ontario saw at its highest.

223. Q. Right, so when you take that into consideration this peak in April, on the Florida chart, is actually...reflects a larger number of case counts than Ontario's peak at the same time; is that correct?

A. It appears that way, yes. You would have to...in terms of absolute numbers, that's true, you would have to do a bit of a rate. I can't recall the population of Florida, but, yes, it certainly represents a high rate of transmission.

224. Q. So there's a striking similarity both in shape and size to this peak and the rise in case counts leading up to it, and the falling

case counts after it, and the chart that we see at page 24 of your affidavit...both charts that we see at page 24 of your affidavit; is that correct?

A. Well, I think you can see peaks at roughly the same time. I'm not sure what conclusion one can draw from that. You know, you would have to have a lot more information about what's going on in Sweden and Florida and Ontario.

225. Q. So these happen at roughly the same time as the imposition of the states of emergency in Ontario, both of these peaks, the second and third states of emergency in Ontario?

A. Roughly, as we've said, yes.

226. Q. So there's a correlation between these peaks, and the peaks in Sweden, and the period of time during which the state of emergency was declared in Ontario; would you agree?

A. Well, I would go so far as to say that the peaks were happening at the same time.

227. Q. Sure, but you wouldn't say that that's a correlation?

A. No...yes...I'm not sure. Since

they're different jurisdictions, which don't have any...there's no reason to believe that they would be linked in terms of the timing of the pandemic, so I'm not sure that "correlation" is the right word.

228. Q. In Ontario, the correlation that you noted between the imposition of the public health measures and the drops in case counts was rooted in the fact that they occurred at around the same time, essentially; was it not?

A. Well, the alignment in time is a significant observation when the measures are being applied to the same...to the population with the intent of actually causing that reaction.

So, you know, you're looking for that trend to go in the way in which it did. You know, if we hadn't implemented public health measures, then you wouldn't have expected to see any impact of public health measures because they weren't implemented.

So I think the relationship between the two things is significant when it's in the same population, and when you are intending to have that outcome. I'm not sure how to think about

the relationship between trends and a different population in another continent.

229. Q. So am I to understand that you find a correlation because you are looking for it?

A. No, I don't think that's the reason you find a correlation. I think you are looking for an impact of measures which are taken intending to produce a particular outcome, and in that context, the finding of that impact is significant.

230. Q. So the evidence to support your conclusion that the Ontario public health measures were effective was essentially that those health measures happened at the same time as a drop of cases in Ontario; is that correct?

A. Well, the drop in cases is what would have been expected if the public health measures were effective, and that was, in fact, what we saw.

231. Q. Right, so...

A. I think it's entirely reasonable to conclude a causal relationship in that context.

232. Q. So if the public health measures

taken in Ontario were effective at causing a drop in case rates in Florida, then why would you not come to the same conclusion about the...why would you not see a correlation there, when you see one in Ontario?

A. It's not on the face of it a reasonable conclusion that Ontario's public policy would have an impact on rates in Florida. You know, I think...I think if you look around the world, there are many, many jurisdictions. I'm sure it's possible to find a number of jurisdictions in which there is a similar timing of the trends in the COVID pandemic.

There probably are lots of jurisdictions in which there are very different trends because of factors in those jurisdictions, and differences in the timing of implementation of public health measures, and other factors. You can...as I say, here, you picked and presented a couple of jurisdictions in which the timing aligns.

I don't think that means that there is a relationship between Ontario's public policy and what is happening in other jurisdictions. It's not a reasonable conclusion to draw. I think

it's a very reasonable conclusion to draw that public health measures in Ontario, which were implemented in order to produce the impact that we see, had, in fact...we had, in fact, observed the impact that we would expect if the measures were effective.

233. Q. To a certain extent, that presupposes that the measures were effective, though; doesn't it?

A. Well, the measures were implemented because we anticipated that they likely would be effective, partly because of what we've seen in some other jurisdictions, which had implemented them earlier, and partly because of our understanding of how the virus is transmitted. If you take measures which reduce contact between individuals, you would expect to see less transmission and that is, in fact, what we saw.

234. Q. All right, so here, despite the fact that these peaks and drops in Florida occurred at more or less the same time as the imposition of the states of emergency in Ontario, you view this as a coincidence?

A. I don't view them as a causal

relationship, certainly. It's not reasonable to think actions in Ontario could cause changes in Florida in this way. So, no, I don't know whether I'd call it a "coincidence", but... because there may be some overarching, global factors in transmission that affect all jurisdictions similarly. So...but, beyond that, no, I don't think these trends reflect an impact of Ontario's measures in Florida.

235. Q. All right, similarly, do you view the similarity in timing between the peaks and the following drops in cases in Sweden...sorry, I'm going to rephrase that. Do you view the fact that there were two similar peaks and two following drops in the chart that I showed you relating to Sweden, the fact that those peaks correspond, roughly, with the timing of these peaks, and they correspond, roughly, with the timing of the peaks and the imposition of the states of emergency in Ontario, do you view that as a coincidence?

A. You would have to look at what was going on in Sweden at the time, what was happening with vaccination, with public health measures. And it is possible that Sweden

implemented similar measures at the same time. I can't recall from our information gathering, but I think those are the more relevant factors. The fact that there were some peaks at similar times between jurisdictions in different parts of the world, I don't think is something that we can really understand in the way that you are suggesting.

236. Q. So in the case of Ontario, you view it as evidence of a causal relationship that these...that the Ontario peaks happened at the same time as the states of emergency, but the same...

A. Yes, I do. I do, because that's a reasonable conclusion to draw given that you are dealing with the application of the measures to the population, which had the trends that you would expect if the measures were effective. I think, you know, there are...I'm sure you could find a number of events around the world, events that had nothing to do with COVID, which happened to coincide in timing with the trends in COVID in Ontario. I don't think it's reasonable to conclude that there's a causal...or even any kind of a relationship between them.

237. Q. Do you agree that you could find a number of events relating to COVID case counts in Ontario that correspond with public health measures taken in Ontario, and yet were a mere coincidence?

A. Yes, I think, as we discussed before, it's always possible that events happen for a coincidence. If you...if someone...if I'm a doctor and someone comes to me with an illness, I give them medication, which I have reason to believe will cure their symptoms, and the symptoms go away, I don't immediately think it was a coincidence. Because in that particular context, it's entirely reasonable to believe that the medication that was intended to have the desired effect, in fact, had the desired effect. That doesn't rule out the possibility that the person could have gotten better on their own without any impact from the medication. But that wouldn't be the most likely explanation.

238. Q. But in that circumstance, your mind is open to the possibility that the recovery was a coincidence?

A. Well, I think we have to be open to the possibility in all circumstances. I'm

just saying that being open to that possibility, I come to the same conclusion, that the public health measures were likely responsible for the improvements in COVID transmission and hospitalization that we saw.

239. MR. KITTREDGE: All right, well, thank you. I'm going to close this...oh, I would like to mark this image as Exhibit B to my cross-examination.

MR. HUNTER: That's fine, same...

240. MR. KITTREDGE: Right, agreed.

--- EXHIBIT B: Daily Trends in Number of Cases and Cumulative Incidence Rate of COVID-19 Cases in Florida reported to CDC, per 100,000 population

241. MR. KITTREDGE: And I'll close this window.

BY MR. KITTREDGE:

242. Q. And if I can take you back up to, yet again, the charts at page 24 of your

affidavit. And are you at page 24 of your affidavit, Dr. McKeown?

A. I am.

243. Q. Would you agree that the charts shown on page 24 of your affidavit show a downward trend in case counts and hospitalizations only during the second and third states of emergency?

A. Yes, in terms of what is on the graph, yes, that's true.

244. Q. But both charts show an upward trend during the period between September 2020 and the imposition of the second state of emergency, and another upward trend during the period between the second and third provincial states of emergency; is that correct?

A. Yes.

245. Q. So while they may show a correlation between the public health measures in place during the second and third states of emergency and falling case and hospitalization counts, these charts also show a correlation between rising case counts and the public health measures in place at other times; would you agree?

A. No. I think the rising case counts occurred in a context in which public health measures were largely being withdrawn, or adjusted to be minimal.

246. Q. So you described a number of public health measures, some of which were in place during these periods of upward trend shown on these charts; wouldn't you agree with that?

A. Yes, there were public health measures in place, but as the affidavit points out, the intensity of those measures, and the strictness of them, varied quite a bit over the course of the pandemic.

The states of emergency coincided with times when the public health measures were made more strict for a period of time, and the other times there were some public health measures in place, but they were generally...the government was, generally, reducing them over time.

247. Q. But there were public health measures in place at all times shown on this chart, nonetheless; am I correct?

A. Yes, but...yes, with different levels of restrictiveness and different levels of intensity.

248. Q. But they were public health measures?

A. Yes, I'm just trying to point out that although you...saying that they are public health measures means very different things at different times in the pandemic, depending on what the policy was at the time.

249. Q. Right. At paragraph 55 of your affidavit, at the start of this "Impact of Ontario's Public Health Measures" section, you say that,

"...The public health measures implemented by Ontario had a significant impact on decreasing the transmission of COVID-19 across the province..."

Is that correct?

A. Yes, that's what it says.

250. Q. Do you mean only the public health measures that were in place while case counts were falling?

A. No, I think...I think even when fewer public health measures were in place, they were likely having some effect. The most effective public health measures were the ones that were the most restrictive, and which were

implemented during the states of emergency, and I think that reflects the graphs that you're talking about.

251. Q. Do you think the evidence that you have provided, in this section 3, supports the proposition that public health measures that were in place during periods of a rising trend, rising case counts and rising hospitalizations... do you think that the evidence that you provided in this section 3 supports the proposition that those public health measures were effective in controlling COVID-19?

A. It's, obviously, more difficult to tell in that case. The...undoubtedly, there was increases in transmission despite the measures that were in place, at the time, which were, during those times, less restrictive than at times when we saw decreases.

I think that's part of the relationship which supports the effectiveness of the measures ...is when you make the measures more strict, case rates go down, when you make them less strict, case rates can rise.

252. Q. Can you point to the evidence that you provide, in this section 3, to support

the proposition that public health measures in place during periods of rising trend were effective in controlling the transmission of COVID-19?

A. I'm sorry, can you repeat the question?

253. Q. Can you point to any evidence in this section 3 of your affidavit that supports the proposition that public health measures in place during periods of rising trend were effective in controlling the transmission of COVID-19?

A. I think I would say that they were less effective than the more strict measures that were put in place. It's difficult to...you can compare the impact of strict measures versus less strict measures. It's difficult to compare the impact of less strict measures with no measures, okay, unless we actually do that, which we haven't done.

254. Q. But it's possible...it's possible to evaluate the effectiveness of less strict measures; is that correct?

A. If you can compare them with a scenario with no measures at all, yes.

255. Q. In other words, if you had some evidence to support that analysis?

A. Yes. I'll concede that it's more difficult to judge the effectiveness of the less strict public health measures in the context of rising case rates; I think that's true.

256. Q. Would you agree that there is no evidence, whatsoever, in this section 3 to support the proposition that the public health measures in place during periods of rising trend were effective?

A. I think you would have to look at...if you look at some of these periods of rising effectiveness, different measures were in place in different parts of the province. And, again, that's not presented in the affidavit, but my recollection is that, where we saw measures particularly under one of the frameworks which explicitly applied different public health measures based on local epidemiology in different parts of the province, where we saw that, you could...

257. Q. I'm not sure...excuse me for interrupting, but I'm not sure that's a particularly responsive answer. I'm asking if

you would agree that there is no evidence presented in this section 3 of your affidavit to support the proposition that the public health measures in place during periods of rising trend were effective?

A. Yes, I can agree with that.

258. Q. All right, thank you. The "Keeping Ontario Safe and Open Framework" was released on November 3rd, 2020; is that correct?

A. November 3rd? Yes.

259. Q. One goal of the framework...I'll call it the "framework", was to keep Ontario safe from the COVID-19 pandemic; correct?

A. I think that's an absolute statement. I can't recall what the objectives were phrased as, but I don't think...I don't think that absolute safety was an objective of any of the framework.

260. Q. The framework is called "Keeping Ontario Safe" and "Keeping Ontario Open"...

A. Yes...

261. Q. ...but nonetheless, I'll move on.

A. Yes.

262. Q. During the period of time between the enactment of the framework in early November

and the end of 2020, did the case counts and hospitalization charts on page 24 of your affidavit show an upward trend or a downward trend?

A. Yes, provincially, there was an upward trend during that period.

263. Q. Right, the province shut down and declared its second state of emergency on January 12th, 2021, just over two months after the "Keeping Ontario Safe and Open Framework" was enacted. Do you agree that between early November 2020 and January 12th, 2021, the framework did not succeed in keeping Ontario safe and open?

A. Well, the framework succeeded in opening Ontario, because it was designed, in part, to reduce public health measures and their impact on the province. Again, we've talked earlier about how it's difficult to assess the impact of public health measures in the face of rising case counts, but it certainly was less effective, overall, than the subsequent frameworks, which applied stricter public health measures.

264. Q. Well, I asked...the question that

I asked was whether the framework, during the period of time that I mentioned, succeeded in keeping Ontario safe and open. And you mentioned that it may have opened Ontario, somewhat, although I would argue that it had the opposite effect as it was followed immediately by a state of emergency and a lockdown.

But I don't think you really addressed the part of my question which asked whether it succeeded in keeping Ontario safe. And would you agree that it didn't succeed in keeping Ontario both safe and open during the period of time that I referred to?

A. Let me try and do a better job with your question. As the title said, it attempted to do two different things. It was attempting to open Ontario, as much as possible, to reduce the impact of public health measures and control COVID transmission, and, I think, those are difficult things to achieve at the same time.

As you pointed out, during the time that that framework was in place, Ontario was more open, but we were also seeing rising rates of infection. So I would say that it's difficult to

achieve both objectives, and it was not entirely successful in meeting both objectives at the same time.

265. Q. All right. I would like you to compare the charts that we've been discussing on page 24 of your affidavit, with some other pages in your affidavit. Do you have a paper copy of your affidavit in front of you? Are you able to...

A. I do.

266. Q. ...look at two pages at the same time?

A. I should be able to.

267. Q. All right, can you hold on to the charts on page 24 and look at the tables that you provide at...on pages 36 and 37 of your affidavit, and that is paragraphs 91 and 92, I believe.

A. Right.

268. Q. All right. So let's start with the table on page 36, which is paragraph 91, which summarizes the restrictions imposed on my clients, The Church of God, and other churches in the southwestern PHU. Is that a fair description of that table?

A. Yes, I think so.

269. Q. The first row of this table discusses restrictions applicable from July 13th, 2020 to December 25th, 2020; is that correct?

A. I think that's what it says, yes.

270. Q. During that time period, limits were placed on the right of people in the PHU to freely assemble and practise their religion; would you agree with that?

A. I'm sorry, I was reading it while you were speaking. Could you please repeat?

271. Q. During that time period, limits were places by the province on the right of people in the PHU to freely assemble and practise their religion; is that correct?

MR. HUNTER: Counsel, he can talk about the whether or not limits were placed on assembling and worship. Leave it to the judge whether rights were limited.

272. MR. KITTREDGE: Sure. Okay, fair enough. I'll rephrase the question.

BY MR. KITTREDGE:

273. Q. During that time period, limits

were placed on people's ability to freely assemble and worship; is that correct?

A. Yes, certainly, restrictions were placed on people's ability to assemble, for sure.

274. Q. And to practise their religion in the manner to which they are accustomed; is that correct?

A. I'm not going to disagree with you, but I'm not...I can't judge...I don't have the information to judge people's ability to practise their religion as they choose to, just because I'm not that familiar with all of the faiths and what their practices are.

275. Q. Okay, so can you tell me what the restriction on outdoor services was, for example, during this time period?

A. During this time period, no more than 100 people were permitted to gather outdoors.

276. Q. So to the extent that a group of...that a religious group was accustomed to gathering in numbers greater than 100, would you agree that they were...their ability to practise their religion in the manner to which they are accustomed was limited?

A. Yes.

277. Q. What were the limits that the province imposed on indoor services?

A. During that time period?

278. Q. During that time period, I'm sorry.

A. Yes, equated as thirty percent of room capacity was the indoor services limit.

279. Q. Right. Now, please take a look at the first row of the table on page 37, which summarizes the restrictions applicable to my client's Trinity Bible Chapel, and other churches in the Waterloo PHU.

A. M'hmm.

280. Q. Are the indoor and outdoor capacity limits the same as in the southwestern PHU for approximately the same period?

A. It looks like it. Outdoor, 100 people, indoor, 30 percent.

281. Q. Right. Now, please consult the case count and hospitalization charts on page 24. Do the charts show an upward trend or a downward trend, generally speaking, during that time period?

A. Hang on. So we're talking about

July...mid-July to December. It looks like increase in case counts.

282. Q. Yes, it does. And now, if you could turn back to page 36, paragraph 91, and the southwestern PHU chart, and if you can take a look at the third row, February 16th, 2021 to March 28th, 2021, and can you tell me what the restrictions on indoor and outdoor services were during that time period, in this PHU?

A. It looks like 100 people outdoors, 30 percent indoors.

283. Q. Right, and if you can turn to the next page, paragraph 92, look at the third row of that table, and are the restrictions, essentially...are the restrictions identical during the identical time period?

A. It looks like it.

284. Q. Now, if you can turn back to page 24 and take a look at the two charts there. Look at the time period between February 16th, 2021 and March 28th, 2021, the time period we were looking at on the other charts, and tell me whether there is a, generally speaking, upward or downward trend in case counts and hospitalizations at that time?

A. It looks like it was increasingly upward towards the end of that period.

285. Q. Right, and if we can turn back to page 91...or, sorry, paragraph 91, again, the southwestern PHU chart...table, and look at the fourth row, which covers the time period March 29th, 2021 to April 2nd, 2021. And could you tell me what the capacity limits were on indoor and outdoor services in the southwestern PHU during that time period?

A. Outdoor, no limit as long as people could physically distance. Indoor, 30 percent.

286. Q. All right, and can you turn to the next page and confirm that the restrictions were the same for that time period?

A. Yes, it looks like they were.

287. Q. And can we go back to the charts on page 24, and can you tell me whether that time period had a, generally speaking, upward trend or a downward trend?

A. It looks like upward.

288. Q. Right. So during...all of these periods of time that we just discussed, restrictions were imposed, but case counts

continued to climb; would you agree with that?

A. Yes.

289. Q. Now, turning back to the restrictions summary table at paragraph 92, on page 37. This is the Waterloo PHU page. Are you looking at it?

A. Yes, I am, sorry.

290. Q. All of the headcount capacity limits listed in this table are multiples of 10...

A. M'hmm.

291. Q. ...10 or 100 people are the capacity limits. And all of the room capacity percentage limits are multiples of 15, 15 and 30 percent; is that correct?

A. Yes.

292. Q. I find this to be an interesting coincidence; do you?

A. I don't know what you mean.

293. Q. Well, you say, at paragraph 88 of your affidavit, that these restrictions are informed by key indicators, such as weekly incidence of COVID-19, test positivity rate, the effective reproduction number, and the evidence of recent outbreaks; correct?

A. Yes.

294. Q. And these key indicators are assessed objectively in every case?

A. I think based on the best available information and expert opinion, yes.

295. Q. And capacity limits and restrictive PHU...or public health measures are designed with a view to minimally impair the right...the freedoms of Canadians and Ontarians; would you agree with that?

A. Well, as we've discussed, the framework in place, at that time, tried to achieve a balance between COVID control and the adverse impacts of the control measures.

296. Q. And that balance, after objective consideration of those key indicators, in every one of the relevant time periods in which they were assessed, led the province to determine that capacity limits of 10, 100, 15 percent and 30 percent struck that perfect balance that you described?

A. If you are asking about why the numbers were the way they were...

297. Q. I'm asking...you just said that the province, in setting these capacity numbers,

they set them because it struck a perfect balance between minimal impairment of freedoms and control of COVID transmission; didn't you?

A. I don't think I used the phrase "perfect balance". I think I may have said something...

298. Q. Well, you said...

A. ...like "try to strike a balance", yes.

299. Q. Right.

A. To try and achieve both objectives at the same time.

300. Q. I mean, wouldn't a capacity limit of 99 on religious gatherings have been at least as effective as a limit of 100 in controlling the spread of COVID?

A. I don't think it's possible to...I don't think we can distinguish between 100 and 99.

301. Q. How about 190?

A. Well, I think...I think the numbers were chosen for a couple of reasons. Sort of best...

302. Q. I'm not really asking...

A. ...best judgement...oh, sorry, go

back...

MR. HUNTER: Counsel, let the witness answer the question.

THE DEPONENT: All right. I think that the numbers that were in the, sort of, staged implementation of measures where there were different levels of restriction, were chosen to be different enough that we believed that it would make a difference, but also, you know, a number that's reasonable for people to work with.

I don't think 99 has any advantages in terms of a number versus 100. So we picked 100 because it was different from 30, and 50, and so forth. So the numbers were picked for ease of implementation, in part.

BY MR. KITTREDGE:

303. Q. So it struck a perfect balance between...or it struck a balance between minimal impairment of freedoms and control of COVID transmission, and ease of implementation, then; correct?

A. Well, ease of implementation is...yes, ease of implementation played a role in the final levels of the restrictions that were chosen, but the overall plan was to try to minimize the impact of COVID restrictions on society and the economy, at the same time as controlling COVID.

And if you remember that framework, that was very much a geographic framework, where different measures were put in place in different parts of the province. So if a part of the province was having very low rates of COVID, fewer restrictions were placed because it wasn't necessary, and areas of the province with very high rates of COVID had higher restrictions, more restrictive public health measures, in order to achieve control. So the idea was to have as few restrictions as were necessary to try to reduce transmission of the virus.

304. Q. But that was balanced with a desire for ease of implementation. So, presumably, when you're striking a balance between two numbers...I mean, if you take, as an example, the idea of taking the average of two numbers...

MR. HUNTER: Counsel, I think you are misinterpreting the witness's answer. He said when talking about 99 versus 100, they picked a number that was easy to implement.

305. MR. KITTREDGE: I think you're answering the question for your witness here.

MR. HUNTER: I'm just saying what he said, so if you want to...

306. MR. KITTREDGE: I don't...

MR. HUNTER: ...ask some follow-up questions, feel free, but the question you...and we can have it read back if you like, the question you asked was, why not 99 over 100, and the witness answered a question about ease of implementation. He did not give a general answer about all possible spread of numbers. But feel free to ask your question...

307. MR. KITTREDGE: I think...well, I guess, rather than...I mean, there's no point...no need to repeat it. It will be in the transcript if it's there. I

believe it is, but...and, you know, to the extent that it is, it's there and I don't need it again, so...and if it isn't, perhaps you are correct, but I believe it is.

So I guess we're at five minutes to noon here, do we want to take a bit of a break?

MR. HUNTER: Do you have...I'm, obviously, not going to hold you to it, but do you have an estimate about how much longer you expect to be?

308. MR. KITTREDGE: Probably, it wouldn't be too much longer. I would expect less than an hour.

MR. HUNTER: Okay, so do you want to take a lunch break or...

309. MR. KITTREDGE: I wouldn't mind taking a lunch break. Do you want to reconvene in...I don't know, an hour?

MR. HUNTER: So 1:00, just to make it a round number?

310. MR. KITTREDGE: Yes, there you go. Sounds good. Ease of implementation. All right.

--- upon recessing at 11:57 a.m.

--- A LUNCHEON RECESS

--- upon resuming at 1:00 p.m.

DR. DAVID McKEOWN, resumed

CONTINUED CROSS-EXAMINATION BY MR. KITTREDGE:

311. Q. All right, Dr. McKeown, I don't have too many more questions for you, but I'll take you, now, to paragraph 82 of your affidavit, at page 32, where you list the number of risks that you feel are specific to religious gatherings. Is that a fair description of the contents of this section? Do we have audio from Dr. McKeown?

A. Sorry, I was muted for a second. Tell me the paragraph number, again, please?

312. Q. Paragraph 82 on page 32, and it's section 5...

A. Got it.

313. Q. ..."The Risks of COVID Transmission at Religious Gatherings".

A. Yes, got it.

314. Q. You outline a number of concerns in this section that you feel are specific to

religious gatherings and why you feel that religious gatherings pose a particular risk with regard to COVID-19 transmission; is that correct?

A. Yes.

315. Q. One of the concerns that you had is that you felt that religious gatherings often last for more than an hour; is that correct?

A. Yes, a concern about situations in which people from different households are near each other for an extended period of time.

316. Q. Right, but religious gatherings aren't the only sorts of gatherings where people might be together in the same space for more than an hour?

A. No, they're not.

317. Q. I mean, in a grocery store, people are together in the same space. Sometimes, people shop for more than an hour; is that correct?

A. I don't think they're together in the same sense. I think a better comparison would be a movie theatre, or a concert performance, where people are seated next to each other for an extended period. When I go grocery shopping, I'm wandering around the store, and I

don’t have very prolonged contact with any one other shopper.

318. Q. Right. Did you consider restricting religious gatherings in terms of their duration, in addition to, or instead of, restricting their capacity?

A. I don’t recall that specific suggestion coming up, no.

319. Q. Did you consider restricting the seating arrangements at religious gatherings such that people from different households are separated by a larger distance than they would otherwise be?

A. Well, that is one of the public health measures. At different points in the pandemic, religious services were required to limit members to the number who could be socially distanced, or physically distanced, at two metres, so that’s an example of, I think, what you are talking about.

320. Q. But members of the same household wouldn’t...there wouldn’t be much benefit to members of the same household observing that distance from each other; would there?

A. No, that’s true. And one church

that I'm familiar with arranges seating so that household members sit together, and non-household members don't, wherever possible.

321. Q. Sure, and did you consider making a recommendation to the effect that churches, across the province, should take those kinds of measures?

A. I think they were implicit in the requirement for social distancing.

322. Q. Did the requirement for social distancing exempt members of the same household, while they were at church, from those requirements?

A. I can't recall the exact wording, but in many...many times when we've talked about social distancing, it has been about people who are not in the same household.

323. Q. Right, but in most of the announcements for...like, where social distancing is required in public settings, can you...would you agree that most of the announcements where social distancing is required in public settings, do not make any mention of exempting members of the same household from those requirements?

A. I recall...I recall statements

which do mention that. As far as the regulations and how they apply to religious organizations, I would have to check the regulation for the details.

324. Q. Right. In the set of restrictions that you outline in the tables at pages 90, 91, 92, there's no mention of allowing members of the same family where social distancing is required, for example, in the outdoor services from March 29th, 2021 to April 2nd, 2021...there's no mention that capacity could be...you know, that social distancing guidelines wouldn't apply to members of the same family and...would you agree with that?

A. Yes, I agree it's not mentioned here. This is, sort of, a short form, so that's why I would want to check the actual regulation to make sure it's there or not.

325. Q. Right. Where there's a limit of 10 people, that wouldn't...that number wouldn't increase? Like, for example, between December 26th, 2020 and February 15th, 2021, that number wouldn't increase if, say, four of the members of the congregation of 10 were members of the same household; would it?

A. No, that's true, the 10 people did not take that into account. The 10 people was intended to allow a service to be delivered virtually. We weren't really anticipating that the convenor and the video operators, and so forth, would be family members, but I suppose it's possible.

326. Q. And if they were, there wouldn't be much of an impact to allowing them to gather more closely together than they would with members of other households, would there, in terms of transmission of COVID-19?

A. No, that's true. None of the public health measures were intended to separate members of the same household because we recognize that members of the same household are going to interact and have transmission opportunities, which are, essentially, unavoidable, you know, shared sleeping, shared bathroom, and kitchen arrangements. So all of the social distancing has, generally, been for non-household members.

327. Q. But in the restrictions on capacity of religious services that are calculated by headcount, where it's...as we noted

earlier on in your cross-examination, it's either 100 or 10 people in these charts, there's no effort to increase that number by allowing members of the same household, or members of several households, to gather more closely together than they would with the rest of the members of that congregation, thereby, perhaps, increasing the number from 100 to 120, or something like that?

A. Well, you could say that if we hadn't factored that in, we would have said 50 people. So, you know, I think 100 people could easily be said to be taking into account household members being part of the 100.

328. Q. So you mentioned that you were contemplating, in the setting of the limit of 10 participants in religious services, that part of the reasoning there was for assistance to the officiant, you know, people producing video recordings of the service, and disseminating it. I think you say, at one point, that you expected that, of the 10 people, several of them...oh, here it is,

"...Among other things, the higher capacity limits allowed a small number

of people, who may not be in the same household, to produce and disseminate virtual religious services to a wider community..."

It doesn't really sound like that number 10 was drafted, or designed, with the idea in mind of having a number of those people be members of the same household, from what I'm seeing here; would you agree?

A. Yes, I don't think we anticipated that those...that that small group would be members of same household, that's correct.

329. Q. But it would have minimally impaired the ability of Ontarians to gather... more minimally impaired the ability of Ontarians to gather...

MR. HUNTER: Counsel.

330. MR. KITTREDGE: ...and worship...yes?

MR. HUNTER: Minimal impairment is a legal concept, so I'm not going to let the witness opine on...

331. MR. KITTREDGE: I mean, it's also an English concept, but it's a...in the straightforward English sense, it's a term that people understand, wouldn't

you agree? No? All right.

MR. HUNTER: If you rephrase, I'm happy to consider letting the witness answer.

332. MR. KITTREDGE: Sure. No, I will.

BY MR. KITTREDGE:

333. Q. So wouldn't you agree that if the capacity limits allowed, for example, 15 people, where five of those people were members of the same household, that people in Ontario would be more free to gather and worship as they choose?

A. I can't speak to the impact on worship, but, yes, if household members had been taken into account, then there could have been slightly larger numbers in some religious settings.

334. Q. All right. Going back to paragraph...where were we...80...82, you seem to be concerned, at the end of paragraph 82, that physical distancing and mask-wearing won't be...guidance on mask-wearing and physical distancing won't be followed by people who attend religious services. Is there something specific about people who attend religious services that

makes you think that they would not follow guidance on these things, or not be concerned about their health?

A. No, I don't have any reason to believe that the compliance would be lower. I think it's a factor in all venues when we know that compliance is never 100 percent.

335. Q. Right. So there's nothing in particular about religious gatherings that makes you think that people in attendance would be more...or would be less likely to wear masks or less likely to physical distance?

A. I can't think of one.

336. Q. All right. You mention that services indoors in poorly ventilated areas are a concern. Why is that...is that a particular concern of yours with regard to religious gatherings?

A. No, I think, again, this is something which is a concern in many different venues. It's a concern in schools, it's a concern in movie theatres. Any place which has very poor ventilation, and which also contains, you know, large numbers of people in close proximity, poses a transmission risk.

337. Q. Right. You mentioned that you are concerned that people at religious services would sing, chant, and pray loudly. Did you consider imposing restrictions on singing...

A. We did...

338. Q. ...at religious services?

A. Yes, we did, in fact, at different points in the pandemic, limitations on singing, or separation between singers and other participants, those were part of the public health measures at different times.

339. Q. Right. You, also, appear to be concerned that people at religious services will be tempted to socialize. Isn't it true that most people are tempted to socialize?

A. I think socialization is common in many venues, maybe less so in some venues. You know, when I go to a movie theatre, I'm not really interested in...I don't know any of the other people who are there in the movie, other than the people I came with.

But, certainly, I think...it has been my experience, and others, that religious communities do have a sense of community, and many of the members, or the participants in

congregations, do know each other very well, and so, yes, I think it's a slightly higher risk in that setting than for other settings where people don't even know each other.

340. Q. You also mention that when prevalence of COVID-19 is high in community, risks at religious gatherings are proportionately higher. Isn't that the case for any gathering, or any setting at all?

A. Yes, that's true. Yes, some of these factors that are listed here that apply to religious gatherings, also apply to some other settings.

341. Q. Many of them, apparently. Would you agree?

A. I haven't made a count to see.

342. Q. All right. Activities which take place outdoors involving small numbers of people, say, five people or fewer, where social distancing can and does take place, are not considered to be a significant risk for COVID transmission; is that accurate?

A. I think that's accurate.

343. Q. Is outdoor-only golfing, where participants don't go into a clubhouse at any

point, but just do all of their golfing activities outside on a golf course, would that be a significant vector for COVID transmission, in your opinion?

A. No, I would say that would be a low risk situation.

344. Q. Have any COVID outbreaks been linked to outdoor-only golfing in Ontario?

A. I haven't looked, but not that I'm aware of.

345. Q. How about camping on Crown land, is that a significant vector for COVID transmission?

A. I wouldn't expect so, as long as the camping is small groups of people and not large gatherings.

346. Q. Has camping on Crown land been linked to any COVID outbreaks in Ontario?

A. Again, I don't recall any instances of that being reported. The tracking of venues for outbreaks is not exhaustive in its listing. So there may be some settings that aren't tracked in the data system, but I wouldn't expect to see a lot of outbreaks in that situation, no.

347. Q. Right, and camping in provincial parks, has that been linked to any COVID outbreaks in Ontario?

A. Again, not that I recall.

348. Q. Would you consider that to be a significant vector for COVID transmission?

A. No, outdoor activities, in general, are much lower risk than indoor activities, and that has been reflected at various times...sometimes, very explicitly, in the province’s policies.

349. Q. Right, and back country camping, camping in areas of provincial parks that are only accessible by long hikes or canoe trips, or things of that nature, do you consider that to be a significant vector for COVID transmission?

A. Again, as an outdoor activity with small numbers of people, I would not expect it to be a high-risk activity, no.

350. Q. And am I correct to assume that that has not been linked to any COVID outbreaks in Ontario, either?

A. Again, not that I know of, but it’s possible that there may be a small number, but I’m not aware of any.

351. Q. You think it's possible that back country camping led to a small number of outbreaks of COVID in Ontario?

A. I don't think it's likely.

352. Q. Right.

A. I wouldn't rule it out. Outdoor...

353. Q. Would you say it was...

A. ...activities are not risk free, they're just lower risk than indoor activities.

354. Q. Right. Would you say that back country camping, where the camp sites are only accessible by a long hike or a long canoe trip, is likely to be linked to any...sorry, is unlikely to be linked to any COVID outbreaks in Ontario?

A. I think it is unlikely.

355. Q. Would you say that it's highly unlikely?

A. I'm not sure what the quantitative equivalent of that is, but I would say it's pretty unlikely.

356. Q. All right, and, yet, at various points during the COVID pandemic, outdoor golfing, camping on Crown land and provincial

parks, and back country camping in provincial parks, have all been prohibited under the public health measures; isn't that the case?

MR. HUNTER: I fail to see the relevance of why other measures are or are not justified. This is a challenge to specific measures that apply to your client.

357. MR. KITTREDGE: Well, it's a challenge to whether the measures are...I mean, first of all, these regulations are referenced in the affidavit. They are public health measures. They're said to have been effective in...I think we were looking at page 24, around those charts, for most of the morning. So I think they're addressed in a number of places in the affidavit, and I think they are fair game.

MR. HUNTER: This is not a global challenge to every public health measure Ontario has taken. I have led you quite a bit of leeway, but we're not...you know, if you want to tie it into how

it's relevant to churches, I'm happy to let...consider letting the witness answer, but we're not going to go through every single measure and how...you know, whether there was an outbreak and whether that justified.

Quite frankly, if that wasn't justified, fine, let someone who is subject to that bring a challenge. If it was justified, great. This is a question about whether the measures that your clients were subject to, which were all about religious gatherings were justified, and the risk that they pose to the public health.

358. MR. KITTREDGE: All right, I'll move on.

BY MR. KITTREDGE:

359. Q. Liquor stores, and cannabis stores, and beer stores, have been open throughout the pandemic; have they not?

A. Yes, they have been at different times.

360. Q. And liquor stores, and beer

stores, and cannabis stores may have poor ventilation?

A. Yes, they may.

361. Q. People may talk loudly in a cannabis store, or a liquor store, or a beer store?

A. Not frequently, but it’s possible.

362. Q. People may socialize in a cannabis store, a liquor store, or a beer store?

A. Perhaps.

363. Q. When prevalence in the community is high, risks at a cannabis store, or a liquor store, or a beer store, are similarly high; would you agree with that?

A. Well, I would say...

364. Q. Proportionately.

A. Yes, as the rate in the community goes up, the rate in any...the likelihood that someone who is infected is going to be in a particular venue, including the ones you mentioned, would be higher, yes.

365. Q. When people show up at a retail store, or grocery store, do they always run in quickly just to pick up a few items?

A. No, sometimes it’s longer.

366. Q. Sometimes, people at a grocery store...

A. But people have to do it...

367. Q. Oh, sorry.

A. I think what’s important to transmission is the nature of the interaction between the shoppers, and between the shoppers and employees, which is usually not a long period of being close together.

368. Q. Right, but people, sometimes, do spend long periods of time in a store?

A. Oh, yes.

369. Q. And sometimes more than an hour?

A. That’s possible, yes.

370. Q. And people shopping in stores in neighbourhoods where they live or work might encounter friends, colleagues, or neighbours there; is that correct?

A. Indeed, they might.

371. Q. And they might be tempted to greet them?

A. Yes.

372. Q. And they might be tempted to socialize?

A. Yes, and they would be subject to the general advice that was given when those stores were open. With or without capacity limits, the advice was always to wear a mask and keep your distance. So we would hope that people would follow that advice in settings like retail stores, which remained open.

373. MR. KITTREDGE: Right. Well, I think that brings me to the end of my questions, so thank you very much for your time today, and I will pass it over to my friend.

MR. HUNTER: Thank you.

-- upon recessing at 1:21 p.m.

--- A BRIEF RECESS

--- upon resuming at 1:31 p.m.

DR. DAVID McKEOWN, resumed

RE-EXAMINATION BY MR. HUNTER:

374. Q. Dr. McKeown, you were asked a number of questions about presence of viral load in the nose versus having COVID-19 disease; do you remember those questions?

A. Yes.

375. Q. Now, is there any public health impact of people who have a viral load present in their nose or pharynx, such that they would test positive on a test, but are not showing signs of COVID-19 disease?

A. Well, first of all, there's a bit of confusion. "Viral load" is a different concept. The case definition for a confirmed case of COVID-19 is the detection of the virus in the specimen, in a person. So that's what gives people...makes someone a case.

Your question about, "Is there any implications?", yes. If someone is infected with the virus and has the virus in their body, even though they do not have symptoms, or do not yet have symptoms, still pose a risk of transmission to other people.

376. Q. You were asked some questions about, you know, the predominance of serious outcomes from COVID-19 in different age groups; do you remember those?

A. Yes.

377. Q. And you were asked about the predominance of those severe outcomes in older people, or people with underlying conditions.

What, if any...I guess, are there such outcomes in younger, healthy people, without underlying conditions?

A. Yes, there can be, just at a lower rate. But there certainly can be. In fact, there have been deaths from COVID-19 in Ontario in youth. Not very many, but some.

378. Q. And you were asked questions about, you know, whether most people recover fully. Is that the case for all young, healthy people who contract COVID-19?

A. No, most people recover fully. There is something called “long COVID”, which is a chronic condition that we are learning quite a bit about, which affects a proportion of people who were infected and may leave them with long-term symptoms.

379. Q. And even for those who, you know, either don’t develop symptoms, or do recover quickly, is there any public health impact of young, healthy people contracting COVID-19?

A. Well, certainly, they are unable to attend school, they can’t work for a period of time, there’s the possibility that they will transmit to other people who are more vulnerable

and may have a more severe illness. So, yes, there are lots of implications. I don't think we should think of infections in young people, even if they are mild, as having no implications for the population as a whole.

380. Q. Now, you were asked, at one point, about comorbidities, and you said, "Our understanding of comorbidities has evolved". How has it evolved?

A. I think we've just gotten more experienced. As COVID has spread, and more and more people have become infected, we've had more examples of people who have comorbidities who have acquired COVID, and we've seen that they can have a more severe outcome.

So, I mean, COVID is, essentially, a viral respiratory disease. So people who have pre-existing respiratory conditions, for example, are more likely to wind up in hospital, or intensive care, or to die, and we've seen...we've just had more experience with that over the months that the pandemic has happened.

381. Q. And, you know, obviously, it's a technical/medical term, "comorbidities". Can you just explain, like, what that term means, and

what are some examples of things that might have an impact on COVID-19?

A. Well, because COVID-19 is an infectious disease, anything which...any condition which renders the person's immune system less effective at responding to an infection is going to be a problem.

So, for example, people who are on immune suppressant therapy for transplant, or for drug...for...sorry, for cancer treatment, may have a more severe infection because their immune system doesn't respond as well. Another example would be the one I gave. People who have chronic illnesses, which affect the parts of the body which are most impaired by COVID, such as the lungs, may have poorer outcomes and more likely to be ill and end up in intensive care, or to die.

382. Q. Now, you were asked a number of questions about the two graphs that are in your affidavit, and the paragraphs about them, and you said, at one point, that you believed that there's a high degree of likelihood public health measures caused the drops in case counts and hospitalizations, as opposed to just being

correlated with them. Why do you think that?

A. Because these are the outcomes which we have been tracking, which we believe to be strongly related to the impact that COVID is having on the population. Things like hospitalization rates, case incidence, test positivity, these are all the things which are, we believe, valid indicators of the level of activity of the virus in the population.

And so, when we see those changing, we believe that that's a real phenomenon that is happening, when a transmission is less frequent, and the consequences of that transmission are less frequent. So when that happens in relationship to measures which are being taken which we expect would have a positive impact, I think it's reasonable to conclude that that's what's happened.

383. Q. And why did you expect those measures to have that positive impact?

A. Well, there's a few reasons. It has been recognized for some time that those types of measures can be useful in responding and reducing transmission of a respiratory virus. They've been part of plans that have been made

for epidemics or pandemics of respiratory viruses.

From what we understand about how the virus is transmitted through small and large particles, droplets that are expelled when people cough, or talk, or sing, or speak, we would expect, then, that the wearing of a mask, or keeping people separated, not having people gather, you would expect them to have that effect of limiting transmission. And so it appears that they do.

And over the course of the pandemic, quite a lot of research has been done, and there are individual studies, studies of outbreaks, studies of household transmission, which do show that the kinds of contact the public health measures limit is what is responsible for transmission of the virus.

384. Q. Now, at paragraph 55 of your affidavit, if you have that in front of you. It's on page 23.

A. Yes.

385. Q. You were asked a number of questions about the last sentence of that paragraph, about whether the implementation of

public health measures during the second and third states of emergency were shortly followed by a substantial decrease in the number of COVID-19 cases and hospitalizations, and you mentioned "Among other things". That's also in your affidavit. What are some of those "other things"?

A. Well, as I said, in addition to this relationship that we see, both in time and, also, geographically...you know, the graphs don't show this, but there were many points in the pandemic in which rates were higher in some parts of the province than in other parts of the province, and then, when public health measures were implemented in those areas, the rates came down. So there's lots of examples of that.

But, in addition to that, as I said, our understanding of transmission, and how it works, and what kinds of measures would be expected based on our understanding of the transmission to limit viral transmission from person-to-person, those...that's what underlies the public health measures. And so it's not surprising, I think, to see that it actually works.

In addition, we have looked at the

experience of other jurisdictions to see how the relationship between the implementation of public health measures in those jurisdictions...what it leads to in terms of measures of transmission of the pandemic. So those are some of the things which, I think, are inputs into the conclusion that is listed in that paragraph.

386. Q. And you mentioned looking to experiences of some other jurisdictions. What did you learn from those other jurisdictions about what did or what did not have an impact?

A. Well, in general, there was, first of all, the observation that when public health measures were implemented, it had a favourable impact on transmission. Secondly, that when...if measures were implemented quickly once there was an increase in evidence of transmission, it was more likely to bring that transmission down.

And lastly, I would say that more restrictive, or more severe, public health measures had a bigger impact than less severe ones. And, finally, that if measures were put in place, that they should be put in place for long enough, you know, at least four to six weeks, to

make a real difference. Those were, sort of, conclusions that many people reached looking at the experience from different jurisdictions around the world.

387. Q. Now, you were asked the question, and agreed with it, that correlation does not necessarily equal causation. In your experience, can correlation be evidence of causation, and how do you tell when it is and when it isn't?

A. Well, certainly, correlation isn't always causation, but, when it is, and it often is, what you see is...there's a few things which help you distinguish between correlation. One of them is a gradient effect.

So if the intervention that you are putting in place, if as you put a bigger intervention, you get a bigger impact, then that's a good sign that you are looking at a causal relationship rather than a correlation relationship.

If there's a biological basis for believing that the intervention would lead to the outcome you are seeing, that makes it more likely that it's causal. That was why I didn't believe that the jurisdiction...the interjurisdictional

comparisons that happened to have peaks at the same time, should appropriately be identified as causal. And...well, I'll stop there. There are, sort of, theoretical lists that measure, but those are some of the prominent ones that help you distinguish a causal relationship from one which is not.

388. Q. And you were also asked about, you know, whether the data proved things, or certainty of things. Just how do those concepts of proof and certainty, how do they play into public health practice?

A. Well, I would say, in particular, during this pandemic, with a novel pathogen, there's always some uncertainty. So I would be hesitant to use words which implied 100 percent certainty when we're dealing with something which we haven't seen before. We've learned a great deal over the past 21 months about COVID and what causes it, what controls it, but I wouldn't say that our knowledge is perfect, yet, and so I think it's appropriate to have a bit of humility.

389. Q. You were taken to Exhibit Y of your affidavit, and, in particular, a chart of vaccination rates; do you recall that?

A. Yes.

390. Q. And so...and you were asked questions about, you know, whether public health measures were justified given those levels of vaccination that occurred by this point, in May 2021. Looking at the vaccination data in the chart, in your opinion, would there still be a need for public health measures to slow the spread of COVID-19 given this vaccination rate?

A. Yes, and I think...we didn't talk about variants of concern, but, over the course of the pandemic, of course, we've seen the evolution of the virus, and we've gone from the original virus to the Alpha becoming the predominant variant, to, now, Delta is the predominant variant.

Each of those have been accompanied by an increase in transmissibility, and the...for example, the original estimates that were made, and built into the roadmap to recovery, were based on, you know, 60, 70, 75 percent of vaccination coverage being sufficient to allow public health measures to be lifted. It has become clear that when it comes to Delta, because of its increased transmissibility, much higher

levels of vaccination would be required to be effective at the population level.

So, now, as you probably know, our target is 90 percent fully vaccinated. And even with that, many people including the Science Table have said we will continue to need public health measures for some time.

391. MR. HUNTER: All right. Now, I'm going to take you to some of the questions you were asked about Florida, and then Sweden. So let's start with Florida. Now, Mr. Kittredge, I have prepared some screen shots of the same webpage you were using. I can take Dr. McKeown to the webpage live, and then we can just upload the screen shots, or I can go to the screen shots, whichever is easier. You are on mute.

MR. KITTREDGE: It's the same page that I was looking at? I mean...

392. MR. HUNTER: Some of the other tabs on the same page.

MR. KITTREDGE: Oh, okay, sure. I mean, you know, I'm fine with you marking whatever you want, but...

393. MR. HUNTER: So, for this one, since I was able to PDF them nicely, I will go to the screen shots. Of the WHO one, it doesn't PDF as nicely, so that one we may just have to do live. So let's start with the Florida one. Just a second.

BY MR. HUNTER:

394. Q. Okay, can you see this, Dr. McKeown?

A. Yes.

395. Q. Okay, so we're just showing... this is the same page. At the top, we have "Florida" and "Daily Cases".

A. Yes.

396. Q. Let's just scroll down to see the actual chart.

A. Right.

397. Q. And I understand...if you can just read off...in your view, what were the levels of daily cases per 100,000, at the various peaks, in this data?

A. I think I was...I commented on this in response to earlier questions. On the

daily case side, which is the lefthand side...but if you want to look at cases per 100,000, in the second major wave...we were in Florida, that is...was in the...about...it looks like about 9,500 per 100,000. Actually, I have a little trouble reading it because it's...

398. Q. I'll see if I can zoom in. Actually, I see...I think it's actually just talking about total cumulative cases per 100,000.

A. Yes, yes, so that's...it wasn't clear to me, but that's it. The other side is easier to understand because it's daily cases, so you can compare it with other jurisdictions.

399. Q. And how would those be comparable to Ontario's case counts at similar times?

A. You have to take into account the difference in the population, and I don't have Florida's population off the top of my head. But I remember, at the time, doing the calculation, and Florida's numbers and rates were very significantly higher than Ontario's, through this period, particularly in the most recent wave.

400. Q. I'm just going to show the...this is, now, the deaths, as opposed to just cases. Do you see that chart?

A. I can see. I see the chart, but I don't see the heading above it.

401. Q. Sorry, I'll go back up. It's just...

A. "Florida Daily Deaths", and it's showing a seven-day moving average. Okay, got it.

402. Q. And so, basically, the same question: Where does this peak in the number of daily deaths for the various waves?

A. Well, we're seeing, you know, 200 in the first couple of major waves, and then the third one that is shown here, they reach 400, which is astonishingly high, and much higher than Ontario's.

403. Q. Just on the cumulative, where did they end up on the cumulative cases per 100,000?

A. Cumulative? It looks like about 17,000 or 18,000.

404. Q. And how would that compare to Ontario?

A. Ontario has had less than 10,000.

405. Q. Sorry, is that total or per 100,000 for Ontario?

A. No, that's total cumulative.

406. Q. And this is total cases per 100,000; is it not?

A. Yes, it does look that way. So it would be 17,000 per 100,000. That doesn't sound right, Mr. Hunter.

407. Q. I've got one more that may...

A. I'm not sure how to interpret that side of the graph.

408. Q. Fair enough. We're all trying to guess how the CDC tracks its data, so perhaps this one will be helpful. This is the cumulative deaths and total cases per 100,000. So what do you interpret this graph as meaning, the cumulative death count...

A. Again...

409. Q. ...on the left axis?

A. Yes, so the left one is the one that's easier to understand. That's absolute numbers rather than rates. I'm not sure about the rates on the right. Absolute numbers, well, now, they're up to 60,000 deaths.

410. Q. And, sorry, what was the comparison for Ontario? Obviously, keep bearing in mind the populations are different.

A. Yes. We are a little under

10,000. So even taking into account a slightly larger population, it's a much higher cumulative death toll.

411. Q. And just for completeness...I don't think there's much more to ask, but just for completeness, I'm just going to show you the cumulative cases chart, just so we have all the comparative data. And what's the, I guess, cumulative case count of Florida to date?

A. Well, it looks like about 3.6 million.

412. Q. And what's the comparator for Ontario?

A. A little over 600,000.

413. MR. HUNTER: So can I have those marked as an exhibit? I can either do it as four separate exhibits, or one joint exhibit, whatever is easier for you, Mr. Kittredge.

MR. KITTREDGE: I really have no preference, so whatever you would like.

414. MR. HUNTER: So why don't we just mark them as one exhibit of screen shots from Centers for Disease Control and Prevention, COVID data tracker.

--- EXHIBIT C: Screen shots from Centers for Disease Control and Prevention, COVID data tracker

BY MR. HUNTER:

415. Q. I'll stop sharing that. I'm now going to show you this. And, unfortunately, I was not able to put it into nice screen shots, but we will do the live webpage. Can you see that, Dr. McKeown?

A. I don't have anything right now.

416. Q. Okay, it says it's sharing. Let's just...

A. Oh, hang on. Yes, now I've got it.

417. Q. Okay, so do you recognize this as the World Health Organization webpage Mr. Kittredge took you to earlier? I'll scroll down. It might make it easier to recognize the chart.

A. Yes, that I recognize, yes.

418. Q. So this was just talking about Sweden. I just want to direct your attention, at the top of the webpage, there's a map of, I guess, northern Europe, Scandinavia, in

particular.

A. M'hmm.

419. Q. And, unfortunately, it only pops up if I drag the mouse over the various maps, but if I put the mouse over Sweden, you see that there was 1,186,387 confirmed cases?

A. Yes, I see that.

420. Q. And 15,107 deaths?

A. Yes.

421. Q. And just if you look at...well, first of all, I guess we ask...if I just look at some of the neighbouring Scandinavian countries, which...I'm just going to go through them one by one. I'm going to read the data, and then I'll ask you the question, just because, unfortunately, I can't show them all at once. So in Norway, 232,826 confirmed cases, 995 deaths. In Finland, 173,632 confirmed cases, and 1,247 deaths. Just to finish off Scandinavia, Denmark, 434,798 confirmed cases and 2,786 deaths.

Now, obviously, we don't have the relative populations of those, but given there seems to be a significant difference in the number of cases, and number of deaths, are you aware of any public health reasons why those

might be different?

A. Again, you would have to look at the pattern of the underlying population and the pattern of implementation of both vaccination and public health measures. But I believe...my recollection is that Sweden has...Mr. Kittredge said was one of the jurisdictions which used fewer public health measures.

422. MR. HUNTER: I'll stop sharing that. Now, Mr. Kittredge, we're going to try...we might just take a break at the end to see if we can actually try and get that PDF that can be stamped as an exhibit. I'm just worried that the map does not PDF well, but we'll try that at the break just before we end, if that's all right with you.

MR. KITTREDGE: Sure. I mean, you know, I'm at your leisure, I suppose. But, yes, I mean, I have no objection to any of that, whatever you got to do. If you've got to poke around at it for a while, that's fine with me.

423. MR. HUNTER: Perfect. I'm almost done.

MR. KITTREDGE: If you needed to, you could screen shot it several times with the mouse over top of the various areas, if that's what you want to do.

424. MR. HUNTER: There's actually some technical problem with their website because they're upgrading it, or something, right now, so that's what is causing the trouble.

MR. KITTREDGE: Oh, really? Okay.

425. MR. HUNTER: Their website is too fancy for their own good, I think is the problem, but...

MR. KITTREDGE: Right, yes, for sure.

426. MR. HUNTER: Anyways, let's just wrap this up.

BY MR. HUNTER:

427. Q. Now, you were asked a number of questions about the impact of public health measures in between the states of emergency when cases were on an upward trajectory. Do you remember those questions?

A. Yes.

428. Q. What impact would you have

expected to see from public health measures, or would have expected to see if public health measures were not present?

A. Well, I think if public health measures...if sufficient public health measures were implemented, I think we would have expected to see a slowing of transmission and a decline in the number of cases.

The periods of time in which we didn't see that, when the cases were still rising despite the implementation of some public health measures, were, in general, times when the government backed off on public health measures, and was trying to give some relief to the institutions and businesses, and so forth, that were affected by the measures.

In my view, looking back on some of those times, particularly the one before the third wave in which there was a colour coded approach, was less successful in controlling COVID. And I think it was successful in opening up the province more, but in trying to achieve both objectives, I think, the one that was less successful was controlling COVID because the public health measures were not strongly enough

applied, in my view.

429. Q. And so you were asked some questions about the impact of public health measures on cases and hospitalization rates. You know, when you're looking at the data and you lift a measure or increase a measure, like, how do you see that track through into cases and hospitalization rates?

A. Well, first of all, there is a lag time, right? So the measure has to have an impact on people's behaviour and the degree of contact between individuals, and once it has that impact, then there's an incubation period.

Once you stop transmission, it...you know, the cases that would have occurred, don't occur, but one incubation period forward. So we normally, in implementing these, advise the government to wait four to eight weeks to see the impact of the public health measures because of that lag time.

430. Q. And you were asked some questions about members of a household, I think it was particularly in the church setting, and about whether they posed a risk to each other. Do you remember those questions?

A. Yes.

431. Q. Is the risk that members of a household pose to each other the only risk that would be relevant from a public health standpoint?

A. Well, first of all, let me say that household members do pose a risk to each other. If one member of a household is infected, there's actually a very high likelihood that other members will be affected. The trouble is it's not very amendable to public health measures. If people are sharing a household, sharing a kitchen, sharing a bathroom, sharing a bed, it's not practical for them to be separated in that way.

That's why we made allowances and applied public health measures differently to household members. Not because of the risk of transmission, which is, in fact, very high. So household members who do become infected, of course, can transmit the infection not only to other members of their household, but also to other people in the community. So, I mean, we are concerned about household members becoming infected for that reason.

432. Q. And does it make any difference when you are in a community, say, in a church setting, whether you have one member of a household or five members of a household there vis-a-vis capacity limits?

A. I don't understand your question, sorry.

433. Q. I guess my question is, you know, you were asked questions about why couldn't you allow a whole household. Does it make any difference whether you allow...I think you made the difference, we could have had 50 or 100. Does it make any difference if you count members of a household together or separately?

A. Well, no, I think...I think we have, in many settings during the pandemic, made allowances for household members. So we used... for example, the outside gathering limits were gathering limits for people who aren't members of the same household.

But that doesn't mean that there isn't going to be transmission in that setting. It just means that the transmission could also occur in the household, and it's not practical to keep people apart. But certainly, you know, the more

members of a household you have in any venue, the more likely you are to have transmission between household members and non-household members.

434. Q. And then you were asked about, you know, whether...wouldn't it make sense to put restrictions on other settings, and you talked about movie theatres and concerts that you said had similar risks. What, if any, public health measures were put on those settings, and were they the same or different than churches?

A. Well, I think the affidavit points this out. In almost all the times, through the measures that were used in the pandemic, the measures that were applicable to religious services, rites, and ceremonies, were less restrictive than for comparable settings. And when I say "comparable settings", I mean settings where you would have groups of people from different households gathered together, you know, sitting near each other for an extended period.

So when compared with those settings, which are, kind of, apples-to-apples comparisons, religious services had less strict restrictions, and I believe the reason the government made that

decision was in recognition of the importance of religious services to people's lives.

435. MR. HUNTER: Thank you. Those are my questions.

--- upon adjourning at 2:03 p.m.

MATTHEW HODGE, affirmed

CROSS-EXAMINATION BY MR. KITTREDGE:

1. Q. I represent the moving parties in this matter, and I am going to ask you a series of questions today. I understand that you submitted some evidence in this matter by way of an affidavit that you affirmed on July 2, 2021. Do you have your affidavit in front of you now?

A. I do.

2. Q. Great. In your CV attached at Exhibit A of your affidavit, you mention that your COVID work has included engagements with PHAC during the pandemic, in addition to parking with Public Health Ontario and Peel Region Public Health. What does the acronym PHAC stand for?

A. Public Health Agency of Canada.

3. Q. Thank you. Other than in your affidavit, did you provide advice, comments, or recommendations relating to non-pharmaceutical COVID interventions to the Province or to the Government of Canada, at any point during the pandemic?

A. Sorry, could you restate the

question?

4. Q. Did you provide advice, comments, or recommendations relating to non-pharmaceutical COVID interventions to the Province or the Government of Canada, at any point during the pandemic?

A. My role with the Public Health Agency of Canada included comments on what might be described as, sort of, draft options for travel-related matters.

5. Q. All right. Were you involved...so, that answers my next question. Other than in your affidavit, did you provide any advice, comments, or recommendations related to the religious gathering restrictions that are in place...that were in place in Ontario during the pandemic?

A. No.

6. Q. All right, thank you. Let's start with a little bit of background on the nature of COVID-19. I understand that there is a distinction to be made between the virus and the disease that it causes. Am I correct to understand that SARS-CoV-2 is the name of the virus, and COVID is the name of the disease...the name given to the disease caused by the SARS-CoV-2 infection?

A. I think that would be an accurate

representation of common use, yes.

7. Q. So, the term "COVID-19" means a SARS-CoV-2 infection, essentially?

A. Generally, although, for practical purposes, it usually means a person with that infection, in the sense of having symptoms or having a risk of spreading it to others.

8. Q. Right, which brings me to the next question. A person whose SARS-CoV-2 infection is completely asymptomatic throughout its course, would that person be, nonetheless, considered to have COVID-19?

A. That is an open question. If they were tested, and they had a positive test, then they would be counted as a COVID-19 case, regardless of their symptoms. If they never sought testing, they would have...not show up in the statistics, in the data.

9. Q. I understand that viruses are fragments of genetic material, DNA or RNA, which are able to replicate themselves by infecting the cells of a host organism; is that accurate?

A. I think the viruses would argue they are not so much fragments, because they are intact organisms, but I am not here to represent the virus,

so...

10. Q. Right, fair enough.

A. ...if we think of it as a viral genome could be DNA or RNA, and contains all of the equipment, for lack of a better term, that a virus needs to replicate, typically, in the case of our conversation today, in a human host.

11. Q. So, what would the...if "fragment" isn't the right word, what is the right word to refer to, like, a single virus? "A virus"?

A. They are a viral particle.

12. Q. A viral particle, all right. And a virus is simply a collection of genetic code, which can't really be said to be alive; is that correct?

A. I think it's...it's dangerous to generalize across all viruses. There are literally, probably thousands of millions of viruses, some of which we have characterized, some of which we haven't. Viruses typically exist in relationship to a host, so they cannot survive...and that could be a human, it could be another...it could be a bacteria, it could be a tree, and they typically cannot survive for long periods of time without connection to that host.

13. Q. A viral particle can be damaged or

degraded, to the point where it is no longer capable of reproducing itself or infecting a host; is that correct?

A. You are asking me questions about virology, which is not my area of expertise. I would say that I am reasonably confident there are some viruses that proceed as you describe. I don't think that it would be...the science would not support a general statement about all viruses.

14. Q. Right. Well, in particular, the SARS-CoV-2 virus, it's possible to damage or degrade it, to the point where it is no longer capable of infecting an individual; is that correct?

A. Sure. I mean, if I cough into my hand, and then wash my hands, the virus particles that I coughed into my hand are generally rendered ineffective in infecting subsequent humans.

15. Q. Would it be fair to call such a damaged virus, damaged and non-infectious virus, a dead or inactive virus, and an infection virus, an active virus?

A. If you wish to classify it that way. I think it...our understanding of the virus is still evolving. And, so, what is not clear is how much damage a single viral particle can sustain before it

is unable to reproduce. It may reproduce at a much lower efficiency than a fully fledged particle, but if it can reproduce at all, and it finds a willing host, it can establish itself, and then, once it gets its mechanics going, I would expect it to be infectious.

16. Q. But I am, essentially, just creating some definitions here, that I am going to use later on. So, I am not looking for a...I don't need to get terribly in-depth about this, but it is possible to deactivate a SARS-CoV-2 virus, for example, by exposure to a sanitizer or a soap or sunlight or ultraviolet radiation, or something like that, to the point where it couldn't infect someone?

A. Yes, I mean, certainly the sanitizers are effective as antiviral agents. They render the virus incapable of reproduction.

17. Q. And they would leave a viral particle that could be called dead, in the sense that I described earlier?

A. That seems reasonable.

18. Q. All right. A person can't become infected by exposure to dead or inactive SARS-CoV-2 virus particles; is that correct?

A. If they are truly dead, dead, dead,

then...the issue is not whether they are dead or alive, it's their reproductive capability. So, if we agree that "dead" is unable to reproduce, then...they also...typically, the virus that is unable to reproduce, can't establish infection, because it can't hook onto the host cell and perform the gymnastics it needs to do to insert its genetic material into the host to begin the reproduction. So, think of...viruses are basically lazy. They have a genome, DNA or RNA, typically, and they use the host to make multiple copies. When those copies reach a certain point, the host cell typically explodes, and seeds virus. So, you have this phenomenon where the viral particle needs to both adhere to the host and have its own machinery to insert its genetic material into the host cell.

19. Q. Right. And in the event that an individual, a human, comes in contact with a dead or inactived SARS-CoV-2 virus particle, that human could not become infected by the virus?

A. As far as we know, yes.

20. Q. Right. So, a quick bit of background on the immune system, as well. I understand that antibodies are one of the most important lines of defence. We develop antibodies

to viruses and bacteria that our bodies have been exposed to in the past; is that generally correct?

A. I think that may be overly simplistic. The body's immune system, for simple human minds, is divided roughly into antibody mediated immunity and humoral mediated immunity. There is relatively few situations where the human host would defeat an invader, bacterial, viral, or parasitic, using only one of those sets of immune defences.

21. Q. All right, and, as far as a definition for infection, if a person is exposed to a virus, but that virus is killed by an immune process like the ones you have described, before it can reproduce, would that person be considered to have been infected?

A. No, I think that's...that's a question that's...if you ask six people, you will get 12 different opinions.

22. Q. Right.

A. And I think it depends on perspective. So, if we talk about, for example, tuberculosis, different...different organism, but we have clear...we have hundreds, if not decades, if not hundreds of years of understanding of TB and, in

the case of TB, individuals can be infected, they can have...they can never develop symptoms, and they can never transmit to somebody else. There is some suggestion that, with other organisms, you can be infected, transmitted to somebody else, but never get symptoms yourself. With COVID-19, it would seem that we have some people who are infected, transmitted to other people, and they themselves get symptoms, and some people where that doesn't seem to happen. And, depending on the population and how that is measured, there has been a range of estimates about what those proportions are, as I think one of your experts cited in their affidavit.

23. Q. Right. If an individual is exposed to, let's say, just for the sake of argument, a single virus particle, and that particle enters their respiratory system through their nose, something like that, and their immune system is able to deactivate, or kill the virus before it is able to attach to a cell and reproduce, first of all, is it possible for the immune system to kill a viral particle in that way?

A. I am afraid that is out of my area of expertise.

24. Q. Right, okay, fair enough. Thank

you. All right. At a number of points in your affidavit, including when you site various COVID-related statistics, you refer to numbers of cases of COVID-19, or numbers of people diagnosed with COVID-19. I would like to understand a bit more about what the terms "case" and "diagnosis" means. First, by "case", I imagine you mean confirmed case, rather than probable case; is that correct?

A. I would say, since probably May or June of 2020, that's reasonable. There was an early phase where access to testing was limited, and so there were clinical syndromic definitions used to define people as "probably cases". But, at this point, widespread testing availability means that caseness means you have a positive COVID test.

25. Q. So, a person with a case of COVID-19 has received a positive test for COVID-19 and, therefore, has been diagnosed with COVID-19?

A. So, I would say up until the point you said "diagnosed", yes, then there are certainly people out there who have...they would count in the case statistics, but they would never seek healthcare. So, they would...we can split hairs about whether diagnosis is a reserved act for

healthcare professionals or is done through testing. I think that the use of the term "case" is probably the safest one, in the sense of it is broadly agreeable that those are persons who have had a COVID positive...a test for COVID that was positive. Their motivations for testing mean that some of those people have symptoms, some don't have symptoms. Of those who don't have symptoms, some will develop them, some never will.

26. Q. Right. So, a positive test result...and when we say "test", we are typically referring to a PCR test; is that correct?

A. In Ontario, yes.

27. Q. A positive test result is required in order to diagnose a person with COVID-19 in Ontario?

A. I mean, I think, again, if we, sort of, move forward, past the first wave, that is a reasonable statement. If we take the totality of the pandemic experience, there certainly was a time when people were being clinically diagnosed with COVID-19, in the absence of test results.

28. Q. And, after that date in, what was it, May and June 2020, or after that early time frame, a positive result on a PCR test is sufficient

to diagnose a person with COVID-19 in Ontario. In other words, there are no other diagnostic criteria that must be met in order for a patient to be counted as a case of COVID-19?

A. Well, perhaps I wasn't clear about diagnosis versus caseness.

29. Q. Right, sorry.

30. Q. So, if you have a positive test...let's say you and I, we go to an assessment centre, bingo, we got positive tests, those results will be counted in the testing results for today, and published by Public Health Ontario. If we have no symptoms and/or we never seek healthcare, whether we are diagnosed or not, we are counted as a case and, depending on where it happens in Ontario, the local public health unit may or may not follow up to find out, "Do you have symptoms? Where were you exposed?", all those other questions. I think, in a clinical context, when people show up in the emergency department really short of breath, like, in the last week, and they are unvaccinated, and we test them, and they have a positive test, we also diagnose them with COVID-19 pneumonia, in this case.

31. Q. So, in short, I guess, a positive PCR test is sufficient to be counted amongst the

cases of COVID-19 but, to be diagnosed with COVID-19, they would have to visit a doctor?

A. I think that is a reasonable way to frame it. And, from a public health perspective, being a case, when it comes to an infection like COVID-19, is the basis for counting and decision-making, and all that follows. There are other respiratory infections, for example tuberculosis, where that would be quite different. So, it is important, perhaps, to specify that, with regard to COVID-19, a positive PCR test means that you are now considered a case, and you would show up in the daily case count.

32. Q. Right. So, we have talked a bit about PCR tests. I understand that PCR tests are conducted by taking a sample from a patient, typically from inside of their nose, and a positive result is returned if one or more SARS-CoV-2 virus particles are found in that sample; is that correct?

A. It's actually not looking for the particle. It is looking for a specific gene, or genetic sequence, that is found in intact virus. So, if you are familiar with the PCR testing, think of it as there are primers that are specific to the virus, they get mixed with the sample, there is a

series of amplifications, and then they look to see if those primers found their genetic counterparts. And the primers are not actually sequences, but they are the antisense sequence for what is in the viral genome.

33. Q. All right. So, we discussed the concept of a dead, or inactive, virus, that is to say a virus that has been damaged or degraded in such a way that it can no longer infect a host. If a dead virus particle is found in a PCR test sample, or if the genetic sequence is matched, the PCR test will return a positive result; correct?

A. Yes.

34. Q. And it is possible...when you say "intact virus"...you mentioned "intact virus" a moment ago. What does that mean?

A. So, the...I don't have the numbers at my fingertips, but the genetic material of the SARS-CoV-2 is some hundreds of amino...nucleic acids. And, so, an intact virus is one that has the complete set, and is more likely to be alive. To be alive, you have to have the complete set. You could be a dead virus and have the complete set, but much less likely, because the viral particle itself begins to degrade quite quickly.

35. Q. So, in short, if a dead virus particle is found in a PCR test sample, the PCR test will return a positive result, and the test can't distinguish between an infectious and non-infectious virus particle?

A. I mean, it doesn't distinguish in a, sort of, thumbs up/thumbs down way. The cycle thresholds have been used, which is the number of amplification cycles to distinguish between more likely live virus and more likely dead virus, with a higher cycle threshold number being used to be, "That's more likely dead virus".

36. Q. Right. The CT...was it a CT threshold you mentioned?

A. Yes.

37. Q. The CT threshold used in Ontario, is that standard across the province, for all PCR tests?

A. That is out of my area of expertise.

38. Q. All right.

A. My understanding is that Public Health Ontario has established expectations for laboratories that do COVID-19 testing and, in most cases, the appropriate way to do the test is fairly closely specified, so that if you test in North Bay,

and you have a biological condition of infection, you should get the same result as if you test in Windsor or Kingston.

39. Q. Right, but it is not unheard of for a PCR test in Ontario to return a positive result, when the virus particle that was located was, in fact, a dead virus particle, and not infectious?

A. I don't know what the frequency of those events are, but the way the test is designed, that is going to happen at some non-zero rate, yes.

40. Q. So, some...

A. And we see that with recovering patients, where they will have positive tests after their symptoms have resolved, and even after most experts would say they are no longer capable of transmitting infection, and we assume that is...or we understand that to be left over dead virus that the body is just getting around to cleaning up.

41. Q. So, in some cases, PCR test results are a false positive?

A. I think that it's probably...from my perspective, they are less false positives than they are...they have limitations. And, so... notwithstanding the esteemed efforts of the media to keep us up-to-date about how many hundred cases

there are every day. I mean, one of the things that, in practice, became a driver of Ontario's policy-making was hospitalizations. And, so, we can all...we could spend the rest of our time together, and months, haggling over the merits of PCR testing and what the rate of false...so-called false positives is, but I think relatively few people would haggle over the fact that a patient in a bed needs care, and all that follows from that. So, you know, if you think of it as there is a large number of people who are infected, some of them get tested, some of them have positive tests. From a health system point of view, we can use that to predict the expected number of hospitalizations, but it is actually the sick people who are driving many of the choices, and the goal of limiting the number of people who are sick, so that harms to them are reduced, and also that the health system doesn't fall off a cliff.

42. Q. Right. I think we can move forward, if we can agree to the proposition that some PCR test results are false positives.

A. So, I would say that, from my perspective, there are limitations of the test. And, so, from a policy-making framework, we want a

test that probably overcalls the positive slightly, rather than undercalls. If you wish to call them "false positives", I am not going to fight with you about it, but I think the presence...we can't know, at the point of testing, if this is dead virus or a live virus, and we also...there is an evolving understanding around how much...how dead the virus has to be, such that it is incapable of transmission to another host. So, there is certainly some unsettled science there, but, for practical purposes, why don't we agree to agree.

43. Q. And maybe I will just put it a slightly different way, that is maybe a little less controversial. It is possible for a person who was never infected with the SARS-CoV-2 virus to have a PCR test, and have that test return a positive result?

A. Oh, you have actually gone a completely different place. So, if I am never infected, if I understand your line of logic, then, by definition, I never had any SARS-CoV-2, so I can't have a positive test. It's much...the scenario that we were initially discussing was the virus is...it's living in my throat, but it's dead, it's not capable of making me sick or making anybody

else sick.

44. Q. But if a viral particle was introduced that was already dead, as we have defined that earlier on, like, say I, you know, inhaled a particle that, you know, for whatever reason, has been in the air too long and became inactive, or, you know, for whatever reason, is no longer infectious, that particle lodges in my nose, and a PCR test sample is taken that captures that individual piece of inactivated virus, the PCR test could return positive, despite the fact that I was never infected, and could not have been infected, because that viral particle was never active at the time when it was in my system; would you agree with that?

A. So, I think what I would say is that the probability, or likelihood of the scenario you describe, I cannot confidently say it is zero, but it is somewhere down there with getting struck by lightening three times in a week, or perhaps the Toronto Maple Leafs winning the Stanley Cup, I don't know. Because the amount of virus that is present, if it is a single viral particle, the probability of it being viable long enough between when it entered your nose and got on the swab and got to the lab, I

mean, we are talking about very low likelihood events that are multiplied together. So, I think the presence of virus in a human host is likely to be enough to yield a positive test. Some human hosts will have virus that is dead because they had an infection, they've cleared it, and they still have virus, and I am willing to concede that a small number of humans may have, in a very, sort of, simultaneous way, collected some dead virus, and it is hanging about long enough to get into the PCR test, but that is exceptionally rare.

45. Q. Fair enough. I think we can call that a day on the PCR aspect of things. So, when a person who has been diagnosed with an active case of COVID-19 dies, that...in other words, they have a positive PCR test result, and their case of COVID-19 isn't considered resolved, that death is recorded by the Province as a COVID-19 death; is that correct?

A. I mean, the coding of deaths is not so much by the Province. There is a series of steps that happens. So, typically, the attending physician would complete a death certificate. The fact of a COVID-19 infection may or may not be noted there. If the coroner is involved, there is typically a more complex death investigation, and

the writing on the death certificate may change. But, even before COVID-19, I mean, physicians, unfortunately, are notorious for screwing up death certificates, because there is typically an immediate cause, which is due to an antecedent cause, and then there are contributory causes. So, when we say it is attributed, there is an important, albeit, sort of, hair splitting thing about it, is it the immediate cause? Is it an antecedent cause, or is it a contributing cause.

46. Q. And for deaths that the Province reports, COVID-19 deaths, in every case, are those the...sorry, can you repeat the types of causes of death?

A. So, my recollection is that it's intermediate...sorry, immediate, antecedent, and contributing.

47. Q. So, is there a requirement in order for it to be recorded as a COVID-19 death for it to be the immediate cause of death?

A. I think the first requirement is it has to be recorded somewhere, and then I would have to defer to somebody with more knowledge of the death registration system. In clinical practice, the general tendency would be, if you were diagnosed

with a COVID-19 infection, admitted to hospital because you couldn't breath, and died on a ventilator, you died of COVID-19. If you had a hip fracture and, in the course of your pre-op workup, were found to be infected with COVID-19, and rolled off the operating table and died, I think it would depend on how the particular physician coded the death.

48. Q. All right. So, could you briefly explain what the term "infection fatality rate" means in the context of a disease like COVID-19?

A. I think it means different things to different people, and that's part of the challenge we are facing with this particular infection. So, the...it is a numerator, which would be the number of deaths over a denominator, which is typically the number of persons with infection. And, so, the fatalities, notwithstanding the conversation we just had, can be counted. The number of infections is much more challenging to count.

49. Q. Right. So, at paragraph 11 of your affidavit...and I will give you a moment to turn to that now. It is on page 5.

A. M'hmm.

50. Q. So, I believe it's the second

sentence reads:

"...Based on Ontario's COVID-19 experience, 5 percent of people with COVID-19 will require..."

I am sorry, I jumped to the wrong one. We are coming back to that one later. I will take you to the top of page 6. I am sorry about that. A little spoiler for where we are going next.

A. All right.

51. Q. So, still in paragraph 11, at the top of page 6 you say:

"...As of June 24, 2021, in Ontario, 543,571 people have been diagnosed with COVID-19, and 9,101, approximately 1.7 percent, have died..."

Do you see where you wrote that?

A. Yes, yes.

52. Q. In order to calculate that 1.7 percent number, you divided the number of confirmed cases of COVID in Ontario by the number of recorded COVID deaths in the province; is that correct?

A. Yes.

53. Q. That calculation is not an accurate method of determining the infection fatality rate of the virus, is it?

A. I think it is a practical...if you think of it as...the true IFR was probably not able to be known for a virus that is as ubiquitous as COVID-19, so we want to establish bounds, or a range within which it falls. So the number of cases that, in this case, are diagnosed in Ontario, and the number of deaths, is one part of establishing that range and, in this case, it's 1.7 percent, and...

54. Q. And if this number is part of a range, it's likely to be at the high end of the range?

A. So, I think that you are right, inasmuch as more people will have COVID-19 infection and not be diagnosed than will die of COVID-19 and not be found, but there is probably some variability in both numbers, a little bit more in the denominator, as you point out.

55. Q. Right. The true infection fatality rate of COVID-19 is much lower than 1.7 percent, isn't it?

A. What do you mean by "true"?

56. Q. Well, the actual number that is given, or the actual percentage that is given by taking the number of people who are actually infected, or have actually been infected with COVID-

19, and dividing that by the number of people who have actually died from COVID-19.

A. So, I think I would agree with you, it's less than 1.7 percent. I don't know whether it's 1.2, 0.8. And what we can reasonably say is that, if we apply a similar approach to other infectious diseases, we can establish a sense of how does this compare to other infectious diseases with which we are more familiar.

57. Q. Right. So, I am going to be going over some ground that you have already touched on, but just for the interest of setting down a record that I can take a succinct quote from, your calculation is based on the assumption that Ontario's cumulative case count was 543,571, as of June 24, 2021, but that number represents only confirmed cases, in other words, cases which had been confirmed by testing; wouldn't you agree with that?

A. Yes this is...so, this is persons with a positive test.

58. Q. And the actual number of cases in the general population was much higher, wasn't it?

A. I don't know what you mean by "much". So, it was...it was definitely higher, but

whether that is 5 percent, 10 percent, 50 percent, I think is open to conjecture.

59. Q. In your opinion, is it likely to be 5 percent?

A. I think it is more likely to be 5 to 10 percent than to be 50 to 100 percent.

60. Q. There is an inherent sampling bias in the cohorts of people who wind up having PCR tests done, isn't there?

A. Tell me more.

61. Q. In the sense that high risk populations, people who are experiencing severe symptoms, people who are, you know, concerned about their health, for one reason or another, but those people are going to be over-represented because they are going to be more likely to want to be tested; wouldn't you agree with that?

A. I mean, I think that that's...it's an open question, because we, as a society, haven't mandated testing. What is pretty clear is that there are people with clinical COVID illness who avoided going for testing, because they didn't want to know or because they were worried they couldn't go to work, and we know there are people with no evidence of COVID illness, certainly in the summer

of 2020, who were getting tested every week so they could go to cottages with different groups of friends. So, I think it...you know, the challenge with any sort of testing-based data is, unless testing is mandated, there will always be what you would call sampling bias, or what your expert is calling, perhaps, sampling bias. But the more important question is what is the likely magnitude of the bias in relation to the signal we have, and which direction do reasonable people think it would tend? And I think, in the case of COVID testing, we can make, particularly after the first wave, we can make an argument in both directions, that we had people who were sick, who were not getting tested, and we had people who were definitely not sick, who were getting a lot of tests.

62. Q. Would you agree that most asymptomatic cases would have gone undiagnosed? That is to say that most people infected with COVID-19, but who experienced no symptoms whatsoever, would you say that the majority of those people wouldn't have gone and been tested?

A. I don't know. I don't have any basis for having that...giving you a number on that.

63. Q. Right. But, in any event, the

Province's cumulative case count underestimates the actual number of cases?

A. So, I think it underestimates the actual number of people with symptomatic COVID-19 infection, and it probably does that less so than its underestimate of the total number of people who were infected, because, as you mentioned, there is some number unknown, the persons who get infected and never develop symptoms, so they would have no reason...they would have no way of knowing they had COVID-19, and they would have no particular motivation to be tested, unless their employer required serial testing.

64. Q. So, again, at paragraph 11, you note that the number of cumulative cases of COVID-19 in Ontario is likely higher than the number of recorded cases, since some individuals who acquire COVID-19 are not tested and diagnosed. You offered a few percentage ranges earlier on, but, based on your experience, can you give me an idea of what percentage, or approximately what percentage, or what range of percentages of, unrecorded cases would there be, you know, relative to the number of cases that have been recorded through PCR tests?

A. I mean, I think that I would be...I

would be guessing much the way you would, it's just I would guess as a physician and you would guess as a lawyer.

65. Q. Right.

A. I think, if we think of...one of the ways of, sort of, trying to narrow uncertainty in statistics is are we talking about 1 percent range, 10 percent, or 100 percent? I would propose that the 10 percent space is the most likely of those three. It's not a little bit. It's not, like, we missed the forest for a tree. But the...there are...other jurisdictions have made efforts to try to narrow that range using seroprevalence surveys. And certainly, when Ontario was doing that sort of work, we were not seeing evidence of widespread undetected infection. I believe that work came to an end in September 2020. So, I don't know what, if any, of that has continued.

66. Q. So, just to step back to the numbers there, for a second. When you say 10 percent may have gone undetected, that seems like a reasonable range to you? In other words, 90 percent of cases, of active cases of COVID, would have been detected by PCR testing, in Ontario?

A. I think that probably, based on what

I think clinically and what I saw as a public health person, most people who had COVID-19 were getting tested. They wanted to protect themselves, they wanted to protect others, they were directed by their employer, they were terrified of what they had heard about COVID.

67. Q. Right. So, if we are looking at a total of...sorry, whatever it was...550,000, essentially, cumulative cases of COVID, as of June 24, if...so, that would represent, in your estimation, 90 percent of the cases that had...to date, in Ontario, in total, including...or 90 percent of the total number of infections in Ontario, since the beginning of the pandemic?

A. Yes, so, if we go back to June, at that time, we had 543,000 cases, I would expect the true number of cases, if there were some higher force that could reveal that, to be somewhere around that, plus 10 percent. So, probably around 600,000.

68. Q. I am actually surprised that the number would be so high. So, when I see a case count, a daily case count, like, does that percentage carry over from the cumulative case count to the daily case counts that we see? So, in other words, if today there were 90 new COVID cases, you

would say that there would be another 10 that were undetected, and that would be a relatively reasonable estimate of how many total cases there were in the population?

A. I would actually add a caveat, because COVID now is very different from COVID even in June, and COVID in 2020. So, if we look at the COVID now, what we are seeing is high rates of cases among unvaccinated persons and, for many unvaccinated persons, they are unlikely to seek testing for COVID if they are of the view that COVID doesn't exist or COVID is fake news. So, there is also a regional and a rural/urban divide. Last night, I worked up in Markdale and, if you want a COVID test in Markdale, you have got to drive up to Owen Sound to get it, whereas, in Toronto, where I live, I mean, I could probably walk five minutes and have a couple of choices of how to get a COVID test. So, there is a lot of challenging to quantify factors that are going to affect that daily count. I think, from a practical...like, in the practice that I do as a public health physician point of view, we try to both acknowledge those, but also recognize that, if they are unmeasurable, we don't have the luxury of wringing our hands for six

months, trying to figure out how to measure them. We need to act based on the best information that is available.

69. Q. Right, but that best information would include, you know, models and estimates based on your experience and the experience of the people you are working with. You know, you are not going into this without even considering the prevalence of COVID in the general population, I imagine?

A. I mean, I think it...it probably turns on the specific question that is at hand. So, that undetected COVID burden is less important, provincially, if you are sitting...managing something for the Province than if you are in a particular region of Ontario with limited access to testing, as an example. So, it is probably important to be a little more specific about the decision and the geographic scope that is at state, because that is going to drive the...both the accuracy of the available information and how much energy people are going to put into making it more accurate or more complete.

70. Q. Right. Just...we are getting a little bit afield here, since, you know, we are talking about today rather than June 24, but this is

a bit of a matter of personal curiosity, so I am going to take advantage. How much do you think...you mentioned a few factors that would change your estimate of the percentage of undetected cases in the population, such as unvaccinated people being less likely to seek testing, for example, things like having to travel further for a COVID test, that sort of thing...if the number was...and again, I am not, you know, holding you to a specific number here, but if your estimate would have been 90 percent in June, how much would that have changed today?

A. You know, I think it depends on where you are sitting in the COVID pipeline. So, if I wear my emergency medicine hat, I've referred, I don't know, half a dozen patients for admission for COVID over the last month, not a single one of them had a positive test. So, their positive test is going to arrive when we do it in the emergency department and say, "Oh, yes, you clinically have COVID and, bingo, you have a positive test, and you were not vaccinated". So, from the hospital sector perspective, it's probably higher. The good news has been that the total number of people showing up who need a bed because of COVID has gone down

dramatically, to date, because of immunization.

I think, at a population level, you know, a number of people have attempted to use test positivity as a way to look for signal changes, in terms of which way is the case count moving, the thinking being that, as positivity goes up...I mean, it is kind of obvious, but it's worth saying anyway...as positivity goes up, all things being equal, that means there is more people with COVID walking around there, in whatever community that positivity is measured, and also that it may represent people coming in to testing, because there is a heightened level of concern. And that is probably a bit of wishful thinking and, to some degree, has been shown with other infectious diseases that as, sort of, the temperature goes up, people start to pay more attention. Some people pay attention when the temperature is very low, and then there is a, sort of, population gradient, and then we have some people who pay no attention at any time.

71. Q. All right. So, we were talking about infection fatality rates earlier, and your calculation that resulted in a 1.7 percent death rate. We discussed...we agreed that the actual

infection fatality rate, taking into account all cases in the general population, would be lower by some amount than 1.7 percent. That would be the fatality rate across the entire population, not accounting for age; is that correct?

A. Yes, this is what's called a crude rate. So, it's just the total number of deaths divided by the total number of cases.

72. Q. If we divide up the infection fatality rate by age cohort, isn't it true that, for people under the age of 65, the infection fatality rate for COVID-19 is quite significantly lower than 1.7 percent?

A. Yes, because we've had deaths clustered among the elderly.

73. Q. Right.

A. Which happens with virtually every cause of death, unfortunately.

74. Q. Sure. COVID's age distribution for death skews quite old though, doesn't it? Like, I mean, relative to other diseases?

A. Well, certainly compared to, say, HIV/AIDS, yes, but if you look at infectious disease, in general, if we exclude the childhood infectious diseases, which have, essentially, been

eliminated in Canada. We see a similar pattern with influenza. And, in fact, my understanding is that, in Canada, the death rates for COVID are much much higher than those for influenza in that, sort of, midlife age range of, sort of, 40 to 70, and then, in the 70 and over, influenza and COVID start to converge.

75. Q. All right. I would like to show you a document that I have sent to my friend, Mr. Hunter, to pass along to you. Could you pass that along to Dr. Hodge, please?

MR. HUNTER: We did.

BY MR. KITTREDGE:

76. Q. Great. That document is a PDF, and it's called, "Benatia et al, Estimates of COVID-19 Cases". Could you open that document and take a look at it?

A. Sure.

77. Q. And are you looking at it now?

A. Yes, it's just opening up.

78. Q. Sure.

A. Okay.

79. Q. Are you familiar with this document?

A. No.

80. Q. Can you describe what it appears to be to you?

A. It looks like either a preprint or a reprint of a journal article from Canadian Public Policy.

81. MR. KITTREDGE: Right. I would like to mark this document as Exhibit A to the cross-examination, and we can call it, let's say, estimates of COVID-19 cases across four Canadian provinces.

--- EXHIBIT A: Estimates of COVID-19 cases across four Canadian provinces

BY MR. KITTREDGE:

82. Q. And I am just going to very briefly direct your attention to page 2. The right-hand column, in the second paragraph. The first sentence of that paragraph reads:

"...Our results also suggest widespread undetected COVID-19 infection across Canadian provinces. We calculate that, for every diagnosed case, there were 12 population infections in mid-April..."

And this is referring to mid-April of 2020:

"...The ratio of population infection to diagnosis ranges from 8.6 in British Columbia to 14.8 in Ontario..."

Again, this refers to the period very early in the pandemic, in March and April of 2020. Do those ratios seem reasonable to you?

A. You know, I would need to review the...this is a modelling study, so it could be garbage in/garbage out. I can't give you an honest...an appropriate response, just being asked a question out of the blue.

83. Q. Right.

A. But I do note that these numbers would be not at all consistent with seroprevalence surveys that were done in Ontario, and...so that most public health people, rather than economists, would argue that that is a more accurate assessment. And, so, that's where people giving blood or getting tests for other medical conditions, their blood gets checked for antibodies to SARS-CoV-2.

84. Q. All right. So, would you estimate that the ratio of cases, COVID cases counted in this early period of the pandemic, to cases of COVID in the general population that were not counted, would remain something in the neighborhood of 90 percent

were detected and counted, and 10 percent went undetected and uncounted, or would that ratio be different at this point in the pandemic?

A. I mean, I think the...my way of thinking of it...and I am not an economist, so if I were asking questions about how to invest my savings or how to build an economy, I might ask an economist, but, as an epidemiologist, the event of hospitalization represents something by which there is relatively little debate. And, so, when I look at the proportion of persons...or proportion of COVID-19 cases that are hospitalized, that reaches a steady state, essentially, from the fall of 2020, over the last 12 months. And, so, I think that is a reasonable basis for saying that we are capturing a reasonably stable proportion of all COVID infections through testing.

85. Q. All right, can you please turn to the spoiler, page 5 of your affidavit, paragraph 11, again? Let me know when you are there.

A. Sure. Yes, I am there now.

86. Q. Great. So, once again, the second sentence here reads:

"...Based on Ontario's COVID-19 experience, 5 percent of people with COVID-19 will

require hospital-based care..."

Do you see where you wrote that?

A. Yes.

87. Q. That is not a true statement, is it?

A. That's quite a leading question, so maybe you could expand it a little for me.

88. Q. I am here to ask leading questions in the cross-examination. Well, that percentage, that 5 percent percentage was obtained by taking the total number of confirmed cases and dividing by the number of COVID hospitalizations; isn't it?

A. That's right.

89. Q. So, even if you take your estimate that...the number of confirmed cases...let me just do this calculation.

A. I think I can help you here. If I see where you are going, you want to add 10 percent to the case count...

90. Q. I do.

A. ...you get 600,000...

91. Q. And I want to see...

A. ...and you divide by the number of hospitalizations, it drops to, like, 4.7, 4.5.

92. Q. Fair enough. So, it is not precisely a true statement?

A. I think if it...it's not a matter of it's truth or not. It is a matter of, based on limitations of the data, that's where we end up.

93. Q. Right, but we know...

A. When we acknowledge those limitations, we can revise our estimate, but we are not moving from 5 percent to 1 percent, and we are not moving from 5 percent to 50 percent; right?

94. Q. But in the event that, you know, the actual number of undetected cases was something closer to 20 percent, the error in this would be more significant, obviously; would you agree?

A. Well, that is just arithmetic, but I haven't seen any basis to make it...to have a stronger argument for it to be 20 percent than roughly 10 percent.

95. Q. All right. At paragraph 28 of your affidavit...and I will give you a moment to turn there.

A. M'hmm. On page 13?

96. Q. Yes, I believe so. Yes. You note that:

"...By mid-June of 2021, 59 COVID outbreaks had been associated with places of worship, with 526 associated cases of COVID..."

Is that correct?

A. Yes.

97. Q. And Ontario's total case count, as of June 24, was 543,571, give or take 10 percent, according to your paragraph 12; is that correct?

A. M'hmm.

98. Q. So, slightly less than one in every 1,000 cases was associated with an outbreak at a place of worship; is that about right?

A. Well, in the available data, those associations were made for, yes, on the order of 1 in 1,000 cases, and then there is some notes that go with this, from Public Health Ontario, about the fact that they may not be able to associate all cases with any transmission event, and that, with any given outbreak, there may be...there is expected to be an undercounting of associated cases.

99. Q. Using your estimate that 5 percent of people infected with COVID will require hospitalization, which we have already established is somewhat low...or somewhat high, I am sorry, of those 526 associated with places of worship, perhaps 21 may require hospitalization; is that about right?

A. Well, that is arithmetic, but the good new is that, because of temporary restrictions

on attendance at places of worship, the number of outbreaks was substantially lower than it would have otherwise been. So, yes, there is a small number of people...small number of cases associated with outbreaks, but these outbreaks are all happening when attendance at religious gatherings has been limited by the public health measures that were put in place.

100. Q. Right, so, I am just going to ask the question again, and hope for a yes or no answer. Using your estimate that 5 percent of people infected with COVID will require hospitalization, which we have already established is somewhat high, of those 526 cases associated with places of worship, perhaps 21 might require hospitalization; would you say that is generally correct?

A. I agree with your arithmetic, yes.

101. Q. Thank you. Was there ever a time during the pandemic when an additional 21 cases requiring hospitalization would have overwhelmed the healthcare system?

A. Certainly if they were all in the same community they would have. There is no question about that. Let's imagine that that community, somewhere like St. Thomas, has a hospital

that has maybe 12 ICU beds. I mean, I think it's...part of the challenge, provincially, is that Ontario is a province of many provinces, if you think of it. You know, the thing that holds Canada together is people hate having to spend two days just to drive through Ontario to get on their cross-Canada trip. So, in a large centre like Toronto, there is much more healthcare capacity, in a smaller centre, like St. Thomas, much less. And the COVID infections have not been randomly, or uniformly distributed across the population. I think, in some ways, your focus on the 526 misses the point that substantial numbers of outbreaks were likely prevented by the limits that your clients are objecting to.

102. Q. Well, I mean...

MR. GUTTMAN: Mr. Kittredge, just for the record, I want to just correct the math. 5 percent of 526 is 26; is that what you were trying to say?

103. MR. KITTREDGE: Perhaps it was.

MR. GUTTMAN: You used the figure "21", and it should be 26.

THE DEPONENT: I will leave the arithmetic to the lawyers, and I will agree

with what you all settle on.

104. MR. KITTREDGE: All right, yes, I will agree with that. It was 26, so you are absolutely right. My apologies.

BY MR. KITTREDGE:

105. Q. So, you say, yourself, elsewhere in your affidavit, that due to Ontario's limitations, in terms of hospital capacity, much of Ontario's response included transferring patients between hospitals, as a matter of course, in order to move patients to hospitals with adequate capacity to handle them; isn't that correct?

A. There were movements of patients from heavily affected COVID hospitals to less affected COVID hospitals. There was also an almost complete cancellation of virtually every diagnostic and surgical procedure in order to accomplish that.

106. Q. Right, but the 26 cases that we were discussing, that might require hospitalization, it wouldn't have been impossible to accommodate 26 people, moving them around the province, and not all of these patients would be requiring, you know, ICU beds, or anything like that; wouldn't you agree with that?

A. I mean, I don't accept your initial premise that 500 cases is the basis for a planning process around outbreaks in places of worship. I would say that, if you look in the news, I believe, last week, the Sault area hospital was looking to transfer out patients because they were overwhelmed, and they had on the order of 20 COVID patients, and that is a fairly large sized hospital. It is an important regional centre. So, small numbers of patients can make a huge difference, particularly if hospitals are already full of patients with all the other reasons that people go to hospital, heart attacks, hip fractures, strokes.

107. Q. Right. Would you say that, at any point during the pandemic, Ontario's healthcare system lacked the capacity to accommodate an additional 26 patients?

A. You know, I don't have the visibility into Ontario's healthcare system. I can tell you that individual institutions certainly did. I can say that I think there is pretty clear evidence that it was incredibly disruptive for families to be told, "Oh, your sick uncle, father, or brother is being sent to Kingston. If he survives, we will tell you how to go visit him and

pick him up when he is ready to come home".

And I think the other piece which is important to note is that the capacity of the health system is a function of beds and equipment; that's the easy part. The humans to care for those patients is much more challenging. And, so, even if the hospital in Upper Armpit has 10 empty beds, if they've never had a sick COVID patient, it is not clear that their medical and nursing staff are going to be equipped to do what they need to do to take care of those people. So, it is a somewhat more complex question than the way you posed it.

108. Q. Well, I think you are making it more complex, to be fair. I mean, you do discuss, in a number of places in your affidavit, that one of the main concerns that you have, and one of the main justifications for restrictive non-pharmaceutical interventions in response to COVID is a concern that the healthcare system would be overwhelmed, and I am finding myself having a hard time pinning you down on what exactly that means. It seems to me that you should be able to answer the question in a more straightforward manner. Was there ever a point in the pandemic where Ontario's hospitals could not have accommodated 26 more COVID patients?

A. I think that I would say that it's unlikely that that question can be answered definitively, because Ontario's response was marked by a continuous process of adaptation and, essentially, punishing the rest of the population. So, 400,000 cancelled surgeries, 2.5 million postponed diagnostic procedures, like, that's the price of those 26 or 200 more, or whatever the number is, persons with COVID. So, the answer to your question is, "Yes and". Yes, those 26 people would be accommodated, and your uncle, who has a heart attack, "Sorry, he is not going to get anything", or your family member who has been waiting six months for cancer surgery, where that is going to affect their likelihood of survival, "Oh, they are going to wait another three months now". So, you know, it's not without its costs. I think that is...that is perhaps the difference in our perspective.

109. Q. I am going to circle back to that point a little bit later on. There is another point where it may flow with some other questions that I have for you, but I want to move ahead, now, on a few more questions about these outbreaks associated with places of worship. Let me just make a note of

where I am here. All right. So, we were discussing the outbreaks, the 59 COVID outbreaks that were reported as being associated with places of worship, and the 526 associated cases of COVID. Is it fair to assume that these outbreaks did not all occur at the same time?

A. That's right. They were over a period of, at the time this was done, approximately 15 months.

110. Q. At your paragraph 26, and elsewhere in your affidavit, you point out that probability of COVID transmission at a gathering depends on a number of factors, including the number of people attending and the background infection rates in the community; is that a fair summary?

A. Yes.

111. Q. Restrictions on attendance at religious gatherings were at their most restrictive, in other words, capacities were most limited, when background infection rates were at their highest in Ontario; is that accurate?

A. It varies slightly be region, because there was a period when, with the traffic light system, some regions had different restrictions than neighboring regions, but the

10-people limit in place from April through June and, similarly, from December through, generally, the end of February, depending where you were in Ontario, appears to have been the most restrictive, yes.

112. Q. So, those periods of restriction, capacity restriction to 10 people indoors, for example, would have coincided with the periods of time when background infection rates in Ontario were at their highest; would you agree with that?

A. Certainly the case counts in Ontario were at their highest, yes.

113. Q. Okay. And that, according to your estimate earlier on, likely accounts for 90 percent of the cases in the community. So, there would be an extra 10 percent of cases, or something in that neighborhood?

A. Yes, with some variability. Again, as we have discussed, basically, test-seeking behavior, and the people you represent, in one case, certainly are from a region of Ontario with relatively lower rates of testing in the population. So...

114. Q. Right, but, generally speaking...in any event, I have got enough of an answer there.

A. M'hmm.

115. Q. So, therefore, those outbreaks linked to places of worship, which occurred at times when background infection rates were high, would have resulted in fewer cases than at times...than outbreaks at times where the capacity limits were higher and the background infection rates were lower; would you agree with that?

A. I think that's really an "It depends". It would be professional misconduct for me to make such a broad generalization, because the identification of outbreaks in places of worship is not complete, the identification of cases associated with those is not complete, and I don't have the timeline from Public Health Ontario about where and when the outbreaks occurred.

116. Q. So, the average that you have given, the average number of cases per outbreak associated with these outbreaks at religious gatherings is apparently 8.9 cases per outbreak. Would capacity limits...does that number include the patient zero, the first...the person who brought the infection to the gathering?

A. My understanding is, no, it does not. So, those are all persons who were identified

as having had most likely their transmission event, where they received the virus, occur in a place of worship.

117. Q. So, to the extent that any of these outbreaks occurred when capacities were limited to 10 people indoors, would you agree that it is unlikely that each and every one of those would have...in a room full of 10 people, one of whom is patient zero, do you agree that it would be unlikely that, in every single case, that person would infect 8.9 of the remaining people? In other words, all of the remaining people, except for 10 percent, one of them...or, you know, do you agree that it is unlikely that, in a room full of 10 people, the average infection rate, case rate per outbreak, would be 8.9 cases?

A. I mean, in the abstract, you are absolutely correct. I think the important thing to bear in mind here is that we don't have the timeline in front of us. The outbreaks...some of these outbreaks occurred during the time periods of the greatest restrictions in places of worship where those restrictions were, shall we say, not being followed. So, the number 10, if all religious gatherings followed the rules, we could say, yes,

that is an accurate representation. I think that the other piece of it, some public health units had more and less energy to devote to tracking down people who may have attended a religious service, encouraged them to get tested, asked...some...there was variation among the 34 public health units as to the degree to which they even knew they should ask. For example, if you are living in Huron, and you drive to Waterloo to go to church, how do the people in Huron know there was an outbreak in Waterloo that they should ask you about? And then the final piece is that some religious organizations, as a matter of faith-adjacent belief refused to participate in contact tracing, or had very low rates of testing uptake. So, too many, what we would call confounding factors, in our business, whose magnitude is really impossible to estimate.

118. Q. So, where are you getting these numbers? What is the reporting on which you are basing this sentence here, that we are looking at?

A. This is in paragraph 28?

119. Q. Yes, it is.

A. About the number of outbreaks?

120. Q. Yes.

A. These are data that were provided

for the purpose of the affidavit by Public Health Ontario.

121. Q. Right. Is that data attached as an exhibit to your affidavit?

A. I believe it's footnote 30, data summarized by Public Health Ontario. Josh, if you can speak to whether it was...I don't believe it was an attachment explicitly...or there may have been a summary table. I didn't print out all the exhibits, I am afraid, for today's discussion.

122. Q. Since we are...I don't see it as an exhibit, and I am fairly certain it's not in there. I mean, there are many pages of exhibits, and I have been drowning in pages of exhibits over the last little while, but I am fairly certain I didn't see them in there. Assuming they are not, can I get an undertaking to produce that data?

MR. HUNTER: We will take that under advisement. I have to check whether there is any confidentiality concerns with Public Health Ontario.

U/A

123. MR. KITTREDGE: Sure. It just seems we are really getting in the weeds on the details of this, and if we are...you know, if I am to be expected to struggle my way

through that, I think I need the actual data.

MR. HUNTER: To be clear, we will make...advise what data is available to Public Health Ontario. We obviously don't have access to the underlying data that is kept by various public health units in Ontario, who aren't Ontario.

124. MR. KITTREDGE: Right. So, I am looking for the data on which this was based. Yes, okay.

BY MR. KITTREDGE:

125. Q. All right. So, a moment ago, we got in some other weeds while discussing whether an additional 26 patients would have posed a risk of overwhelming the healthcare system at any point during the pandemic. So, I will note, first of all, that you agreed that these outbreaks didn't occur at the same time. And, so, those...you know, if 5 percent of the associated cases required hospitalization, those 26 patients would have been spread across the course of the pandemic, and I would argue...I guess, would you agree with that?

A. Yes, the outbreaks were recorded

between March 2020 and June 18, 2021.

126. Q. Right. So, do you think that there would have been any real risk that spread out over the course of the entire pandemic, those 26 additional patients ran any risk of overwhelming the healthcare system?

A. Well, I would say that the question I think you are trying to ask me is, if there hadn't been the restrictive measures, how many more dozens or hundreds of outbreaks would there have been, and how many more dozens or hundreds of patients would we have had to spread out over the healthcare system?

127. Q. That is not precisely the question I am trying to ask you. I am asking...

A. I am struggling to follow your line of inquiry, so perhaps you could do me the favour of restating it?

128. Q. Sure. So, we have 526 cases associated with places of worship spread out through the course of the entire pandemic. Of those 526 cases, based on your estimate, 5 percent may need hospitalization. So, 21...26 people. And those 26 hospitalizations were spread across the entire course of the pandemic. Did the healthcare system,

at any point during the pandemic, reach a point where it was overwhelmed?

A. I think that it is reasonable to say that individual hospitals, essentially, had their backs to the wall. And, so, in the GTA, for example, mid-November of 2020, there was the overnight standing up of a GTA IMS structure to move patients around, because, certainly in Scarborough, we had a day where every emergency department bed, as I recall, was occupied by a COVID-infected person requiring hospital admission. So, the system...we, as citizens, may often imagine a system that is organized and all the pieces work together, and that is a helpful fiction. In reality, it is, sort of...it's more like baling twine and spit holding it together. So, there was a series of reactions to the evolving need for hospitalizations. The overall goal was to reduce the number of COVID infections in order to prevent the direct harms of COVID, people getting sick, people dying, and to preserve the healthcare system, whether it is your 526 patients you have identified here or a couple of thousand associated with sports practice. The challenge, from a policy framework, is, how do we put in place a set of measures that can be reasonably expected to

save the healthcare system from being pushed off a cliff, and reduce the harms directly to individuals? So, to pick out any one of those measures and say, "Well, what about these 500 people?" That's in the context of all the other 500s or 1,000s that were potentially also going to need care. Or, to flip it around, from a public health perspective, all the, ideally, hundreds to thousands of hospitalizations that we prevented, because Ontarions were willing to do the right thing and generally follow the measures that were put in place.

129. Q. So, a moment ago you used the phrase, "putting measures in place that would keep the healthcare system from being pushed off a cliff". Would you say that the measures put in place did, in fact, keep the healthcare system from being pushed off a cliff, in the manner that you used that phrase?

A. I mean, I think that we didn't end up like New York City, with people dying in the waiting room. So, if we define the cliff edge as people dying in the waiting room, okay, we did all right. The number of nurses who are leaving the practice of nursing in hospitals is staggering, to the point where, currently, where I work, we can't

staff a regular day in the emergency department. So, if we use that as our metric, we screwed up. We pushed too far, or we ran too close to the edge of that metaphorical cliff. I think that probably the millions of people whose diagnostic procedures were delayed, they might have a perspective that is somewhere between those two. I don't know.

I think that the...one of your experts chose a bed count approach to assessing healthcare capacity, and I think that that is table stakes. That's, like grade 4 level. But healthcare is functionally about people who deliver care to other people, and is about systems and processes, and I think we are going to find, in Ontario, we came...if we use New York as the standard, we didn't do as badly as New York, but we came perilously close, and that is a long-term outcome that will...if we are in this conversation in a few years, we will see who turned out to have the best sense of how bad that was.

130. Q. Well, you mentioned the bed count...what was in, a kindergarten approach?

A. Well, I will give him credit, grade 4.

131. Q. Grade 4, okay, fair enough. Well,

let's go through the exercise anyway. So, is it fair to say that Ontario had nearly 25,000 acute care hospital beds as of April 30, 2020?

A. I think that is an overestimate, based on...this was in the affidavit from Dr. Schabas, I believe.

132. Q. Yes, it was, the reply.

A. Point me to that paragraph, just because I have got...

133. Q. It was paragraph 6 in the reply affidavit, sworn on the 23rd.

A. Thank you. I think that, you know, Dr. Schabas' source for this is the government press release, which is perhaps generous of him to give it that much credence. The fundamental problem is the staffing. So, it's not...if you have nothing to do one evening, and you can slink into your local hospital, you will see that there are wards where there are physical beds, there's even linen on the beds, but there are no patients and no staff. And, so, for the purposes of, sort of, planning and thinking about how Ontario is going to navigate this, I think the OECD estimates and the OHA information that I cited in my affidavit are probably a more accurate basis for decision-making.

And, if we take the 1.4 number, we come up with a total that is about slightly shy of 20,000, which is somewhat lower than the one cited by your expert. That is in paragraph 14, page 7 of my affidavit.

134. Q. Okay, paragraph 14, page 7.

A. And part of my rationale for choosing this measure was to highlight why Ontario may have needed to move in a different way than other Canadian provinces or other jurisdictions. And, so, certainly the comparison with Alberta is an apt one, where Alberta's bed per population is approximately the same as the United States, which is almost double what it is in Ontario. So, the planning for best summer ever, I presume, included a recognition that they could tolerate higher levels of COVID than, say, Ontario could. Unfortunately, they may have overestimated.

135. Q. Well, all right. So, at no point in the pandemic have COVID patients occupied 10 percent of that 25,000 number. And let's just use that number, rather than your 20, for the sake of calculating 10 percent. So, at no point have there been more than 2,500 beds occupied by COVID patients in Ontario, have there?

A. That's correct, yes.

136. Q. Thank you. And the maximum count of COVID patients in Ontario was 2,360 on April 20,2021, was it not?

A. I would have to confirm that, but I will accept that as accurate, yes.

137. Q. Sure. And, in light of the COVID-19 pandemic, has the province increased hospital bed capacity since April of 2020?

A. Well, as your expert noted, they have certainly made media releases about announcing new beds. I am not aware that your expert or the government, have figured out how to manufacture nurses. So, there is a certain amount of smoke and mirrors when it comes to healthcare financing and, rather than get distracted by that, I would say that one of the things about...that COVID did for us in the health sector was that, initially, hospitals were emptied out and all procedures were cancelled, because we didn't know what to expect. That was wave one. Were we going to be Italy or were we going to be New York City? And Ontarions pretty much complied with the rules. We were fortunate that didn't happen. And then, people whose care had been delayed started to come to hospital. And, so, the census starts to rise, completely unrelated to

COVID, people who have congestive heart failure, people who have bad diabetes, people who need post-op care after hip fractures. So, the Ontario hospital system, as the OHA has pointed out, has the lowest number of beds in the OECD, which means that adding an additional 10 percent to the number of people who need a bed can be potentially catastrophic, compared to a system that is running along at 75 percent of capacity. Yes, you add another 10 percent, you go up to 85 percent. Ontario is running at, like, 105 percent. And, so, we already filled the cafeteria with people. Where are we going to put these extra people, and where are we going to find staff, even if we can find a place to put them?

138. Q. Okay. At paragraph 7 of your affidavit you state that your, "opinions are informed by, among other things, the challenge of minimizing adverse effects of measures that establish limits on human behavior"; correct?

A. M'hmm.

139. Q. But other than, insofar as you list and reject the intervention alternatives suggested by Dr. Kettner, Dr. Schabas and Dr. Warren, paragraph 7 is really the only time you make any

reference to the challenge of minimizing the impact of public health measures, is it not?

A. In general, yes.

140. Q. In fact, the Province could have implemented less restrictive interventions without significantly compromising the goal of controlling the spread of COVID; wouldn't you agree?

A. I think you'd need to specify what you mean when you say "less restrictive".

141. Q. So, for example, where an outdoor capacity limit was 10 people, it could easily have been 11 people, or 15 people, or 20 people, without bringing the healthcare system to its knees; wouldn't you agree?

A. I think the challenge for any policymaker is there is an arbitrariness to a number, and so a number must be chosen. I don't think that...my role as an expert is not to provide a recommendation as to whether it is 10 or 11. I think that my role is to provide a recommendation based on the burden model, saying, like, this looks like it is a pretty big deal and, therefore, we should consider these types of measures. And then, governments, in the process of iteration and contending perspectives decide how restrictive or

less restrictive they wish those measures to be.

142. Q. Non-pharmaceutical interventions can't be looked at in isolation. It would have been open to the Province to enact a less restrictive religious gathering restriction and make up for the resulting case count impact by imposing tighter restrictions in another sector, would it not?

A. I think you need to help me understand with an example what you have in mind.

143. Q. So, like, for example, if the Province set a capacity limit of 20 people in a religious gathering, and then made an according adjustment that would, you know, have a corresponding impact to, say, retail capacity. For example, they might have reduced capacity in beer stores, liquor stores and cannabis stores to offset the potential increase in cases from a larger religious capacity limit?

A. I mean, certainly, if public health were that simple, I wouldn't have had to spend all the years I did training. I think you are missing key features of religious gatherings that directly drive COVID risks of transmission that are profoundly different from retail establishments, a liquor store or beer store. And there is...

144. Q. Are you saying that there is no amount of...no restriction, no matter how restrictive, on retail, for example, dropping everything to online only and delivery only. You are saying that there is no adjustment that could be made that would make up for the difference in allowing an extra two people or five people or 10 people to attend a religious gathering?

A. I think you are asking me to opine on two, sort of, mixed up matters. So, maybe I can try to disentangle them. The first is, is there a mechanistic way we can say five more people in religious gatherings and X few people in a liquor store? And I would imagine that somebody, mechanistically, could come up with a model for that. There is a practical implementation aspect, which is that the restrictions were, in part, informed by, what is the risk of COVID transmission in a particular setting? And I would propose that, with regard to religious gatherings, despite there being higher risks than liquor stores or beer stores or, shall we say, other non-congregate living gatherings.

That is probably a better comparison. I mean, live music has been shut down for much much

longer, with much tighter restrictions, and live music and religious gatherings share, from a COVID transmission perspective, similar risk patters. So, the government appears to have deferred to the relatively greater importance of religion in the social context compared to live music performances in its choices. But the risk factors for transmission in a liquor store are profoundly different from those at a religious gathering.

So, the idea of somehow having a slider that you could move back and forth, it's a bit like trying to...you know, how many apples can I trade for a bicycle? Well, you have got to find a way of comparability between those two things. You might find somebody who is willing to trade bicycles for apples, but, as a society, we generally don't make those trade-offs.

145. Q. Well, you are always making those trade-offs in determining what interventions are going to be applied. I mean, there is nothing magic about the number 10 that instantly emerges as the correct capacity limit on a religious gathering, is there?

146. Q. I am not a religious person, myself. My understanding is that 10 was a recognition that

there are religious practices that require a gathering of persons who are of adherence to a particular faith. And so that 10 was a practical recognition of banning religious gatherings that was felt to be excessive, and there would be some, not zero, but minimized COVID risk if the limit was put at 10.

147. Q. But the limit could have been 12 just as easily?

A. I suppose. I wasn't at the table where these matters were discussed, so...

148. Q. Right.

A. I mean, my understanding is, in the Jewish tradition, the 10 is actually specified as the number that shall gather. There may be other religions that would have 12 as their minimum. I don't know.

149. Q. I mean, certainly a limit of 12 would accommodate a requirement for 10, would it not?

A. Yes.

150. Q. Thank you. The point being that any number of changes to the parameters of the interventions that were put in place would have been conceivable and possible, and there is no one set of

interventions that are absolutely known to be the right set; would you agree with that?

A. I think you are absolutely right that there is no perfect knowledge. I mean, as your experts, and I, have made the point, or attempted to, that knowledge is evolving about COVID and how to protect the population, and to strike a balance between the intended effects of those protections and the unavoidable harms of those protections. I think, if we look at non-congregate living voluntary gatherings as a class of exposure events, the restrictions for religious gatherings were less restrictive than other non-congregate living voluntary gatherings, despite having similar risk factors for COVID transmission. So, I take that to be an example of how governments sought to define that balance, and the number of times those restrictions changed reflect the desire to constantly...not constantly, but regularly rejig that balance between restriction and COVID risk.

151. Q. Can you point to anywhere in your affidavit where you make any comment that is critical of any of the NPIs imposed by the Province? And by "NPIs" I mean interventions, non-pharmaceutical interventions.

A. I mean, that was not my...whether they are...to criticize them was not the focus of the affidavit. I think that...

152. Q. So, is the answer to that question "No"?

A. Well, I think, if you turn to...let me just find the paragraph. So, if you look at paragraph 30, I think that I tried to provide some...my understanding of the, sort of, thinking process behind the NPIs:

> "...There is a bundle of temporary public health measures, referred to as NPIs. They seek to reduce close contact among persons from different households, and thus reduce COVID-19 risk. NPIs implemented temporarily in Ontario are broadly similar to those implemented in most, if not all, OECD jurisdictions, and include limits on occupancy of indoor spaces, mobility limits, limits on prohibitions of gatherings and events and school closures..."

153. Q. So, how would you say that that paragraph is critical of the NPIs imposed by the Province?

A. It's not been my...my affidavit sought to provide an explanation as to why the Government of Ontario chose the bundle of temporary measures.

154. Q. Right. So, the answer to the question is you can't find a point in your affidavit where you have made any comment that is critical of the NPIs imposed by the Province?

A. That is correct.

155. MR. KITTREDGE: All right, thank you. And thank you for your time. And, on a personal note, thank you for your work over the past two years, it is appreciated, and I am sure it has been challenging and tumultuous, and all that. And I have no further questions.

MR. HUNTER: And, so, why don't we just take a 10-minute break, and then we will come back and see if we have any re-exam?

156. MR. KITTREDGE: Sure.

THE DEPONENT: Okay, thank you.

--- upon recessing at 2:40 p.m.

--- A BRIEF RECESS

--- upon resuming at 2:50 p.m.

MATTHEW HODGE, resumed

RE-EXAMINATION BY MR. HUNTER:

157. Q. Thank you, Dr. Hodge. I just have a few questions arising out of the questions Mr. Kittredge asked you. First of all, you were asked some questions about dead viruses and live viruses and the possibility of transmission and, at one point, you talked about asymptomatic COVID-19 patients. First of all, could you just define what you mean by an "asymptomatic patient"?

A. So, that would be a person who, at the time of their assessment, has no symptoms of COVID-19 and, with the passage of time, they would either remain asymptomatic or they would be reclassified, after that moment, as, oh, they were actually pre-symptomatic, because, 48 hours later, they have a cough and a fever and they are short of breath.

158. Q. What relevance, if any, do those asymptomatic patients have to public health decisions?

A. Well, part of their relevance is that it's not clear if they are going to be pre-symptomatic...sorry, if they are, in fact, pre-symptomatic, but misclassified at that moment

and, therefore, are going to become sick. But the other, bigger, concern is that it's clear that persons can transmit COVID before they develop symptoms. So, some of those people who are asymptomatic at a moment in time may be, effectively, transmitting virus, and because they don't know that they have...if they don't know they have the virus, they may also be mixing more widely, not following the same measures to reduce those risks.

159. Q. You were asked some questions just about the way in which...if someone does die, and they had tested positive for COVID, that might be recorded, and you used a number of terms. I just want to make sure I understand those terms. So, you talked about "immediate", "contributing" and "antecedent" causes. Can you just give a short definition of what each of those terms mean, in your experience?

A. Sure. So, in the...there is an Ontario death certificate which is used for the recording of a death, and the first thing is the immediate cause, and then the next one is antecedent, as I recall, and the last one is contributing. So, for example, somebody who has

diabetes is at much higher risk of having coronary artery disease. So, they may come in and die of a heart attack, so myocardial infarction, the contributing cause would be diabetes. And there is a debate about whether it is an antecedent or a contributing, that is hair splitting, but the notion is that, for many deaths, particularly where there is not an injury or a trauma, there would be multiple factors that contribute to that final pathway out of this mortal life.

160. Q. And how would that play out in the case of a patient who had tested positive for COVID-19?

A. So, that depends on the clinical scenario. I think in our earlier discussion I used the example of two patients, one who is short of breath, has pneumonia, dies, they had a COVID-19 test. We would typically say their immediate cause of death was COVID-19 pneumonia, or pneumonia caused by COVID-19. Somebody who comes in because they fell and has a hip fracture, they get tested for COVID-19 as part of their preoperative screening, it turns up positive, they then fall off the operating table and sustain a catastrophic brain injury and die, they would be classified differently, to my

understanding.

161. Q. And what about if they, you know...say, someone, you know, an elderly patient had a stroke or a heart attack, and they had tested positive for COVID-19?

A. That would probably vary. COVID-19 appears to increase the risk of clotting events. So, certainly it's standard practice, when patients are admitted, we put them on medications to try to prevent clots. So, if the stroke appeared to be...for some physicians, they would link that to the COVID-19 infection, others might not. And there is some recoding of deaths that is done by...at the hospital level, so that there is a more standardized set of data that moves to vital statistics and to CIHI, but those are processes with which I am not familiar.

162. Q. Just for the record, CIHI?

A. Canadian Institute for Health Information.

163. Q. Thank you. You were asked a number of questions about, you know, infection fatality rates, and different numerators and denominators. First of all, just, you know, is an infection fatality rate a measure that is typically used in

public health practice and, if so, why and, if not, why not?

A. I would say, if we define "practice" to include people sitting around the table shooting the breeze, then, yes, it's widely used, but in practice practice terms, it's not, because it's mainly valuable, and it has been primarily used in relation to COVID, either for modelling purposes or to establish comparisons with other infectious diseases. So...

164. Q. And, so, from a practice practice point of view, making recommendations as to what measures should be taken, what measures would be used?

A. You know, I think...I was not at the tables where those recommendations were formulated. My understanding of the general process was to seek to find a set of measures that would have the effect of reducing risks of transmission into household, because, once it was inside a household, it was going to spread like wildfire, and the state has relatively few levers with which to interfere inside a household grouping, for disease control purposes. So, how do you prevent it getting into a household? And it is basically non-pharmacologic interventions

until we had vaccinations. So, for the first, say, 12 months, 15 months of COVID-19, it was only NPIs, and then...so, limit mobility, limit gatherings, facilitate distancing, mask mandates. The idea is, sort of, a multi-layer approach to protection, and trying to also recognize that people need to function in the world. So, for example, putting everybody under lockdown for two weeks, with inability to go to the doctor or get groceries probably isn't, on balance, going to be effective, because the population would be unable to tolerate it. It might be really good for COVID-19 control, but it is not practically implementable, so...

165. Q. And at one point you said that caseness, or being a case, is the basis for public health measures for COVID-19; why did you say that, or what do you mean by that, I should say?

A. Well, I mean that the testing data represent a way of taking...if I can use an analogy, taking the temperature of the pandemic in Ontario. We know that people get tested. We are reasonably confident in how to interpret the test results, and we have an accumulated body of experience that shows that, as test positivity goes in this direction, i.e. goes up, we see more people coming to hospital,

say, a week later. There is a number of those types of associations that have been learned over the course of the pandemic. So, while it would be...there are many theoretically better denominators to have. It would be great to have perfect knowledge and know exactly who is infected, and when they got infected, and how they got infected, but, absent that, it represents, like, kind of, the best we've got.

166. Q. So, you were asked, at one point, to compare the number of acute care beds in the Province, whether it was 25,000 or 20,000, and the number of COVID cases. In your view, is that a proper comparison to draw, for public health purposes?

A. I mean, it was the comparison that your esteemed colleague drew, and I tried to work with him to explain, from my perspective...the challenge is, if the system is at 105 percent of capacity...so, I am going to use the 20,000 number, because I can do the arithmetic on the fly...that means that there are 21,000 people in beds, but there are only 20,000 beds. So, there is a bunch of, sort of, Three-card Monte that is going on, whether it is beds in the cafeteria or people being

discharged sooner than would be optimal, in order to admit the next person, because they are sicker, and then you add another 2,500 people to that, I mean, that is just unfathomable. It would be different if we were, say, 20,000 or 25,000 beds, and only 70 percent occupancy. We could easily...more easily, let's say, accommodate another 10...2,500 patients.

And the other piece that is important to bear in mind on this, which I am happy to get into if you wish, is throughput. Many people with COVID stay in hospital for a relatively long time. So, if we look at bed days, that is probably a more accurate measure. The share of bed days attributable to COVID patients was far greater than 10 percent of bed capacity, because they were staying for longer than patients with CHF or patients with broken legs.

167. Q. Sorry, CHF?

A. Congestive heart failure.

168. Q. And, just so you know, those, I think it was, 2,000 or so COVID patients who needed hospitalization, would all of them only need an acute care bed, or would any of them need more than that?

A. So, I believe the number that Dr.

Schabas cited was the...all patients in hospital, of whom, at that point I would estimate probably between 400 and 800 were in ICU-level care. So, what had happened in many hospitals was that, as a matter of policy and practice, if you required certain interventions, you were in the ICU, and that's a physical location, and when that filled up, other places were designated as ICU beds. They didn't have all the whiz-bang equipment.

And the other piece of it is, generally, in the ICU, patients are staffed either one nurse per patient or one...sorry, one nurse per two patients, whereas, in a regular ward bed, it's one to four or one to five. So, in some cases, the designation of an ICU is also about the human resources that are available. So, patients weren't...it wasn't that they were, "Oh, we don't have an ICU bed. You just have to stay here and suffer". They would receive the care they needed, with everybody either working more or working faster, or changes in the staffing complement.

169. Q. So, you were also, at one point, taken to a...it was identified as an academic article, and you said it looked like it was a preprint or a reprint. What do those terms mean?

A. So, a reprint is simply a copy of an article that has appeared in a journal. And, so, that would be usually the PDF form. In the old days, it was a physical piece of paper that the author mailed you when you wrote and asked for it, now we just have PDFs of those. A preprint is a paper that is published on the internet, but has not been through a peer-review process. So, among printed articles, for which there would be reprints, there will be a very small number of retractions, or changes, down the road, typically related, unfortunately, to academic fraud, whereas, among preprints, because they haven't been through that review process, there is a fairly...a much higher proportion of preprints that never see it into a formal publication, whether because they were found to be methodologically unsound or because the author has retracted the paper, rather than have it go through the review process and be found to be not up to the standards of publication.

170. Q. Now, you were asked a number of questions about reports of cases and outbreaks in places of worship, and you said that both the cases...the number of outbreaks and the number of cases in an outbreak might be undercounted; why is

that?

A. So, part of the challenge for the people doing case-and-contact management is that some people will have exceptionally accurate recall of everywhere they have been and everywhere they have gone, and some people, at the other extreme, will actively not wish to participate. And, so, the art of case-and-contact management is trying to draw out, from the case individual, information that can help to establish where was the most likely transmission location where they received COVID, and where did they go that they might have given COVID to other people. So...and because of the way Ontario is structured, and people's lives are not centered within what the Province calls their public health unit, individuals may travel, for example, to attend what I called non-congregate living voluntary gatherings, such as live music or a religious gathering. And, so, when they return to their PHU of residence and are tested, it may not be known to the person doing the case investigation in, say, Durham Region that there is an outbreak at a church in Elgin, St. Thomas, or Southwest Public Health, that they should ask a direct question to the case person, "Did you attend a religious gathering at

this church, on this date, in the town of X, Y, Z?"

So, there is a lot of, if you think of it, missed connections there, because we don't have perfect knowledge, and it is humans who are doing case-and-contact management. Then, once two cases are identified associated with a location which would constitute an outbreak, there may be incomplete information about who else attended. So, most religious congregations do not record the names and contact information of persons attending. And, for some religious practices, my understanding is that they...part of the expression of their faith is to be open to all persons. So, they would actually explicitly not wish to record names and contact information, so there will be an incomplete census available to public health. It would be some of those people who won't answer the phone, some of them who aren't available, some of them who are informed but don't get tested. So, all of that contributes to the undercounting of the cases within the outbreak, and the underdetection is the piece I initially described. So, I hope I made that clear.

171. Q. And, just also, when you are talking about outbreaks at places of worship, if I understand your answer correctly, it was...you were

asked about the number of cases that are counted, and you said it wouldn't include patient zero, as it were, and it would include the cases contracted at the place of worship; is that right?

A. It would include cases where the most likely epidemiologic link, to use the jargon, is an exposure to the case at the place of worship. So, it's been rare in Ontario that we can use sequencing data to confirm that this virus is exactly the same as the virus that was in whatever the location was, but this notion of the most likely transmission location is one that is used and it is referred to as an "epidemiologic link".

172. Q. And would it include people...you know, if those people went home, and then gave it to their friends or co-workers or family members, would they be counted in the outbreak, those cases?

A. So, that's going to depend, again, on the local public health unit practice as to whether they think to make those associations, and then, you know, how the sausages are made, whether they link those cases within the IT system, so that they are seen as secondary cases from the outbreak.

173. Q. And you were asked, you know, some questions about comparing places of worship to

liquor stores or beer stores, and you said that was not an appropriate comparison, and other settings were. Why is that?

A. Well, I think it's for a number of reasons. Recognizing the diversity of religious practice, there is an inherent intentional social contact that's the basis of most religious gatherings, or many religious gatherings. I might go to the liquor store to meet my buddy, or I might run into a neighbour and say, "Hey, how's it going?", but I am not likely to be there with a large group of other people. I am not likely to be singing or speaking in high volume. I am not likely to engage in the passage of liquor or significant material in a way that may also increase the risk of infection, the way there is in some practices, religiously-significant materials are passed from person to person. So, there are a number of features of religious practice, broadly defined, which are associated with higher risks of COVID transmission, and those typically involve singing, speaking or singing at a loud volume, entry and exit into a space as a group. Religious services typically start at a designated time. People tend to show up, they are going to gather in those entry

and egress spaces. And then this notion of, sort of, the intentional social function, which is part of why many people value participation in those, may have the effect of reducing people's vigilance and adherence to masking and physical distancing.

174. Q. And the last question is, you were asked a number of questions about whether, I think it was, 526 cases and 26 hospitalizations would overwhelm the healthcare system, and you said, I think a couple of times, you disputed the premise of those questions; why is that?

A. Well, I think that the...I would say I looked at it from a couple of different perspectives, one was those 526 cases arose despite temporary restricted measures on religious gatherings. So, they represented some combination of bad luck, intentional non-compliance, and other factors. So, what that tells me is that it's not about 526 in religious gatherings, it's about...we had all these restrictions and we had 526 cases. So, without the restrictions, would that number have been 5,000, 50,000? I don't know.

And I think the related point to it is that the NPIs, as implemented in Ontario and in most OECD countries, tried to strike a balance, which I think

I would attribute to Michael Bloomberg, the former mayor of New York City. He introduced a housing policy, and everybody was opposed to it, and he was reported to have said, "I think I probably got it just about right, because I pissed off everybody". Inherent, or built into the notion of NPIs is we all have to sacrifice somewhat. And, so, to cherry pick out and say, "Well, like, let's just say we will treat...we will make it 12 people instead of 10" starts us down a path that...with no end, towards undermining the whole premise of NPIs, which is a broad set of measures that limit opportunities for virus transmission, and they do that by restricting mobility, by restricting opening hours, by restricting gatherings.

175. MR. HUNTER: Thank you. Those are my questions.

--- upon adjourning at 3:05 p.m.

Les auteurs estiment les taux d'infection par le coronavirus 2019 (COVID-19) de la population de quatre provinces canadiennes, de la fin de mars au début de mai 2020. Dans leur analyse, ils associent les données quotidiennes relatives au nombre de tests effectués et au nombre de cas diagnostiqués au moyen d'une méthodologie grâce à laquelle les données sont corrigées pour tenir compte du caractère non aléatoire des tests. Ils estiment la relation entre l'évolution quotidienne du nombre de tests effectués et de la proportion de cas positifs dans l'échantillon non aléatoire (généralement moins de 1 pour cent de la population) et utilisent ce gradient pour extrapoler une prédiction quant à la proportion de cas positifs qui seraient diagnostiqués si les tests étaient administrés à la population entière. Au cours de la période d'échantillonnage, les taux estimatifs d'infection de la population se situent dans les intervalles suivants : 1,7 à 2,6 pour cent au Québec, 0,7 à 1,4 pour cent en Ontario, 0,5 à 1,2 pour cent en Alberta et 0,2 à 0,4 pour cent en Colombie-Britannique. Dans chaque province, ces estimations se révèlent largement inférieures au taux moyen de cas positifs, ce qui s'explique par l'administration non aléatoire des tests aux populations qui présentent un risque plus élevé. Ces résultats indiquent également que les cas de COVID-19 non diagnostiqués sont largement répandus. Pour chaque cas diagnostiqué jusqu'à la mi-avril, les auteurs estiment à environ 12 le nombre de cas d'infection dans la population.

Mots clés : COVID 19, taux d'infection de la population, tests non aléatoires

This article estimates population infection rates from coronavirus disease 2019 (COVID-19) across four Canadian provinces from late March to early May 2020. The analysis combines daily data on the number of conducted tests and diagnosed cases with a methodology that corrects for non-random testing. We estimate the relationship between daily changes in the number of conducted tests and the fraction of positive cases in the non-random sample (typically less than 1 percent of the population) and apply this gradient to extrapolate the predicted fraction of positive cases if testing were expanded to the entire population. Over the sample period, the estimated population infection rates were 1.7–2.6 percent in Quebec, 0.7–1.4 percent in Ontario, 0.5–1.2 percent in Alberta, and 0.2–0.4 percent in British Columbia. In each province, these estimates are substantially below the average positive case rate, consistent with non-random testing of higher-risk populations. The results also imply widespread undiagnosed COVID-19 infection. For each identified case by mid-April, we estimate there were roughly 12 population infections.

Keywords: COVID-19, non-random testing, population infection rates

Introduction

The first cases of coronavirus disease 2019 (COVID-19) in Canada were documented in late January 2020, and by 5 May more than 63,000 cases had been reported (CSSE 2020). Because testing has been limited to a small fraction of the population and infected individuals with mild or

doi:10.3138/cpp.2020-035

https://www.utpjournals.press/doi/pdf/10.3138/cpp.2020-035 - Tuesday, November 23, 2021 1:08:40 AM - IP Address:142.113.217.28

no symptoms may not seek testing, however, the potential exists for widespread undocumented infections (see Bai et al. 2020; Dong et al. 2020; Hoehl et al. 2020; Lu et al. 2020; Pan et al. 2020).

In this article, we estimate population infection rates for COVID-19 across four Canadian provinces—Quebec, Ontario, Alberta, and British Columbia—from late March to early May. The analysis is based on the methodology developed in Benatia, Godefroy, and Lewis (2020) that corrects observed infection rates among tested individuals for non-random sampling to calculate infection rates in the overall population.[1] To implement the procedure, we estimate the relationship between the number of tests and the share of positive tests. This gradient is informative for the severity of selection bias. For example, a negative slope indicates positive selection bias, because individuals who are most frequently tested have the highest probability of infection. If the functional form of this relationship can be consistently estimated, we can compute the population infection rate as a combination of the observed sample infection rate and the estimated selection gradient, which corrects for non-random testing.

In practice, our approach faces two main empirical challenges. First, there is concern that the supply of testing may respond endogenously to underlying disease prevalence. For example, if policy-makers expand testing in response to increases in underlying disease prevalence, our estimation strategy would underestimate the selection bias gradient and thus overestimate total population infections. To address this concern, we focus on high-frequency day-to-day changes in the number of completed tests across US states and all Canadian provinces.[2] Because there is little scope for evolution in disease prevalence from one day to the next, daily changes in testing should be orthogonal to changes in population infection rates. To further validate this assumption, we estimate models that control for province and state fixed effects, thereby allowing for daily exponential growth in disease prevalence that is specific to each jurisdiction.

The second empirical challenge stems from uncertainty regarding the true functional relationship between the positive test rate and the size of the tested sample. In the empirical implementation, we specify a flexible functional relationship that appears to fit the data well. Nevertheless, the results ultimately depend on an untested assumption that the estimated relationship—based on data from the sample of tested individuals who typically make up less than 1 percent of the population—can be extrapolated to the rest of the population. Despite this limitation, we believe the approach offers significant advantages over existing methods used to estimate population infection rates (described later). In ongoing work, we hope to refine the estimation procedure to address this functional form concern.

We find wide cross-province differences in both the level of population infection rates and their trends. Average population infection rates over the sample period ranged from 0.3 percent in British Columbia to 3.0 percent in Quebec. Infection rates in British Columbia declined modestly over the sample period. In Ontario, infection rates rose from early to mid-April and subsequently declined. Meanwhile, Quebec and Alberta experienced increases in population infection rates over the month of April. These trends need not reflect increases in the number of newly infected individuals because our population infection rates capture both newly infected individuals and those with continued detectable viral load over the sample period.[3]

Our results also suggest widespread undetected COVID-19 infection across Canadian provinces. We calculate that for every diagnosed case, there were 12 population infections in mid-April. The ratio of population infection to diagnosis ranges from 8.6 in British Columbia to 14.8 in Ontario. These estimates are comparable to recent evidence on the rates of undetected infection in the United States and internationally (Ferguson et al. 2020; Johndrow, Lum, and Ball 2020; Perkins et al. 2020; Verity et al. 2020). For example, Aspelund et al. (2020) estimate that 80–90 percent of COVID-19 cases went undiagnosed in Iceland from late March to early April. Benatia et al. (2020) estimate a ratio of 12 population infections per diagnosed case in the United States by early April. More recently, the CDC (2020a) reported results based on seroprevalence that suggest that total infections were 10 times higher than the number of confirmed cases.

This article provides new evidence on overall population infection rates for COVID-19 in Canada. Our findings complement evidence for COVID-19 prevalence nationwide. Using survey results for COVID-19 symptoms, Reid (2020) finds that more than 100,000 households reported COVID-like symptoms after adjusting for seasonal influenza rates. The results do not account for potentially large numbers of asymptomatic infections. Meanwhile, Verity et al. (2020) combines assumptions regarding the age-adjusted case fatality rate with COVID-related deaths to estimate total population infections in Canada on 31 March. These estimates indicate that the case detection rate was just 5 percent through March. Our analysis provides the first provincial-level estimates. Given wide cross-province differences in per capita testing, official case counts may mask important geographic differences in the severity of the outbreak. Indeed, whereas the official case count in Quebec was 55 percent higher than in Ontario, our results show that gap in total cases was less than 20 percent.

Our empirical framework complements existing methods used to estimate population infection rates in the United States and internationally (Ferguson et al. 2020; Javan, Fox, and Meyers 2020; Johndrow et al. 2020; Li, Pei, et al. 2020; Perkins et al. 2020; Riou, Hauser, Counotte, and Althaus 2020; Verity et al. 2020). One approach has been

https://www.utpjournals.press/doi/pdf/10.3138/cpp.2020-035 - Tuesday, November 23, 2021 1:08:40 AM - IP Address:142.113.217.28

based on the Susceptible Infectious Removed epidemiological model, which calibrates parameters to the specific characteristics of the severe acute respiratory syndrome coronavirus 2 pandemic to estimate current and future infections. A challenge for this approach is the large uncertainty regarding the relevant parameter values for the virus and the fact that the parameter values will evolve as societies take different measures to reduce transmission. Other research has relied on Bayesian modelling to infer past disease prevalence from observed COVID-19 deaths. Although these models require fewer assumptions regarding the underlying parameter values, because they scale up observed deaths to estimate population infections, small differences in the assumed case fatality will have substantial effects on the estimates. Given considerable uncertainty regarding the true case fatality, which may depend on local sociodemographic and environmental conditions, and the fact that COVID-19–related deaths may be undercounted during the course of the pandemic, these estimates may not capture the overall extent of population infection (see Clay, Lewis, and Severnini 2018, 2019; Clay et al. 2020; Han et al. 2020; Katz and Sanger-Katz 2020; Prakash and Hall 2020; Riou, Hauser, Counotte, Margossian, et al. 2020; Wu et al. 2020).

Most closely related to our article is Manski and Molinari (forthcoming), who use data on the total number of tests and the positive test rate to estimate ranges for population COVID-19 infection rates for Illinois, New York, and Italy in early April. Their approach requires only the imposition of weak monotonicity assumptions for identification. Their estimated bounds for infection rates are 0.1%–51.7% for Illinois, 0.8%–64.5% for New York, and 0.3%–51.0% for Italy. These are wide, model-free bounds. In this article, we estimate much narrower intervals, which are conditional on the accuracy of our model. Although we have developed our method for use during this crisis to employ the available information as fully as possible, policy-makers should be aware that bounds that include model uncertainty would be wider than ours by some unknown amount, which is not uncommon in econometric analyses. The model-free bounds of Manski and Molinari (forthcoming) serve as a remind of that issue.

Data

Our analysis draws on daily data on total test results (positive plus negative) and positive tests across Canadian provinces and US states for the period 31 March–5 May. Provincial data were obtained from the Epidemiological Data from the COVID-19 Outbreak in Canada project (Berry et al. 2020). This project is conducted by a team of researchers from the Universities of Toronto and Guelph and provides information on cases and testing across provinces based on publicly available information from government reports and news media. We exclude days on which there were identified changes in provincial reporting standards and days on which provincial health authorities did not release information on completed tests.[4] In addition, we use information on the number of positive tests by age group, which is available from provincial health departments, and provincial population estimates from Statistics Canada (2020). We supplement these data with information on total test results and positive cases across US states for the same time period from the COVID Tracking Project, a site launched by journalists from *The Atlantic* that publishes high-quality data on the outbreak across US states (Meyer, Kissane, and Madrigal 2020).

Figure 1 reports the daily tests and positive cases across the four provinces. Daily testing was fairly stable in Quebec throughout April. In contrast, daily testing substantially increased in both Ontario and Alberta and to a lesser extent in British Columbia.

Methodology

In this section, we present the theoretical framework developed in Benatia et al. (2020) to estimate COVID-19 prevalence. This framework motivates estimating Equation (6).

Theory

To evaluate population disease prevalence, we develop a simple selection model for COVID-19 testing and use the framework to link observed rates of positive tests to population disease prevalence. We consider a stable population, normalized to a population of one, and denote A and B as the number of sick and healthy individuals, respectively. Let p_n denote the probability that a sick person is tested and q_n the probability that a healthy person is tested, given a total number of tests, n. Thus, we have $n = p_nA + q_nB$, and assuming the test is accurate, the number of positive tests is $s = p_nA$.

This simple framework highlights how non-random testing will bias estimates of the population disease prevalence. Using Bayes's rule, we can write the relative probability of testing as

$$\frac{p_n}{q_n} = \frac{Pr(sick|\, tested, n) \,/\, Pr(healthy, tested, n)}{Pr(sick|\, n) \,/\, Pr(healthy, n)},$$

which is equal to one if tests are randomly allocated, $Pr(sick \setminus tested,n) = Pr(sick \setminus n)$. When testing is targeted to individuals who are more likely to be sick, we have $Pr(sick \setminus tested,n) > Pr(sick \setminus n)$, $Pr(sick \setminus tested,n) > Pr(sick \setminus n)$, and $Pr(healthy \setminus tested,n) < Pr(healthy \setminus n)$, so the ratio will be greater than one. In this scenario, the ratio of sick to healthy people in the sample, p_nA/q_nB, will exceed the ratio in the overall population, A/B.

We assume that the severity of selection bias can be expressed as a function of the number of tests,

$$\frac{p_n}{q_n} = f(n;\theta), \tag{1}$$

https://www.utpjournals.press/doi/pdf/10.3138/cpp.2020-035 - Tuesday, November 23, 2021 1:08:40 AM - IP Address:142.113.217.28

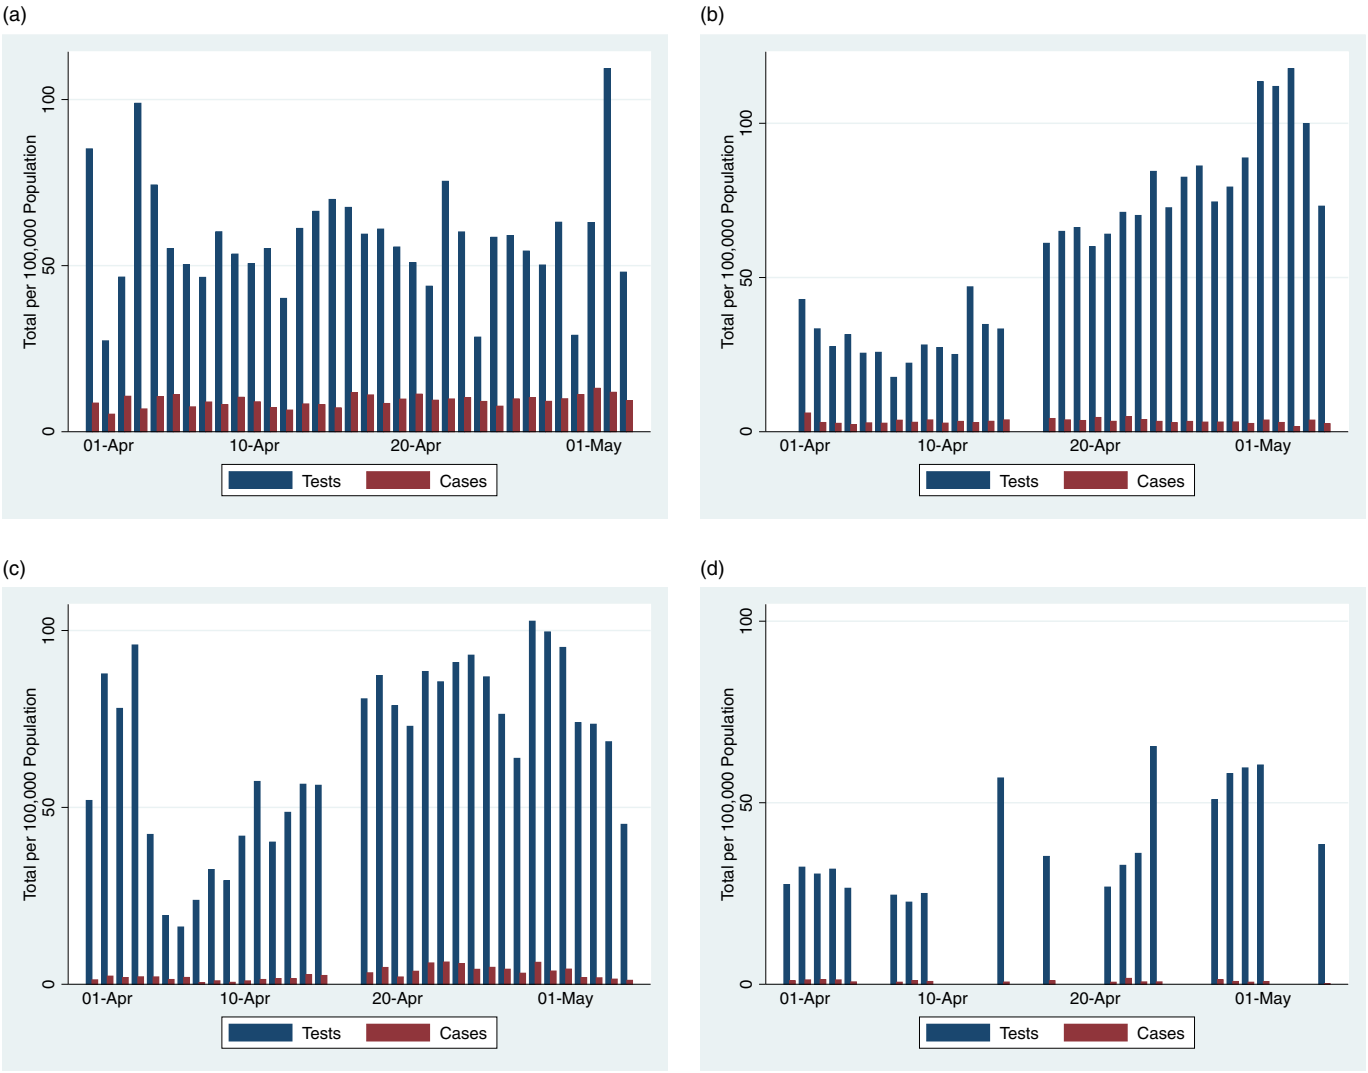

Figure 1: Daily Testing and New Cases across Provinces: (a) Quebec, (b) Ontario, (c) Alberta, and (d) British Columbia

Notes: This figure reports the total daily coronavirus tests and the number of new cases per 100,000 population by province. The trends are based on data from Berry et al. (2020). We exclude days for which there were identified changes in provincial reporting standards and days for which provincial health authorities did not release information on completed tests.

Source: Berry et al. (2020) and Statistics Canada (2020).

where n is number of conducted tests and θ is a vector of parameters to be estimated.

According to this setup, we can write the fraction of positive tests, s/n, as follows:

$$\frac{s}{n} = \frac{1}{1 + \frac{q_n}{p_n}\frac{B}{A}}. \tag{2}$$

Taking logs and using the fact that the latter term in the denominator is much larger than one, we can make the following approximation:[5]

$$\log\frac{s}{n} \approx \log\left(\frac{p_n}{q_n}\frac{A}{B}\right) = \log\left(\frac{p_n}{q_n}\right) + \log\left(\frac{A}{B}\right). \tag{3}$$

Equation (3) shows that the log share of positive tests in the sample can be approximated by the sum of the log ratio of the relative probability of testing, p_n/q_n, and the unobserved log ratio of sick to healthy people in the population, A/B.

From Theory to Estimation

To conduct the estimation, we adopt a first difference estimator, using as the dependent variable the difference $\log\frac{s_{i,t}}{n_{i,t}} - \log\frac{s_{i,t-1}}{n_{i,t-1}}$ on two consecutive days $t - 1$ and t in a given province/state i. Given the last equation, this first difference is equal to

https://www.utpjournals.press/doi/pdf/10.3138/cpp.2020-035 - Tuesday, November 23, 2021 1:08:40 AM - IP Address:142.113.217.28

$$\log\frac{s_{i,t}}{n_{i,t}} - \log\frac{s_{i,t-1}}{n_{i,t-1}} = \log f\left(n_{i,t};\theta\right) - \log f\left(n_{i,t-1};\theta\right) + u_{i,t}, \quad (4)$$

where $u_{i,t} = \log\left(\frac{A_{i,t}}{B_{i,t}}\right) - \log\left(\frac{A_{i,t-1}}{B_{i,t-1}}\right) + \varepsilon_{i,t}$ is a mean zero error term that depends on the change in ratio of sick to healthy individuals in the population from $t-1$ to t and an idiosyncratic component, $\varepsilon_{i,t}$.

Equation (4) forms the basis of our empirical analysis. Our identifying assumption is strict exogeneity in the error term: $E(u_{i,t} \backslash n_{i,t}, n_{i,t-1})$. This assumption ensures that the errors are uncorrelated with any function of changes in the number of tests, $\Delta n_{i,t}$, and will be violated if changes in the population infection rate were systematically related to testing capacity. This assumption is supported by the short time interval in the daily first difference specification, which limits the scope for disease evolution. Also, in robustness tests, we control for province and state fixed effects, which allow for jurisdiction-specific exponential growth in underlying disease prevalence from one day to the next. These controls do not affect the main coefficient estimates.

Notice that by focusing on a daily first difference estimator, we are able to partial out the unobserved log ratio of sick to healthy people in the population, $A_{i,t}/B_{i,t}$. As a result, changes in the share of positive tests depend on the number of tests only through a selection channel.

How does this assumption enable us to estimate population infection rates? Using day-to-day changes in the share of positive tests and day-to-day changes in the number of tests, we can recover $\log f\left(n;\hat{\theta}\right)$ by estimating Equation (4). This term captures how changes in the share of positive tests are predicted to change with n. We can then use this prediction to recover population infection rates. Denote $\widehat{\frac{s_{pop}}{n_{pop}}}_{i,t}$ as the predicted fraction of positive tests if the entire population in province i was tested on date t, that is, $n_{i,t} = pop_i$. We can rewrite the first difference Equation (4) as

$$\log\widehat{\frac{s_{pop}}{n_{pop}}}_{i,t} = \log\frac{s_{i,t}}{n_{i,t}} + \log f\left(pop_i;\hat{\theta}\right) - \log f\left(n_{i,t};\hat{\theta}\right). \quad (5)$$

That is, the predicted log fraction of positive tests in the population is equal to the log fraction of positive tests in the sample plus an adjustment factor that corrects for non-random testing. One could also view our exercise as a reduced form estimation of the relationship between the fraction of individuals who test positive and the size of the tested population (holding constant the population share of those who are sick). Once this relationship has been consistently estimated, we can predict the share of positive tests for any value of n, including when $n = pop_i$.

Empirical Implementation

To implement the procedure described in the preceding section, we specify the following functional form for the selection process into testing, $f(n;\theta)$:

$$\frac{p_n}{q_n} = f\left(n;\theta\right) = 1 + e^{\gamma+\beta n}.$$

The term $e^{\gamma+\beta n} \geq 0$ reflects the fact that testing has been targeted toward higher-risk populations, with the intercept, γ, capturing the severity of selection bias when testing is limited. Meanwhile, the coefficient $\beta < 0$ identifies how selection bias decreases with n as the ratio p_n/q_n approaches one. Intuitively, as testing expands, the sample will become more representative of the overall population, and the selection bias will diminish.

We substitute this function into the first difference regression model, taking a third-order power series approximation of the log function, which yields the following estimating equation:[6]

$$\log\frac{s_{i,t}}{n_{i,t}} - \log\frac{s_{i,t-1}}{n_{i,t-1}} = \alpha_1\left[e^{\beta\frac{n_{i,t}}{pop_i}} - e^{\beta\frac{n_{i,t-1}}{pop_i}}\right] + \alpha_2\left[e^{2\beta\frac{n_{i,t}}{pop_i}} - e^{2\beta\frac{n_{i,t-1}}{pop_i}}\right] + \alpha_3\left[e^{3\beta\frac{n_{i,t}}{pop_i}} - e^{3\beta\frac{n_{i,t-1}}{pop_i}}\right] + \nu_{i,t}. \quad (6)$$

We estimate Equation (6) by non-linear least squares, allowing for heteroskedastic errors.[7] After estimation, we derive predicted values for population infection rates based on Equation (5), using the delta method to construct confidence intervals.

Before turning to the main results, several caveats should be highlighted. First, the estimates of population infection rates depend on a correctly specified functional relationship between the positive test rate and the size of the tested sample.[8] Although the model fits the data well (see Figure 2), an important assumption underlying our analysis is that this observed relationship in the tested sample—who typically make up less than 1 percent of the population—would continue to hold if testing were expanded out to the broader population. The accuracy of this extrapolation depends on a smoothness condition on the functional form and may be violated if, for example, some segments of the population can easily be tested and others cannot.

We also constrain the population coefficients (a_i, β) to be the same across jurisdictions. This assumption requires that decisions regarding how to prioritize tests were made similarly across provinces and US states. Although states had latitude to implement their own diagnostic testing procedures, the guidance laid out for testing prioritization by the CDC (2020b) was broadly similar to the policies implemented across Canadian provincial health departments. We also estimate the model for three distinct

https://www.utpjournals.press/doi/pdf/10.3138/cpp.2020-035 - Tuesday, November 23, 2021 1:08:40 AM - IP Address:142.113.217.28

one-week intervals, 31 March–7 April 7, 14–21 April, and 28 April–5 May, to allow for the possibility that decisions about how to allocate tests across the population may have changed from late March to early May. Because policy decisions regarding testing of elderly populations may have differed across jurisdictions, we also report estimates based solely on cases among individuals aged younger than 70.

Finally, our analysis depends on the quality of diagnostic testing, and systematic false-negative test results may affect the population disease prevalence estimates (Ai et al. 2020; Liu et al. 2020; Yang et al. 2020). Because our analysis focuses on day-to-day variation, however, changes in the rates of misdiagnosis should not be systematically related to changes in the number of implemented tests.[9] As a result, these errors should not bias the coefficient estimates, but they may reduce precision through classical measurement error (Wooldridge 2002).

Results

Table 1, Panel A, reports the estimates for Equation (1) across three time periods: 31 March–7 April, 14–21 April, and 28 April–5 May. We estimate the model separately for all ages (Columns [1], [3], and [5]) and excluding cases among individuals aged older than 70 years (Columns [2], [4], and [6]). Consistent with the theoretical framework, we find large estimates of β ranging from –1,093 to –1,391, which implies that the sample selection in testing approaches zero as the number of tests approaches the total population size. We also find alternating signs on coefficient $\hat{\alpha}_1, \hat{\alpha}_2, \hat{\alpha}_3$, consistent with the estimates of the power series approximation developed in Benatia et al. (2020).

Figure 2 presents scatterplots of the relationship between daily changes in per capita testing and the share of positive tests across states and provinces for the three time periods. The downward-sloping relationships imply that

larger day-to-day increases in the number of conducted tests are associated with decreases in the share of positive tests. A symptom of selection bias is that variables that have no structural relationship with the dependent variable may appear to be significant (Heckman 1979). So, these patterns strongly suggest non-random testing, because daily changes in testing should be unrelated to population disease prevalence except through a selection channel.

Table 2 reports the results for Quebec, Ontario, Alberta, and British Columbia that adjust observed COVID-19 case rates for non-random testing on the basis of the procedure described in the Methodology section. Column (2) reports the estimates for all-age population infection rates on 4 April, 18 April, and 2 May, along with heteroskedasticity robust 95 percent confidence intervals. Column (4) reports the average estimates for the three time periods 31 March–4 April, 14–18 April, and 28 April–2 May. These

Notes: Column (1) reports the fraction of positive tests on the relevant day. Columns (2)–(3) report the coefficient estimates for population prevalence of COVID-19 based on the methodology described in the Methodology section. Heteroskedasticity robust 95% confidence intervals are reported in parentheses. We report the results for all age prevalence and prevalence among individuals aged younger than 70 y. Columns (4)–(5) report the average estimates for population prevalence of COVID-19 for the three time periods. COVID-19 = coronavirus disease 2019.

Source: Authors' calculations.

latter averages mitigate sampling error in the daily prevalence estimates, which depend on the observed share of positive tests on any particular day.

The results reveal widespread disparities in COVID-19 prevalence across provinces. Population infection rates range from more than 2.2 percent in Quebec to less than 0.4 percent in British Columbia Trends in infection rates differed significantly across provinces. Infection rates in British Columbia declined modestly over the sample period. In Ontario, infection rates rose from early to mid-April and subsequently declined. Meanwhile, Quebec and Alberta experienced steady increases in population infection rates over the sample period.

Columns (3) and (5) report the estimated population infection rates among individuals aged younger than 70 years.[10] These estimates will not be influenced by specific policies regarding the testing of the elderly population and residents of senior residential facilities that may have differed across provinces.[11] The results for Alberta and British Columbia are similar to the overall population prevalence. Meanwhile, the estimates are systematically lower in Ontario and Quebec, particularly in the latter

https://www.utpjournals.press/doi/pdf/10.3138/cpp.2020-035 - Tuesday, November 23, 2021 1:08:40 AM - IP Address:142.113.217.28

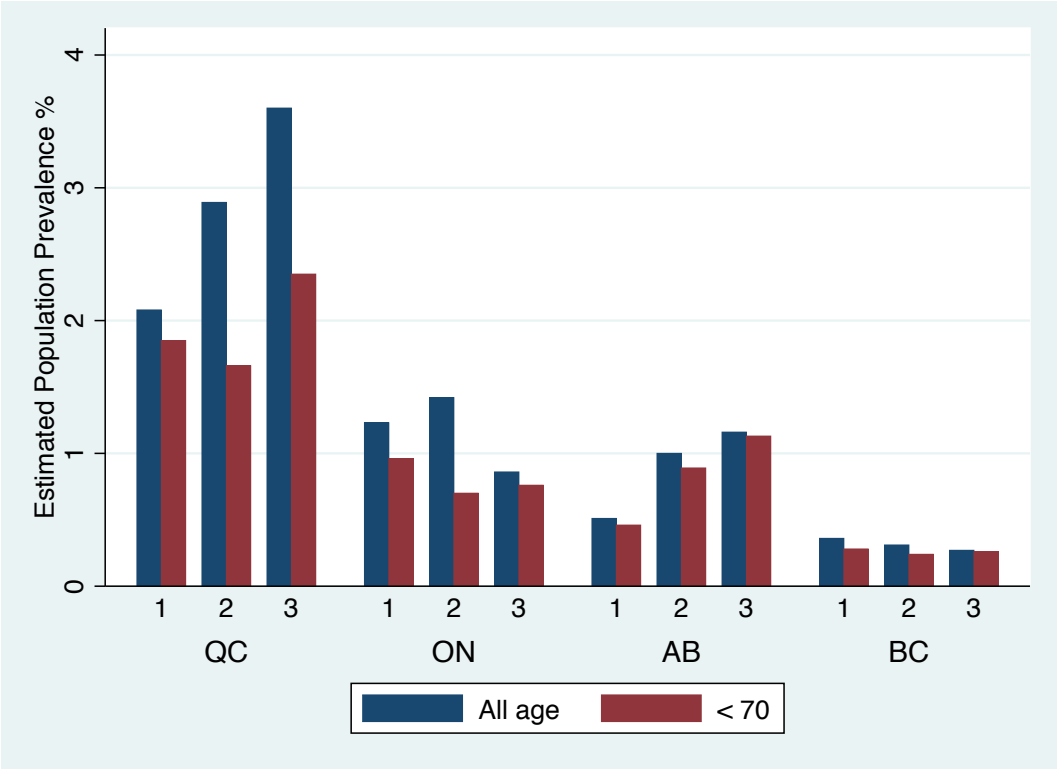

Figure 3: Population COVID-19 Infection Rates by Province and Period

Notes: This figure reports average population infection rates across provinces for three different time periods: (1) 31 March–4 April, (2) 14 April–18 April, and (3) 28 April–2 May. These average infection rates are obtained using the estimation procedure described in the Methodology section. All age population prevalence estimates are based on all cases and tests. To derive population prevalence for those aged younger than 70 y, we subtract the number of cases among elderly persons from the total daily cases and total tests across provinces. COVID-19 = coronavirus disease 2019.

Source: Authors' calculations.

periods. These results are consistent with the timing of the shift in testing in elderly facilities in these two provinces (Hinkson and Stevenson 2020; Jones 2020).

Table 3 explores the robustness of the main estimates to controls for province and state fixed effects. These controls allow for growth rates in underlying disease prevalence that are specific to each locality, to account for the fact that the true infection rate may evolve even within a 24-hour period. Because the intercepts are allowed to differ across each jurisdiction, they also account for variation in the daily evolution of the disease across states and provinces as a result of differing enforcement of social distancing or other location-based determinants of disease spread. The results (reported in the even-numbered columns) are virtually identical to the baseline estimates. Moreover, the augmented model tends to produce more precise confidence intervals, although as noted earlier we emphasize that these confidence intervals are conditional on our model.

To interpret the findings, we calculate the total population infections in mid-April and compare them with the number of diagnosed cases in each province. We multiply the average estimated prevalence from 14–18 April (Table 2, Panel B, Column [4]) by the total province population and compare it with the cumulative diagnosed cases by 23 April. The gap in the two periods captures the typical five-day incubation period to account for the fact that individuals may not seek testing until symptom onset (Lauer et al. 2020; Li, Guan, et al. 2020). In principal, these numbers capture two distinct measures of COVID-19 spread: current infections versus cumulative infections. Nevertheless, given limited COVID-19 infection before mid-March and the fact that viral presence is detectable by PCR testing three weeks after initial symptom onset (Cai et al. forthcoming; Zhou et al. 2020), population infection rates in mid-April are likely to be similar to cumulative infections since onset.

Table 4 presents the results. We find widespread undetected population infection. By 23 April, 41,371 cases had been identified across the four provinces; however, our estimates suggest that there were more than a half million infected individuals. In Quebec and Alberta, we find

https://www.utpjournals.press/doi/pdf/10.3138/cpp.2020-035 - Tuesday, November 23, 2021 1:08:40 AM - IP Address:142.113.217.28

that there were 11–12 population infections per diagnosed case. In Ontario, there were 15 population infections per diagnosed case. These gaps align with differences in testing across provinces (Alberta and Quebec, 27 and 22 per 1,000, respectively, vs. Ontario, 13 per 1,000). Meanwhile, British Columbia had the smallest fraction of undetected cases, despite conducting just 14 tests per 1,000 population. This discrepancy can likely be attributed to the fact that the scope of the outbreak was substantially more limited in British Columbia, allowing officials to better identify clusters of cases.

Discussion

This article provides new evidence on the population prevalence of COVID-19 in Quebec, Ontario, Alberta, and British Columbia from late March to early May. Our analysis adapts a sample selection model approach developed in Benatia et al. (2020). We find widespread population

Table 4: Diagnosed Cases and Estimated Total Cases of COVID-19

Province	Positive COVID-19 Tests, by 23 April (1)	Estimated Total COVID-19 Cases (2)	Ratio of Total Cases to Positive Tests, (2)/(1) (3)	COVID-19 Tests per 1,000 Population (4)
Quebec	21,832	245,215	11.2	21.9
Ontario	13,995	206,845	14.8	13.4
Alberta	3,720	43,713	11.8	27.0
British Columbia	1,824	15,721	8.6	13.5

Notes: Column (1) reports the cumulative number of positive COVID-19 tests by 23 April. Column (2) reports the total number of COVID-19 cases implied by the average estimated population prevalence from 14–18 April (Table 2, Panel B, Column 4). Column (4) reports the cumulative number of COVID-19 tests by 23 April per 1,000 population. COVID-19 = coronavirus disease 2019.

Source: Berry et al. (2020); Statistics Canada (2020); authors' calculations.

infection that exceeds official reported cases by factors of 9 to 15 across provinces.

Our findings are comparable to recent prevalence estimates from the United States and countries in Western Europe. The estimated infection rates in Quebec are similar to those of the United Kingdom (2.7%) and several US states (Pennsylvania, 2.4%; Rhode Island, 2.4%; and Massachusetts, 3.4%). Meanwhile, the rates in Ontario are similar to those in Austria (1.1%), Denmark (1.1%), Vermont (1.4%), Virginia (1.4%), and Idaho (1.5%) in early April (see Benatia et al. 2020; Ferguson et al. 2020; Johndrow et al. 2020; Javan et al. 2020). Our results are also consistent with recent evidence from serological testing across several US jurisdictions that shows widespread undetected infection by mid-April (Bendavid et al. 2020; Conarck and Chang 2020; Goodman and Rothfeld 2020).

Our analysis provides a complement to existing methods used to estimate population infection rates. These approaches require either strong assumptions about unknown disease parameters or accurate measurement of COVID-related deaths, which may be undercounted over the course of the pandemic. Our estimation approach builds on standard econometric techniques. As high-frequency test data become more widely available at finer geographic units, this approach could be applied to estimate population infection rates at the city or district level. The current estimates depend on the accuracy of an extrapolation of the functional form relating the number of tests and the positive case rate to the large untested population. In ongoing work, we hope to refine the estimation procedure and explore the sensitivity of the results to various functional form assumptions.

As physical distancing policies continue to be relaxed, it will be essential that policy-makers have access to timely data on infection rates. Given the potential for widespread undiagnosed infection, the expansion of randomized population-based PCR testing may play a key role in identifying localized outbreaks. Meanwhile, widespread implementation of serological testing will help identify the large numbers of individuals with some level of immunity to the virus.

Notes

1 A large body of research in economics is devoted to the issue of non-random sampling. See Blundell and Costa Dias (2002); Das, Newey, and Vella (2003); Heckman (1976, 1979); Heckman, Lalonde, and Smith (1999); and Newey (2009). Epidemiologists have also devoted considerable attention to the issue of sample representativeness (for a detailed discussion, see Davey Smith and Ebrahim 2013).

2 To improve the precision of the estimates, we include all Canadian provinces and US states to estimate the selection bias gradient. Once this gradient has been estimated, however, our estimates of underlying prevalence rely solely on the shares of positive cases across the four Canadian provinces we study.

3 There is an extended period over which individuals may test positive for COVID-19. Polymerase chain reaction (PCR) testing has identified cases days before symptom onset and detected continued viral RNA presence more than three weeks after symptom onset (Cai et al. 2020; Huang et al. 2020; Zhou et al. 2020). These positive cases often occur among individuals who are no longer symptomatic, and it is believed that they reflect lingering viral material that no longer poses a risk of transmission.

4 British Columbia has a large number of missing observations because daily testing results were not always released.

5 The median ratio of negative to positive tests, $\frac{q_n}{p_n}\frac{B}{A}$, across Canadian provinces was 21 during the sample period.

6 The first difference derivation is based on the following equation: $\log\frac{s}{n} \approx \log\left(1+e^{\gamma+\beta n}\right)+\log\frac{A}{B} \approx \sum_{k=1}^{M}\frac{(-1)^{k-1}e^{k\gamma}}{k}e^{k\beta n}+\log\frac{A}{B}$.

https://www.utpjournals.press/doi/pdf/10.3138/cpp.2020-035 - Tuesday, November 23, 2021 1:08:40 AM - IP Address:142.113.217.28

https://www.utpjournals.press/doi/pdf/10.3138/cpp.2020-035 - Tuesday, November 23, 2021 1:08:40 AM - IP Address:142.113.217.28

The results are not sensitive to the inclusion of higher-order terms. Our baseline estimating equation does not include a constant, although we explore the robustness of the results to jurisdiction-specific intercepts.

7 Similar standard errors are found in models that allow for within-state/within-province serial correlation.

8 There is little guidance from theory about the functional form of relationship, and there are no individual-level survey data to shed light on who is tested.

9 To see why this is the case, let $\pi < 1$ denote the fixed probability that a test is positive if an individual is sick, so that some fraction of sick individuals may not be detected by testing. In this case, the researcher observes s/n, but the actual share of positive cases among the tested sample is $\frac{s}{\pi n}$. Provided that the rate of false negatives is constant over time, the term π drops out of the first difference Equation (4), so it will not affect the main estimates.

10 Figure 3 presents both all-age and aged-younger-than-70-years population infection rates.

11 To derive these estimates, we subtract the number of cases among elderly individuals from the total daily cases and total daily tests across provinces. Because we lack data on total tests by age group, negative tests among elderly individuals are included in the denominator, so these estimates should be interpreted as a lower-bound estimate for disease prevalence.

DR. RICHARD SCHABAS, SWORN

CROSS-EXAMINATION BY MR. JOSH HUNTER:

1. Q. Good afternoon, Dr. Schabas, or I suppose good morning where you are in British Columbia.

A. Yeah, thank you. Good morning, good afternoon.

2. Q. My name's John Hunter, I'm counsel with the Province of Ontario and I'm going to be asking you some questions today about an affidavit you swore in this proceeding. Do you have a copy of your affidavit with you with its exhibits?

A. I do. I don't -- I don't have all the exhibits, but I think I have them online, so I can access them if I need to.

3. Q. Great. If there's anything we really turn up we can go to it. The one I will ask you to have in front of you is do you have Exhibit A? That's your curriculum vitae?

A. I do.

4. Q. And before --

A. I should point out by the way, before we get into that, that there is a small error at the beginning of my affidavit. For some reason it

says I was Chief Medical Officer of Health from 1987 to 1998, that's not true. I -- I resigned in the -- towards the end of 1997, so just 10 years. I got a little time off for good behaviour I think.

5. Q. Fair enough. Actually, you anticipated my next question, was just was are there any corrections or amendments to your affidavit before we get started?

A. I think that's the only one, but -- but that one I'd like to correct, yeah.

6. Q. Well, let's turn to your CV then. And I just want to ask you a couple of questions about it. First of all, is this a up-to-date curriculum vitae?

A. I think so. I -- I -- I retired in -- in -- rather in 2016, at the end of 2016, and I haven't update it since then because I've been retired, so I guess there's nothing since then.

7. Q. Okay. And you're not currently licensed to practice medicine, right?

A. I am not.

8. Q. And you have not been since, I think it was March 2017?

A. I -- I don't -- my -- my licence in Ontario would have expired some time in 2017. I think

it was probably June, but somewhere around there, yeah.

9. Q. And you do not currently hold any academic appointments.

A. I do not.

10. Q. I think that last one you did was in 2016.

A. Yeah. I was -- I was at Queen's University. That was my last academic appointment, correct.

11. Q. Now, your CV says you've held a hospital appointment in Campbellford since 2005. Do you still hold that appointment?

A. No, I resigned that in 2016 when I retired.

12. Q. And you cite a number of academic papers on your CV. And if I'm reading it correctly, I think the most recent one was from 2012.

A. That could be. I -- I -- I -- without reviewing it I couldn't say, but probably. Probably the one on clostridium difficile, 2012. David Fisman of all people is the co-author.

13. Q. Yes, there was one. Clostridium difficile is the last one listed from the Canadian Journal of Infectious Diseases. Have you published

any more recent peer reviewed articles since 2012?

A. I don't -- I -- I don't recall any. I don't think so, but I -- I -- if they're not in my CV then I presume I haven't.

14. Q. But you have published some newspaper articles since then.

A. I have. I have, yes.

15. Q. I'd like to actually take you to one which you may recall. Let me just share my screen here. Just make sure it's working. Can you see the Globe and Mail article I'm sharing?

A. I see the beginning of it. I can't see the whole article.

16. Q. I'll maybe just zoom out a little.

A. Sure.

17. Q. It's an article, opinion article titled, "Strictly by the numbers, the coronavirus does not register as a dire global crisis," by a "Richard Schabas." It looks like it was published March 9th and updated March 11th of 2020. Do you remember writing that article?

A. I -- I wrote the article. I didn't write the headline of course.

18. Q. Fair enough.

A. You don't write your own headlines.

19. Q. If only you could. I just want to ask you a couple of questions about the views you expressed in that article.

A. Yes.

20. Q. Now, you state in the article that "COVID-19" was only, "A global crisis, for people who can't add"; is that right?

A. At that time, that's what I wrote, yes.

21. Q. And it was the:

"The Incredible Shrinking Pandemic."

A. At that time numbers were coming down, that's correct.

22. Q. And your opinion at that time, COVID-19 didn't seem, "Very transmissible among humans."

A. I -- I -- I said that. What I said actually is that -- is that most people don't transmit it, that it's transmitted by a relatively small number of people which turns out was a very pressing observation. I think I was probably the first person maybe to publish that observation anywhere in the world, and it turns out to be the over distributed nature of the infection, but indeed it's -- it was not

a highly infectious disease. And, yes, that's what I said at the time, correct.

23. Q. And you also said that, "The vast majority of infected" people:

"Spread the disease to precisely no one."

A. Correct, which I -- which I believed at the time and I still believe.

24. Q. And then so you concluded then, you know:

"Quarantine belongs back in the Middle Ages. Save your masks for robbing banks."

A. Correct. I did -- I concluded those and -- and by in large I still -- still maintain those views, yes.

MR. HUNTER: Can I have that marked as an exhibit, please? And objection, Mr. Kittredge?

MR. KITTREDGE: No objection.

MR. HUNTER: Thank you. That'll be Exhibit 1, Globe and Mail article by Richard Schabas, dated March 9th, 2020.

EXHIBIT NO. 1: Globe and Mail Article by Richard Schabas, dated March 9th, 2020.

BY MR. HUNTER:

25. Q. All right. Let's go into your affidavit then. Can I get you to turn -- we'll start at paragraph 7 of your affidavit.

A. Okay.

26. Q. And I think you'd agree with me that the science around COVID-19 has often been complex and uncertain?

A. That's what I said, yeah.

27. Q. That's a view you hold, right?

A. Yes.

28. Q. And that scientific understanding is constantly evolving?

A. Yes.

29. Q. Public health practitioners often don't have the luxury of waiting for science to solidify before they recommend action.

A. Absolutely true.

30. Q. And they have to act with the information that's available to them.

A. Absolutely true.

31. Q. And if public health measures are taken too slowly disease may spread and you may need even more stringent measures to regain control?

A. You may.

32. Q. And also, you know viruses themselves evolve.

A. We're seeing that happen before our eyes with COVID-19, yes.

33. Q. They can become more contagious.

A. Yes.

34. Q. They can spread more easily.

A. Well, become more contagious and spread more easily are pretty much the same thing, but, yes, they can certainly do that.

35. Q. They can cause more severe disease.

A. More or less severe disease, yeah.

36. Q. But sometimes they can cause more severe.

A. You know I think that's unusual. I -- I -- I -- that's a theoretical possibility. That's not what we normally see with the evolution of -- of -- of viruses. Generally speaking, there's evolutionary pressure on viruses to become more infections.

As the population immunity grows, there's evolutionary pressure on the -- on the virus to become more contagious, but here's no real evolutionary pressure on it to become more variant, in fact quite the opposite.

I think the -- the -- the general experience with infectious diseases or viruses is that over time they become less variant, so although that's possible, I wouldn't -- I wouldn't put that as being something that we would expect.

37. Q. And as you just mentioned, and we've seen it with COVID-19, we had the original variant and then we had the Alpha variant and now the Delta variant replacing each other as the dominant strains in Ontario.

A. That's correct.

38. Q. You know, and there's new variants like we're all now hearing in the news about Omicron variant and we're still learning about that.

A. Indeed.

39. Q. And you know, at least from what we know so far, it appears these variants have increased transmissibility and perhaps increased severity compared to the original generation of COVID.

A. Yeah, I think -- I think -- I certainly agree that they -- they have had fairly consistently greater infectivity. The issue of severity I think -- I think there's -- there's -- there's relatively little evidence to support that. It's possible. It's possible, but I'm -- I'm not

persuaded by that evidence.

40. Q. Now, are you aware that currently the spread of the Delta variant has led to increased cases in most Public Health Units in Ontario?

A. I'm aware of the fact that Ontario currently, as we speak now, is -- is starting to -- to see an increase in cases, and Delta's the dominant variant, yes.

41. Q. I'll just share my screen. And you're aware that Ontario has a COVID-19 science table?

A. I've -- I've -- I've read about it, yes.

42. Q. And you're aware that they provide advice and modeling to government?

A. I'm -- I'm aware of that, yes.

43. Q. And I'm just showing you an excerpt from their most recent publicly released advice which was on December 7th, so earlier this week. I'm just showing you now the chart of the various public health units and the weekly cases on November 15th and November 28th of this year.

A. Um-hmm.

44. Q. Would you agree that you know COVID cases are currently increasing in the majority of

Public Health Units in Ontario?

A. Well, certainly this graft shows cases increased from November 15th to November 28th. November 28th was what, two weeks ago. And there's about a two-week lag between when infections occur and cases get reported, so this tells us what happened about a month ago. I -- I very much suspect cases are continuing to increase, but I don't know that.

I certainly can't tell you that from this graft because as I say this is telling me -- this is giving me insight into what happened about a month ago in Ontario.

45. Q. Fair enough. So I'll have to get the more recent data to know what's happened since then. And do you understand what the concept of "test positivity" refers to?

A. Yes, I do.

46. Q. And how would you explain that?

A. Well, I presume you're talking about the percentage of test positivity. So one of the parameters that we measure is to what percentage -- the assumption is that if testing practice stays consistent as the percentage of positivities increase, so that's an indication of -- of -- of a true increase in disease, a true increase in cases. It's one of the

markers.

47. Q. And so I'm just going to show you two charts from the same data. The first actually is exactly that, testing rates. And you'll see the black line which represents the Ontario trend. And the title, as says, "Testing Rates Are Flat Since Mid July." Would that be your assessment of the data shown by the black line for all of Ontario?

A. The testing rates have been stable since July, yeah, it looks like it. It's a pretty flat line.

48. Q. And so given those unchanged testing rates, and given the next graft which shows the test positivity rates, would you agree that at least in several Public Health Units of Ontario would seem that as you say the disease is increasing?

A. I -- I couldn't hear that. There's a little plumbing up above that -- could you repeat that again? Sorry.

49. Q. Certainly, well, you just said that if you have consistent test rates, and you're seeing an increasing --

A. No, I -- I didn't say that. I said if you have consistent test practices as well as test rates. Has to be both.

50. Q. So therefore, assuming that nothing has changed in test practices which I take -- I'll accept is an assumption, if you were to see increasing test positivity rates as shown in this chart would that be evidence to you as a public health practitioner that disease rates were increasing?

A. Well, you asked me to comment on the -- on the testing rates from July, but in fact I see an increase in test positivity in the early part of September that was actually higher than what we're seeing now.

So, no, I'd make the observation -- if you want me to make the observation since July that in fact testing rates have been stable and percent positivity, although its fluctuated, has been fundamentally stable. Now, I don't know if rates are increasing in Ontario now, but that's what I see on this graft.

51. Q. Fair enough.

MR. KITTREDGE: Can I have that marked as an exhibit, please? That'll be Exhibit 2, Ontario science table projections.

MR. KITTREDGE: So no, no objection from me, although I'd note that Dr. Schabas hasn't had a chance to review that in any detail

EXHIBIT NO. 2: Ontario science table projections.

BY MR. HUNTER:

52. Q. Fair enough. All right. So in paragraph 7 of your affidavit, Dr. Schabas, you say that:

"Ontario has responded with a variety of restrictive measures."

That you generally characterize as a "lockdown." And so I just want to make sure I understand what exactly it is you mean when we're talking about a "lockdown." So in your view, when you use the term "lockdown," would that include reducing capacity in large indoor venues?

A. That's -- that's one component of it, yes.

53. Q. So if that was all we were doing was that a lockdown or was that just -- that's one indicia of --

A. No, no, no. I -- I think -- a lockdown, as I think you realized is a general term. And it's applied to a -- a whole variety of -- to a whole concept of approach to COVID, but -- but certainly restrictions on public gatherings is one part of that, yes.

54. Q. And so would prohibiting large organized public events be a lockdown?

A. It's part of a lockdown, yeah.

55. Q. And would reducing the number of people who can gather in person at a religious event be a lockdown?

A. It's part of a lockdown, yeah.

56. Q. Well, let's take a look actually at some of the measures that have been in place over the course of the pandemic in the areas of Ontario where Mr. Kittredge's clients are located. So let me just pull that up. Okay. It should be up now. Scroll, Niagara is no longer relevant.

So I'm going to go through -- we've got here charts for the three Public Health Units that were part of this case. One church is no longer a part of it. So I'm going to focus on Waterloo. They were similar for south-western, but some of the dates were a little different, so I'm just going to walk you through.

And what I'm going to do is I'm going to just quickly describe what the restrictions were at various times in the pandemic. I just want your view whether -- when you use the term "lockdown" are these the restrictions you're talking about? And so will

this be evidence that we were in a lockdown during these periods of time?

A. Oh, okay. So let -- let me -- let me just clarify to that, the -- the -- the fundamental difference in my opinion is between advice we give people about how to behave, about how to socially distance, about how to [indiscernible] themselves to reduce their risk of getting COVID-19 and transmitting COVID-19, and things that we -- things that public health has done that amount to orders.

And obviously the -- the -- the components of the orders vary from the sorts of things you're showing me here to things like stay-at-home orders and school closures, but it's all part and parcel of the same thing. Is there a difference between what we know in an advisory sense and what we do in terms of a kind of a statutory sense, how we order people to do.

So when we -- you know what -- what -- the whole -- the whole [indiscernible,] the whole package I think is part and parcel of a lockdown -- of a lockdown approach to the problem.

57. Q. And so I guess that's actually the example in your view. So in your view when we were -- for example, from July to December 2020, when

religious services could still have 100 people, indoor services could still have -- outdoors, 30 percent of room capacity indoors, drive-in services any capacity, or even say in March and April 2021 when there was no capacity limit outdoors, 30 percent indoors and drive-in services with no capacity limit, that would still be a lockdown in your view because the was capacity limits being imposed by orders?

A. Yeah. And indeed, putting restrictions on outdoor services, when the risk of COVID transmission outdoors is so trivial, is not only lockdown, it's absurd. In my opinion it's absurd.

58. Q. And so in your view we'd still be in a lockdown today when there's no capacity limit outdoors and no capacity limit indoors if you have proof of vaccination, if not it's just the number that can --

A. No.

59. Q. -- maintain physical distancing?

A. I didn't say that. I -- I said in my affidavit that Ontario has introduced a group of measures which can be generally described as "lockdown." I didn't say when you cross the threshold from restrictive measures into what was called "lockdown," and I don't know where you draw that line.

That -- that -- that's -- that's a work of art that I'm not sure I can do on a day-to-day basis or a restriction-by-restriction basis.

I can certainly say for the periods of time that Ontario was under stay-at-home orders and when there were travel bans, that that was a lockdown. Are we in lockdown now? It's certainly not the same as it was then, but it's also -- also there are significant restrictions on at least some activities, so I don't know when -- when we cross that line.

But I think we all know what I'm talking about when we talk about that as being an approach to COVID. It's -- it's a regulatory authoritative legal approach to limiting people's ability to do things to limit their -- their daily activities to greater or lessor degrees, which is fundamentally different as I said from simply advising them how they should behave.

60. Q. And so I notice in your affidavit you cite some articles that are talking about the harms of "lockdowns." And I think they draw a different distinction than you between lockdowns and restrictive public health measures.

For example, the Savaris article you cite, the whole point was taking a difference between

restrictive things like gathering limits and -- gathering limits, restrictions on capacity and stay-at-home lockdown, don't leave your house except to walk your dog, et cetera, kind of orders. Would you agree that's a fair characterization of the point of that study?

A. No, I'm not sure. Maybe you could point me to where they actually made that --

61. Q. Sure.

A. -- distinction?

62. Q. Let me actually bring that up.

A. I do not --

MR. KITTREDGE: Josh, can I just interject here and ask you to send me a link to this?

MR. HUNTER: These are the affidavits he -- these are the articles he cited --

MR. KITTREDGE: Oh, they are.

MR. HUNTER: -- piece of paper.

MR. KITTREDGE: Okay. Oh, yeah, I missed -- I was looking away when you started with this, sorry.

BY MR. HUNTER:

63. Q. And, sorry, I apologize, I actually had the wrong paper. It was the Chin (ph) paper I was asking about. I'll just find the passage.

A. Show me the paper.

64. Q. You cited two in the same footnote, but it was to Chin. I'll just take you to their conclusions in one second. So in that article they discuss two different models --

A. Um-hmm.

65. Q. -- that they were examining, and one was -- I'll just get the reading of it. Model one was doing a complete lockdown as they called it. And then their hope and their conclusion is that that didn't produce much benefit because they in fact had already had a number of significant measures under model two which had already --

A. Sorry, did you say -- did you say they said "complete lockdown"?

66. Q. They used the word "complete lockdown" --

A. Yeah, I -- I didn't use --

67. Q. -- or "total lockdown."

A. -- that term. I didn't use either of those words.

68. Q. Yeah, but that's what they -- that's what says and you're expanding was the impact of a total or a complete lockdown according to their own introduction.

A. Okay.

69. Q. So that was just my point is that when you're saying that's about lockdown, you're talking about a broader range, more colloquial use of lockdown to refer to not just the stay-at-home phase when you know you couldn't legally leave your home except for specified purposes, but the broader range of regulatory measures --

A. Yeah.

70. Q. -- that were used throughout the pandemic.

A. Yeah. I think that's what I said in my affidavit, yes.

71. Q. Okay.

MR. HUNTER: Oh, just before I move on, I'd just like to mark that chart as an exhibit. I'll stop sharing it. That'll be Exhibit 3, summary of COVID measures on religious gatherings.

MR. KITTREDGE: No particular objection from me, but if you can send that over to me after the examination that would be great? Thank you.

EXHIBIT NO. 3: Summary of COVID measures on religious gatherings.

MR. HUNTER: Yeah, we'll send all the exhibits over after.

BY MR. HUNTER:

72. Q. All right. Moving on in your affidavit, in paragraph 8 and 9 you state that:

"Ontario has rigidly applied the same rules to all public gatherings, regardless of the relative harm."

And I would suggest to you that in fact throughout most of the pandemic Ontario has applied less stringent rules to religious gatherings than it has to other social or organized public gatherings.

A. [Indiscernible] less stringent, yes. I believe -- I believe the percentages were a little higher for religious gatherings, but the spirit of the restriction was the same.

73. Q. But sometimes they were considerably higher. In fact, at times you know you still have 10 or 50 people for a social gather, you could have 100 or even just physical distancing for religious gathering.

A. Okay. Well, then if -- if -- that's -- that's fair enough.

74. Q. And you know if we just looked at the chart the severity of the rules, the capacity limits are in place, they varied over the course of the pandemic.

A. Yeah, but they were all entirely arbitrary, not based on good evidence. And they were -- there were limits.

75. Q. There were limits, but the limits were loosened when the situation permitted, when the situation improved.

A. The -- the -- the -- again, I'll stand by what I said, none of those -- none of those limits were -- were particularly evidenced-based. They were -- they were arbitrary. That doesn't mean they were wrong, and it doesn't -- but -- but they -- they were -- they were in and of themselves arbitrary and they were fixed limits.

76. Q. Although of course by "fixed," sometimes it was an actual fixed number and sometimes it was a percent of capacity.

A. Yeah. Those are still affixed.

77. Q. And sometimes it was just enough to maintain two metres social distancing.

A. Yeah. Fair enough.

78. Q. And you'd agree that that's the generally recommended distancing to decrease the --

A. Yeah, that's -- that's the recommendation. That's recommending to people about how they should conduct themselves prudently to reduce

their risk of -- of getting or transmitting COVID-19 which -- which is entirely reasonable, yeah, but that's July. I wouldn't -- I wouldn't characterize that as an arbitrary limit or as a measure of lockdown.

79. Q. And at times there were different rules in different parts of the province. I think actually we looked at chart, you know Waterloo. Local public health officers kept some restrictions in place a bit longer than the provincial limits.

A. It's quite possible. I don't know.

80. Q. Let's talk about some of those -- you say they increased the risk of contracting COVID-19. Would you agree with me that the prevalence of COVID-19 in the community affects the risk that you're going to contract COVID-19?

A. Yes.

81. Q. The level of vaccination in the community affects that risk?

A. Well, that's a more complicated question. Your own personal vaccine status will affect your risk of getting the disease, but the level of disease in the community is still -- is going to be what it is, so, no, the vaccination provides -- will reduce the overall amount of transmission in the

community and it will provide a substantial measure of individual protection.

82. Q. And so if a substantial number of those individuals are protected, and either don't have COVID or you know are symptomatic or capable of spread, they may not be symptomatic for a shorter period of time, there's going to be less people you're going to run into who are capable of giving you COVID; would that not be true?

A. If you were with people who are infected with COVID the less likely you are to run into somebody who's infected with COVID, that's true.

83. Q. I think you actually just mentioned this, but you have a higher risk of contracting COVID-19 indoors than outdoors?

A. Oh, yeah, there's very good evidence of that. The -- this goes way back to Wuhan. The risk of contracting COVID-19 outdoors is -- is -- is quite trivial. It's a disease like any respiratory virus that's primarily spread indoors.

84. Q. And of course, "trivial" is not zero, but it is much lower than indoors.

A. There are very few zeros in the natural world, so it's not zero.

85. Q. And so the more people who are

present in a given venue at one time the higher the risk of someone being there who has and can spread COVID?

A. Yes.

86. Q. And the more closely people are crowded together the higher the risk?

A. The -- the -- the risk of transmission of COVID, one of the determinants is -- is -- is -- is proximity and length of exposure. So you know close -- prolonged close contact, particularly with a symptomatic person indoors is -- is at least one of the -- one of the fundamental ways in which COVID is spread. It's not the only way because aerosol spread, which is a little different, is also important, but certainly those are important factors, yes.

87. Q. I think you anticipate my next question, which is if you're sitting next to someone for an hour or two it's more likely they're going to transmit COVID than if you just walk by them quickly?

A. Only if they're infected.

88. Q. But if they are --

A. If they are infected, and particularly if they are symptomatic then in fact there's a much -- then, yes, yes, it increases in

proportion, an inverse proportion to the distance of separation and in direct proportion to the time of contact, yeah.

89. Q. And would you agree that you know if you're singing or talking loudly that increases the risk you might spread COVID to those around you?

A. That certainly could increase droplet production, so if you are infected it may well indeed increase the risk of transmission to somebody else, yes.

90. Q. All right. So moving on to paragraph 14 of your affidavit --

A. Yeah, yeah.

91. Q. -- yeah, you suggest that perhaps rather than looking at Ontario and predictions, we should look at jurisdictions such as Sweden, Brazil and Florida that have used less restrictive public health measures.

A. No. What I said here is that the models which predicted -- which the models predicted much higher rates of disease even in -- in places that didn't use restrictive measures. We had -- going back to two years ago almost, the models had a range of projections, and one of them was what happens if you lock down, what happens if you -- if you don't lock

down, and they made projections for a variety of countries which were with huge rates of disease.

My point here is that even places that didn't embrace the kind of lockdown approach that Ontario embraced still had rates of disease that were far far lower than the models predicted. The models on which we based our initial response to COVID, and which to a great degree still influence our thinking about COVID were just fundamentally wrong.

They were wrong -- they -- they -- their predictions, projections were just -- were really just wildly wrong. And -- and that's not only true for places like Ontario, but it's true really everywhere in the world.

You may recall that the -- the -- the famous Imperil College model said there would be 40 million dead within the first five months. Well, we're now two years into it and it's five million dead. Now that's still a lot of deaths, but it's not 40 million deaths within five months.

Ontario, according to I believe the Fisman model from that time, or rather Canada, was going to have 330,000 deaths. Well, we have 30,000 deaths, but we don't have -- and two years later almost we don't have -- we don't have 330,000 deaths

by the mid summer of 2020, so those projections were just fundamentally wrong.

And the reasons that they were wrong, and I should say that these models, these modelers, that these models have a long track record of making bad predictions, so -- and it was like we -- we accepted them as being -- as -- as having good strong science, but if we look back at their projections for -- for bird flu, for H1N1, for SARS, they had a very bad track record of -- of -- of projections.

And the projections were wrong because they used the wrong parameters for infection fatality rate. I still think they used the wrong projections for -- for -- for are not, but the bottom line is -- and -- and because their models are very simplistic. They're very very simplistic. They don't [indiscernible] other factors that may influence it.

But the bottom line is that these models were -- were not -- not just wrong, not just wrong, they were -- they were wildly wrong.

92. Q. Well, now that we have the benefit of two years of actual data, I just want to ask you some questions about these three jurisdictions. You suggest them, so I just want to kind of compare their experience with here in Ontario.

I think we'd all agree that those three jurisdictions took a less restrictive approach to public health measures than Ontario did.

A. That's why I assigned them, yeah.

93. Q. Yeah. And they all have had significantly more cases per capita than Ontario has had.

A. Well, I think -- I think we need to be very careful with that. There -- there's a geographic distribution to COVID-19 that we don't begin to understand, so -- so indeed there are differences.

In Canada as a whole, for whatever reasons, has actually had relatively low rates of disease compared to many other countries, certainly compared to the United States and compared to western Europe, but there's no particular correlation between the -- the -- the lockdown measures and -- and rates of disease.

So that -- that indeed we can look at -- at -- looking just at Canada, for example, the -- the rate -- the population mortality rate from COVID-19 in Quebec is about twice as high as it was in Ontario, even though Quebec, if anything, took more restrictive measures than Ontario. And Ontario's

rate, population mortality rate is about twice as high as it is in British Columbia even though Ontario, if anything took substantially more restrictive measures than British Columbia, so it's not about the restrictions.

If we look at examples like Brazil, indeed Brazil took a more relaxed approach to COVID. It was -- it was the whipping boy for not taking an aggressive approach.

Argentina on the other hand, right next door, was the poster child for lockdown, but two years into the outbreak or a year and a half into the outbreak, when you look at their population mortality rate they were almost identical.

Sweden took a much more relaxed approach than many other European countries. It's now in the lower half of mortality rates for European countries, so, yeah, they had more than Ontario because western Europe had more than Ontario, Latin America had more than Ontario, and the United States had more than Ontario or more than Canada for reasons, again that -- that I don't think we truly understand, but which are certainly complex.

But to sort of attribute all of that to what we did or what we didn't do, I think -- I think

that's a fallacy. I think we have attributed far too much to human activity to the -- to the impact of what was done or wasn't done because we don't truly understand the dynamics of what has caused a geographic spread or lack of spread of this virus, but it cannot be attributed in my opinion simply to what -- what jurisdictions did or didn't do.

94. Q. You're the one who picked these three jurisdictions as examples of --

A. Yeah, but for a purpose.

95. Q. -- less restrictive measures.

A. But -- but I did that for a purpose, to show how the models were wrong. I didn't pick them as poster child's of what we should emulate. That's not what I said in the affidavit.

I used that as an example, because people say, oh, yeah, yeah, the models -- the models that we didn't achieve the levels of disease most because we locked down, because we did these things. I'm saying, no, that's not correct, because even jurisdictions that didn't do these things still had rates of disease far far lower than the model we projected.

It's to make the point that the models were wrong, not to hold these up as models for what we

should or should not have done.

96. Q. But the facts remained that -- I mean, obviously we can go through the math if that's helpful, but if you adjust for the different populations Sweden had about 11,000 more -- if we had had the same rates as those places --

A. Yeah, but you're -- you're completely misrepresenting my point. As I said again, I'm not suggesting that we should have emulated -- and that's another discussion, whether we should have emulated Sweden or Brazil or wherever. That's a totally different discussion.

That you want to reference paragraph 14, let's stick to the point I'm making in paragraph 14. It's to show that the -- that the exaggerated predictions of the models had nothing to do with whether people walked out or not, because even places that didn't had far lower rates of disease than the model projected. That's the point I'm making in that paragraph.

97. Q. So in paragraphs 15 to 17 you argue that we should have followed the Canadian Ontario pandemic influenza plans, and we'll come back to whether COVID-19 --

A. I don't think I said that. I don't

think I've said that. I -- I -- I said that we should have paid more attention to what was done that. That was our [indiscernible] that our fundamental basis for our starting point for how to handle COVID-19.

I'm well aware that there are differences between COVID-19 and influenza but that was the building block. We spent a lot of time for conceptualizing how to deal with a pandemic of a respiratory virus. And there were some fundamentals in the pandemic influenza plan that I think we would have been well advised to pay attention to.

98. Q. That's where I wanted to go, was ask you about some of those fundamentals.

A. Sure.

99. Q. So Canada's Pandemic Influenza Preparedness Plan, which you've attached as Exhibit C, recommends that:

"Jurisdictions in a moderate to severe pandemic."

And I'd assume you'd agree with me that COVID-19's at least equivalent to a moderate pandemic?

A. Um-hmm. Yeah.

100. Q. That:

"Jurisdictions consider social distancing matters or strategies to

minimize close contact among people in public places, for example, proactive school closures and cancellation or modification of public gatherings."

So I would suggest that cancelling and modifying public gatherings would be consistent with Canada's pandemic influenza plan.

A. It -- in -- in a moderate to severe pandemic, yes, with the caveat, with the caveat that -- that -- that -- that influenza outbreaks typically last about six weeks. So the expectation in handling an influenza outbreak, the feasibility of taking these measures in the context of influenza is that -- is the expectation that these will be short-term measures, that these will not be -- we're talking about a matter of a few weeks, not a matter of a few years.

101. Q. Pandemic influenza doesn't always last just a few weeks.

A. Yeah, outbreaks of pandemic influenza do actually last a few weeks. Influenza outbreaks are very typical. They -- they last between six and eight weeks in any one jurisdiction, so indeed they do.

102. Q. But there's often multiple waves of those infections if it's travelling around the world.

A. Generally speaking, a pandemic wave of -- of -- of -- the wave of a pandemic is usually just one wave. That was the case -- one -- one large wave. That was the case in 1957, 1968 and 2009. There were -- there were small waves before, but with very low rates of disease, so -- so, no, I don't agree with that statement.

103. Q. Going back to the Influenza Preparedness Plan, it does recommend looking at mathematical modeling as one of the ways of deciding which public health measures to use, correct?

A. Yeah, indeed.

104. Q. I'm sorry, now I'm turning actually to Ontario's Influenza Pandemic Plan, which is at Exhibit D. And it recognizes that:

> "As our understanding of a pandemic's severity evolves, orders may have to be made to close an organization or modify activities within organizations."

A. Okay.

105. Q. Do you agree that's part of Ontario's Influenza Pandemic Plan?

A. I -- I -- I -- you're reading in -- I'll take your word for it, yeah.

106. Q. All right. If you'd like to take a look it's on pages 10 --

A. With the caveat -- with the caveat that the difference is of course that these are short-term closures. By the nature of influenza these are short-term -- these are short-term measures.

107. Q. Let's switch to COVID then and planning for that. I'm showing you now interim guidance. It's issued by the World Health Organization:

"Considerations for implementing and adjusting public health and social measures in the context of COVID-19."

And it was last updated June 14th of 2021; do you see that?

A. I -- I see it, yeah. Um-hmm.

108. Q. I'm just going to take you to pages 7 and 8. So what this document recognizes is that there's different situational levels of SARS-CoV-2 virus, you know ranging from no known transmission to basic measures. Then you're getting into the levels two:

"Risk of community transmission behind clusters."

And then over on page 8 we have,

"Sustained community transmission," and then you know eventually level four, which hopefully we will never get to, the:

"Uncontrolled academic and the health system's falling apart."

But in level two which is:

"Low community instance or risk of community transmission."

It recommends -- this is the fourth bullet down, can you see that, starting, "Apply risk-based approach"?

A. Um-hmm.

109. Q. And it says:

"For public gatherings risk assessments should be undertaking by local and national public health authorities and event organizers with input from all relevant stakeholders. And this is to inform the decision to restrict, modify, postpone, cancel or proceed withholding any mass gatherings, including medium and small events."

So you would agree that the -- WHO is recommending that nation states consider, once you're getting into community transmission consider

restricting and modifying gatherings.

A. I'm sorry, you're showing me a complex technical document from the World Health Organization. You're showing me one paragraph and asking me to comment on the whole document. I'm not going to do that. If you want me to review the document I'll take the time to do it, but --

110. Q. I didn't ask you to comment on --

A. -- I can't do that.

111. Q. I mean, we're happy to --

MR. KITTREDGE: You're asking for a comment on what the WHO is recommending which I think it's fair to say that in order to understand that Dr. Schabas would have to have some time to review and understand the document itself.

MR. HUNTER: Sure. I'm happy to go off the record. And my question is actually quite simple, is just is the WHO recommending restrictions on mass gatherings be one of the measures that nation states consider.

MR. KITTREDGE: I mean, if you want to ask a specific question about the wording of that paragraph or something like that, I think I could accept that, but an opinion on what the WHO recommendation is overall would involve review of the

document.

BY MR. HUNTER:

112. Q. I mean, obviously if we need to take time we will, but I think my question was pretty simple, it's just is one of the measures that WHO recommends, and I'll give you a few minutes just to read this paragraph and the next one, you know what they call:

"Situational levels two and three."

That:

"Consider restricting, modifying, postponing, cancelling or proceeding with mass gatherings including medium and small events."

I'm not saying you have to cancel them all, but they're suggesting this is one of the measures that nation states consider at this level of risk.

MR. KITTREDGE: Why don't you ask him more specific --

THE WITNESS: Do you want me to read that paragraph? And which other paragraph do you want me to read?

BY MR. HUNTER:

113. Q. It's the same paragraph under, "Situational level three." It's the second from last bullet.

A. Okay. It simply says how you should approach any decision on that matter. It doesn't advise as to whether you should take that decision or not. That's what it says.

114. Q. But it suggests that you apply a risk-based approach to those decisions, correct?

A. That's what it says, yes.

MR. HUNTER: I'd like to mark that as an exhibit.

MR. KITTREDGE: All right. I mean, it's markable, but I -- and I think Dr. Schabas included enough caveats in his answer that I have no objection to it.

MR. HUNTER: Thank you. I think we're up to Exhibit 4 now, stop sharing.

EXHIBIT NO. 4: Document from World Health Organization.

BY MR. HUNTER:

115. Q. Now, at paragraph 23 of your affidavit --

A. Hang on. Yeah, okay.

116. Q. -- do you agree that COVID-19 is a

serious public health problem?

A. You say that, yes.

117. Q. Yeah. And at that time there were three million reported deaths. I think we're now, as you mentioned, we're over five million now.

A. Yeah.

118. Q. Yeah. And you make a comparison to children who unfortunately die from diarrheal illness.

A. Yes.

119. Q. Having a greater impact on premature mortality than COVID-19. Are you aware how many children in Canada die from diarrheal illness here?

A. Fortunately, very few. We're a developed country. No, this was a global statement, but indeed diarrheal illness is not an important cause of mortality in children in Canada, thank goodness.

120. Q. And that's both because, as you say we're a develop country with good sanitation, but also because childhood vaccinations have largely eliminated a number of those diseases in Canada?

A. No. It has -- it has very little to do with -- with immunization. It has to do with sanitation, generally good nutrition. There are a variety of what we would call the -- the -- the

determinants of health that really make a difference there.

121. Q. And now, in the next paragraph, paragraph 24, you focus on the deaths caused by COVID-19.

A. Correct.

122. Q. And you know I think we agree that obviously those two are very age stratified, but younger people can still have serious outcomes from contracting COVID-19, correct?

A. Yes.

123. Q. They can include death.

A. Yes.

124. Q. It can include long-term so called long COVID.

A. Yeah. I'm -- I'm a little cautious. Maybe you'd like to define what you mean by that if you want me to answer that question.

125. Q. I mean, they can have long-term respiratory, circulatory, kidney, liver, other damage from having the disease?

A. Yeah. I think -- I think those sorts of outcomes in healthy young people are -- are very unusual, but -- but indeed, yeah, if there are any -- COVID-19 has the capacity to cause serious

illness in younger people, but -- but it's - but it's -- it's -- it's -- the rates of -- of serious illness and -- and long-term consequences are very very much lower in -- in younger people.

In fact, fundamentally in people I put at the age of 60 the rates are very low. For people under the age of 60 the rates to that are -- are pretty comparable to what we see from influenza. And in fact, in children -- in children influenza appears to be more serious that COVID.

126. Q. And of course, people you know who contract COVID-19, and even if they recover they can sometimes require a period of time in the hospital or even in the ICU.

A. Yes.

127. Q. And of course --

A. It's a very serious illness, absolutely.

128. Q. Yeah.

A. Absolutely.

129. Q. When they're using that bed it's not available for someone else who might have had a heart attack or a car accident or anything else.

A. Yes, that -- they certainly use up -- we don't put two people in hospital beds, so when

somebody's in a bed, yeah, nobody else can use it, that's true.

130. Q. Now, in public health practice, when you're making recommendations to the public you want to make them easy for the public to understand, right?

A. You want to make them as easy as you can. You know sometimes the advice is complex. That's not -- that's not a rationale for oversimplifying. Indeed, you want to make it as comprehensible as possible, but -- but -- but sometimes advice is complex, and we have to recognize that.

131. Q. But as much as possible you want to make it -- like let me give you an example.

A. Sure.

132. Q. You know if you have -- you decide that the proper capacity limits should be 6.3 people in a room, might you round that down to five or if it's 9.8 you might round it up to 10 just because it's easier for people to work with round numbers?

A. I have absolutely no idea how you could come up with a number like 9.5 for -- for capacity limits, so I'm -- I'm sort of baffled by that, by that analogy.

133. Q. I just want to make the point that you know -- I believe Mr. Kittredge asked some of our witnesses, but why 10 people? Why not 11? Why not 9? And I'm just suggesting that --

A. Yeah. Well, it's -- it's kind of like we did with social distancing, because the actual evidence for social distancing, which was -- was that there was a benefit at one metre distance. And in fact, the WHO recommended social distancing of one metre. And a number of European countries adopted one metre.

The United States pretty much arbitrarily said, well, we'll go with six feet. Well, we didn't go with six feet in Canada because we're metric, so we went with two metres, so now we're out six and a half feet. It just -- yeah, that's -- sometimes simplification can -- can -- can lead you down that road, yeah.

134. Q. [Indiscernible] if you're going to tell -- you know you're going to make it businesses across the province would have to comply with something, giving them you know a number that's easier to calculate, divide your square footage by two rather than 1.5 or 1.7.

A. Fair enough, but -- but again, what

I -- what I -- yeah, okay. Yes.

135. Q. Now, at paragraph 28, I'm giving you this concept you call "arbitrarily," and I think by "arbitrarily" you mean just picking a bright line rule for all religious gatherings, is that what you mean when you say "arbitrarily" in that paragraph?

A. Well, all of the limits. None -- none of -- none of the limits, the percentage limits or the attendance limits where they posted a number, in my opinion are based on -- on -- on -- on strong science, so basically they -- somebody made a decision in their best judgment, but there's an arbitrariness to that decision, so it's not -- as I say not based on strong science.

136. Q. Are you aware of science that would allow a precise determination of exactly how large would be available?

A. No. No, I'm not. I'm not, but that doesn't make the decisions any less arbitrary.

137. Q. And you suggest that:

"Public health should work constructively with religious congregations to find ways to [indiscernible] risk."

And you give some examples. You

suggest that they could, for example, require a social distancing. Were you aware that Ontario in fact did require social distancing in a number of venues, including religious places of worship?

A. I'm certainly -- yeah, recommend social distancing, yeah. I think that -- I think that -- that in discussing with religious congregations that want to meet indoors the -- the -- these are the sorts of measures, social distancing, and the other things that I mentioned, are things that could mitigate the risk that could allow them to continue to practice their religion as they choose to by -- and mitigate the risk of transmission, yeah, but that does not --

138. Q. Are you aware that some of the rules are being challenged in this application include rules requiring social distancing?

A. Yeah. I'm not -- I'm not suggesting these would be rules. I don't say these should be rules. They -- they -- these -- these are examples of things that they could -- they could find ways with the congregation to mitigate the risk, to reduce the risk to allow that would be acceptable to the congregation rather than simply saying go ahead and -- and have your -- your -- your -- your religious

gathering, let's talking about things that we can reasonably do, but there's -- there's -- I'm not talking about imposing rules here.

139. Q. Okay. So you're saying that each religious -- you know you should have a conversation, but at the end of the day each congregation decides for itself?

A. No. I -- I think -- I think what I'm saying is that -- is that the -- the practice of religion is very fundamental to the public health of some people in the province. I make that point very strongly in my affidavit. We're not talking about -- we're not talking about retail stores or we're not talking about restaurants. We're not talking about hockey games or rock concerts.

We're talking about something that is -- is very fundamental to the -- the psychological and social wellbeing, which are two of the -- the pillars of people's health. So when we -- when we look at -- at the risk of COVID in that context we need to apply, I think a different standard than we do to hockey games and rock concerts and -- and retail stores because of the importance.

Not -- I'm not talking from a human rights perspective, that's not where my expertise is.

I'm talking about from a public health perspective. So indeed, I think that if there are people whose -- who the practice of religion, the -- the -- the ability to congregate to practice their religion in the way that they choose is so important to their own health that they are willing to face the risks of -- of COVID-19, even if it includes things like singing things that I would not recommend, then I think that that's something that we have to be respectful of, yes.

Yes, I think that -- that the people are able to make -- that people -- one of the -- one of the -- the -- the principles of public health as I always practiced is that people are allowed to make decisions about their own health. We don't think people should smoke, but we let them smoke.

I don't think people should go to a religious gathering and -- and -- and sing and -- and -- and be in close contact, but -- but if that's so important to them that they're -- that they're willing to face that risk I think we have to be respectful of that.

We have to at least document that -- that -- that it's causing a problem before we're taking measures to stop it. As I -- as I say in the

affidavit and make the point, and the Ontario data supports it, there's precious little avenues in the real world of Canada in the COVID outbreak that religious gatherings have been an important source of transmission, precious little evidence.

And yet we've taken these arbitrary measures and we've denied people something which for them, not for me, I'm not religious, this matters not to me at all, but I respect it for these people, practicing their religion is fundamental to their health.

140. Q. I'll come back to that in a minute, because I think that's the next paragraph. I just want to do one more thing before we move this paragraph. You mentioned that you could -- examples is that:

> "Public health could work to determine attendance limits based on the characteristics of the venue."

And I assume you mean each unique thing, correct?

A. Yeah, yeah.

141. Q. Are you aware of how many places of worship there are in Ontario?

A. I -- I don't. I don't have a

number. Do you have a number?

142. Q. I don't, but I would suggest it's at least in the tens of thousands, if not --

A. I would suspect there are. I would suspect there are tens of thousands, yes, indeed.

143. Q. And you know I would suggest that you know public health, with their many other responsibilities, especially during a pandemic, it would be very challenging for them to have those discussions with each and every place of worship to have an individualized discussion.

A. Yeah, I -- I find -- I find that a curious argument that when we're talking about something that's so fundamental to people's lives as the ability to practice their religion that the first -- that one of the lines of argument is that I'm sorry, we don't have no resources to take measure to -- I find that -- I find that on its face a very -- a very questionable argument.

I'd also say of course that -- that while there may well be tens of thousands of religious venues probably the great majority of them are not in fact going to -- going to -- going to want to go down this road. I suspect with all the fear that's been generated about COVID-19 the great majority of

religious -- of religious bodies are going to say, fine, we'll go with your recommended limits. We'll do as you say.

But even then, even then Ontario -- Ontario Public Health departments employ about 1,000 public health inspectors, trained public health inspectors who would be ideal people to do these kinds of assessments. And those people have been -- have been very -- have -- have -- important parts of their work in fact have disappeared with COVID-19 pandemic, restaurant closures, pool closures, all kinds of things that they would normally have to do.

So, no, I don't accept that we don't have the human resources to make at least a very good try at accommodating what I would think would be relatively few religious congregations that would want to go through this sort of assessment. So -- so, no, I don't think it's a daunting task at all. And I think it's quite shocking that Ontario hasn't even tried to do it.

144. Q. So your view you know those religious who want to stay open, they should just be able to decide that for themselves?

A. As I said I think -- I -- I've said -- this is -- this is -- this is a very nuanced area,

but the -- but what we've done is before there's been spread in religious congregations on any scale we've said you can't do this, but I would say, no, let's -- let's work with these bodies.

Let's make sure people are aware of their risk and then let's balance their freedoms, their freedom and their -- their need to practice their religion with the risk of COVID. And, yes, for some people it's going to mean a higher risk than we -- than I would think wise or you would think wise or Ontario Public Health would think wise, I agree with that.

And I wouldn't do it. I'm not going to go to a church and start singing in the choir. You're not going to find me there. But I respect that some people will make that decision that they will make the equation that the risk is -- you know the risk -- yes, COVID-19 can cause serious illness and death, but in fact the risk is -- for -- for many people, for most people it's actually quite small.

The risk of serious illness, hospitalization and death is really very small, even if they contract COVID-19. And that some reasonable people who put a very high premium on their ability to practice their religion they way they choose would

make a different decision. And I think we've made no effort to accommodate that, and I think that's wrong.

145. Q. And of course, they're not only taking those risks on for themselves.

A. Well, okay, so then we get into the issue indeed. It's an infectious disease, but we don't -- the contribution of churches are spread within religious gatherings, so the total burden of COVID-19 in Ontario has been trivial and almost certainly would be trivial.

And -- and so, yes, if we take the approach, which I must say I think has -- has -- has -- has poisoned a lot of the Ontario approach to COVID-19 that somehow we're going to stop this thing out, we're going to have zero COVID, we're going to get rid of the infection, yeah, if that's the priority, if that's in -- if that's in people's minds then in fact we can't do that.

But I think that's wrong. I think we have no capacity even with the vaccines to eliminate the disease. We have to accept there's a certain burden of illness, and in all other things we have to look at the balance here.

Where is the population level threat of these churches, the amount of spread in these churches

or other religious congregations. Is it so substantial that we are therefore -- that it's necessary for us to take these draconian or arbitrary measures? I'm not convinced of that.

MR. HUNTER: Can we just go off the record?

MR. KITTREDGE: Sure.

MR. HUNTER: Okay. So why don't we take let's say a 10-minute break to 2:20? I just want to talk to my team to see if there's anything else we want to --

MR. KITTREDGE: Okay. Sounds great.

MR. HUNTER: All right. So, Dr. Schabas, can you just turn your mic and -- your mic and screen off if you want? Obviously, I remind you you can't talk to Mr. Kittridge --

MR. KITTREDGE: Yeah.

THE WITNESS: You want to come back in 10 minutes?

MR. HUNTER: Yeah. So we're just going to take a 10 minute break. I'm going to talk to my team and then we'll see if we have any more questions for you.

THE WITNESS: Okay.

MR. KITTREDGE: And I'll keep my mic

and video off in the meantime.

MR. HUNTER: Great. We'll see you at 2:20.

---RECESS TAKEN AT UNKNOWN

---UPON RESUMING AT UNKNOWN

BY MR. HUNTER:

146. Q. All right. So, Dr. Schabas, just before the break we were just discussing you know your view that public health has overreacted, and at the end of the day we can't beat this virus. Would it be fair to say that public health officials in Ontario did not follow your recommendations?

A. What -- what --

147. Q. Your recommendations that we shouldn't be doing these lockdowns and strict rules we've just been talking about.

A. I'm sorry, when did I recommend that?

148. Q. Well, your whole affidavit states that we've overreacted by imposing restrictions on different gatherings.

A. That's one component of lockdown. You're -- you're characterizing that as we shouldn't have done any of these things, and that's not what I've said. I'm -- my affidavit relates specifically

to the issue of restrictions on religious practices, yeah, but yeah, I mean if what you're asking did Ontario Public Health introduce arbitrary measures on restriction of religious gatherings, yeah, that's true, they did.

149. Q. And in fact, public health authorities across Canada imposed restrictions on religious gatherings.

A. Yes, but I -- I -- I believe that's true, although I certainly know in British Columbia there was a lot less. I know when I wrote the affidavit I did a quick check of provinces and there were no restrictions at that time I believe in British Columbia, for example, so there's been variation.

150. Q. Just at that time they have certainly imposed restrictions --

A. Yeah, quite -- quite possibly. Quite possibly, yeah.

151. Q. And would it be fair to say that you would therefore be in the minority of Canadian public health practitioners vis-à-vis putting restrictions on congregate gatherings like religious --

A. I'm not taking a vote. I can't comment on that. I'll hold my opinions, you know.

Scientific matters are not decided by majority vote.

152. Q. Do you remember an interview you gave, when was it, back in March 2020 where you stated you were in the minority, a very small minority with your views?

A. Quite possibly. Was that -- so it's probably a fair statement, and certainly wasn't in March of 2020. I don't know what the situation is now. I hope -- I hope people are -- are -- are opening their minds up to the fact that maybe the things we've done have been without purpose and have caused great harm, but don't know that for a fact.

153. Q. Thank you.

MR. HUNTER: Those are all my questions.

MR. KITTREDGE: I just have a couple for re-examination. And I'm ready to go right now if you are.

MR. HUNTER: Yeah.

RE-EXAMINATION BY MR. KITTREDGE:

154. Q. Okay. Great. Thanks for your time today, Dr. Schabas. Early in his cross-examination Mr. Hunter showed you a Globe and Mail opinion piece that you wrote. Can you describe some of the ways that your approach to writing an opinion piece for a

newspaper differs from say authoring a paper for peer review?

A. Oh, sure. Opinion pieces in newspapers are -- are -- are short. They -- and they -- they -- they have to -- they're -- they're -- they're directed at a different audience, so I think there is a -- a need to hopefully not oversimplify, but to simplify and to make the -- make the piece punchy to get people to pay attention to what your key points are.

I think looking back at the -- at the Globe and Mail article, the -- the key point that -- that I was trying to make, and I'm not sure how well I made it, but that I was trying to make is it really related back to my experience with SARS. I was, as you -- you probably know through my CV, very intimately involved in the SARS outbreak in 2003.

And probably the most important lesson I took away from 2003 was that we've spent far too much time worrying about what we were afraid might happen and not enough time, not enough focus on what was actually happening. So in the -- in the Globe and Mail article I think what I said is let's look at the facts. Let's look at the data.

And I referred to the WHO webpage.

We've since started using things like world [indiscernible] and world data, but the idea is rather than speculate about the future and what might happen let's really focus on what -- on what -- what the data show.

And at the time the data showed that the case counts were -- were coming down. I said that's -- that's what it was. I also went on to say, but we've got to keep our minds open. We've got to keep any eye on the data, because what's happening, I mentioned in the -- in Korea at the time was worrying, and that this certainly could get -- get much worse, but I think that was my key message.

And I think the point I was trying to make is pay attention to the numbers, pay attention to the data. Let's deal with -- let's deal with the facts and not with the fears.

155. Q. Great. You were also asked several questions about hospitalization and the pressure that COVID puts on our healthcare system. Can you tell us a little about the capacity of Ontario's healthcare system and how it has coped during the COVID pandemic?

A. Sure. I think -- I think one of the kind of mantras that's developed is -- is this talk about the collapse of the healthcare system. We

have to prevent our healthcare system from collapsing. And -- and I think that's -- I think that is -- is -- is really very overdrawn.

The -- COVID-19 certainly has had the capacity to put pressure on ICU capacity. We've seen that, and we saw that initially in Italy where they made a whole bunch of serious errors, but -- but since then, even -- even in -- for example, in Ontario there's no question that it's put ICU capacity under some -- some strain, but ICU capacity is not the whole healthcare system.

The whole healthcare system is a much broader thing. And, no, our healthcare system has not brought to the -- to collapse or to the edge of collapse because there are pressures on -- on -- on ICU capacity.

Having said that -- having said that, even looking at Ontario, for example, and ICU capacity, we have roughly 2,000 ICU beds. And in April of 2020 Premier Ford announced that we had another 1,000-bed surge capacity, and that was right at the beginning.

And -- and -- and everyone knew, and I think should have known that in fact, the one -- the one -- the one pressure point in our healthcare system

was going to be ICU capacity, Canada went out and allegedly bought 40,000 ventilators. I have no idea what happened to them, but then like a year later, when we're in the midst of a COVID wave suddenly all we have are 2,000 beds.

What happened to the other 1,000 surge capacity beds? What happened? What have we been doing for the last year to try and build our capacity in the one place where there was going to be a problem?

I was the Chief of Staff at York Central Hospital in 2003 where we were one of four hospitals in -- in -- in North America that was hit by deal with SARS. And we were actually able overnight to double our ICU capacity.

We created a SARS unit that had -- had as many beds as -- as our ICU. Now, it was a stocket (ph) measure. We had to beg and borrow, but we weren't -- we weren't able for that period of the few weeks that we were dealt with with SARS, we weren't able to increase our capacity.

So, yeah, I don't -- I don't dismiss the pressures on our healthcare system, but remember, remember our healthcare system gets put under pressure every winter when there's an influenza outbreak. Go

back through the headlines in the Toronto Star for the last 10 years, and almost every Christmas time there are headlines about the pressure on our healthcare system from influenza.

There's nothing new or unique in this. The Ontario healthcare system is designed to be full. Our hospitals are designed to be full. Our ICUs are designed to be full. And -- and -- and what's happened with COVID is really not very -- very different.

So, no, I'm not dismissing the problem. Yes, it's an issue that we need to be aware of, but to use that as an excuse for the kinds of draconian measures that have been taken, I -- I don't accept that.

156. Q. Right. And so you probably answered this question, but at one point Mr. Hunter referenced a WHO level four scenario where hospitals are overrun and the nation's healthcare system collapses, how close do you think we've come to that scenario?

A. Well, in Canada not close at all. I mean, I don't think -- I said in my affidavit I think it's still true, I don't think Ontario's ever been over 10 percent of hospital beds occupied by

COVID patients. You know I don't think we've come remotely close to that.

I don't think any developed world jurisdiction, after Italy, and you can talk about what happened in Italy in March of 2020, but they made a whole series of -- of errors admitting people without symptoms at the hospital, poor infection control, and mistakes that haven't been repeated, so we learned that lesson.

So again, I think -- I think that's a fear that has been -- I think that's -- that -- that has been overblown and has been used as an excuse for measures, for justifying measures that -- that I don't think are necessary or appropriate.

157. Q. And you mentioned influenza. How comparable do you think COVID is to the severity of influenza in a given year?

A. Okay. Well, the -- the -- the COVID-19 outbreak, certainly in Canada, has been -- has been more severe than influenza, substantially more severe, but -- but maybe not as -- maybe not as much as -- as people think.

The -- typically -- and influenza occurs in a wave, and typically we get one wave of influenza, seasonal influenza every year, and we

expect somewhere in the neighbourhood of three to six-thousand influenza attributable deaths associated with that.

We've had four waves of COVID, and we've had about 30,000 deaths, so that's worse than we would have expected within influenza. And indeed, we've had more waves. We've had two waves a year, whereas we wouldn't expect that with influenza, so, yes, it's worse than influenza, but it's not so much worse. The idea that it's in a totally different ballpark, a totally different magnitude, I don't -- I don't think that's been true.

It's not true globally either. We expect in the neighbourhood of about a million deaths a year from influenza. And we've had two years with COVID and five million deaths. Yes, that's more. It absolutely is more. And I'm not suggesting that it hasn't been more severe.

But I think there's this notation that it's just a totally different thing. I -- in my affidavit I spoke about 1957, and that's -- I'm -- I'm -- I'm looking at Josh, and you're not young enough to remember, but you're -- you're -- you're too young to remember. I remember the Asian flu. You know I was six years old or whatever. I remember the Asian flu,

people talking about the Asian flu.

The Asian flu killed two to four million people globally in a world that had one-third of the population. And that was in the first year. That was in the first wave. And Asian flu, H2N2 came back every year as seasonal flu for the next 10 years proportionately to the disease burden of COVID.

It was a massively greater problem than we've seen. So we've been there before. It's -- I'm not -- I'm not -- I'm not minimizing it. I'm not saying it's not something we should respond to, and we should deal with, but the mindset we've gotten ourselves into that this is some sort of microbiological apocalypse is just not true.

And the level of -- the -- the degree of reaction, our panicked reaction, the way we've adopted measures of dubious effectiveness that come at huge costs, that we've used fear as an agent of public policy incurred -- public health, we've always always tried to give people a balanced view of things.

Fear is not a good strategy for public health, but public health has abandoned that and used fear as a strategy in this case. And maybe worst of all we've done it without any real idea of what it is we're trying to accomplish.

We don't really know where we're going with this, and that's why it's like a merry go round, and we're back where we started with Omicron. And we're just going round and round because we don't really know what we're trying to do. And -- and I've -- I -- I -- yeah, I -- I'm -- that's what I think.

158. Q. And you were asked a number of questions about mathematical modeling of the COVID pandemic and asked about how infection fatality rate estimates played a role in modelling. Can you tell us --

MR. HUNTER: I never asked that.

MR. KITTREDGE: Pardon me?

MR. HUNTER: I never asked that.

MR. KITTREDGE: You discussed the role --

MR. HUNTER: I merely said that the WHO recommended reliance on them. Dr. Schabas indicated he didn't really like mathematical modelling, had concerns about how they underestimated the results of certain countries. I never got into any of the details, so I don't think that's proper re-exam.

MR. KITTREDGE: Okay. I mean, you did mention infection fatality --

MR. HUNTER: No, I didn't

MR. KITTREDGE: Well, you just said that you did, but --

MR. HUNTER: No, I said I talked about mathematical modelling. I never talked about infection fatality rates or any other kind of fatality.

BY MR. KITTREDGE:

159. Q. Okay. Well, I mean, I don't have a transcript in front of me, but can you -- Dr. Schabas, can you tell us a little bit about the accuracy of the information that's fed into the mechanical modeling algorithms?

A. Yeah. No, I think I did make reference. I did talk about how the -- in my testimony I did -- I did make reference to the fact that they -- they -- they were wrong on their input parameters. And I specifically mentioned the infection fatality rate, you know the typical parameters were in the neighbourhood of one percent.

I know when David Fisman testified it was for the House of Commons, he -- he -- he used a number of 1.2 percent that he derived from Spain. You do the simple multiplication by 80 percent of the population, and you come up with these cataclysms of death -- death rates. So it's not only an inaccurate

input, it's a very very simplistic approach.

The WHO meta-analysis, which was conducted by John Ioannidis, and I think it's one of my references that came up with an estimate of, I think it was 2.3 percent based on seroprevalence studies. And Ioannidis himself was of the opinion that the real rate was substantially lower than that. That's around -- around -- I'm sorry, 2.3 percent. He thought it was more like about .15 percent.

And of course, now with -- with the use of immunization people who are immunized have a -- have a -- have a risk of death that's you know roughly an order of magnitude lower than that. So what that means of course is that -- is that -- is that people who -- who -- who are immunized have a -- have a -- have a very low risk of death.

The problem is you know we have to estimate infection fatality rates. And the reason for that is of course that we can't count all of the cases. In fact, as you -- you probably know, and I hope I'm not telling you something that -- that -- that you already know, but I presume you already know actually, that the -- that in fact we never -- we -- we count cases.

We measure cases, people with positive

PCR tests, but we know that that's just the tip of the iceberg of real infections. I think there was pretty good evidence in Canada from early on from the seroprevalence study in -- in British Columbia, for example, and other places that the ratio was -- was roughly 10 percent, maybe a little higher, maybe a little lower of -- of actual infections were detected by the PCR test.

I think that there's reason to think that those numbers have improved, but they're still -- we're still -- I'm very confident we're only catching a very -- a relatively small minority of cases we're testing, and that's inevitable with a disease of this kind where so many infections are either asymptomatic or have -- have very -- have very mild symptoms.

So -- so we -- we -- when we look at infection fatality rate we have to -- we have to estimate it because the case fatality rate of course is quite misleading because we're -- we're purportedly detecting a small portion of the cases.

160. Q. And what is the case fatality rate?

A. Well, the case fatality is the number of reported cases, the number of deaths divided by the number of reported cases, and that's -- that in Canada, I haven't looked at it recently, it's running

in the neighbourhood of one percent. We know that's way too high.

We know the infection fatality rate in Canada, particularly with immunization is -- is -- is maybe one-tenth that. So -- so we're still obviously, obviously dramatically under counting cases.

MR. KITTREDGE: All right. Well, I have no further questions. So thank for your time today.

THE WITNESS: Okay.

MR. KITTREDGE: Do you have anything?

MR. HUNTER: No.

MR. KITTREDGE: Great.

---Whereupon the proceedings concluded 2:46 p.m.

TRANSCRIBER'S CERTIFICATE

I, Sandi Baxter, Transcriber, certify:

That the foregoing proceedings were recorded on audio digital recording;

That the contents of the recordings were thereafter transcribed by me;

That the foregoing is a true and correct transcript to the best of my skill and ability of the audio digital recording so taken.

OPINION

Strictly by the numbers, the coronavirus does not register as a dire global crisis

RICHARD SCHABAS

Richard Schabas is a retired physician. He was Ontario's chief medical officer of health for 10 years, and was chief of staff at York Central Hospital during the SARS crisis in 2003.

In the three months or so since it started, the new coronavirus and its related COVID-19 disease – which emerged in the Chinese province of Hubei late in 2019 and now numbers more than 110,000 cases around the world – have caused more than 4,000 deaths, mostly in China. As the case numbers grow around the world, including in Canada, where there are now more than 70 cases, people have become concerned that a pandemic is inevitable.

But in the same three months, there have been about three million deaths in China from other causes, and about 14 million deaths worldwide. During the same three-month period, according to Health Canada, there have been almost 10,000 deaths in Canada from tobacco addiction, for instance – and just one from COVID-19.

Is COVID-19 a global crisis? Certainly for people who can't add.

I learned some powerful lessons from SARS in 2003. Maybe the most important one was how important it was to focus on what has happened rather than on what might happen. In other

words: “Just the facts, ma’am."

I pay close attention to the daily situation reports issued by the World Health Organization, particularly the new cases and the new deaths. I pay no attention to the various pundits and talking heads, because they are always wrong.

The information in the WHO reports is not perfect for many reasons, some technical and some political. Deaths are a more reliable measure, but deaths lag weeks behind the real outbreak. However, WHO is the best information we have, and it’s getting more complete and more reliable. And, as was the case with SARS, it paints a compelling picture.

The WHO started issuing daily situation reports on Jan. 21, six weeks ago. Initially, the numbers matched the perceptions: The new cases and new deaths, almost all from Hubei province, increased rapidly. Then, in the first week in February, the rate of new cases peaked at 4,083. Deaths peaked on Feb. 13, at 254. Then the number of daily cases dropped down quickly toward the end of February.

That’s because the Hubei outbreak peaked in late January. Indeed, it’s almost over.

Around the beginning of March, the number of new cases rose again because of outbreaks in South Korea, Italy and Iran. These outbreaks are smaller than the one that happened in Hubei. For the past week, the daily statistics have averaged fewer than 3,000 new cases and about 100 deaths worldwide.

Over the past month, the geography of COVID-19 has changed, but the global numbers have, if anything, become smaller. By the numbers, this is The Incredible Shrinking Pandemic. If we accept that testing capacity and vigilance have increased substantially in the past month, this observation is even more powerful.

A couple of important caveats: First, far more cases are out there than are being reported. This is because many cases have no symptoms and testing capacity has been limited. There have been about 100,000 cases reported to date, but, if we extrapolate from the number of reported deaths and a presumed case-fatality rate of 0.5 per cent, the real number is probably closer to two million – the vast majority mild or asymptomatic.

Likewise, the actual rate of new cases is probably at least 10,000 a day. If these numbers sound large, though, remember that the world is a very big place. From a global perspective, these numbers are very small.

Second, the Hubei outbreak – by far the largest, and a kind of worst-case scenario – appears to be winding down. How bad was it? Well, the number of deaths was comparable to an average influenza season. That's not nothing, but it's not catastrophic, either, and it isn't likely to overwhelm a competent health-care system. Not even close.

The only plausible explanation is that COVID-19 is just not very transmissible among humans. Thank goodness. When it comes to pandemic potential, transmissibility isn't the most important thing – it's the only thing.

When COVID-19 finds a sweet spot – a cruise ship, a South Korean church, an Italian hospital – it can spread efficiently. And the bug has a nasty bite. But these are the exceptions and not the rule. The vast majority of infected people spread the disease to precisely no one.

Could the situation change? Could COVID-19 become a true pandemic with millions of cases and tens of thousands of deaths every day? Of course. The current situation in Italy particularly is concerning. But as the days pass and the global patterns stay the same, this becomes less and less likely.

I am not preaching complacency. This disease is not going away any time soon; we should expect more cases and more local outbreaks. And COVID-19 still has the potential to become a major global health problem, with an overall burden comparable to that of influenza. We need to be vigilant in our surveillance.

Symptomatic travellers from areas with active disease should be tested, as should all patients hospitalized with atypical pneumonia. People infected with COVID-19 need to be isolated, and their close contacts should be monitored.

But we also need to be sensible. Quarantine belongs back in the Middle Ages. Save your masks for robbing banks. Stay calm and carry on. Let's not make our attempted cures worse than the disease.

Update on COVID-19 Projections

Science Advisory and Modelling Consensus Tables

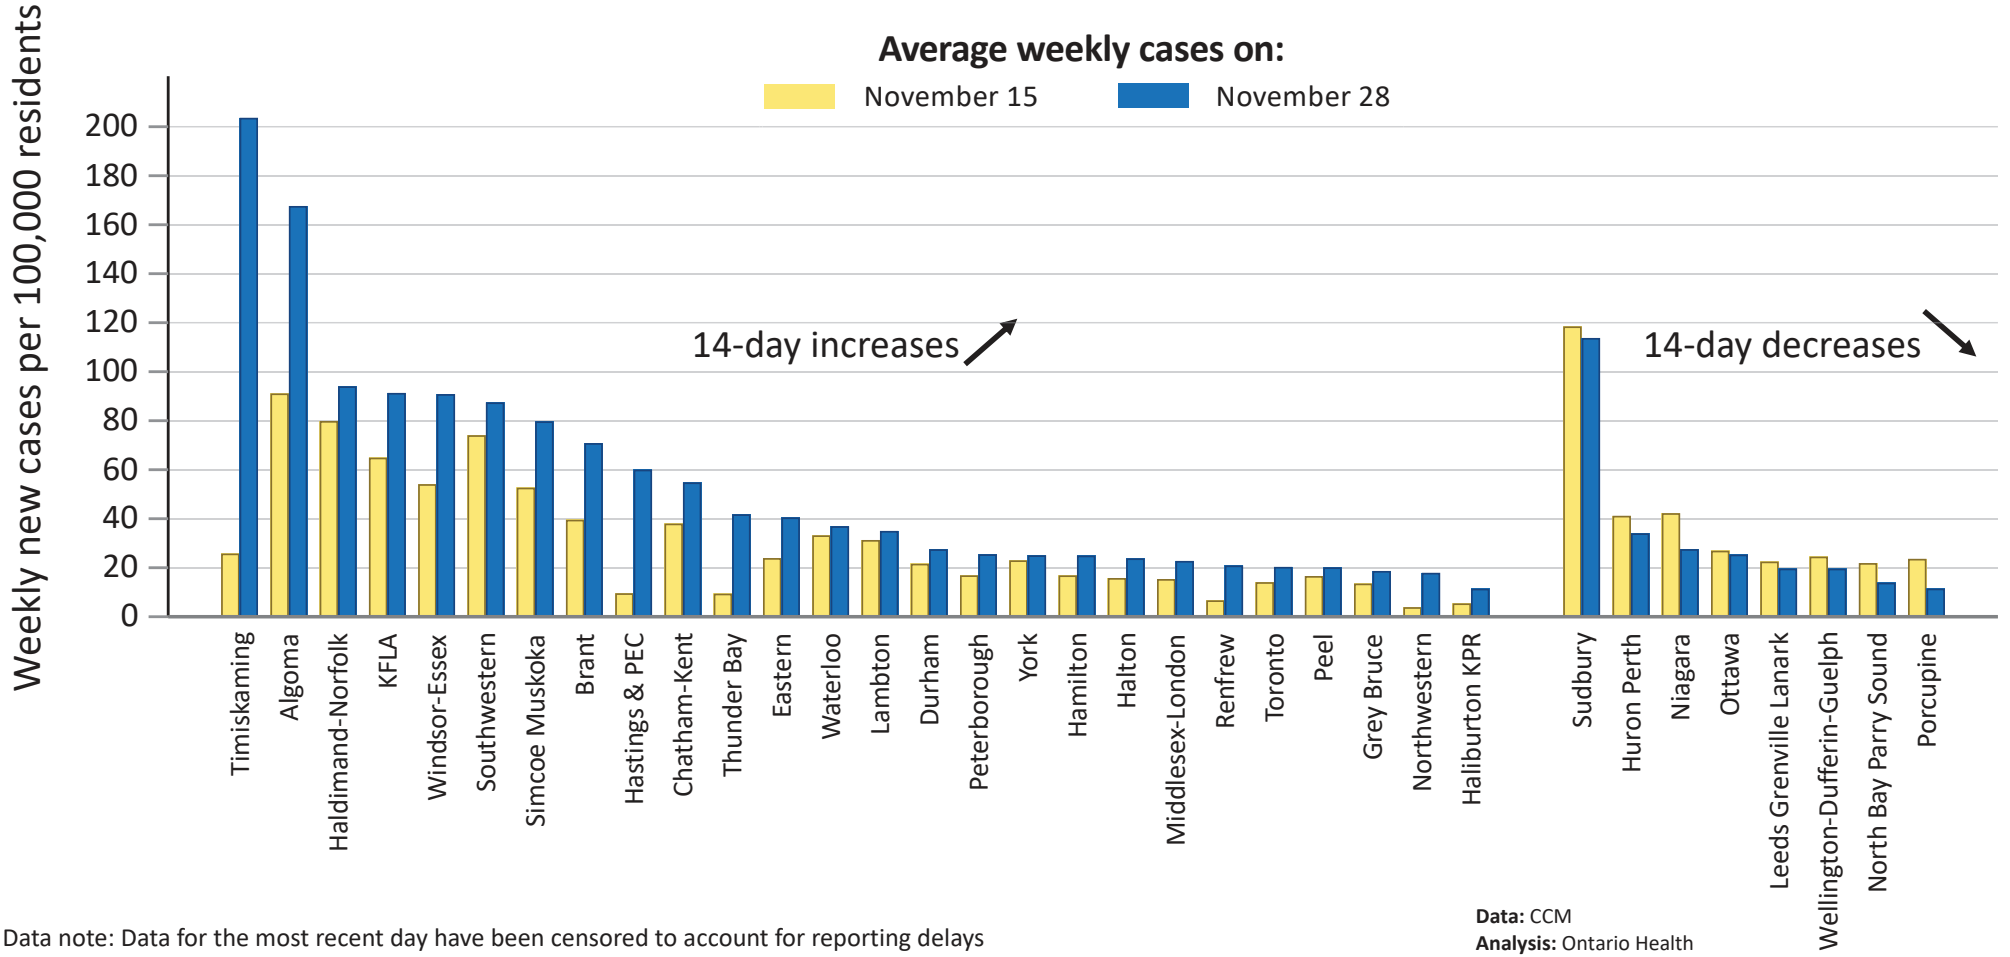
December 7, 2021

Key findings

- COVID-19 cases are rising in most Public Health Units due to the Delta variant. Testing has not increased, but positivity is rising. This is a real rise in cases.
- Vaccine effectiveness in Ontario remains very high but experience in other countries suggests we will need to boost immunity with third doses.
- Even without Omicron, ICU occupancy will likely grow to 250-400 beds in January, putting hospitals under strain again.
- To control cases and the impact on our health system, we need to **increase vaccination** (particularly 5-11 year-olds) and **continue to use public health measures** to reduce transmission now.

- Spread of the new Omicron variant will likely drive COVID-19 cases above current projections.
- In South African data, vaccination appears to protect against serious illness due to Omicron and most hospitalizations are in the unvaccinated. There is likely an increased risk of re-infection even amongst people those who have had COVID-19, emphasizing the importance of vaccination.
- Low global vaccine coverage means that we can expect new variants to arise.

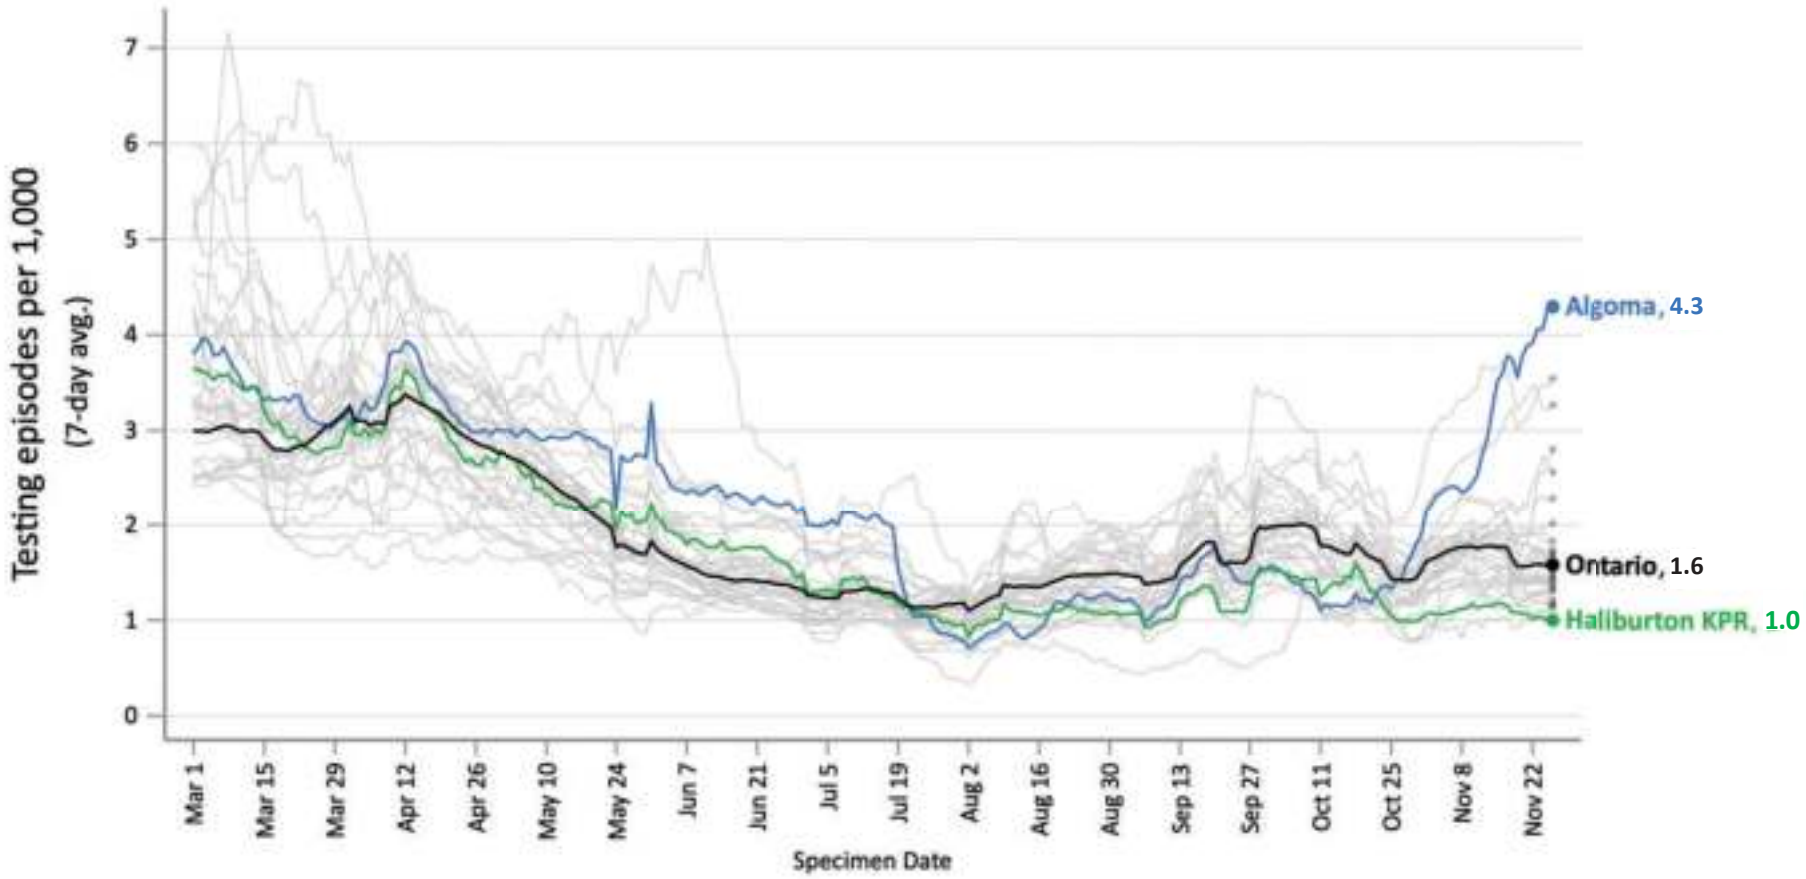
Cases are increasing in most public health units while Delta is the dominant variant



Data note: Data for the most recent day have been censored to account for reporting delays

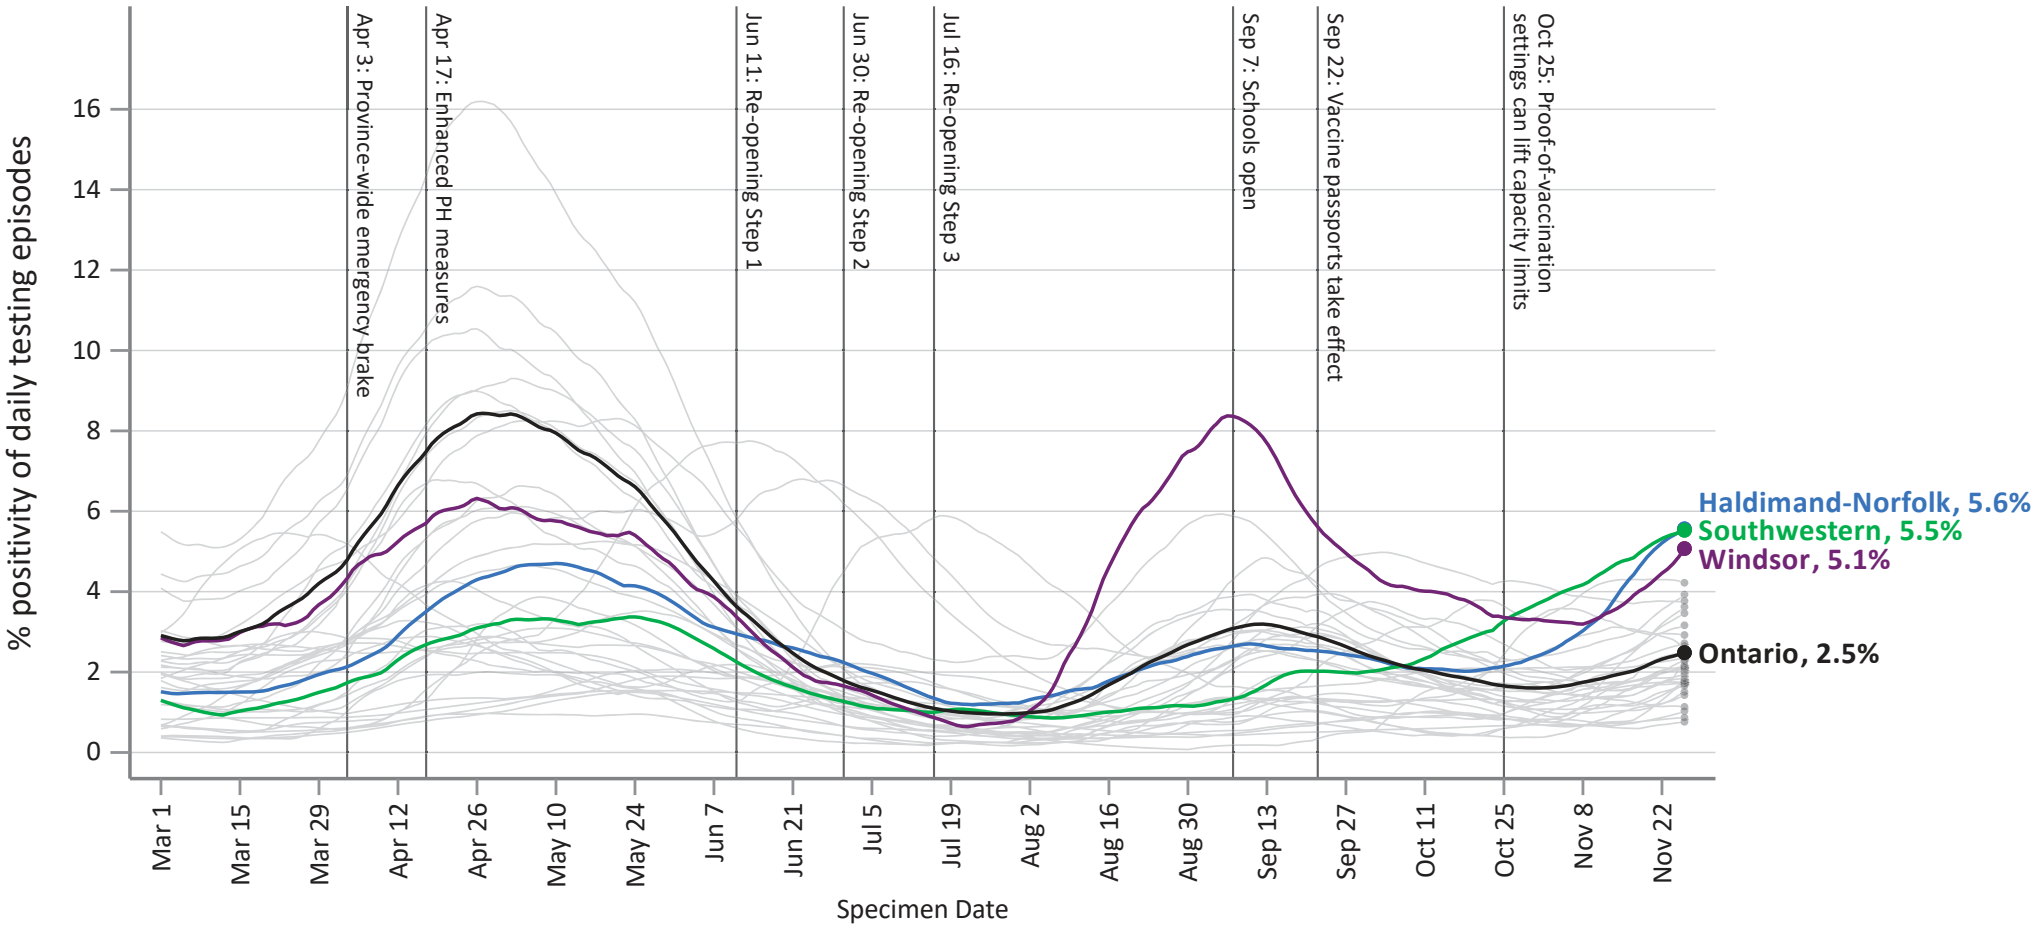
Data: CCM
Analysis: Ontario Health

Testing rates are flat since mid-July



Data: OLIS via SAS VA, data up to November 26
Analysis: Ontario Health

Even with unchanged testing rates, test positivity is rising

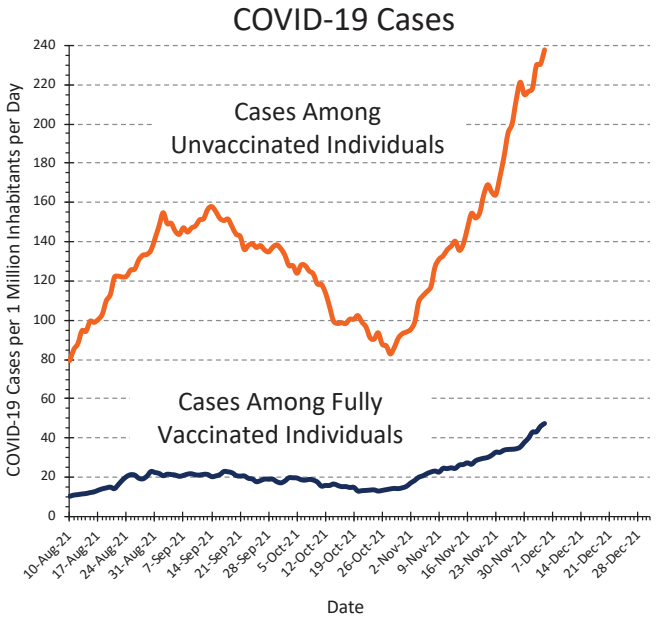


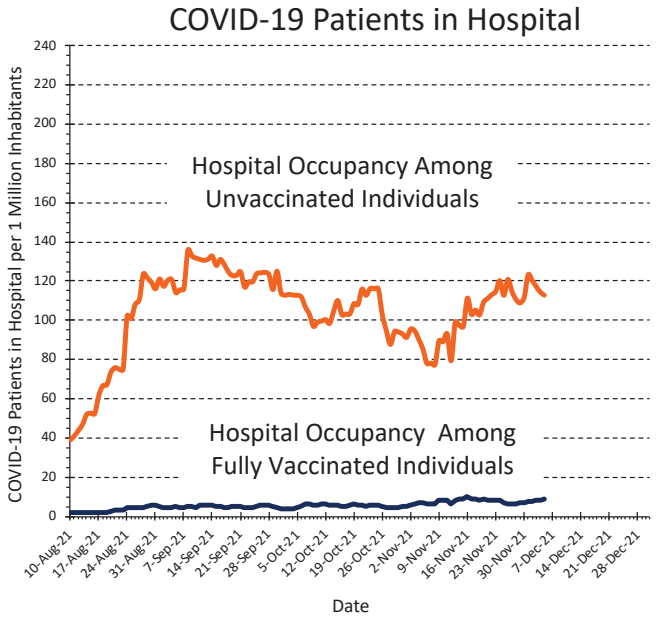
The most recent 3 days have been removed to account for incomplete data. Data are smoothed.

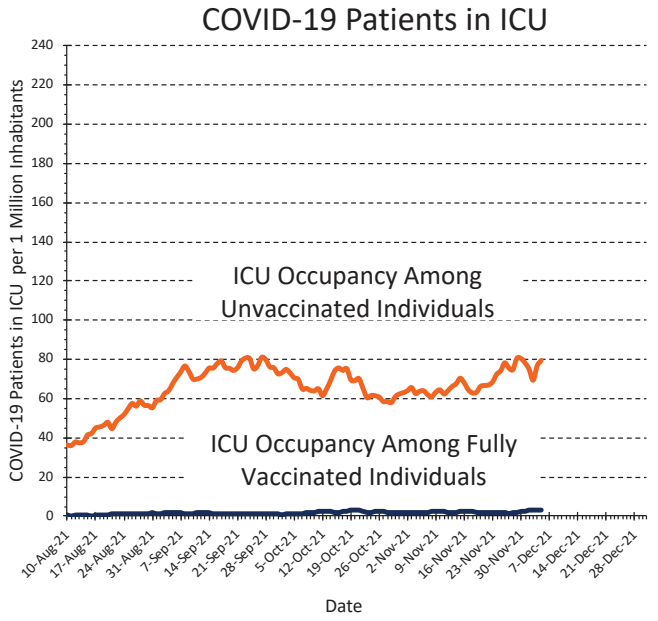
Data: OLIS via SAS VA, data up to November 26
Analysis: Ontario Health

Vaccination continues to be highly effective

Unvaccinated people have a 5-fold higher risk of symptomatic COVID-19 disease, a 13-fold higher risk of being in the hospital and 23-fold higher risk of being in the ICU compared to the fully vaccinated

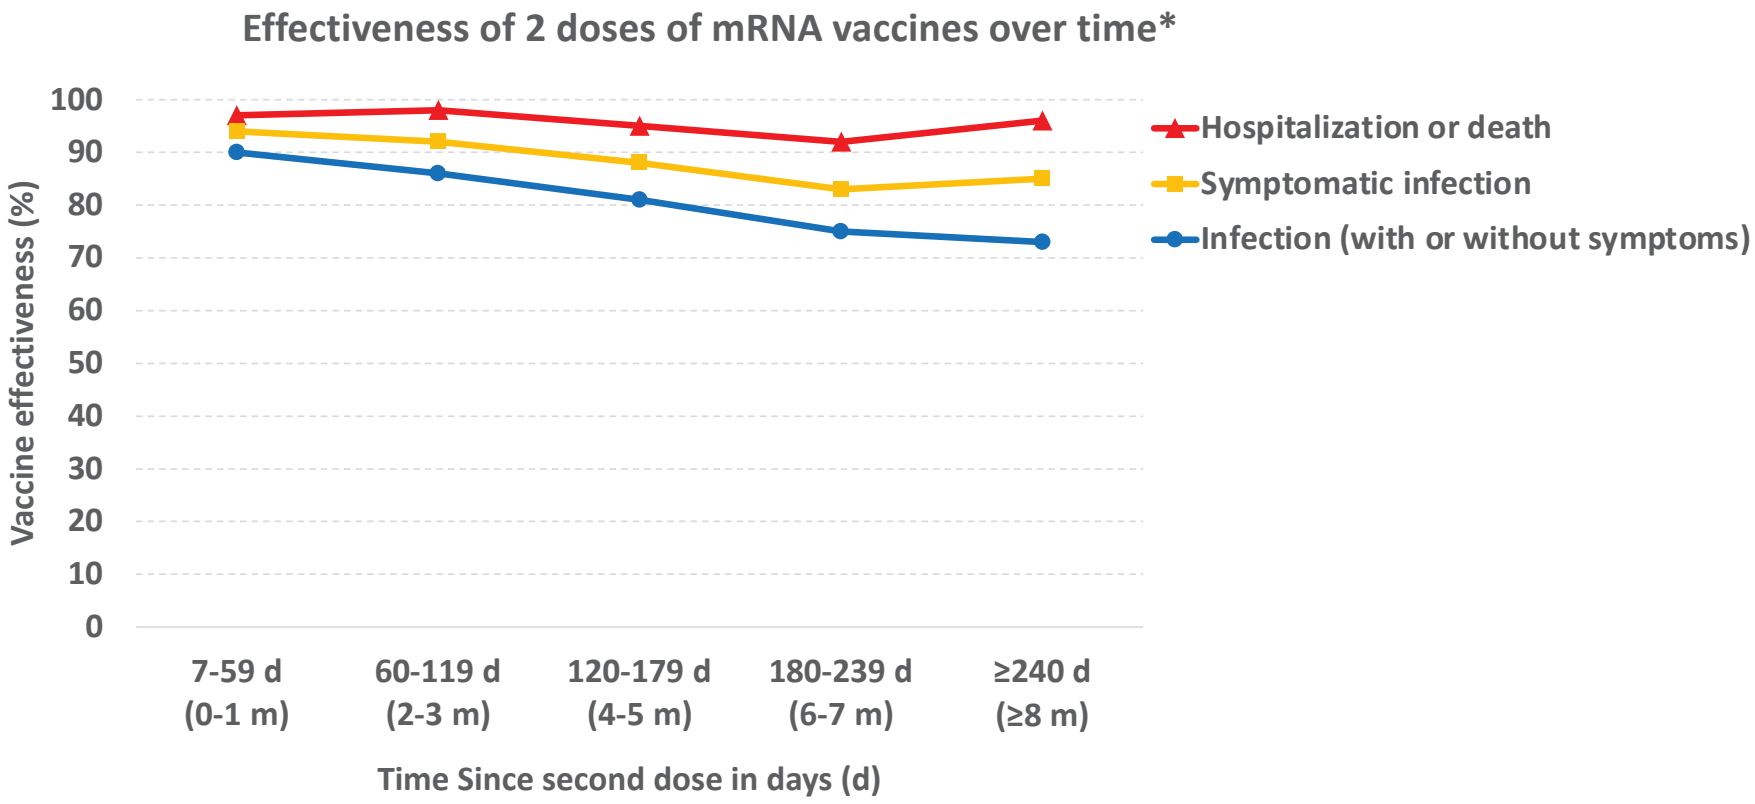






Data: https://data.ontario.ca/ and CCM plus; estimates of patients in hospital and ICU are age standardized
Analysis: Secretariat of the Science Advisory Table (https://covid19-sciencetable.ca/ontario-dashboard/)

Ontario data shows vaccines maintaining high effectiveness



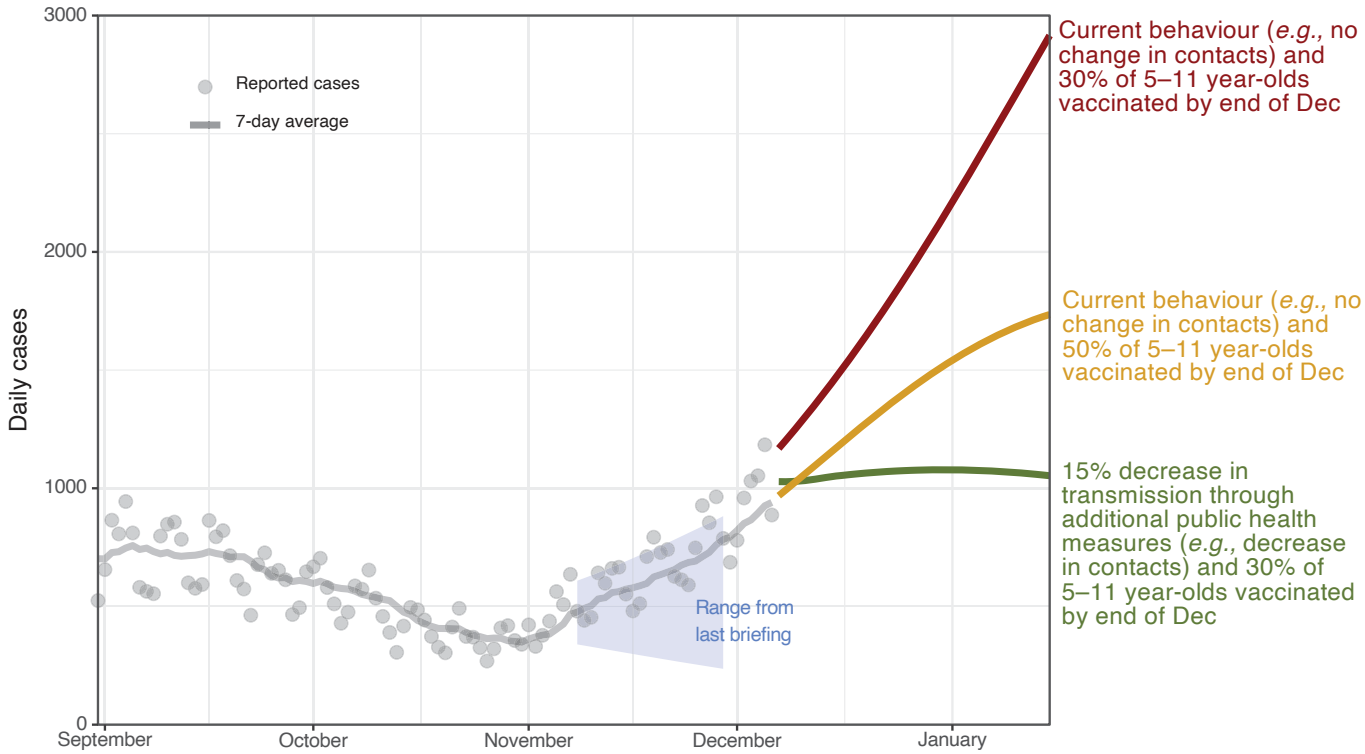
* Ontario, test-negative design, ≥16 years, any SARS-CoV-2 lineage, data to 1 Nov 2021

Data Source and Analysis: ICES

Cases continue to rise substantially, even without Omicron. To flatten the curve, we need to reduce transmission by increasing vaccination and public health measures.

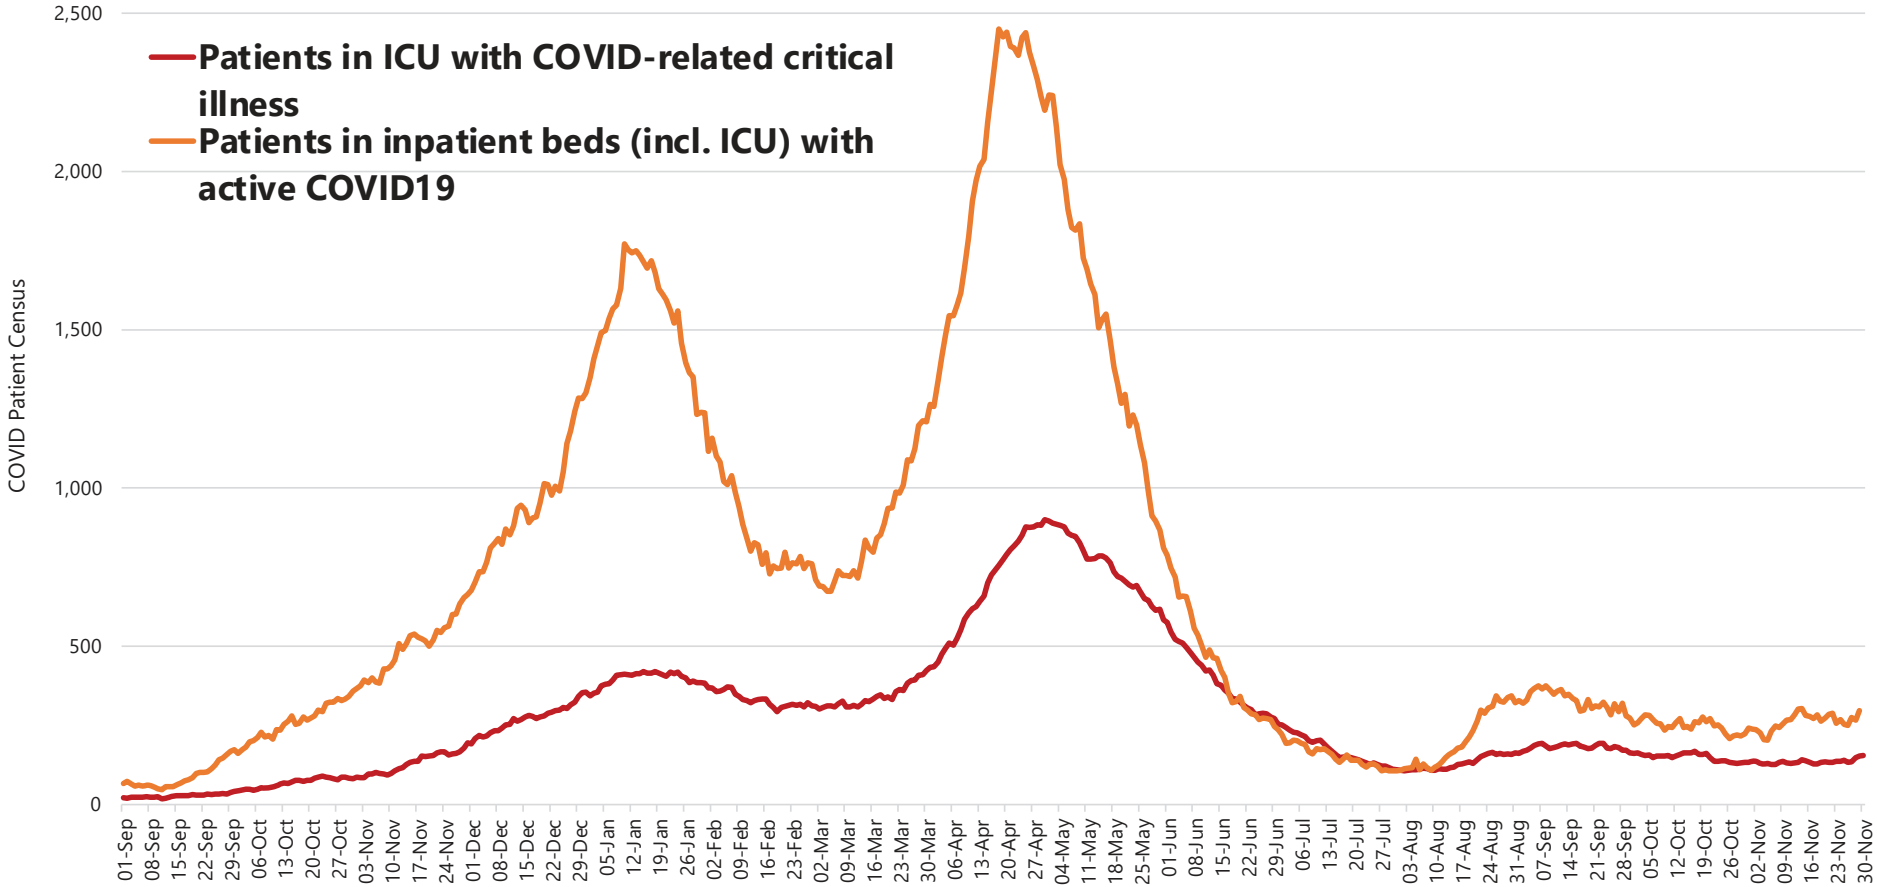
Figure shows predictions based on a consensus across models from 4 scientific teams.

- All scenarios assume continuing current public health measures.
- All scenarios include vaccinating kids 5-11 years of age, but differ on the proportion of kids vaccinated by end of December.
- Different models use different approaches and assumptions.
- Omicron not included in these scenarios, and would likely worsen these projections.



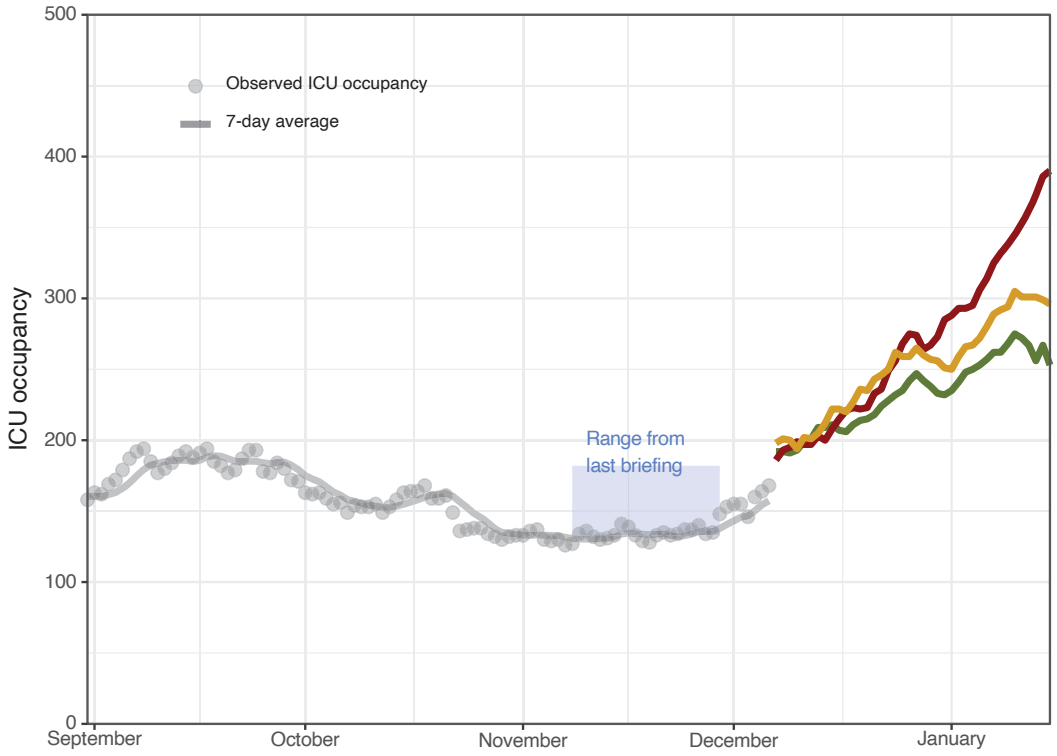
Predictions informed by modeling from McMasterU, PHO, WesternU, YorkU
Data (Observed Cases): covid-19.ontario.ca

COVID-19 hospitalizations and ICU admissions are stable for now



Analysis: Ontario Health

As cases increase, ICU occupancy will also increase, likely exceeding 250 by end of December without accounting for Omicron



Current behaviour (*e.g.*, no change in contacts) and 30% of 5–11 year-olds vaccinated by end of Dec

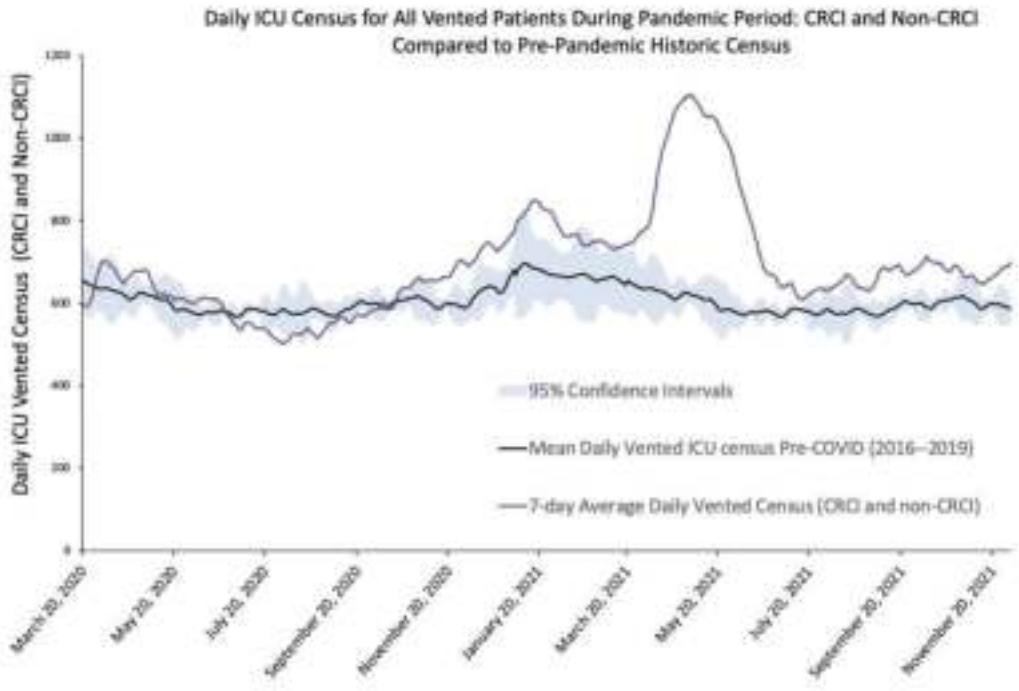
Current behaviour (*e.g.*, no change in contacts) and 50% of 5–11 year-olds vaccinated by end of Dec

15% decrease in transmission through additional public health measures (*e.g.*, decrease in contacts) and 30% of 5–11 year-olds vaccinated by end of Dec

Predictions: COVID-19 ModCollab based on case predictions in previous slide
Data (Observed ICU Occupancy): CCSO

Ontario ICUs have been under unprecedented pressure and will have trouble responding to another surge in patients

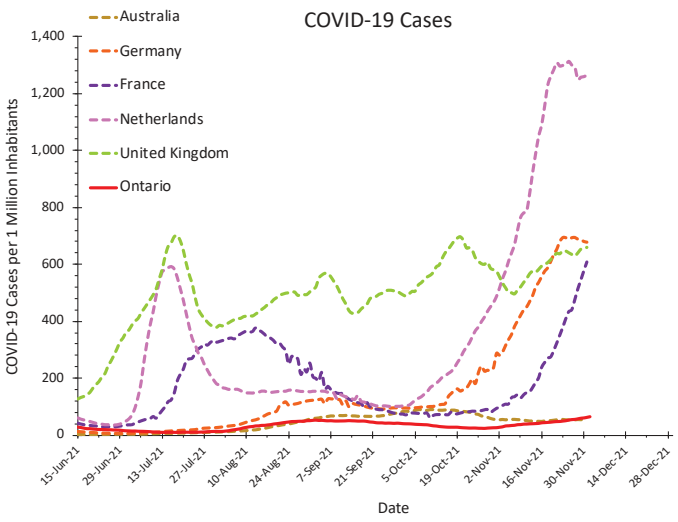
- Due to the need for urgent non-COVID-19 patient care, fewer staff are available to be redeployed and fewer staffed surge spaces are available
- Number of patients on ventilators has been above average for over a year; the pressure on ICUs has not let up
- There is a growing crisis in staffing for critical care patients with significant contribution from health care worker burnout
- Despite new beds and strong management, ICUs will be challenged in responding to any new surge in patients because of staffing constraints

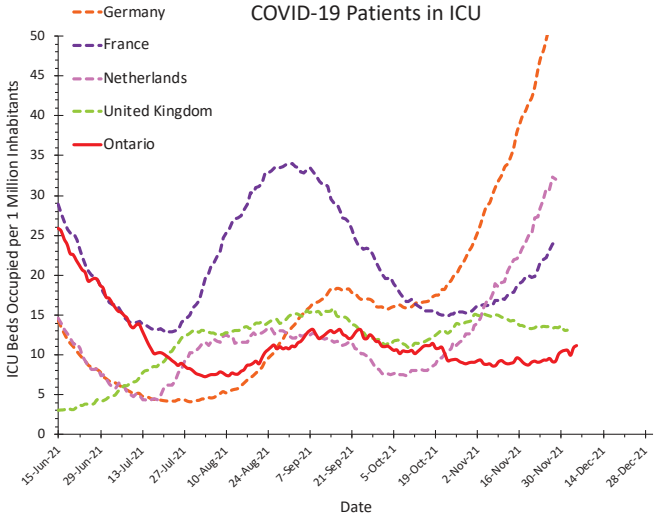


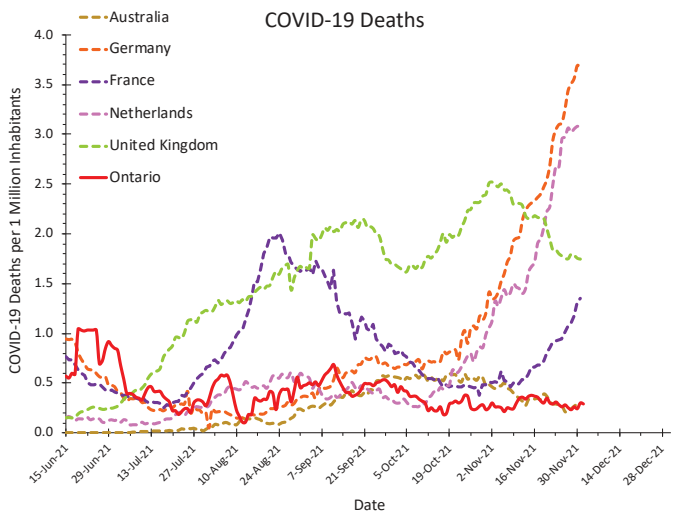
CRCI: COVID-19 related critical illness

Source: Science Briefs of the Ontario COVID-19 Science Advisory Table (https://doi.org/10.47326/ocsat.2021.02.51.1.0)

Rising cases, ICU occupancy, and deaths in European peer jurisdictions show potential risk



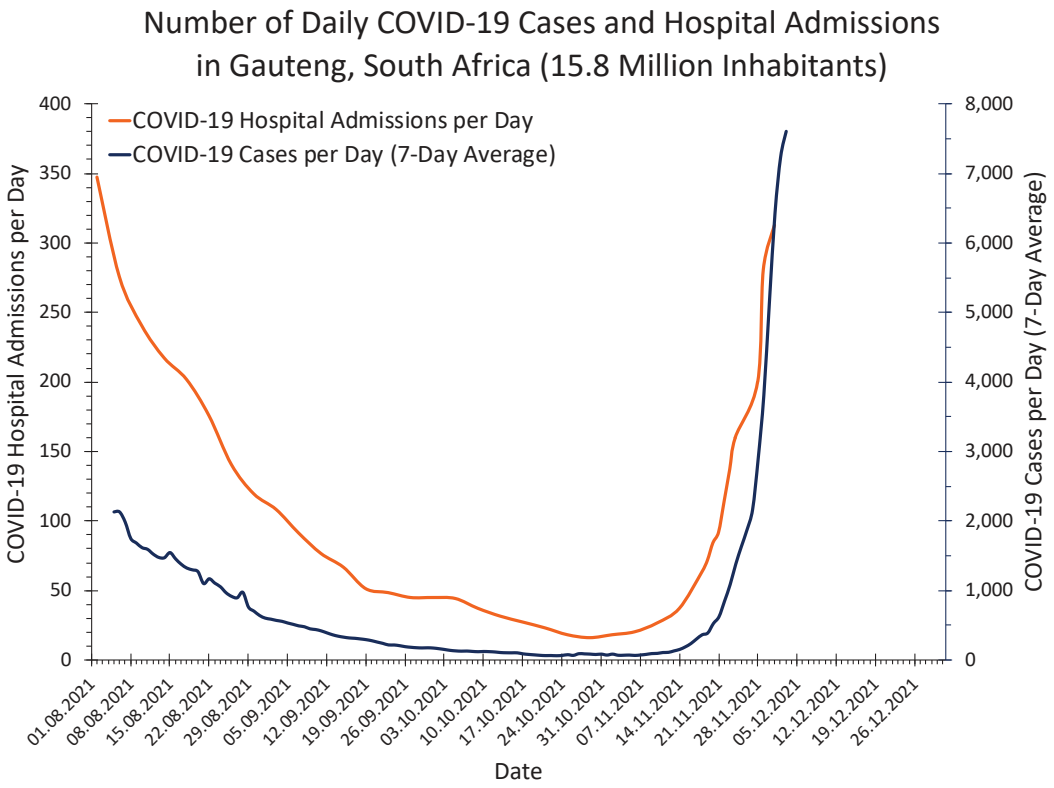




The Ontario Stringency Index (44) is similar to UK (47); the Netherlands are at 56, Australia, France and Germany are at ≥67.
Ontario vaccine coverage (77% of population fully vaccinated) similar to Netherlands and Australia (74%),
higher than remaining peer countries (~68%).

Data: https://data.ontario.ca/ and https://ourworldindata.org/explorers/coronavirus-data-explorer
Analysis: Secretariat of the Science Advisory Table (https://covid19-sciencetable.ca/ontario-dashboard/)

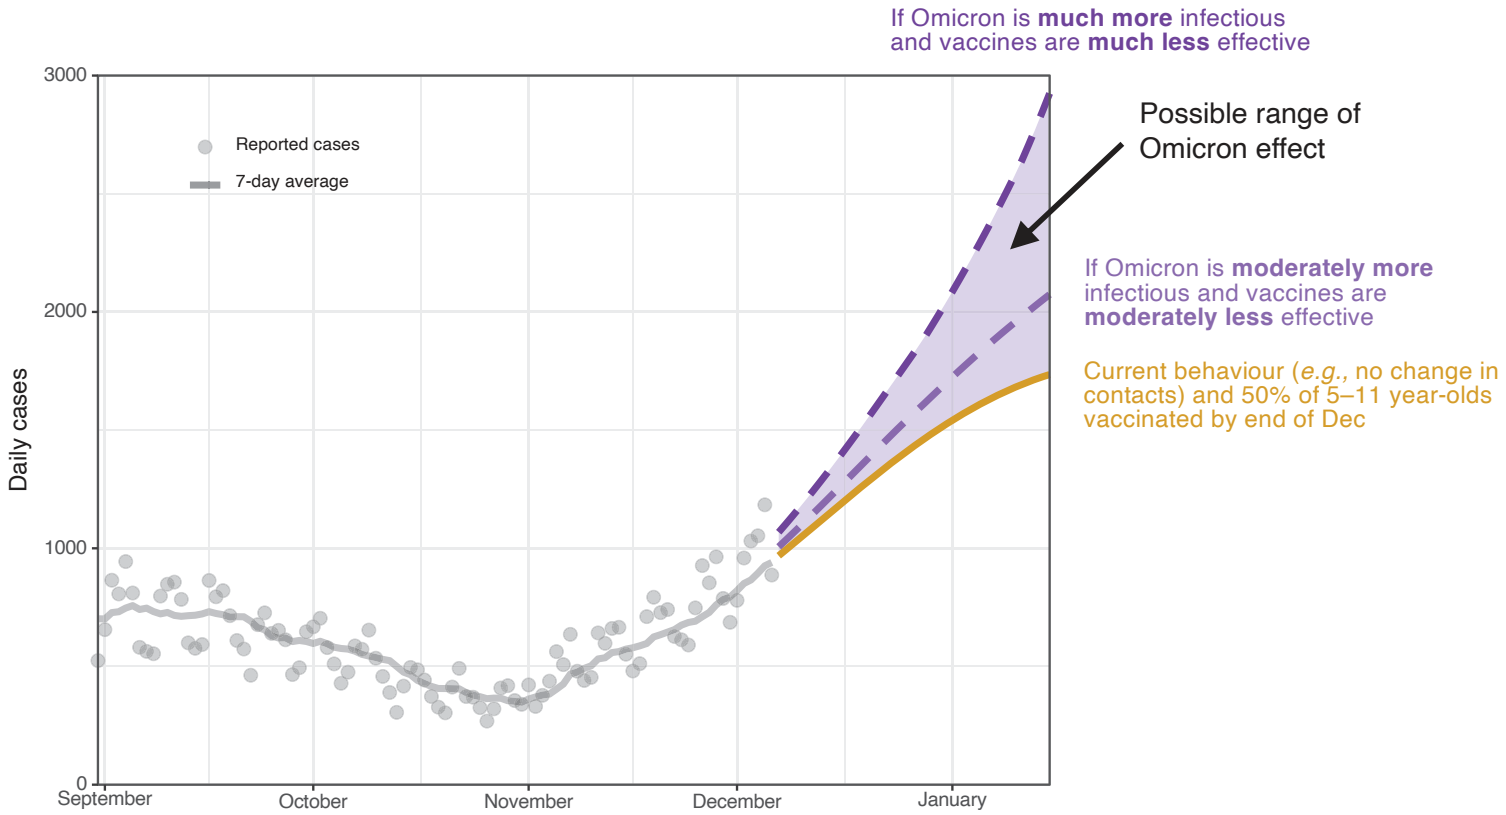
A new variant of concern called Omicron became rapidly dominant and caused a steep increase in cases in the province of Gauteng, South Africa



- Rapid increase in daily cases in Gauteng indicates that Omicron is more transmissible than Delta.
- Previously infected people have an increased risk of reinfection, suggesting partial evasion of immunity by Omicron.
- Hospital and ICU admissions are increasing because of steep increase in cases.
- Early data suggests vaccination protects against hospital admission caused by Omicron. Most patients admitted to hospital are unvaccinated.
- Omicron is transmitted exactly the same way as previous SARS-CoV-2 strains. Public health measures still work.

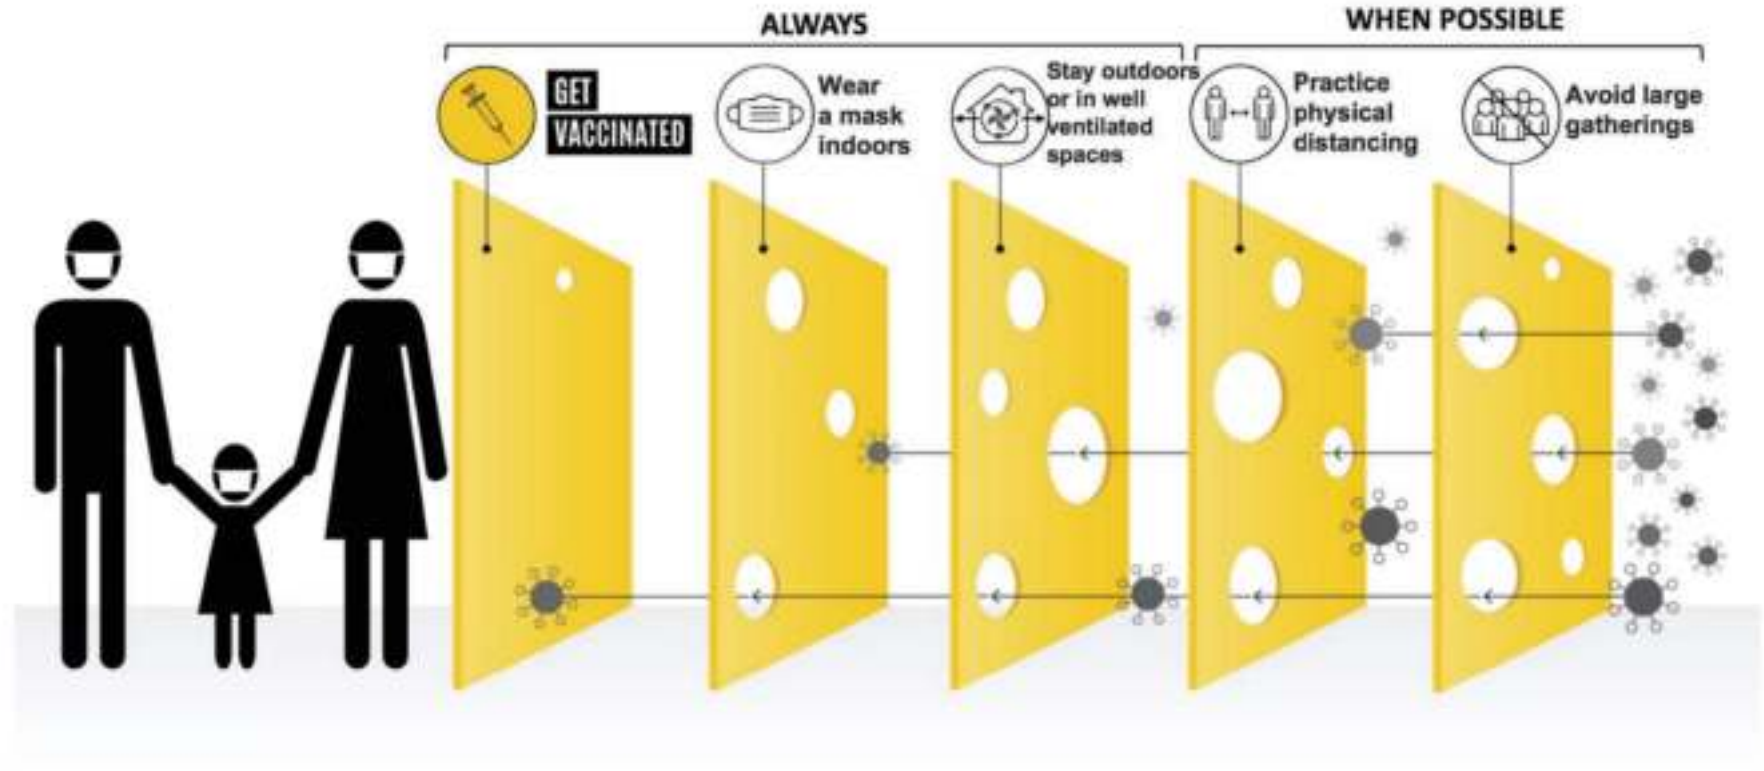
Data: https://www.sacmcepidemicexplorer.co.za/; https://www.nicd.ac.za/ and https://sacoronavirus.co.za/
Analysis: Secretariat of the Science Advisory Table (https://covid19-sciencetable.ca/)

The current situation is very uncertain, but the potential impact of Omicron on cases could be substantial



Predictions informed by modeling from McMasterU, WesternU

Current public health measures are effective against Omicron



Adapted from: https://uihc.org/health-topics/why-swiss-cheese-may-be-key-keeping-you-safe-covid-19

Key findings

Considerations for implementing and adjusting public health and social measures in the context of COVID-19

Interim guidance

14 June 2021

World Health Organization

Key Messages

- Public health and social measures (PHSM) have proven critical to limiting transmission of COVID-19 and reducing deaths.
- The decision to introduce, adapt or lift PHSM should be based primarily on a situational assessment of the intensity of transmission and the capacity of the health system to respond, but must also be considered in light of the effects these measures may have on the general welfare of society and individuals.
- Indicators and suggested thresholds are provided to gauge both the intensity of transmission and the capacity of the health system to respond; taken together, these provide a basis for guiding the adjustment of PHSM. Measures are indicative and need to be tailored to local contexts.
- PHSM must be continuously adjusted to the intensity of transmission and capacity of the health system in a country and at sub-national levels.
- When PHSM are adjusted, communities should be fully consulted and engaged before changes are made.
- In settings where robust PHSMs are otherwise in place to control the spread of SARS-CoV-2, allowing the relaxation of some measures for individuals with natural or vaccine-induced immunity may contribute to limiting the economic and social hardship of control measures. Applying such individualized public health measures must take into account a number of ethical and technical considerations.

Introduction

Public health and social measures (PHSMs) are being implemented across the globe to suppress SARS-CoV-2 transmission and reduce mortality and morbidity from COVID-19.1 PHSMs include personal protective measures (e.g. physical distancing, avoiding crowded settings, hand hygiene, respiratory etiquette, mask-wearing); environmental measures (e.g. cleaning, disinfection, ventilation); surveillance and response measures (e.g. testing, genetic sequencing, contact tracing, isolation, and quarantine); physical distancing measures (e.g. regulating the number and flow of people attending gatherings, maintaining distance in public or workplaces, domestic movement restrictions); and international travel-related measures. In this context, it does not include medical countermeasures such as drug administration or vaccination. PHSMs act in concert, and a combination of measures is required to ensure adequate control. Measures should be implemented by the lowest administrative level for which situational assessment is possible and tailored to local settings and conditions.

Several important developments have occurred since the publication of the previous *Considerations for implementing and adjusting public health and social measures in the context of COVID-19*.[2] First, several COVID-19 vaccines have been approved by national regulatory authorities and through WHO Emergency Use Listing (EUL).[3] Vaccination has begun in most countries, bringing the prospect of significantly reducing severe disease and mortality further. Initial observational studies following rollout of vaccines suggest that vaccines may lead to protection against infection and a reduction in transmission,[4–6] which in addition to PHSMs will help control the spread of the virus. Second, four WHO-classified variants of concern (VOCs) have emerged since December 2020,[7,8] which are more transmissible and some of which may cause more severe disease[9] and/or lead to a degree of vaccine escape, requiring potential adjustments to response measures to account for their different characteristics, including their impact on vaccine effectiveness. Several other variants of interest (VOIs) are also being monitored. Finally, more evidence is now available on the effectiveness of a range of individual and community-level measures (outlined in Table 3 below).

Control of SARS-CoV-2 will depend on: i) the prevalence of infection and of circulating variants; ii) the rate of growth or decline in incidence; iii) the types, use of and adherence to control measures in place; iv) the speed with which vaccination occurs; v) the targeting and uptake of the vaccines among high-risk groups; and vi) vaccine effectiveness and natural immunity in the population.[10] National vaccination strategies should prioritize older individuals at highest risk of severe outcomes and health workers, to rapidly reduce mortality and the burden of disease and protect health care services. However, with successful COVID-19 vaccination of older populations following the prioritization of vulnerable groups, the virus may continue to spread among unvaccinated younger population groups.[11] After achieving high vaccination coverage of SAGE priority groups for stage

I and stage II (as outlined in the WHO SAGE Roadmap For Prioritizing Uses of COVID-19 Vaccines in the Context of Limited Supply)[12] across all countries, accelerating vaccination of other priority groups will be required to lower the infection rate, especially in areas of high population density.[13]

While vaccination is underway, PHSMs will need to continue to be implemented, in a tailored and agile way, particularly considering uncertainty in vaccine performance against known and potentially emerging VOCs and limited sequencing capacity to detect variants worldwide.[14] Moreover, significant inequities in global vaccine access mean that, globally, control of disease will continue to rely on PHSM for the foreseeable future, modulated by different levels of vaccination. Implementation of stricter PHSMs, however, needs to be balanced against their socio-economic impacts, especially in settings with high dependence on daily wages and informal economy. Decisions to tighten, loosen, or introduce PHSMs to control COVID-19 must be weighed against the positive and negative impacts these measures have on societies and individuals. Considerations include impacts on health, economy, security, mental health, and psychosocial wellbeing, human rights, food security, socioeconomic disparities, continuity of other public health programmes, treatment and management of medical conditions other than COVID-19 and gender-based violence. Other important considerations include vaccine acceptance and uptake, confidence, trust, motivational elements to get vaccinated and public sentiment and adherence to PHSMs. The overall health and wellbeing of communities should therefore be at the forefront of considerations when deciding on and adjusting PHSMs.

As the pandemic continues to evolve, PHSMs should be regularly reviewed and adjusted according to the local epidemiology. This requires agile decision-making based on ongoing situational assessments at the most local administrative level possible in a coherent and coordinated manner with neighbouring areas at the sub-national and national levels. Such assessments should be based on available data and take a risk/benefit approach considering the local epidemiology, the health system's capacity to respond and other contextual considerations (such as upcoming mass gathering events that may alter transmission or capacity). Epidemiological indicators and their thresholds will depend on a country's testing and surveillance strategies and capacities, data collection capacity, vaccination strategy and coverage and the overall COVID-19 response strategy. In settings where COVID-19 surveillance or testing capacities are limited, it is important to identify and utilize additional indicators on morbidity, mortality and pressure on the health system, such as bed occupancy for both regular hospital beds and ICU beds, to complement available epidemiological data

This document provides guidance to help Member States assess the situation at national and sub-national levels, as well as key recommendations about the implementation of PHSMs. It should be read in conjunction with WHO interim guidance documents on *Critical preparedness, readiness and response actions for COVID-19*[1] *and Considerations for implementing a risk-based approach to international travel in the context of COVID-19*[15,16], which address several other elements of preparedness, readiness and response for COVID-19 beyond PHSMs.

This guidance document is intended for public health and health services decision-makers at all levels at which decisions about tailored PHSMs are made and technical actors involved in relevant sectors (e.g. community engagement, education, social services) supporting or impacted by PHSMs.

The guidance will be updated as our knowledge evolves, in particular in relation to the impact of VOCs on vaccine-induced and natural immunity, the impact of various COVID-19 vaccines on transmission and the impact of PHSMs on VOCs.

Changes from the previous version

This updated guidance provides updates on the assessment framework that drives decision-making for PHSMs, particularly on the type of indicators and the thresholds in different epidemiological settings, and in the context of vaccine roll-out and circulation of VOCs.

It also contains a new section on considerations for individualized public health measures based on a person's SARS-CoV-2 immunity status following COVID-19 vaccination or past infection in the context of contact tracing, international travel, and private social gatherings.

Recently published WHO scientific briefs and guidance were reviewed and key findings were summarised in Table 3. For the evidence on COVID-19 natural immunity, the document is based on the latest WHO scientific brief on *COVID-19 natural immunity.* [17] For the evidence of vaccines effectiveness, the document relies on the following published work: *SAGE working groups Annexes to WHO interim recommendations for use of the COVID-19 vaccine BIBP: GRADE and Evidence to Recommendations*[18]; *Annexes to the interim recommendations for use of theChAdOx1-S [recombinant] vaccine against COVID-19 (AstraZeneca COVID-19 vaccine AZD1222, SII Covishield, SK Bioscience)*[19]; and *Background document on the mRNA-1273 vaccine (Moderna) against COVID-19.*[20]

Transmission scenarios

Knowing the level of transmission is key to assessing the overall COVID-19 situation in a given area and guiding decisions on response activities and tailoring epidemic control measures.[1]

The community transmission (CT) classification is divided into four levels, as shown below. These definitions are abbreviated; details about the transmission classifications can be found in the Annex to this guidance.

- No (active) cases
- Imported / Sporadic cases
- Clusters of cases
- CT1: Low incidence of locally acquired widely dispersed cases detected in the past 14 days
- CT2: Moderate incidence of locally acquired widely dispersed cases detected in the past 14 days
- CT3: High incidence of locally acquired widely dispersed cases in the past 14 days
- CT4: Very high incidence of locally acquired widely dispersed cases in the past 14 days.

The transmission level classification for a geographic area may improve or worsen over time, and different geographic areas within a country will likely experience different levels of transmission concurrently. In settings with limited surveillance and diagnostic capacities, additional indicators – such as influenza-like-illness (ILI) / severe acute respiratory infection (SARI), all-cause excess mortality trends and all-cause hospitalization rates – should be identified to complement information on COVID-19 cases and deaths. These indicators are meant to capture pressure on the health care system and outcomes from undiagnosed COVID-19 cases and can support assessment of local transmission levels when triangulated with COVID-19 epidemiological data.

The process for determining transmission classification is outlined in the Annex to this document.

Health system response capacity

In addition to assessing the level of transmission, it is also necessary to understand the health system response capacity. Depending on whether there is adequate, moderate or limited capacity, the same level of transmission can result in a drastically different situations and require a different degree of PHSMs. For the purpose of this document, 'response capacity' encompasses both health and public health services, including COVID-19 vaccination, and is measured in terms of both the actual ability to deliver services and the performance of those services.

Situational assessment using transmission level and response capacity

Whether or not vaccination has begun, countries should continue to monitor transmission level and take measures as needed.

Where there is a high level of vaccine-acquired immunity among prioritized groups, the epidemiology may start to change. A decoupling may occur between incidence and hospitalization and/or death rates because individuals most prone to hospitalization and death will have been immunized. In this situation, a greater proportion of cases will occur among younger, less vulnerable population groups. Here, recalibrating the incidence thresholds, focusing on hospitalization and ICU rates and analyzing incidence data by age group – as well as assessing the potential caseload of undiagnosed COVID-19 cases – are essential to guiding the adjustment of PHSMs.

As new variants of concern emerge, PHSMs may need to be adapted in the presence of variants that may be more transmissible, cause more severe disease and/or evade immunity induced by vaccination and/or natural infection. All epidemiological and health system indicators should be followed closely and PHSMs applied according to the prevailing epidemiological and health system situation. A greater disease transmissibility (as for all currently identified VOCs) may require keeping PHSMs in place for a longer period or may require intensifying the implementation of existing PHSMs to maintain effects on transmission.

Based on the joint assessment of the transmission scenario and the health system response capacity – which will inform whether and how to adjust PHSMs – a situational level should be assigned to a geographic area (see Table 1). The assessment should rigorously and comprehensively examine quantitative and qualitative information from multiple sources, which should be triangulated to provide an additional reality check on the assessed situational level. The resultant **situational levels should only be considered indicative,** because they may not correspond well to the response required in a specific context and to the COVID-19 control objectives of the country. For example, in a small country with limited capacity or remote areas with limited access to health services, stringent PHSMs may be warranted in the context of a relatively low level of transmission.

Table 1: Situational level assessment matrix using transmission level and response capacity indicators to guide adjustment of PHSMs

	Response capacity*		
Transmission level*	Adequate	Moderate	Limited
No cases	0	0	1
Imported/Sporadic cases	0	1	1
Clusters of cases	1	1	2
• Community - CT1	1	2	2
• Community - CT2	2	2	3
• Community - CT3	2	3	3
• Community - CT4	3	3	4

*Please refer to the Annex for transmission level definitions.

- **Situational Level 0** corresponds to a situation with no known transmission of SARS-CoV-2 in the preceding 28 days. The health system and public health authorities are ready to respond, but there are no significant domestic measures in place and thus no significant restrictions on daily activities.
- **Situational Level 1** is a situation where basic measures are in place to prevent transmission; or if cases are already present, the epidemic is being controlled through effective measures around the cases, with limited and transient localized disruption of social and economic life.
- **Situational Level 2** represents a situation with low community incidence or risk of community transmission beyond clusters. Additional measures may be required to control transmission; however, disruptions to social and economic activities can still be limited. In the context of vaccination, Situational Level 2 may also include areas with moderate levels of community transmission, but limited health service impact given adequate vaccination coverage in at-risk and older age groups.
- **Situational Level 3** is a situation of community transmission with limited additional capacity to respond and a risk of health services becoming overwhelmed. A larger combination of measures may need to be put in place to limit transmission, manage cases, and ensure epidemic control.
- **Situational Level 4** corresponds to an uncontrolled epidemic with limited or no additional health system response capacity available, thus requiring extensive measures to avoid overwhelming of health services and substantial excess morbidity and mortality.

Adjusting public health and social measures

Key principles

Decisions on which measures to implement, lift or strengthen, and the order in which these measures should be implemented, should be based on the following guiding principles:

- Measures with the highest level of acceptability and feasibility and proven effectiveness – and which minimize the negative consequences on health and wellbeing of all members of society and the economy and – should be adopted, using *the* COVID-19 Global Risk Communication and Community Engagement Strategy – interim guidance.21 Acceptability and feasibility should be determined through participatory approaches and shift away from directives and one-way communications. Engaging with the community for this assessment will help to maximize the likelihood of adherence. Effectiveness and potential negative effects of PHSMs should be evaluated through an evidence-based assessment (e.g. literature review, WHO guidance, etc.) and active monitoring of the impact of implemented PHSMs.
- Additional measures should be considered as soon as the situational level rises. Delays in implementation of measures will lead to increased morbidity and mortality and the need for more stringent measures to regain control. In particular, efforts should be made to prevent an intensification in transmission from 'clusters' to 'community transmission.
- When feasible, measures should be adjusted (implemented or lifted) in a controlled, stepwise manner to allow better understanding of the effects of each measure on transmission dynamics.
- Any decision to apply PHSMs must be weighed against the wider impact of the measures on health and well-being (lives lost in the short and long term compared to lives saved by applying PHSMs).

- Public health surveillance data and findings from case and cluster investigations may provide important information on conditions associated with transmission or severity. This is particularly important in the context of circulating VOCs, and potential new variants, since the lifting of PHSMs may provide a better understanding of the transmission and severity characteristics of these variants. Such information may help targeting application or intensification of certain PHSMs without imposing the measures universally on all settings (e.g. settings without these variants).
- Any available information on the level of immunity in the general population – either natural or vaccine-induced – must be taken into consideration when assessing the likely impact on SARS-CoV-2 transmission of lifting PHSMs.
- Protection of vulnerable populations,12 including those clinically at risk for severe disease should be central in the decision to implement, maintain or lift a measure. Vulnerable populations include people aged ≥60 years and/or with comorbidities that increase risk of serious COVID-19 disease; disadvantaged groups such as marginalized populations, vulnerable migrants and refugees; and those in high density/low resource settings and lower income groups. Vulnerable communities and disadvantaged individuals may face immediate challenges in meeting their basic life needs – such as income, shelter and food – when PHSMs are implemented and if implemented without adequate support.22 It is crucial that those essential needs be taken into account when designing different packages of PHSMs and addressed before these packages are implemented to avoid or minimize harm and improve effectiveness. It is critical to safeguard vulnerable and disadvantaged populations by implementing specific measures to support them, mobilizing resources and engaging all relevant sectors and communities to learn about their concerns and receive feedback. This includes ensuring access to health services (using community-based service delivery), which is especially challenging when transportation, clinics/hospitals and other government services are closed or have long waits. Other essential services include supplementary income or food provision; safe places for survivors of and/or those at risk of violence, including gender-based violence; and improvement of infrastructure and safety of public transport (which is used most by workers in vulnerable populations and essential workers) to make it compatible with PHSMs.
- The potential impact of lifting PHSMs on the health and public health systems capacities to rapidly respond to any new increase in cases should be considered. For example:
  - Adequate health system capacities should be in place to detect, test and manage new cases and their contacts.
  - The risk of outbreaks and/or severe disease in settings with vulnerable individuals should be minimized. This requires identifying all major drivers of SARS-CoV-2 transmission (e.g. various types of closed settings such as health care facilities and care homes) in the local context and understanding the vaccination coverage of priority populations in that context, with appropriate measures in place to maximize physical distancing and minimize the risk of outbreaks.
  - Key drivers of transmission in the area under assessment must be well understood using local surveillance data, and measures should be rapidly re-implemented should incidence increase. A particular focus should be on prevention and early detection of potential superspreading events.
- Basic risk mitigation measures aimed at reducing travel-associated exportation, importation and onward transmission of SARS-CoV-2 should always be maintained. For details, please refer to *Considerations for implementing a risk-based approach to international travel in the context of COVID-19*.[15,16]
  - In all cases, international travel should be prioritized for emergencies and humanitarian actions (such as emergency medical flights and medical evacuations); travel of essential personnel (such as emergency responders, providers of public health technical support, and critical personnel in the transport and security sectors such as seafarers); repatriations; and cargo transport for essential supplies such as food, medicines, and fuel.
  - Specific considerations are outlined in this document for the implementation of an individualized approach to quarantine and testing for international travellers with natural or vaccine-acquired immunity.

Community engagement and risk communication strategy

When PHSMs are adjusted, communities should be fully and regularly informed, engaged and enabled before changes are made, to allow them to take ownership of the selected PHSM.[23] It is critical to build and foster trust, especially in contexts where there is little or no involvement of the local population in decision-making. Clear, concise and transparent risk communication, including an evidence-based rationale for adjusting measures, should be developed with communities targeted for PHSM.

In particular:

- Communities should be given recognized roles to provide input and take ownership of when and how PHSMs will be implemented or lifted.
- Communities will be critical to implementing population-wide PHSMs and contributing to the mitigation of the social and economic impact of certain measures (e.g. disrupting availability of food and other needed supplies).
- Civil society organizations, faith-based organizations (FBOs) and volunteers play a critical role in fortifying community services (e.g. provision of food, medicines, mental health and other support services, tests and vaccinations) for those in need (e.g. people who are isolated or quarantined).

- Feedback mechanisms should be established to ensure that any societal impact of changes to PHSMs is quickly identified and reported for action. Communities should lead solutions to ensure adoption of measures that best meet local needs (for example by considering local cultural practices), which can increase the likelihood of adherence.
- Local community-level networks should be leveraged for sustained efforts by building capacity through training of local leaders.
- The infodemic[24] that has emerged from COVID-19 information overload and misinformation should be managed at all stages of the response by providing the right information at the right time to the right people through trusted channels (e.g. community and faith leaders, family doctors and other influential members of society). There should be a monitoring system in place to capture emerging trends (e.g. vaccine confidence and hesitancy, adherence to PHSM) to enable delivery of a targeted communication package.
- A communication and community engagement strategy should be developed before any changes to PHSMs are implemented or adjusted.[3] The strategy should be developed in consultation with relevant stakeholders from government, civil society, FBOs and community groups. Plans should include, at a minimum, behavioural objectives, target audiences, priority channels and a mix of strategies and activities to inform and engage the community.
- The key messages of such plans should cover information important to the community, such as the extent and estimated duration of the measures in place.
- Governments should regularly communicate epidemiological data to the public to further foster trust and increase acceptance and sustained adherence to PHSMs.

Adjustment of PHSMs based on situational assessment

Table 2 provides more detail on the types of domestic measures that may be implemented for each situational level. The measures at each level are only indicative, because some measures may be more or less feasible or appropriate in specific contexts and locations. Note that overall recommendations on international travel can be found in the interim guidance *Considerations for implementing a risk-based approach to international travel in the context of COVID-19*.[15,16]

Measures should be time-bound and regularly re-assessed, at least every two weeks, along with the situational level. The adherence to PHSMs should also be monitored, using sources such as mobility data, and this should be used to further inform future adjustment of PHSMs and the risk communications and community engagement strategy.

At all Situational Levels, individuals should apply personal protective measures such as hand hygiene, physical distancing, respiratory etiquette, staying home if unwell and wearing a mask where appropriate, and environmental measures (e.g. cleaning, disinfection, ventilation). Clear information should be provided to the public about what to do if unwell and whom to contact for advice, testing and/or treatment.

Table 2: Guidance on the implementation of domestic PHSMs for each Situational Level

Situational level	Considerations for implementation of PHSMs by situational level*
Situational level 0: No known transmission of SARS-CoV-2 in the preceding 28 days. The health system and public health authorities are ready to respond, but there are no significant restrictions on daily activities.	Surveillance should ensure that any new case can be detected and managed as early as possible, but there should be no restrictions on daily activities. Authorities may consider implementing the following measures: • Continue strengthening emergency preparedness, readiness and response actions,[1] ensuring adequate stockpiles of medicines and medical equipment and that sufficient staff have been recruited and trained to handle anticipated surges in cases. • Implement or maintain robust surveillance [25] to rapidly detect and investigate suspected SARS-CoV-2 cases and clusters[26] and ensure public health measures such as isolation and supported quarantine[27] are undertaken to reduce onward spread if cases are confirmed and contacts are identified, respectively. • Apply a risk-based approach based on the three steps of risk evaluation, risk mitigation and risk communication to inform the decision to restrict, modify, postpone, cancel or proceed with holding any mass gatherings, including medium and small events. For public gatherings, the risk assessment should be undertaken by local and national public health authorities and event organizers with input from all relevant stakeholders (emergency management, transport, safety and security, etc.). [28,29]
Situational level 1: Basic measures are in place to prevent transmission; or if cases are already present, the epidemic is being controlled through effective measures around the cases, with limited and transient localized disruption to social and economic life.	Specific measures should be taken around cases and/or clusters, and individual measures should be strengthened, with limited impact on social and economic activities. In addition to measures on emergency preparedness, readiness and response actions[1] and surveillance, personal protective measures and risk communications, authorities may consider implementing the following measures: • Emphasis should be placed on case and cluster detection, investigation, and tracing of contacts. • Promote avoidance of the '3 Cs' – Closed spaces, crowded places and close-contact settings. • Apply a risk-based approach based on the three steps of risk evaluation, risk mitigation and risk communication to inform the decision to restrict, modify, postpone, cancel or proceed with holding any mass gatherings, including medium and small events. For public gatherings the risk assessment should be undertaken by local and national public health authorities and event organizers with input from all relevant stakeholders (emergency management, transport, safety and security, etc.). [28,29] Daily activities and services, such as educational settings[30], businesses[31] and leisure/tourism can remain open with precautionary measures in place to limit the risk of spread. • Put in place measures to protect the most vulnerable, particularly ensuring that there are appropriate measures in place in long-term care[32] and other residential facilities.
Situational level 2: Low community incidence or a risk of community transmission beyond clusters. Additional measures with respect to Situational level 1 may be required to control transmission; however, disruptions to social and economic activities can still be limited	Measures should be applied to limit the number of physical encounters with others outside of the household, while ensuring services can remain open with precautionary measures in place. A wider range of PHSMs may be required to control transmission. In addition to measures on emergency preparedness and response and surveillance, personal protective measures and risk communications, authorities may consider implementing the following measures: • Education settings remain open with precautionary measures in place. • Businesses remain open, with precautionary measures in place, with teleworking encouraged as much as possible. • Improve local transport infrastructure to comply with PHSMs (improve availability, frequency, extension of schedules, etc.). • Apply a risk-based approach based on the three steps of risk evaluation, risk mitigation and risk communication to inform the decision to restrict, modify, postpone, cancel or proceed with holding any mass gatherings, including medium and small events. For public gatherings the risk assessment should be undertaken by local and national public health authorities and event organizers with input from all relevant stakeholders (emergency management, transport, safety and security, etc.) [28,29]. • If required, place further emphasis on protecting the most clinically vulnerable, through strict application of infection prevention and control measures, heightened surveillance and managing visits in long-term care and other residential facilities. • If contact tracing is overwhelmed, consider prioritization of contact tracing (see *Contact tracing in the context of COVID-19.*[33]).

Situational level	Considerations for implementation of PHSMs by situational level*
Situational level 3: Community transmission with limited additional capacity to respond and a risk of health services becoming overwhelmed. A larger combination of control measures may need to be put in place to limit transmission, manage cases, and ensure epidemic control.	Strengthening of all PHSMs is needed to avoid more stringent restrictions on movement and other related measures applied under level 4. All individuals should reduce their social contacts, and some activities may need to close while allowing for essential services, particularly schools, to remain open. In settings with high dependence on daily wages and informal economy, mitigation of the potential socio-economic costs of strengthening PHSMs needs to be planned properly in advance. In addition to measures on emergency preparedness and response and surveillance, personal protective measures and risk communications, authorities may consider implementing the following measures: • Adapt the functioning of businesses to minimize COVID-19 risk, including through remote working, modified service provision, or closure where necessary. • Improve local transport infrastructure to comply with PHSMs (improve availability, frequency, extension of schedules, etc.). • Consider limiting in-person university teaching, and institute e-learning. • Childcare services and primary and secondary schools should remain open with adequate safety and surveillance measures in place as long as the local context allows. Continuity of education for children for their overall well-being, health and safety should be at the forefront of all relevant considerations and decisions. • Due to risk of further transmission in an already high transmission level with limited healthcare resources, all PHSMs may be best applied without relaxing any measures according to individuals' immune status. See section below on "individualized public health measures". • Apply a risk-based approach based on the three steps of risk evaluation, risk mitigation and risk communication to inform the decision to restrict, modify, postpone, cancel or proceed with holding any mass gatherings, including medium and small events. For public gatherings the risk assessment should be undertaken by local and national public health authorities and event organizers with input from stakeholders (emergency management, transport, safety and security, etc.) [28,29]. • Quantify the needs in advance and provide the necessary socio-economic support for low-income individuals and households and those at risk of falling into poverty, ensuring no-one is left behind. Socioeconomic recovery for these vulnerable groups and the general population should also be prepared for in advance and resources secured to the extent possible.
Situational level 4: An uncontrolled epidemic with limited or no additional health system response capacity available, thus requiring extensive measures to avoid overwhelming of health services and substantial excess morbidity and mortality.	Reducing transmission in the community will be challenging, and stringent movement restrictions and related measures will need to be put in place to significantly reduce the number of in-person encounters. Such measures should be geographically limited to where they are needed and be time-bound and aimed to be as short as reasonably possible. In addition to measures on emergency preparedness and response and surveillance, personal protective measures and risk communications, authorities may consider implementing the following measures: • All individuals, including fully vaccinated, partially vaccinated and recovered individuals, should stay at home and limit physical contact with people outside the household. • Essential workers will need to continue activities, with maximum support and safety measures in place. Improve local transport infrastructure to comply with PHSMs (improve availability, frequency, extension of schedules, add private transport to public transport infrastructure, etc.). • Close non-essential businesses, and institute remote working. • Consider all options for continuity of in-person learning. If not possible, limit in-person contact. Options may include in-person or blended learning strategies that strictly limit the number of people physically on site (exceptions would include children of essential workers and their teachers) and remote learning. The closure of educational facilities should only be considered when there are no other alternatives. • All long-term care and other residential facilities should consider strict measures to limit the risk of infection, up to and including temporary suspension of in-person visits. • Cancel or postpone any mass gatherings. • Quantify needs (in advance) and provide necessary socio-economic support for low-income individuals and households and those at risk of falling into poverty, ensuring no-one is left behind. Carefully monitor the impact of strict PHSMs on the livelihoods and well-being of these vulnerable groups. Socio-economic recovery for these vulnerable groups and the general population should also be planned in advance and resources secured to the extent possible.

*The specific measures implemented at each level will need to be carefully considered based on the guiding principles outlined above. The measures at each level are only indicative, since some measures may be more or less feasible or appropriate in specific contexts and locations

****

Considerations for the implementation of individualized public health measures

In settings where robust PHSMs are otherwise in place to control the spread of SARS-CoV-2, allowing the relaxation of some measures for some individuals may contribute to limiting the economic and social hardship of control measures. The differential "personal protective measures" for immune (fully vaccinated or recovered from infection) versus non-immune individuals will be referred to as **individualized public health measures**.

Applying **individualized public health measure** recommendations based on someone's immunity status must be carefully considered in the light of a number of aspects, including: the level of transmission of SARS-CoV-2; the evidence around the impact of various COVID-19 vaccines in preventing transmission; effectiveness against disease and duration of vaccine-induced immunity; the level and duration of protection conferred by natural immunity; the COVID-19 response strategy and risk tolerance of the implementing country; the potential circulation of immune-escape VOCs; and important ethical considerations, particularly given current limited availability of vaccines worldwide and existing inequities in vaccine availability across and within countries and population groups.

Ethical considerations

Details on the ethical considerations related to individualized public health measures in the context of COVID-19 are provided in other WHO publications.[17,34] Key considerations can be found below:

- **Proportionate and inclusive approach:** Before implementing individualized public health measures, governments or other competent authorities should, as much as possible, reduce barriers to vaccination; consider measures that least infringe of the rights and liberties of non-vaccinated individuals; and consider options for non-vaccinated individuals such as the results of reliable negative COVID-19 tests and making tests accessible to all (e.g. free testing once a week) or issuing immunity certificates for recovered individuals. This may help ensure that measures for non-vaccinated individuals are proportionate and as socially inclusive (defined here as removing or reducing barriers that prevent people from participating in civil, social and economic life) as possible.
- **Exemptions:** A system of recording and verifying exemptions from COVID-19 vaccination based on medical reasons, or other reasons provided for in law or relevant regulations, should be established if vaccination certificates are introduced to impose individualized public health measures on vaccinated and non-vaccinated individuals. Careful attention should be paid to ensuring that the collection, storage and use of such data are limited to scientifically and ethically justified purposes compatible with sustained public trust and confidence.

Technical considerations for individualized public health measures

Although vaccinated individuals or individuals with documented past infection may still be able to be (re-)infected and transmit the infection, growing evidence (see Table 3) suggests that the risk of infectiousness is substantially lowered. On this basis, countries may decide to relax quarantine requirements for individuals with evidence of immunity, since the burden of quarantine may outweigh the risk of transmission. However, if circulation of variant(s) able to evade established immunity becomes evident, such relaxation may not be advisable, because variants could still be transmitted efficiently.

The lower risk of infection following full COVID-19 vaccination likely varies by COVID-19 vaccine; given the paucity of data for all available COVID-19 vaccines, WHO recommends countries adopt a risk-based approach. This should also consider the local epidemiological context, and the context of the exposure (risk assessment of exposure), as some settings like health-care facilities may pose a higher risk, leading to classification of health-care workers as high-risk contacts.[5]

Table 3 below summarizes the main technical considerations around individualized public health measures in the context of vaccine-induced and natural immunity. The table was drafted based on evidence available as of 14 June 2021.

Table 3: Review of existing evidence on SARS-CoV-2 past infection, COVID-19 vaccines and variants of concern, and main technical considerations for individualized public health measures in the context of vaccine-induced and natural immunity

Element	Considerations
SARS-CoV-2 infection	• Natural immunity confers high levels of protection against reinfection, with estimates varying from around 81% to close to 100% protection in people younger than 65 years or among health workers during follow up of at least five to seven months.[6,35–37] Protection against reinfection appears to vary by age group and is lower (approximately 47%) among people aged 65 years and older.[35,38] • Evidence of immunity to SARS-CoV-2 is most commonly determined by measuring antibodies in sera. Within four weeks following infection, 90-99% of individuals infected with the SARS-CoV-2 virus develop detectable neutralizing antibodies.[14,39,40] • While correlates of protection are yet to be fully established, currently the presence of neutralizing antibodies is the best indication for protection against re-infection. How long protection lasts remains unclear and may differ depending on disease severity. Protection after infection with common cold coronaviruses, which often cause mild disease, is highly transient; and for SARS-CoV-2, there is evidence that immunological memory is 6-8 months.[41,42] • While protection is high, natural immunity does not provide 100% sterilizing immunity. Individuals who have natural immunity are still have a potential risk of reinfection and may be infectious.[43]
COVID-19 vaccination	• Different vaccine products may differ in their effectiveness, including against VOCs. The risk of onward transmission and duration of protection also may vary. Waning immunity and vaccine effectiveness over time will need to be documented as vaccination rollout progresses. • At the time of publication, in human clinical trials, all WHO Emergency Use Listed (EUL) vaccines have demonstrated efficacy (63% to 95%) against symptomatic, laboratory-confirmed COVID-19.[20,44–46] • In human clinical trials, all vaccines that currently have WHO EUL (as of the time of publication) have demonstrated high efficacy (over 89%) against severe COVID-19, indicating that the chance of developing severe disease in a fully vaccinated person is very low for younger and middle-aged adults and very low to moderate for older adults or other persons with underlying risk factors.[47,48] • Results from post-introduction observational studies have reported vaccine effectiveness estimates ranging from 64% to over 97%. The duration of protection remains unclear, because vaccine effectiveness has been measured only shortly after the introduction of the vaccines; but a recent eight-month follow up of recipients of one vaccine reported a durable response to the studied vaccine.[49] • One studied vaccine prevented infection for 70% of individuals at 21 days after a single dose and 85% of individuals at 7 days after two doses, providing real-world estimates of vaccine protection against infection.[50] • There is emerging evidence that vaccination substantially reduces the risk of onward transmission of SARS-CoV-2 to susceptible contacts.[51,52] • There is also emerging evidence that use of COVID-19 vaccines at the population level has a positive impact on the disease dynamics in the population.[53,54]
Variants of concern (VOCs) (as of the time of publication)	• Some SARS-CoV-2 variants, including all currently identified VOCs (i.e. Alpha [B.1.1.7], Beta [B.1.351], Gamma [P.1] and Delta [B.1.671.2], exhibit increased transmissibility as compared to previously/co-circulating variants.[8] This primarily influences transmission levels and the potential need to keep general PHSMs in place for longer or at a higher intensity, rather than specifically influencing considerations for individualized public health measures. • Evidence of increased resistance of some SARS-CoV-2 variants (including all four VOCs) to natural or vaccine-induced neutralizing antibodies has been reported, raising the concern that reinfection after natural infection or breakthrough infection after vaccination may increase in settings where such VOCs circulate widely.[8,55] • The convergent evolution of mutations thought to be associated with higher transmissibility or immune escape (e.g. N501Y, E484K) in VOCs highlights the fact that variants will likely continue to emerge under selective pressures such as population immunity.[56]

Note: references cited do not represent an exhaustive list of all relevant references on these topics

Implementation of individualized public health measures based on available evidence (as of 14 June 2021)

After taking into consideration ethical and technical considerations and transmission levels, countries may consider relaxing some measures for individuals meeting either of the following criteria:

- completion of full vaccination with one of the WHO EUL vaccines or approved by a stringent regulatory authority (and at least two weeks after completion of vaccination)
- SARS-CoV-2 infection confirmed by RT-PCR within the past 6 months and no longer infectious as per WHO's Criteria for releasing COVID-19 patients from isolation.[55]

Depending on the transmission level, below are some options for individualized measures in:

- waiving quarantine following close contact with a confirmed COVID-19 case
- waiving testing and/or quarantine requirements in the context of international travel
- allowing congregating in indoor private settings with other fully vaccinated or recovered individuals without wearing masks and without applying physical distancing.

Decision makers should apply a risk-based approach when considering the use of masks for the general public regardless of vaccination or natural immunity status. In areas of known or suspected community or cluster SARS-CoV-2 transmission: WHO advises that the general public should wear a non-medical mask in indoor (e.g. shops, shared workplaces, schools) or outdoor settings where physical distancing of at least 1 metre cannot be maintained. If indoors, unless ventilation has been be assessed to be adequate, WHO advises that the general public should wear a non-medical mask, regardless of whether physical distancing of at least 1 metre can be maintained.[56] As part of the risk-based approach, local authorities may consider allowing congregation of fully vaccinated or recovered individuals without wearing masks and without applying physical distancing in indoor **private** settings in regions with low SARS-CoV-2 incidence (<20/100000 population). **In community or health care settings, where measures such as mask wearing are recommended, they should continue to apply to everyone.**

Figure 1 provides guidance for a risk-based approach to individualized public health measures, which takes into consideration both risk to individuals and to the population. This figure, which is based on the evidence in Table 3, shows that as the transmission level increases (left column), the risk of infection for individuals and the overall risk of additional infections and onward transmissions increases (arrows in columns 2-5), as does the overall risk of additional cases of severe disease arrows in columns 6-9. The differing gradients of the arrows in columns 2-9 further show that the degree of increased risk varies according to an individuals' age and immunity status.

The resulting options are shown in the column labelled "options for individualized public health measures". At the lowest levels of transmission, individualized measures (waiving quarantine in the context of close contact, waiving quarantine and/or testing in the context of domestic and international travel, freely congregating in private settings with other fully vaccinated or recovered individuals without wearing masks or physical distancing) can be considered for all immune individuals. At the highest transmission levels, measures should be retained for all individuals, irrespective of immune status. At intermediate levels of transmission, there is a disproportionately high risk of transmission and severe disease in recovered individuals ≥60 and/or with underlying risk factors, and authorities may consequently wish to consider retaining measures for this group. Considerations may need to be further tailored to local contexts. For example, in situations with no known domestic circulation, a full quarantine may be required for all travellers, regardless of immunity status, to control the residual risk of importation. Further, in situations where healthcare capacity is extremely limited, measures may need to be retained at relatively lower levels of transmission to avoid overburdening the health care system with any additional cases.

Figure 1. Options for Individualized Public Health Measures

Exposure risk (transmission level)	Factors involved in informing options for individualized public health measures								Options for individualized public health measures	Factors that could increase the risk
	Fully vaccinated ≥60* and/or with underlying risk factors	Fully vaccinated <60	Recovered individuals ≥60 and/or with underlying risk factors	Recovered individuals < 60	Fully vaccinated ≥60 and/or with underlying risk factors	Fully vaccinated <60	Recovered individuals ≥60 and/or with underlying risk factors	Recovered individuals <60		
	Infection risk / Net transmission Risk				Net risk of severe disease					
Lower ↓ Higher	↓	↓	↓	↓	↓	↓	↓	↓	Relax measures for all immune individuals† ↓ Consider retaining measures for recovered individuals ≥60 and/or with underlying risk factors‡ ↓ Retain measures for all individuals§	Presence of immune escape variants

* Most transmission evidence uses an age category of 65 and older, while most severity evidence references persons 60 years and older; for consistency, the more conservative grouping of 60 years and older is retained in this table.

† Relaxing of restrictions and preventive measures (waiving quarantine in the context of close contact, waiving quarantine and/or testing in the context of and international travel, freely congregating with other fully vaccinated or recovered without wearing masks or physical distancing in private settings) for all immune individuals

‡ Due to increasing risk of severe disease and of transmission

§ Due to moderate to high risk of further transmission, all individuals should stay at home and limit physical contact with people outside the household.

The risk matrix presented above is informed by the scientific evidence on SARS-CoV-2 past infection, COVID-19 vaccines and SARS-CoV-2 variants of concern available at the time of this writing. *Infection risk* is a product of the *exposure risk* (which is proportionate to the level of transmission of the virus) and the *susceptibility to infection, if exposed*. The *net transmission risk* is the product of the *infection risk* and the *risk (if infected) of transmitting infection* to non-immune individuals. Given the lack of evidence to the contrary, for the purposes of this framework *the risk (if infected) of transmitting infection* by individuals with reinfection / vaccine-breakthrough infection is assumed to be equal to that seen in primary infection; thus, the *net transmission risk* is assumed to be proportionate to the *infection risk*. *Net risk of severe disease* is the product of the *infection risk* and the *risk (if infected) of severe disease*.

Considerations for quarantine

As per the evidence presented in Table 3, contacts who are fully vaccinated or contacts without risk factors who have recovered from COVID-19 could be considered lower-risk contacts, both in terms of the likelihood of becoming infected and the severity of disease if infected. Consequently, some countries may decide to exempt them from quarantine. However, these contacts should be advised to monitor their symptoms following their exposure; if symptoms develop, they should be tested for SARS-CoV-2, and isolated if they are found to be infected with SARS-CoV-2. Countries may also need to take into consideration the context of the exposure (risk assessment of nature of exposure), because some settings like health-care facilities may pose a higher risk, leading to classification of health-care workers as high-risk contacts. Tailored adjustment for key groups with low risk tolerance may be considered, such as for health care workers or staff of long-term care facilities for the elderly, to minimize risks of potential onward transmission.

As lower risk contacts may still pose some residual risk for onward transmission, countries may opt to quarantine lower-risk contacts if there are concerns about transmission of immune-escape variants, or if their goal is elimination of local transmission.

International travel risk-mitigation measures

At present, WHO does not support the introduction by national authorities or by conveyance operators of requirements for proof of vaccination or natural immunity against SARS-CoV-2, neither as a condition for exiting or entering a country, nor as a condition for traveling internationally.[57]

In the context of the COVID-19 pandemic, international travel should always be prioritized for emergencies and humanitarian actions; travel by essential personnel; repatriations; and cargo transport of essential supplies such as food, medicines and fuel.

At present, international travellers are not considered contacts of SARS-CoV-2 in principle unless a traveller meets the definition of a contact.[15,16] Furthermore, international travellers should not be categorized as suspected COVID-19 cases. Therefore, WHO does not recommend healthy travellers as a priority group for SARS-CoV-2 testing, in particular when resources are limited, to avoid diverting resources from settings and patients where testing can have a higher public health impact and drive action.[15,16]

In line with the individualized approach to public health measures outlined earlier in this guidance, countries may consider fully vaccinated or recovered individuals as lower-risk travellers and may consider waiving testing and/or quarantine of arriving international travellers. Such decisions should be based on a detailed risk assessment that takes into account the COVID-19 control objectives of the arrival country and the SARS-COV-2 incidence, and prevalence of VOCs, in the departure country. For more details, updated interim guidance: Considerations for implementing a risk-based approach to international travel in the context of COVID-19 is forthcoming.[15]

Annex

Public health criteria to adjust public health and social measures in the context of COVID-19

Introduction

In response to the COVID-19 pandemic, countries around the globe have implemented public health and social measures (PHSM) for the control of SARS-CoV-2 transmission. As the local epidemiology of the disease changes, vaccines are rolled out and new variants of concern (VOCs) emerge, regular adjustment of such measures will be necessary.

This annex updates the annex to *Critical preparedness, readiness and response actions for COVID*-19 published on 4 November 2020 and outlines a process for decision-making on adapting PHSMs to the epidemiological situation, taking into account surveillance and testing capacities, the vaccination coverage in the target population and the health system's capacity for response. It should be read in conjunction with the main body of this document and the earlier interim guidance.[1]

This annex is intended for the public health divisions of national and sub-national authorities in locations that have introduced PHSMs and are considering adjusting them. Its guidance is restricted to the public health domain. Other documents published by WHO address different considerations that should enter into decision-making about introducing or loosening PHSM, including the welfare of a population.

How to use the guidance in this annex

The public health criteria in this annex are grouped into two dimensions that should be evaluated to address two main questions:

1. **Epidemiological situation/Transmission classification** – Is the epidemic controlled?
2. **Health system and public health services capacity and performance –** Is the health system able to detect and cope with COVID-19 cases while maintaining other essential health services?

These two dimensions should further be considered in the context of the national COVID-19 response strategy. Thresholds for action may depend on the country's overall strategy, and whether it is pursuing an elimination or control strategy.

The criteria are not prescriptive, and it may not be feasible to assess some of them, because of a lack of data, for example. Countries should focus on the criteria most relevant for them to inform decision making. In countries with limited surveillance data, vaccination coverage data among target groups can help steer decisions about PHSM, together with indicators from sentinel surveillance in health facilities or bed occupancy. The thresholds are indicative and may need to be revisited as further information about the epidemiology of COVID-19 and the impact of measures become available. It is recommended to systematically assess these criteria at least biweekly at the **lowest operational subnational administrative level** that is practical to inform tailored local responses.

This Annex also includes a third section presenting risk matrices for informing individualized public health measures.

1. Epidemiological situation/Transmission classification

Transmission classification categories can be used to determine the extent to which the epidemic can be considered controlled within each country/area and at sub-national levels. The transmission categories in one country, if published, are also useful to others when considering adjusting policies on trade and travel.

Defining transmission classification

The transmission classification developed in the last guidance has been maintained, with seven categories, as outlined in Table 1.

Annex Table 1: Definition of the categories for transmission classification

Category name	**Definition** *Countries/territories/areas with:*
No (active) cases	No new cases detected for at least 28 days (two times the maximum incubation period), in the presence of a robust* surveillance system. This implies a near-zero risk of infection for the general population.
Imported / Sporadic cases	Cases detected in the past 14 days are all imported, sporadic (e.g. laboratory acquired or zoonotic) or are all linked to imported/sporadic cases, and there are no clear signals of further locally acquired transmission. This implies minimal risk of infection for the general population.

Clusters of cases	Cases detected in the past 14 days are predominantly limited to well-defined clusters that are not directly linked to imported cases, but which are all linked by time, geographic location **and** common exposures. It is assumed that there are a number of unidentified cases in the area. This implies a low risk of infection to others in the wider community if exposure to these clusters is avoided.
Community transmission – level 1 (CT1)	**Low incidence** of locally acquired, widely dispersed cases detected in the past 14 days, with many of the cases not linked to specific clusters; transmission may be focused in certain population sub-groups. Low risk of infection for the general population.
Community transmission – level 2 (CT2)	**Moderate incidence** of locally acquired widely dispersed cases detected in the past 14 days; transmission less clearly focused in certain population sub-groups. Moderate risk of infection for the general population.
Community transmission – level 3 (CT3)	**High incidence** of locally acquired, widely dispersed cases in the past 14 days; transmission widespread and not focused in population sub-groups. High risk of infection for the general population.
Community transmission – level 4 (CT4)	**Very high incidence** of locally acquired widely dispersed cases in the past 14 days. Very high risk of infection for the general population.

* Note that in situations where COVID-19 surveillance is not robust, a lack of identified cases should not be interpreted as an absence of transmission; alternate indicators (see Table 5) should be examined to assess the possibility of undetected COVID-19 cases.

Primary indicators for assessing the level of community transmission

Four primary indicators to determine community transmission are proposed in Table 2. They are based on data that should be routinely collected during the pandemic. The relative importance of each available indicator will vary according to the local context (e.g. the reliability of the data for each indicator); and described limitations to interpreting each indicator should be taken into account. Indicators should be measured at the lowest administrative level of operations possible to inform targeted public health interventions. To develop transmission classification at a higher administrative level, a separate analysis should be conducted using indicators for that level, rather than attempting to aggregate lower-level transmission classifications.

These indicators should be used alongside other epidemiologic information available either routinely or through special studies or modelling estimates, as well as non-epidemiologic data and other considerations, for informing strategic and operational decisions.

It is recommended that these indicators be assessed biweekly, adopting the epidemiological week definition used in the country.

Ranges for the four indicators in Table 2 were developed through a review of existing data. They can be used to guide the application of the transmission classification at sub-national levels. These ranges are indicative and may require adjustment to local contexts and based on the performance (e.g. sensitivity, representativeness) of the local surveillance system and testing strategy and should be revisited periodically. Caution should be exercised when interpreting changes in indicators that occur in the context of changes to the surveillance system (e.g. an increase in testing rate or a change in the population under surveillance). Note that some indicators (e.g. overall incidence) may be higher in the presence of very large clusters, as in the case of superspreading events, than during community transmission.

It is helpful to monitor the testing rate as a measure of the coverage of surveillance. A minimum recommended rate is at least one person tested per 1000 population per week. Testing should not be limited to specific populations (e.g. only those in urban settings with high access to testing, or travellers). Denominator data must be available at the level of disaggregation being assessed (e.g. district, province). Some authorities may choose to specifically track these indicators among groups of individuals at greatest risk for severe disease and death.

After all available indicators are calculated, if the levels calculated based on each indicator are different, a qualitative review should be undertaken to determine the final transmission classification. It is recommended that if data are not available (or reliable) for all indicators, more weight should be given to the indicators considered more reliable in the local context. In many cases, indicators listed higher in Table 2 may be more reliable than those lower in the table.

In places where indicator values are not reliable, but the system is stable, trends can be used as an alternative assessment. One example would be a situation in which there is a very low testing rate, and many cases are likely missed, but the testing strategy is not changed.

Annex Table 2: Primary epidemiological indicators and proposed ranges to assess the level of COVID-19 transmission

Domain	Indicator	Description/Rationale	Major limitations	Level of community transmission			
				CT 1	CT 2	CT 3	CT 4
Hospitalization Rate	New COVID- 19 hospitalizations per 100 000 population per week*	A subset of all incident cases require hospitalization; thus, this is an indirect indicator of incidence. Unlikely to be subject to surveillance policy changes/differences.	May be influenced by hospitalization policy, e.g. if even mild cases are hospitalized for isolation purposes. Delayed measure of incidence.	<5	5 - <10	10 - <30	30+
Mortality	Number of COVID-19- attributed deaths per 100 000 population per week*	A subset of all incident cases are fatal, and thus this is an indirect indicator of incidence. Minimally influenced by surveillance policy if testing is comprehensive.	Delayed measure of incidence. At low levels and in small geographical regions, can be sensitive to minor fluctuations (e.g. one versus two deaths).	<1	1 - <2	2 - <5	5+
Case Incidence	New confirmed cases per 100 000 population per week*	Direct measure of incidence	Heavily influenced by surveillance system performance, testing policy and laboratory capacity. At low levels and in small geographical regions, can be sensitive to minor fluctuations in case counts, particularly due to batch reporting.	<20	20 - <50	50 - <150	150+
Testing	Test positivity rate per week (non-sentinel)*	This may be useful if there are limited sentinel sites. It may capture atypical cases better than sentinel surveillance.	Heavily influenced by testing strategy and capacity.	< 2%	2% - < 5%	5% - <20%	20%+

*Consider averaging over a two-week period to minimize the effect of random fluctuations.

Note: the thresholds in this table may be updated as additional data become available.

Additional indicators

Additional indicators that can provide further evidence to help classify the level of transmission are listed in Table 3. These indicators may not be readily available at the lowest administrative level of operations, however. They are therefore considered secondary to the primary four indicators listed in Table 2. Furthermore, they may not directly reflect transmission or force of infection of SARS- CoV-2 or may be more difficult to interpret and compare than those listed in Table 2. Thresholds are not presented for the secondary indicators, due to a lack of available data, high local variability or both.

As a last resort, where no indicator values are available, subjective assessment can be used, but this should be done over several weeks to avoid influences from transient or anecdotal observations.

Annex Table 3: Additional epidemiological indicators to assess level of COVID-19 community transmission*

Indicator	Description/Limitations
Intensive care unit (ICU) proportional occupancy	The proportion of new ICU admissions attributed to COVID-19, out of all ICU admissions for the same period (alternatively, proportion of current ICU beds occupied by patients with COVID-19, out of all occupied ICU beds)
Instantaneous reproduction number (Rt)	The instantaneous reproduction number is the average number of secondary cases each current case would produce if conditions remained the same. Rt should be estimated over successive weekly time windows and should be considered in combination with the number of cases at a given time. When there is a large volume of cases at a given time, Rt near 1.0 would sustain a high number of cases. While this is a widely used indicator of transmissibility, it requires familiarity with the various methods for calculation and sufficiently reliable and timely data on incidence. It also assumes a known serial interval distribution, which can in practice be hard to estimate for COVID-19 due to limited data on transmission chains.
Daily growth rate	The daily growth rate measures the epidemic growth or decline of an epidemic. It is approximately the percent of increase/decrease in daily case incidence.
Doubling time	The number of days required for the daily incidence to double. This is directly determined by the daily growth rate *r* and linked to Rt and the serial interval distribution. All else being equal, higher Rt will lead to shorter doubling times.
Proportion of unlinked cases among new cases	This is defined as the proportion of cases not previously listed as contacts (alternatively, the proportion not linked to known clusters/transmission chains). It is a measure of the spread in the community beyond known clusters. It is heavily influenced by case investigation and contact tracing capacity.
Test positivity proportion from sentinel sites averaged over a two- week period	Minimally influenced by testing strategy or capacity. Can provide a good, standardized way to monitor evolution over time if adequate number of samples are collected and sites are geographically representative. May not be representative of the general population if there are only limited sentinel sites.
Influenza-like-illness (ILI) or Severe Acute Respiratory Infection (SARI) trends	This is not directly indicative of COVID-19 cases, but sentinel surveillance for ILI and SARI can also capture a proportion of COVID-19 cases, and thus this is useful for monitoring trends for COVID-19. This measure may be helpful where COVID-19-specific surveillance is not robust.
Secondary attack rates (SAR)	This captures the probability that a contact person is infected following exposure to a confirmed case during their infectious period. Comparison of secondary attack rates in different contexts (e.g. vaccinated versus non-vaccinated individuals, different types of exposures, different variants) can shed light on risk factors for increased transmission.

All-cause hospitalization rate trends	This is not directly indicative of COVID-19 hospitalizations but, where COVID-19 cases make up a substantial proportion of hospitalizations, this can be useful for identifying trends in COVID-19 cases. These rates may decline due to restricted service provision and other public health measures. Trends must be analysed in the context of other potential causes of changes in hospitalization rates (e.g. concurrent influenza circulation). These trends may be helpful where COVID-19-specific surveillance is not robust.
All-cause (excess) mortality trends	This measure is not directly indicative of COVID-19 cases/deaths, but where COVID-19 deaths make up a substantial proportion of overall deaths, this can be useful for identifying trends in COVID-19 cases. Trends must be analysed in the context of other potential causes of changes in mortality rates (e.g. concurrent influenza circulation) and ideally compared with baseline data on mortality to identify excess above expected (e.g. seasonal) fluctuations. While this is a widely used indicator of transmission, it requires careful consideration of the inherent biases in mortality estimation methods.[3] This may also be a delayed indicator, depending on death and vital records system processes. These trends may be helpful where COVID-19-specific surveillance is not robust.
Cumulative vaccination uptake (by first dose or fully vaccinated)	Defined as the proportion of individuals who received a) the first dose, or b) the full recommended series of any COVID-19 vaccine, as percentages of the total population of a country or area. Cumulative vaccination uptake can provide a useful indication of population coverage†, especially in the short term. Over longer timeframes, using uptake data to infer vaccination coverage also needs to take into account changes in the population denominator (including by age group), especially mortality among targeted groups. Uptake and coverage data may provide an indication of population protection from COVID-19 disease during the months following vaccination. It is currently unknown whether such protection might wane over longer timeframes or whether new virus variants might affect vaccine efficacy and effectiveness. Evidence about the role of vaccination in preventing infection and preventing transmission is being assessed.

*This list should not be considered exhaustive. † For further information on COVID-19 vaccination uptake, rate, and coverage, please refer to *Monitoring COVID-19 Vaccination*, Page 5.[4]

Trends in transmission

In addition to calculating the category of transmission classification, it is also important to understand the direction of the trends of contributing indicators (stable, decreasing or increasing) over several weeks. This can assist in determining whether measures implemented are improving the epidemiological situation in the area, and for planning future changes, or putting in place anticipatory changes to public health measures based on a likely change in the transmission classification.

2. Health and public health services capacity and performance

The capacity to respond to the existing epidemiologic situation of COVID-19 (i.e., the transmission classification) is a key consideration in the decision to adapt PHSM. Clinical care and public health services are two key domains that reflect the ability of a country to adapt and respond to the requirements of both the COVID-19 caseload and the burden of disease more generally. Sufficient clinical care capacity is required to treat both inpatient and ambulatory cases of COVID-19 while ensuring that the health system is not overwhelmed and can continue to treat the regular caseload of patients with other conditions, particularly during seasonal peaks, such as the influenza season, and at times of rapid or large increases in SARS-CoV-2 transmission. The public health response relies on the capacity of the surveillance system to detect and respond to changes in SARS-CoV-2 transmission and focuses on key activities including case detection, diagnostic testing and contact tracing. Each of the two domains (health services and public health) is divided into two principal sub-domains, namely capacity (output indicators) and performance (outcome and impact indicators).

While this section is not aimed to be overly prescriptive, it provides quantitative thresholds (Table 4) to categorize response capacity and performance into three categories: adequate, moderate and limited. It is important to note that capacity needs to be assessed in the context of the current transmission classification. Response capacity that has been considered adequate may, under a higher incidence scenario, be reduced to moderate or limited response capacity.

Assessing the overall level of health system and public health services capacity and performance

To assess the overall capacity and performance of the health system and public health services, authorities should use the same approach as outlined for transmission classification. This includes:

- prioritizing those indicators that are available and reliable and adjusting thresholds to local contexts and reliability of the data
- interpreting changes to indicators in the context of changes to data collection mechanisms
- undertaking a qualitative review to determine the final health system capacity level if the levels calculated based on each indicator are different
- using trends instead of quantitative thresholds where data are not reliable, but denominators are stable
- using subjective assessment as a last resort if no data are available
- observing trends in indicators to anticipate future changes to the health system and public health services capacity and performance level.

Additional indicators that can be used for triangulation are provided in Table 5. Assessments should be updated biweekly.

Annex Table 4: Primary indicators and proposed ranges to assess level of COVID-19 health system and public health services capacity and performance

Domain	Indicator	Description/	Major limitations	Capacity to respond		
				Adequate	Moderate	Limited
Clinical care capacity	Proportion of occupied hospital beds	High morbidity and mortality will occur if there is insufficient capacity to hospitalize severe cases. Should count all hospitalizations, not only COVID-	May be influenced by hospitalization policy (e.g. if all cases are isolated in hospital), which does not indicate true saturation of hospital capacity.	<75%†	75-<90%†	90%+ †
Clinical care performance	Case fatality rate of resolved (i.e., outcome known) hospitalized cases	Overall impact indicator of adequate COVID-19 care.	Highly dependent on age and various biases.[3] Must take into account any changes in case detection or testing strategy.	Decreasing trend	Stable trend	Increasing trend

Public health response capacity	Number of persons tested per 1000 population per week, averaged over a two-week period	Without sufficient testing, it is difficult to appropriately isolate and treat cases.	Not all laboratories are able to report individuals tested; if possible, can count number of new rather than repeat tests; otherwise can count number of tests, but this may be misleading due to repeat testing. Laboratories not reporting location of cases may mask disparities in testing (e.g. among non-urban populations). If using rapid diagnostic tests, these should be used according to guidance, and thresholds may need to be raised.	4+	1 - < 4	<1
Public health response performance	Proportion of cases for which an investigation has been conducted within 24 hours of identification	This indicates the capacity to identify transmission risks and exposed contacts. Where investigation is not recorded directly, can be measured by proxy indicator - proportion of cases with contacts listed.	May be difficult to obtain timely data.	80%+	60 - <80%	<60%
Public health response performance	Support for / adherence to PHSMs (can be further subdivided into personal protective measures versus other measures)	Qualitative assessment based on observation, media monitoring, perception or behaviour surveys, hotlines, focus groups, etc. Analysis including forecasting of effectiveness of PHSM to be considered, it is important to identify not only the current status but any barriers or enablers to improvement.	May be highly variable between sub-groups and across individual PHSMs and over time.	High (nearly universal adherence to most PHSMs).	Moderate (modest adherence to most PHSMs, or variable adherence across individual PHSMs).	Low (minimal adherence to most PHSMs).

† Hospital occupancy routinely varies considerably between countries and health systems. Therefore, baseline (pre-COVID-19) occupancy must be taken into consideration.

** A significantly low hospital occupancy rate may also indicate barriers to access to hospital care, requiring investigation into the causes and remedial actions to be taken. In situations of community transmission, low hospital utilization may indicate large numbers of community deaths, which would potentially not be captured in facility-based mortality reports.

Annex Table 5: Additional indicators to assess level of COVID-19 health system and public health services capacity and performance*

Indicator	Description/Limitations
Number of trained ICU staff per 10 000 population	This indicates sufficient clinical capacity to respond to cases most likely to lead to mortality. This indicator may be more relevant when measured against a population of clinically vulnerable[i] persons, if data are available. This indicator is difficult to measure. It is a necessary but insufficient measure of ability to provide intensive care.
Number of ICU beds per 10 000 clinically vulnerable population[i]	Mortality from COVID-19 will be highest if capacity for intensive care is exceeded. Strictly counting the number of ICU beds does not guarantee successful care if there is inadequate staffing, equipment or supplies.
Proportion of occupied ICU beds	This indicator assesses sufficient clinical capacity to respond to cases most likely to lead to mortality. It may not be useful in countries with very few ICU beds (can be substituted with proportion of occupied hospital beds +/- oxygen in these situations). If this indicator is very low, overall health system capacity should be considered limited, regardless of adequate levels of other capacity indicators.
Proportion of occupied beds with access to oxygen supply	Oxygen is an important treatment for COVID-19, and sufficient capacity to provide oxygen can be useful even in the absence of ICU capacity. This indicator may be difficult to measure and may not be useful in countries with very low capacity.
Crude case fatality rate of COVID-19	This is an overall impact indicator of adequate COVID-19 care. It is highly dependent on age, other risk factors and various reporting biases.[3] Analysis of trends should consider any changes in case detection or testing strategy. Countries are advised to collect additional information on age, as this measure will be heavily affected by the age structure of the population.
Number of contact tracers per 100 000 population [alternatively per number of new cases in a week]	This indicates capacity to conduct sufficient contact tracing to interrupt transmission. It is an input indicator that may not correlate well with actual contact tracing outcomes. There is minimal evidence base for determining thresholds. This may be difficult to accurately measure where contact tracing is done by persons other than formally designated "contact tracers".
Number of points of entry surveillance officers per 100 000 daily travellers	This is a measure of the ability to successfully mitigate the risk of importation. It is a poor indicator of actual internal domestic capacity; is minimally relevant during widespread community transmission; and may be achieved when human resources are inappropriately diverted from internal domestic use.
Proportion of newly confirmed or probable cases interviewed for contact elicitation within 24 hours of identification	This indicator measures the timeliness of contact listing, which shortens exposure to potentially infected persons. A better metric of contact listing timeliness is the actual proportion of contacts identified and traced/quarantined within 48 hours.
Proportion of contacts of new cases who are monitored for 14 days (or locally specified period)	This indicates that contacts are monitored until no longer at risk for becoming secondary cases (linked to a particular source case). This indicator may be particularly important for assessment of public health system performance in the imported/sporadic and clusters transmission scenarios. It can be spuriously inflated by poor contact listing.
Proportion of identified cases isolated within 24 hours of positive test result (or determination as a probable case)	This indicates that investigation and isolation of new cases is sufficiently rapid to minimize the generation of secondary cases. This indicator may be particularly important for assessment of public health system performance in the imported/sporadic and clusters transmission scenarios.
Time from symptom onset to case confirmation	This measures the ability of the surveillance system to promptly detect, test and confirm symptomatic cases. Individual components (i.e., time from symptom onset to detection, detection to testing and test turnaround time) can also be measured independently.
Proportion of cases arising from contact lists	This describes the extent to which new cases are already captured by and known to the surveillance system through adequate case investigation. When this is low, it suggests widespread existence of "hidden" chains of transmission and/or poor-quality case investigation.
Number and proportion of samples sequenced	Wherever resources allow, laboratories could consider genomic sequencing of SARS-CoV-2 PCR-positive sentinel specimens.

*This list should not be considered exhaustive.

i 'Clinically vulnerable' in this context refers to individuals aged ≥ 60 years and/or with comorbidities that increase risk of serious COVID-19 disease, including heart disease, asthma and diabetes.

CROSS-EXAMINATION OF DR. ZAIN CHAGLA

TUESDAY, DECEMBER 14, 2021

10:05 A.M.

THE REPORTER: Good morning, my name is Giles, on behalf of Professional Court Reporters. We're here to take the examination of Dr. Zain Chagla, in the matter of Her Majesty the Queen in Right of Ontario, vs. Church of God et al., and the Attorney General of Ontario vs. Trinity Bible Chapel et al.

The respective Court File Numbers are CV-21-95 and CV-21-08. Today is the 14th day of December 2021, the time is approximately five minutes past 10:00 a.m.

May I ask the witness to state his full name for the record, please?

THE DEPONENT: Zain Chagla.

THE REPORTER: Mr. Chagla, do you solemnly affirm that the evidence you are about to give today shall be the truth, the whole truth, and nothing but the truth?

THE DEPONENT: Yes.

THE REPORTER: Thank you. Counsel

Kittredge, could you identify yourself for the record, please, Sir?

MR. KITTREDGE: Sure. I am Rob Kittredge, K-I-T-T-R-E-D-G-E, and on the -- I am on for the moving parties in this matter.

THE REPORTER: Thank you. Counsel Hunter, could you identify yourself for the record please, Sir?

MR. HUNTER: Josh Hunter for Her Majesty and for the Attorney General.

THE REPORTER: Counsel Stevenson, could you identify yourself for the record please, Ma'am.

MS. STEVENSON: Yes, Maia Stevenson, Counsel for the Attorney General.

THE REPORTER: Thank you, Counsel Guttman, could you identify yourself for the record, please, Sir?

MR. GUTTMAN: Yes, Daniel Guttman, Counsel for Her Majesty the Queen, Right of Ontario.

THE REPORTER: Thank you. Also present is Sean Kissick and Ryan Cookson as observers.

Counsel, thank you very much. You may proceed with your examination.

DR. ZAIN CHAGLA, affirmed,

EXAMINATION BY MR. KITTREDGE:

1. Q. All right. Good morning, Dr. Chagla. My name is Rob Kittredge and I represent the moving parties in this matter. I'll be asking you a series of questions today.

I have a -- I have quite a few questions for you. But for the most part they're, yes or no, questions and we should be able to get through all of them relatively quickly.

Where possible, I'd like you to answer with a 'yes' or 'no', but if you feel that any -- any of my questions call for a more extensive answer, feel free to expand as required.

If you'd like to take a break at any point, just let me know, okay?

A. Sounds good.

2. Q. I understand you submitted some evidence in this matter in the form of an Affidavit dated July 5th, 2021, is that correct?

A. Yes.

3. Q. Do you have a copy of your Affidavit in front of you today?

A. I can pull it up here, one second.

4. Q. Great. And while you do that, to begin with, I'd like to talk a bit about how the Province of

Ontario tracks the progress and severity of the COVID-19 pandemic.

And I am going to awkwardly figure out how to share my screen and show you a document. Just one second. The benefits of virtual cross-examination are that you can do a cross in your underwear, but you have to figure out how to -- you have to overcome technical issues here. Just one second.

Okay, I'll make sure I am not sharing something mortifying. There it is. All right. So, can you see that document?

A. Yeah, I can.

5. Q. All right, does that document look familiar to you?

A. I believe this is the data site from Public Health Ontario, or the data tracker tool.

MR. KITTREDGE: Yes, that's what it was. I took a screenshot last night. I'd like to mark this document as Exhibit A to the cross examination.

Does the opposing Counsel have any objection?

MR. HUNTER: No.

MR. KITTREDGE: Let's call it Public Health Ontario, COVID Summary December 12th,

2021.

(WHEREUPON Exhibit A : Public Health Ontario COVID Summary December 12th, 2021.)

BY MR. KITTREDGE:

6. Q. Dr. Chagla, among other things, this document shows the number of -- the total number of confirmed cases of COVID-19 in Ontario since the beginning of the pandemic.

Can you read the number of total confirmed cases to date for the record?

A. 633,683.

7. Q. Does sound like an accurate number to you?

A. It's the number of confirmed cases. I would suspect it's not the number of total cases that have been through the pandemic.

8. Q. The Province of Ontario defines a confirmed case of COVID-19 as a person who is SARS-coV-2 infection has been confirmed by laboratory testing, is that correct?

A. Correct.

9. Q. So, all of the cases listed on this page have been confirmed by a laboratory test. And the PCR test is the most -- is the test most commonly used to confirm SARS-coV-2 infection, is that correct?

A. Correct.

10. Q. Confirmed cases counts are an important measure of the progress and severity of the COVID pandemic. And are a fundamental data point used to calculate other important statistical measures of the pandemic, is that correct?

A. Correct.

11. Q. For example, further down on this page we see the percentage of cases that resulted in hospitalization at five per cent. And the percentage of cases that resulted in death at 1.6 per cent. These percentages are calculated based on the confirmed case count; correct?

A. Correct.

12. Q. You note in your Affidavit that the confirmed case count, and you noted just a moment ago that the confirmed case count doesn't capture 100 per cent of the cases in the general population due to a lack of access to testing, for example, or because some people with asymptomatic infection may choose to get infect -- not to get tested.

That may have been the case at the beginning of the pandemic; but testing rates have increased significantly since then. Since at least January of 2021, the vast majority of infections in the general population have been confirmed via testing, and are

included in the provinces confirmed case count, isn't that true?

A. I would still say there's a large testing gap since January of 2021. And I can say even through clinical experiences we diagnose who are admitted to hospital, not testing in the community through a typical assessment centre. Which means that they have been riding out their symptoms without a test for some time.

13. Q. Isn't that a sort of minority opinion though? Like wouldn't -- wouldn't most epidemiologists and other experts agree that testing currently captures the overwhelming majority of cases circulating in the community?

A. No, I -- you know, if you look at seroprevalence data prevalence data, so looking for people who have antibodies in their blood. It often is markedly higher than -- than what has been described as total case counts.

And again, to be identified as a case you have to be someone that has, you know, decided to go get tested for whatever reason, and had a result -- and -- and been classified, right.

So, people who decide not to get tested, or people who have minor illnesses, or as you said people

that are asymptomatic could have COVID-19, but not be captured in these numbers.

14. Q. We have expert testimony in this case to the effect that 90 per cent of COVID-19 cases in Ontario are confirmed by testing and are included in the provinces confirmed case count.

In other words, daily confirmed case statistics at this point capture all but about ten per cent of the cases in the general population.

Do you disagree with that assessment?

A. I would disagree with that. I mean if you look at the seroprevalence data prevalence surveys, you know, across the region, we're talking about, you know, I think the last Canada seroprevalence data prevalence survey was ten to 15 per cent of the population that had described antibodies. And this is around wave 3 from what I recall.

So, you know, it would be less than what would be described here. And certainly, in my clinical experience, again, you know, there are people that are diagnosed with COVID-19, where there's a cluster at home that have it, that have not been diagnosed and -- and it's only because one has ended up in hospital that we've figured out that there's more cases behind them in that sense.

So, I would suspect, you know, there is a discrepancy well more than ten per cent here, in terms of the number of cases that have actually occurred in Ontario.

15. Q. And based on your experience what -- approximately what percentage of the total number of cases do you believe are captured by testing?

A. Yeah, I mean it varies based on where we are in the waves. If there's a lot of cases in the community, then it likely means there's a lot more people that are undiagnosed in the community in that sense. And if there's very little transmission in the community, there's more chance of capturing those cases.

But again, you know, somewhere between one to two, to one to three would probably be a rough estimate of the number of cases that are represented by positives as compared to what likely the burdens are in the community.

16. Q. So, you're saying that there's likely three cases that are not captured by testing for every one case that is?

A. Yeah, and that's considered pretty good in Ontario. I mean globally it's even worse than that. But having more access to testing, more people are --

can get testing in Ontario.

17. Q. So, you'd say rather than 90 per cent of cases being caught, you'd say 25 per cent of cases are caught.

A. Yes, I mean somewhere between 25 and 50 per cent. Again, it varies based on where we are. So, you know, for example at the worst of the third wave, we probably would suggest there were, you know, lots of people that were being captured because testing was hard to come by. And so, all of those measures would be there.

And, you know, at the best of our kind of post lockdown periods we're probably capturing, you know, in the 60, 70 per cent range. But it averages out, I think, to 25 to 50 per cent.

18. Q. Okay. So, that's a pretty big difference, 90 per cent to 25 per cent. Would you agree that understanding rates of testing versus overall rates of infection in the population, at least in approximate terms, is fundamental to understanding and assessing the severity of the COVID-19 pandemic?

A. Yeah, absolutely.

19. Q. Would you doubt that COVID expertise of an infectious disease doctor who believes that testing captures 90 per cent of cases?

A. Yeah, I mean, I think, again, from real world experience it's not -- we're not capturing every case. So, you're not even close to 90 per cent. You know, they're a lot of people who do not get tested. And it is the reality of the situation.

20. Q. Okay. Dr. Matthew Hodge was the expert who provided this testimony. Do you know Dr. Hodge?

A. Not personally.

21. Q. Dr. Hodge was the co-lead for epidemiology and surveillance activities within the incident management system structure of the health protection division of the PHO, from November 2020 until April 9th, 2021.

Does it seem possible to you that someone with Dr. Hodge's experience actually believes that testing captures 90 per cent of cases in the community?

A. Ah, I mean, I presume he looks at a data set that's different than what I have access to. Obviously, he may see different things than I do. But, you know, again as an on-the-ground clinician, you -- there are groups that I know that are uncaptured by testing. And we're seeing many of them every day.

22. Q. So, would you agree that claiming that 90

per cent of cases in the general population are captured by testing, is a false statement?

A. Yeah, I would -- I would suspect looking at seroprevalence data prevalence data it's much less than that.

23. Q. So, Dr. Hodge was -- was wrong on this point?

A. Again, for my opinion, I think we're not capturing as many people with testing as we think we are. And, again, the data from looking at blood donors, and that type of thing, would suggest that it's low -- I mean it's not -- there are more people identified in those types of surveys than we have in terms of cases.

24. Q. So, Dr. Hodge was wrong on this particular point?

A. I mean for my opinion, yeah, I don't we captured 90 per cent of cases. I don't think we -- under even 50 per cent.

25. Q. And not just a little bit wrong, but very wrong.

A. Yeah, and again, that -- that goes back to behaviour and testing. But, yes, I don't think we capture 90 per cent of cases by any means.

26. Q. Okay. I'd like to direct your attention

back to the image that I am sharing. The PHO Confirmed Case Summary. Let's look at that five per cent hospitalization percentage. This percentage was calculated based on the confirmed case count; correct?

A. Yes.

27. Q. And if the confirmed case count vastly underestimates the actual number of cases in the community, then the hospitalization percentage overstates the actual percentage of people with COVID who will require hospitalization. Is that correct?

A. Yes, although, again, I would not say -- how do I -- how do I say this? We test very aggressively when people end up in hospital. So, we will capture the COVID patients that are hospitalized. So, you know, it's less of that discrepancy from the community in that sense.

We're not going to let someone wander into the hospital with symptoms and not get tested in that sense. So, yeah, absolutely, the percentage is -- is probably lower, in the fact that denominator in the community is lower; but, you know, there is a skew to overly test in hospital to make sure that we capture the cases that we need to capture for the sake of making sure that they're isolated, they get appropriate treatment, that type of thing.

28. Q. And what -- what you mean by that -- like, I guess correct me if I am wrong, but it seems like what you mean by that, is that when somebody comes to the hospital with symptoms, or with, you know, where it appears to their physician that they may have COVID-19, they're tested for COVID-19?

A. Yeah, so ---

29. Q. So ---

A. Exactly.

30. Q. So, the number of hospitalizations is likely accurate?

A. Yeah.

31. Q. Like that number ---

A. Absolutely ---

32. Q. --- 38,331 is probably much more accurate than the number of confirmed cases, that is a representation of the number of actual cases?

A. Yeah, sorry, it's 31,689, I think, is the total hospitalized on there.

33. Q. Oh, sorry, I was looking at the new tests --

-

A. Yeah, yeah ---

34. Q. --- I'm sorry, thank you.

A. I agree, that's -- that's accurate. We rarely will miss people who are -- who are COVID

positive ending up in the hospital for the sake of, you know, it causes outbreaks. So, we're very, very keen on making sure that we capture everyone in that sense.

35. Q. Right. So, to the extent that the confirmed case count is off, as in it doesn't represent the actual number of cases in the community, the percentage -- the hospitalization percentage provided there will be overstated by a proportionate amount?

A. Yeah, yeah.

36. Q. All right. Looking at the deaths section, we see another percentage. 1.6 per cent of cases result in death. That, again, is calculated based on the -- the confirmed case count; isn't that correct?

A. Yeah, that's correct.

37. Q. But the risk of death to a person with COVID is actually much lower than 1.6 per cent, isn't it?

A. Yeah, if you look at an aggregate, and you made your denominator is higher, than -- than, yeah, absolutely, it would be lower.

38. Q. Okay. Let's talk a bit about PCR testing. PCR tests are not a hundred per cent accurate, are they?

A. No, absolutely. There are false positives and false negatives.

39. Q. All right, so, PCR tests fail to recognize infection in some cases, and fail to -- and find infection where it doesn't exist in other cases?

A. Yeah, absolutely.

40. Q. How often do false positive and false negative results occur?

A. False negatives are rare. There was a -- a series from Public Health Ontario where they looked at people who are tested again, who are at high suspicion of having COVID-19. And I think they saw one per cent difference amongst people who got tested again. You picked up one per cent more on that second test.

So, you know, it's not un -- that is a population that's at high risk, those are people that are being tested because a clinician thinks that person has COVID-19, and, you know, you see a flip over of that one per cent if you test them again.

False positives are a little trickier in the sense that it's not necessarily just biologic false positives, i.e., this person doesn't have COVID-19, but has a positive test. But it also -- because PCR is so sensitive for molecular evidence of COVID-19 that you capture people that have a positive test, you know, well after they had COVID-19.

41. Q. PCR tests are -- don't direct -- sorry, PCR

tests don't detect infection directly, do they?

A. No, they look for molecular -- the molecular signature of the -- of the pathogen basically. Or the -- the genetic material of the pathogen.

42. Q. Right. So, a sample is typically taken by -- from inside the nose of the patient and that is tested to find if a particular genetic sequence is found in the -- in the sample, is that generally speaking, correct?

A. Yeah, that would be in -- in -- yeah, exactly, genes for the Corona Virus would be found in that sample.

43. Q. Right. But the tests can't differentiate between an action -- active infectious virus particle and a dead non-infectious virus, or a fragment of a virus genome, is that correct?

A. Yeah, so, there is some caveat to that. That we can approximate how much virus there is. And we have data around viral culture. So, you know, what you're talking about to say if someone is truly infectious, actually growing the virus, and how -- what burden of virus on a -- on a PCR test would be in keeping with someone that would have a positive viral culture.

So, we set things like cycle thresholds,

which are, you know, how many times you have to do the PCR to figure out if there is genome that exits there or not. And that lower cycle thresholds it is much more indicative of someone that is actively infectious, as compared to higher cycle thresholds where it's less indicative of someone that's infectious to others.

44. Q. Would you agree that PCR tests for COVID have an estimated sensitivity between 75 per cent and 95 per cent?

A. It's a large rage, but, yes, that was the -- the original Chinese data was around 75 per cent. But I think as tests got more accurate and resolution got better, 90 to 95 per cent is pretty reasonable.

45. Q. Can you briefly explain what the sensitivity of a PCR test means? What it means when we're talking about the sensitivity of a PCR test?

A. Yeah, I mean it's -- it's the -- you know, the common association, it's the rule out value, right? So, if you have a negative test, how well does it rule out having COVID-19? Or, you know, another way of you saying is, you know, your -- your test positives will be your true positives. And -- so, you know, what is -- you know, if you get a positive result, what does that mean in that sense?

46. Q. So, if the range is between 75 per cent and 95 per cent, does that mean that between 5 per cent and 25 per cent of PCR test results are inaccurate?

A. It -- you -- it -- yeah, you do get false negative -- sorry, false positives 5 per cent or higher of the time. And again, the concept of a false positive here isn't necessarily that they -- the test is wrong, i.e., they picked up something that wasn't there. It also is inclusive of people that have had Corona Virus in the past; but had very low levels of nucleic acid that are a part of their assays basically.

47. Q. All right, would you agree that PCR tests are imperfect?

A. Absolutely, every test is imperfect. And, you know, this is where clinical medicine is a part of it. We apply testing to populations we -- we develop a pre-test probability for those populations. And then we interpret the test result in the context of what your pre-test probability was.

So, if someone walks into my emergency room with cough, fever, shortness of breath, and has a positive, you know, COVID-19 test, I am pretty sure that person has COVID-19.

If I am in the community, you know, testing

people before surgery, and they have a positive Corona Virus test, and they have seroprevalence data symptoms and have never had symptoms I am going to look at that result and say, well, my pre-test probability was low. What does this mean? And this is a false positive? Or being a true positive?

48. Q. Right, but regardless that case, if it was a false positive would be included in the provincial case counts, is that correct?

A. Not necessarily. So, the public health units do you have some leeway to retest people. And -- and classify cases as false positives or that type of thing.

And so, you know, these are -- you know, in real life these are the discussions that we have in -- with our local public health unit if we start seeing cases where they don't make sense, people are tested without symptoms, that, you know, public health units will often repeat the tests. That often gives a negative results, and those are considered, you know -- don't get included in the case counts. Or, again, cases get dropped off the case counts as they're resolved in that sense.

49. Q. Right. But -- but some of the cases included in the -- in the case counts are included

based on false positive PCR test results. Would you say that's a reasonable ---

A. Yeah, it's not a perfect system. It's up to public health units to capture them. So, yeah, there is some that -- that, you know, if they're not looking hard enough or if it's a bit of a suspect story, they'll always kind of favour it being a real test result as compared to a false positive.

50. Q. Right. And some smaller number of cases included in the case count are -- are not included in the case count, I'm sorry, because they were false negatives.

Would you agree that's fair?

A. Yeah, yeah, exactly. Like, you know, there are people where, you know, you can do multiple tests and they're negative. And only when you do things like serology, you can figure out that they've -- they've had COVID-19.

51. Q. Right. All right, so, moving on. I guess I will -- if I can figure how to stop sharing this thing. Oh, that's not helpful. Oh, there we go.

Okay, so, moving on, in your opinion COVID-19 is a serious threat to the lives and health of people in Ontario and around the world. Would that be fair to say?

A. Yeah, absolutely.

52. Q. And you're also concerned that uncontrolled spread of the disease could overwhelm Ontario's healthcare system. Is that fair?

A. Absolutely.

53. Q. And the provincial and federal governments appear to share these concerns, would you agree?

A. Yes.

54. Q. In fact, as you discuss in your Affidavit, the provincial and federal governments have taken some extraordinary steps in response to COVID, is that right?

A. Yes.

55. Q. Including implementing a variety of measures such as limiting the number of people who attend gatherings, ordering the closure of certain business, issuing stay-at-home orders, et cetera. What you describe in your Affidavit as non-pharmaceutical interventions or NPI's is that correct?

A. Yes.

56. Q. And the objective of these NPI's is to control the spread of COVID-19, right?

A. Yes.

57. Q. Many of these NPI's significantly limit the freedoms that we normally enjoy in Ontario, don't

they?

A. Yeah.

58. Q. For example, during the pandemic limits have been involved -- limits have been imposed on how, when, and where we can interact with our friends and family. Who we can invite into our homes, and even how physically close we're allowed to get to other people, is that correct?

A. Yes.

59. Q. Touching or hugging people outside of your household has been prohibited, right?

A. Ah, for much of the pandemic it has been discouraged.

60. Q. The Province of Ontario cancelled Halloween in 2020, is that right?

A. Yes.

61. Q. Limits have been placed on how people -- how many people are permitted to attend indoor and outdoor religious services, is that correct?

A. Yes.

62. Q. We haven't even been able to complete -- sorry, we haven't even been completely free to choose what we wear. Masks have been required in indoor public settings for most of the pandemic, is that correct?

A. Masks have been required, yes, since about, I think, May of 2020, they've been part of provincial legislation.

63. Q. And would you agree that these are pretty significant limitations on our freedoms?

A. Either there -- you know, these measures have not been used before in control of an infectious disease. So, they are certainly unprecedented in a -- in a -- in the -- in the pandemic, for sure.

64. Q. And most of these measures weren't even contemplated in the pandemic preparedness plan, prepared by Ontario in response to the -- in, I think it was 2012, is that correct?

A. Yeah, I think -- I believe that was in response to pandemic influenza. But, yeah, certainly, yeah. There -- there has not been a large publication of these measures prior to that point.

65. Q. From a public health perspective NPI's which help to control the spread of COVID19, protect public health, and ensure that the healthcare system is not overburdened to the point of collapse are justifiable and appropriate even if there are -- even if they are restrictive. Would you agree with that?

A. Correct.

66. Q. Would a restrictive NPI that does nothing to

control the spread of COVID protect public health, or protect the healthcare system be justified from a public health perspective?

A. No, I mean and this type of hypothetical -- I mean, again, we are trying to apply measures that work in reducing spread. So, if something were not to reduce spread, then one would not consider it a useful intervention.

67. Q. And you wouldn't consider it justifiable or appropriate from a public health perspective?

A. It -- if there is no benefit, then there shouldn't be a need to justify it. There should be a use to justify it, yeah.

68. Q. And the mere fact that an NPI has been imposed by government is no guarantee that it will be effective, would you agree with that?

A. Yes, although, I would say that many of the NPI's that we have instituted have had, you know, roots in what we think are effective in terms of reducing mixing in certain environments, and reducing risks of transmission based on certain outbreaks.

And so, there is usually a basis for these based on our prior clinical evidence. I am not saying every NPI has been, you know, well justified and brought out, but certainly the major ones that we've

used through the pandemic have had, you know, a justification through reduction in mixing, and trying to control respiratory spread.

69. Q. Right. It's possible to envision a potential NPI that would actually make the public health situation worse, isn't it?

A. Yeah, there -- there could be ones that, you know, have effects that are negative on the pandemic.

70. Q. Would an NPI (inaudible) of COVID-19 be justified and appropriate from a public health perspective?

A. Again, the whole point of NPI's is to reduce spread. So, if they -- if things are hypothetically increase spread, then we would definitely not want to use them.

71. Q. So, to sum that up COVID shouldn't be looked at as a blank cheque that justifies any restrictive order that a government might choose to impose; would you agree with that?

A. Yeah, I mean, again, there are risks and benefits. And we always have to weigh risks and benefits. But again, the NPI's (inaudible) COVID-19.

72. Q. And you've been quite critical of a number of NPI's imposed by the provincial and federal governments, isn't that a fair statement?

A. Yeah, correct.

73. Q. For example, in response to the recent emergence of the Omicron variant, Canada prohibited traveller from a number of African countries. And yet, the Omicron variant is now firmly established in Canada, isn't it?

A. Yeah, absolutely. I -- it's now probably going to be our dominant variant as of the end of this week.

74. Q. Right. And you've been pretty critical of this travel ban, haven't you?

A. Absolutely.

75. Q. Is this travel ban an effective way to control the spread of COVID-19?

A. If we were to know exactly where COVID, this Omicron variant emerged, the moment it emerged, it may have been an effective intervention.

But at the time the travel bans were announced, it was pretty clear that Omicron had been on everyone's soil, and they just had not discovered it at that point.

So, it didn't really make sense on why we would ban travel, rather than, again, trying to protect travel on the other side, on our side to mitigate the spread here in that sense.

76. Q. Right. So, would you consider the travel ban to be justified or appropriate from a public health perspective?

MR. HUNTER: Mr. Kittredge, I have allowed you a number of questions on this. But you do, of course, know that's a federal measure, right?

MR. KITTREDGE: Yes, I do. I do.

MR. HUNTER: I fail to see the relevance of a measure that's not one of the measures your clients are challenging in this proceeding.

MR. KITTREDGE: Well, it's just to establish the fact that not all NPI's are -- are reasonable measures. You know, just the fact that they exist, doesn't mean that they're effective or justifiable.

MR. HUNTER: The witness has already said that to you several times.

MR. KITTREDGE: Yes. Yes, well, that's what transcripts are for.

BY MR. KITTREDGE:

77. Q. So, moving on, can you briefly describe the concept of fomite transmission of respiratory viruses?

A. Yeah, I mean in simple terms it's, you know, the contamination of a surface which then leads to, you know, one touching a surface and then inoculating

a mucous membrane, so, eyes, nose, mouth, from then touching that surface. And then putting it in that mucous membrane and letting it replicate at that point.

78. Q. And fomite transmission doesn't play a significant role in the transmission of COVID-19, though; is that correct?

A. No, I think most international bodies suggest it might play a role in certain settings, but it is not by any means the predominant mode of transmission. And -- and can be mitigated quite easily by hand hygiene.

79. Q. And how early in the pandemic did -- was that fact generally known among experts?

A. I think many had early impressions that it was -- it was less of an issue. I mean there are respiratory viruses that have a significant fomite transmission mechanism. So, always being precautionary was important.

But I think towards July and August, as we started seeing A) our clinical experience, but B) you know, good studies that were sampling the environment, that showed very little fomites, and -- and even in that context, the ability for, you know, good hand hygiene and cleaning to really mitigate that risk. We

had suspected it was probably much less represented outside of very, very certain settings, where it's a bigger issue.

80. Q. All right, so, I am going to once again share my screen, and show you a document. And I have choice of one of about 25 windows that are open here. And I am not sure which one it is from these tiny little thumbnails. Where are we? Oh, here we go.

Okay, so, can you see that? Whoops -- what's going on there. How about that? I have just realized that if you move the window, you can see what's behind it. So, I'll have to be careful about that.

Do you recognize this image that I am showing to you?

A. Yeah, this is from my twitter interaction with Dr. David Fisman, from Toronto.

81. Q. Right, and what's the date on this tweet of yours here?

A. July 8th, 2020.

82. Q. And can you read it to us for the record?

A. Ah, so, Dr. -- do you want me to read the whole thing or just my statement?

83. Q. Just -- just yours.

A. My statement. Yeah, totally agree, not sure

why outdoor playgrounds were considered bad to begin with, especially once we realized this wasn't a fomite disease.

84. Q. So, would you agree that by July 8th, 2020, it was commonly known that COVID-19 isn't a fomite disease?

A. Yeah, that it didn't play a large role in transmission, especially in the community.

MR. KITTREDGE: So, I'll stop sharing that. And Josh, I am just going to mark all of these tweets that I am going to show at the end of the cross-examination. So, they'll come as a collection unless you have any objection to that?

MR. HUNTER: That's fine, unless of course there's any we find objectionable, which we'll let you know at the time.

MR. KITTREDGE: Sure, okay.

(WHEREUPON Exhibit B : Collection of tweets from Dr. Zain Chagla.)

BY MR. KITTREDGE:

85. Q. The SARS-coV-2 virus is generally transmitted by respiratory droplets and aerosols expelled by an infected person; is that correct?

A. Correct.

86. Q. And transmission is much, much more likely

indoors than outdoors, is that correct?

A. Correct.

87. Q. In fact, at least 99.9 per cent of cases are the result of indoor transmission, isn't that true?

A. Yeah, I -- I know there was one study out of Ireland that suggested that 1 in 100,000 was outdoors versus indoors.

88. Q. Right.

A. So ---

89. Q. Well, that's a ---

A. Yeah.

90. Q. That's a very small number. And why do you think that is?

A. Ah, I mean the outdoors has the -- you know, as we talk about ventilation as a particular mechanism for mitigating COVID spread, the more air that's exchanged, the more the air that's diluted basically means less of particularly those small aerosols that are hanging out in the air. And, you know, the outdoors is essentially pure air dilution, in the sense that you're exchanging air every second of the day basically.

91. Q. Right. I am going to -- I have sent a couple of documents to you via Josh.

A. Yeah.

92. Q. And I'd like you to open the document called Why we Need to Change the Narrative on Outdoor Transmission thestar.pdf.

A. Just give me one second here.

93. Q. Sure.

A. Let me -- sorry, literally every five seconds there's an email, so I have to ---

94. Q. I am familiar with the feeling.

A. Yeah, yeah, okay. So, this is an article that myself that Dr. Chakrabarti and Heidi Tworek wrote in April of 2021.

95. Q. Great. Can you read the date of the -- the date it was published for me, please?

A. Yeah, April 12th, 2021.

96. Q. All right. And can you read the first highlighted sentence fragment there?

A. Outdoor activity is generally safe whether there are ten cases a day or 10,000, even with variants of concern.

97. Q. And that was your opinion at the time you wrote this?

A. Yeah.

98. Q. And is that your opinion now?

A. Yeah, still with that mitigated outdoor transmission is safe in that sense.

99. Q. All right, and can you scroll down a little bit and read the second highlighted sentence fragment?

A. Being, ah -- being outdoors is much safer and may prevent transmission indoors.

100. Q. And when you say it may prevent transmission indoors, what do you mean by that?

A. Yeah, I mean I think the context of that article was in April when outdoor activity was largely being discouraged a little bit, or people were talking much more about the risk of outdoor transmission.

And, you know, counterfactual was, you know, if you're not giving people the ability to interact in a safe manner, and doing it outdoors versus indoors, you may be pushing them indoors. Which is the opposite of what we would want to do. We would want people to embrace, you know, mitigation outdoors as compared to indoors. And be able to use that appropriately.

101. Q. So, restrictions on outdoor gatherings could have the effect of increasing COVID transmission; would you agree with that?

A. Yeah, I mean especially in April when -- when things were so restricted. Again, the opinion of that article was really that, you know, we -- we should allow for outdoor activity a little bit more

freely to really use that as our mitigation technique.
102. Q. Some outdoor activities, like for example using playground equipment might be more risky if fomites were a significant COVID transmission factor, would you agree with that?
A. Yes. If it was a real, real concern, then certainly playgrounds would have been an issue. But clearly it wasn't with this.
103. Q. But as we discussed it's been well known that fomites weren't an issue since at least July of 2020; is that correct?
A. Absolutely. And again, outdoor equipment has other issue -- even viral infections on outdoor equipment, there's UV lights, there's temperature issues, and so it's not as simple even as saying -- even if there was fomite infect -- fomite issues that outdoor play equipment would be even then a significant cause.
104. Q. Right. Would you agree that NPI's which limited outdoor activities and gatherings did little or nothing to control the spread of COVID-19?
A. I think there may have some justification for ones that involved significant capacity. So, when you have lots of people that were enclosed is very small outdoor spaces, there may have still been a risk

of transmission there. But certainly, you know, outdoor activities where people could appropriately physical distance, probably were reasonable to do throughout the pandemic.

105. Q. Would you agree that NPI's which limited outdoor activities and gatherings may have, in fact, had the opposite effect, that is to say that might have contributed to the spread of COVID-19?

A. Yeah, I mean I think being liberal about the outdoors was -- was certainly a -- a messaging issue. And again, this is justification for that article. There were many jurisdictions that kept an outdoor facing presence and actually encouraged it.

And, yeah, it -- if people can be given the instructions on how to do an outdoor gathering appropriately, and be able to do it appropriately, you know, it -- it could certainly help with mitigating some of the human needs for, you know, a gathering or being with others.

106. Q. Right. And yet during the pandemic the province has issued quite a few public health orders which limited outdoor activities and gatherings, right?

A. Yeah, there have been capacity limits outdoors throughout the pandemic. There's been

certain activities that haven't been allowed. There's been the need for masking when people have been close contact outdoors. There's been shutdowns of outdoor facilities like ski, parks, that type of thing.

107. Q. And there have been limitations on attendance at outdoor religious services, isn't that correct?

A. Yes, there have been gathering limits, essentially for all outdoor activities, but including religious gatherings.

108. Q. Right. And in fact, in late April 2021, just about a week after the publication of this article, the province issued public health orders that severely limited outdoor gatherings and activities. Isn't that right?

A. I don't know exactly. My timelines are always a bit messed up. I know there was a -- a moment where they really limited things like playgrounds and that type of thing, in April, I don't know the exact dates, but I think it was around the time of this article.

109. Q. Right. And in -- in amongst those restrictions, a number of outdoor activities were banned, for example camping on Crown Land and in provincial parks was banned; is that correct?

A. I be -- yeah, I remember that, yes.
110. Q. Golf courses were closed?
A. Yeah, I remember that.
111. Q. Pickle -- pickleball courts, whatever they may be were closed ---
A. Closed, yes, exactly.
112. Q. Do you believe that these measures were effective ways to control the spread of COVID-19?
A. No, I mean I think we could have given people guidance in terms of what camping means in the COVID-19 pandemic, i.e., you shouldn't be in a tent together and you can distance yourself when you're hanging out together outdoors, and that would largely reduce the vast majority of risk.

And similarly, for, you know, a golf course what the expectations are that people stay outdoors for their golfing activity, that they distance while they're on the course, that type of thing. So, yeah, I -- I don't think, you know, large shutdowns of the outdoors without guidance were necessarily reasonable in that context.
113. Q. And do you think that these measures were justified from a public health perspective?
A. I think there could have been a lot more work. And we've seen in other jurisdictions that

outdoor gatherings were mitigated as compared to closed. And again, that they -- you know, as you said in that article, the worry was that if you start restricting the outdoors more that you may, unfortunately, push people indoors which is exactly what we don't want.

So, I think there was an opportunity there to try to enhance outdoors.

MR. KITTREDGE: Right, and I think I may have overlooked marking that Toronto Star article as an exhibit. Can I -- can the reporter confirm whether I did that or not?

THE REPORTER: Counsel, the -- I've listed your Exhibit A as a Public Health Ontario summary from December 12th, 2021. B I've just put loosely as collection of twitter screenshots, I am assuming there is more to come.

MR. KITTREDGE: Yes.

THE REPORTER: You did not mark -- list or suggest a listing of another exhibit after that.

MR. KITTREDGE: Great. Okay. Let's -- this document that we -- that we identifies as Toronto Star article by Dr. Chagla and others, published on April 12th, 2021, I'd like to make that

as Exhibit, what would that be C?

THE REPORTER: That would indeed be C, yes.

MR. KITTREDGE: All right, to the Affidavit. And let's call it Toronto Star, Why We Need to Change the Narrative on Outdoor Transmission.

Counsel, do you have any objection to that?

MR. HUNTER: No.

(WHEREUPON Exhibit C : Toronto Star article April 12th, 2021.)

BY MR. KITTREDGE:

114. Q. All right, sorry about that Dr. Chagla, a little absentmindedness on my part.

So, the orders that were put in place in April of this year, 2021, also limited attendance at outdoor religious gatherings to just ten people, didn't they?

A. Ah, I don't have the orders off the top of my head, but I believe there were gathering limits for outdoors for outdoor religious gatherings. I don't remember the exact numbers.

115. Q. Right. But does -- do you remember the limit being something in the neighbourhood of ten people. Does that sound ---

A. Yeah ---

116. Q. --- fair ---

A. --- I believe so. I believe so, yes.

117. Q. Yes. And that was on outdoor gatherings, just to be clear.

A. Yes.

118. Q. And that limit was in effect until sometime in June, wasn't it?

A. Yeah, I believe in June it was taken to 25. So, yeah, I guess that was the baseline.

119. Q. Right. Attending an outdoor religious service is generally safe whether there are ten COVID cases a day or 10,000, isn't it?

A. Yeah, as long as people use their mitigation techniques in terms of distancing appropriately, it could be considered safe. Not zero risk, but certainly much decreased risk from indoor gatherings for sure.

120. Q. But you would characterize it as safe?

A. Yeah, I would -- you know, the -- I think if you put all the mitigation techniques in there, then -- then it would be considered safe from -- from that standpoint.

121. Q. Okay. Do you think restricting attendance at outdoor religious gatherings was an effective way

to control the spread of COVID?

A. I would say that as numbers go up, of people at an event, the ability to make sure that mitigation techniques are appropriate and audited and enforced, gets harder and harder.

So, you know, if you could do it perfectly. You know, make sure everyone's distanced, no one's interacting. There's not much, you know, direct contact from person-to-person, then, you know, you could make those events work. But from a practical standpoint, the more people that are out there, the more chance that that you then breakdown some of those barriers that help mitigate outdoor transmission.

122. Q. Right. It's not very hard to find enough space to adequately distance ten people, is it?

A. No, I mean I think we can probably find that in a parking lot or a park, or something along those lines.

123. Q. I mean it's not very difficult for that matter to find space to adequate -- adequately distance 25 people or 50 people.

A. Yeah, no, I agree. Again, you just have to have the space. And you have to have the audits, and kind of the tools to make sure that people are doing appropriately and correct it, if not.

124. Q. Right. And those restrictions on attendance at outdoor religious gatherings may have actually contributed to the spread of COVID, wouldn't you agree?

A. I mean I obviously don't know what happened as people wanted to congregate religiously, whether or not they did it virtually or in their own homes, or otherwise. But certainly, you know, for things like social gatherings, I think, you know, there was always a worry for all of us that people didn't use the outdoors and then came indoors and kind of just didn't need their tools anymore, because they didn't find anyway to do them appropriately.

125. Q. So, it is possible that the religious gathering restrictions on outdoor gatherings contributed to the spread of COVID?

A. Yeah, if people came indoors to do their gatherings, you know, against the provincial rules, then -- then, you know, technically that would be a high-risk scenario.

126. Q. Right. I am once again going to share my screen with another in the series. Can you see that image?

A. Ah, yeah.

127. Q. And do you recognize that image?

A. Yeah, it's a tweet of mine from May 2020, May 31st, 2020.

128. Q. And can you read the tweet to us?

A. Protest is enshrined in universal human rights, for those of you who exercise your rights, please keep track of your symptoms, isolate, get tested in the coming days. I pray there is no transmission, but if there is, keeping others safe is paramount.

129. Q. And do you remember what this was in reference to?

A. I believe this was to the Black Lives Matter protests that were going on in May of 2020.

130. Q. And would you characterize those protests as large gatherings?

A. Yes, quite large.

131. Q. And would you say that proper social distancing was followed at all times during those protests?

A. No, they were chaotic. They were all over the place. And so, you know, I -- and -- and there was really no protocols for a lot of them; they were informally organized.

132. Q. And yet you're supportive of these protests on the basis ---

A. Ah ---

133. Q. --- presumably that protest is enshrined in universal human rights?

A. Yeah, I -- I didn't say that they were necessarily the best thing, but if people chose to do it, you know, these are the mitigation techniques for making sure that people had not acquired COVID-19 at these events.

134. Q. Would you agree that the right to practice one's religion as one chooses is also enshrined in universal human rights?

A. Yeah, but ---

MR. HUNTER: That's a legal question.

THE DEPONENT: Oh ---

MR. KITTREDGE: Well, I mean this is a -- a conclusion that he came to himself about protests. I am asking if he feels the same way about the right to practice religion.

MR. HUNTER: He can answer as to his own views. Obviously, he -- it will be for a Court to determine what if any ---

MR. KITTREDGE: Sure, I am not asking for him -- I am not asking for a legal conclusion.

MR. HUNTER: Yes.

MR. KITTREDGE: I am just asking for his own opinion.

THE DEPONENT: Then my own view that people, you know, should be able to -- to practice their religion.

BY MR. KITTREDGE:

135. Q. Right. You would say that that is also enshrined in universal human rights ---

A. Yeah, I ---

136. Q. --- in that sense that you ---

A. --- think the right to practice religion is -- is to me a fundamental piece of people's rights.

137. Q. All right. So, I would like you to open up another one of the documents that I sent over. And this one may be familiar. It's called Assessment of Burden on Essential Workers .pdf.

A. Yeah.

138. Q. Could you -- is this document familiar to you?

A. Yeah, this is paper, is a collaboration with myself, and a number of folks from Toronto that we wrote and published -- the pre-print was published, I think, in April or May of 2021, but this recently just go published in Jama Network Open I think about two

months ago.

139. Q. All right, can you briefly summarize the study for us and your findings?

A. Yeah, so, this is a study looking particularly as the variants of concern that were identified in December of 2020 started emerging in Canada. Ah, and looked at populations in Peel and Toronto based on income, and that was using census demographic data, and as well as essential work status. And again, breaking down by neighbourhoods.

And looked at these neighbourhoods from highest to lowest essential work, and highest to lowest income, in terms of where COVID cases grew, but also where these variants of concern emerged. And the whole purpose was to, you know, recognize that this was actually a nice time to kind of revisit the pandemic and track where COVID actually was transmitting at the highest burdens, and what mitigation techniques, you know, would be appropriate in that population.

140. Q. And the data is broken down by employment in essential work. How were you able to determine whether a given case was associated with essential work?

A. So, it was not necessarily individual cases

that were essential work. But it was the neighbourhoods that they were in that were represented by essential workers.

So, we couldn't get down to the granular data of does this person work in factory? It was, you know, is this a -- does this person live in a neighbourhood that has a high representation of people that work in factories? So, it's not -- it's an imperfect measure.

141. Q. Okay. What period did the study cover? In other words, when you talk about cases, when did those cases take place?

A. So, this was -- let me just pull them the exact -- but it was during the emergence -- so, February 3rd to March 10th of 2021.

142. Q. Okay. So, it covered about a month then?

A. Month and -- yeah, month and a half, yeah.

143. Q. All right. How many outbreaks involving essential workers occurred during that period?

A. There were several. In the GTA alone I think we heard about many, but there were a lot of workplace outbreaks. I don't know the exact number, but there were several for sure.

144. Q. And several, what do you mean by several? Like a ballpark number? Ten, 100, 1,000?

A. I would say probably in the hundreds given that they were the only things that were really opened at that point in the pandemic.

145. Q. All right, you've been quite critical of the governments failure to take action to support essential workers, haven't you?

A. Absolutely.

146. Q. What do you think the government should have done to support essential workers?

A. Yeah, I mean, I think there were a number of issues. One was the fact that income supports were difficult. And -- and so people's -- again, behaviours to go get tested even if they had minor symptoms, their ability to isolate, and take financial hardships for the sake of, you know, protecting their communities against COVID-19 put people in a very difficult choice.

And, you know, unfortunately, again, transmission in workplaces, led to transmission in-homes. And were overrepresented in terms of what that meant in our healthcare system, particularly in Peel and Toronto, where many other establishments were closed during the third wave. And so, you know, they were the people that were -- had to be out there that were getting infected at the highest quantity.

147. Q. Right, and how much of an impact do you think putting income supports and the other measures that you proposed in place would have had on essential worker COVID infections, hospitalizations, and/or deaths?

A. Yeah, I mean I ---

MR. HUNTER: So, I -- just -- sorry, hang on.

THE DEPONENT: Sorry.

MR. HUNTER: I fail to see the relevance of these questions to a challenge to gathering restrictions.

MR. KITTREDGE: Ah ---

MR. HUNTER: The government had a million different policy choices, and a million different things, with a million different people. What's the relevance?

MR. KITTREDGE: Well, we're getting there. Let me just see if I can just jump to something that's sort of -- should make it clear.

BY MR. KITTREDGE:

148. Q. Well, would you -- would you agree that there have been far more cases and far more outbreaks of COVID-19 associated with essential workers, than there have been -- than there have been cases and

outbreaks associates with religious gatherings?

A. Yes, and workplaces have had to be open throughout the pandemic. So, you know, it's kind of proportional in that sense that there's been a -- more people at risk in the sense that they've been workplaces in that sense.

149. Q. Right. Essential workers working indoors face greater COVID risks than people working outdoors, wouldn't you agree?

A. Yeah, yeah, the same science about outdoor transmission.

150. Q. Many workplaces have suboptimal ventilation, wouldn't you agree?

A. Yeah, absolutely.

151. Q. Essential workers would typically be at their workplaces for extended periods of time, shifts of eight hours, or more are common; wouldn't you agree?

A. Yeah.

152. Q. Coworkers are likely to socialize and talk with each other during their workday, would you agree?

A. Yeah.

153. Q. Yelling or talking loudly is pretty common in some workplaces, in particularly where loud background noise is an issue, right?

A. Yeah.
154. Q. People sometimes sing while they work, right?
A. I presume so. I don't think I have seen that. But sure.
155. Q. And people doing strenuous work may breathe heavily, right?
A. Yes. Yes.
156. Q. People often develop friendships with their coworkers, right?
A. Yeah.
157. Q. Close friendships sometimes?
A. Yeah.
158. Q. And it's not unheard of for people to hug their coworkers, is it?
A. Yeah. No, absolutely.
159. Q. Someone working as a cashier in a retail environment might have close to face-to-face interactions with hundreds of shoppers per day. Does that sound reasonable?
A. Yeah.
160. Q. And plexiglass barriers at checkout counters in retail stores have been a requirement for much of the pandemic, but people typically just stand at one end of the barrier or the other, don't they?

A. Yeah, they're not -- they're an imperfect method for preventing COVID transmission. They may help, but there are -- there are, you know, certainly human behavioural factors that make them imperfect.

161. Q. Right. And as you mentioned before due to financial pressure essential workers may be reluctant to get tested for COVID or to take time off work if they feel sick; is that right?

A. Yeah.

162. Q. Financial pressure may incentivize them not to be truthful with screening?

A. Yeah, absolutely.

163. Q. Infected essential workers who are undiagnosed, asymptomatic, or pre-symptomatic, could spread disease to their co-workers, is that correct?

A. Yeah.

164. Q. Essential workers may not always wear masks properly, may not have access to well fitted masks, and in some cases may not choose to wear masks at all, right?

A. Yeah.

165. Q. It seems that essential workers share a lot of characteristics with churchgoers, wouldn't you agree?

A. Ah, I am -- in what sense?

166. Q. Well, a lot of the characteristics that you point to in your Affidavit as transmission risk factors associated with religious gatherings, are also characteristics of many workplaces, wouldn't you agree?

A. Yeah, I mean the same features that cause COVID transmission indoors amongst people, you know, are there in workplaces.

And, yeah, they were the ones that we mention in the Affidavit around churches in terms of heavy breathing, singing, close contact, poor ventilation.

167. Q. Right. So, moving on to healthcare capacity. You expressed concerns in your Affidavit that Ontario's healthcare system could have been overwhelmed by COVID-19. You say at paragraph 5(b) that there were 891 people in intensive care units at the peak of the third wave. Were those all COVID patients?

A. There were 891 COVID related critical illnesses. So, those are patients who have active COVID-19, but also patients who are not infectious form their COVID19, but still sitting in the ICU.

168. Q. For reasons related to COVID-19.

A. Yeah.

169. Q. They're recovering ---

A. Yeah, yeah, they're still recovering from COVID-19 or not recovering from their COVID-19 in that sense.

170. Q. Right. Approximately how many intensive care beds are there in Ontario?

A. I actually don't know the answer to that question. I think there -- the -- the staffed beds are even 1,200, 1,300 range at the kind of crisis capacity. But -- but active functioning kind of day-to-day beds is much lower in that sense.

171. Q. Intensive care units are designed to run at or near 100 per cent capacity, are they not?

A. Yeah, I mean, I think we -- we all know our ICU's are pretty filled at baseline, for the, you know, regularly staffed beds.

172. Q. And that's the case pandemic or no pandemic, isn't that correct?

A. Yeah, hospital capacities have always been high pre-pandemic.

173. Q. Right. Prior to 2020 it wasn't uncommon for hospitals and ICU's to have occupancy rates of over 100 per cent, would you agree?

A. Yeah, absolutely.

174. Q. You go on to say that these 891 patients

required the potential indication of a triage protocol to limit access to intensive care units for those with the best prognosis.

Ontario hospitals never implemented such a protocol though, did they?

A. They did not. They did make preparations to invoke it. And I was involved in that. But -- but, yeah, they did not have to.

175. Q. You mention that these 891 patients required redeployment of healthcare staff and transferring patients to other hospitals. Pandemic or no pandemic, it's not at all uncommon for Ontario hospitals to redeploy healthcare staff or to transfer patients to other hospitals, isn't that correct?

A. Yes, but the magnitude of it was significantly more than had ever been seen before. You know, we -- it's not uncommon for small hospitals to send large hospitals patients. It is uncommon to see, you know, hundreds of patients going from one hospital to another hospital.

176. Q. You mentioned that these 891 patients caused elective surgeries to be cancelled. In May 2020, in response to the COVID pandemic, the Ontario Government imposed criteria that hospitals had to meet in order to perform non-emergency surgeries, isn't that true?

A. Yes.

177. Q. In order to perform non-emergency surgery a hospital's total occupancy rate had to be 85 per cent or lower; is that correct?

A. Yes, those were the guidelines after the first wave, I believe.

178. Q. Yes. And would you agree that that requirement handcuffed hospitals that were running well over 100 per cent capacity for years?

A. I mean it wasn't easy to impose as part of that. So, you know, certainly it's -- you know, the need to have a buffer was -- was part of us dealing with the surge. But it definitely had impacts on us being able to -- to scale up things like elective surgeries of have need for us to innovate elective surgeries to make sure that they were done, and people go out, you know, not admitted to hospital.

MR. KITTREDGE: All right, and I am just realizing I also forgot to mark the last exhibit.

I'd like to mark the Assessment of the Burden of SARS-coV-2 Variants of Concern Among Essential Workers in the Greater Toronto Area of Canada, Dr. Chagla's paper that I was referring to a moment ago, as Exhibit D, I believe to my -- to the

cross-examination.

THE REPORTER: That's correct. It's marked.

MR. KITTREDGE: Pardon me? It is marked?

THE REPORTER: I've just marked it, Counsel, as Exhibit D as requested.

MR. KITTREDGE: Okay, great. Do you have any objection, Counsel?

MR. HUNTER: No.

MR. KITTREDGE: Okay.

(WHEREUPON Exhibit D : Dr. Chagla's Burden of SARS-coV-2 paper.)

BY MR. KITTREDGE:

179. Q. Do you think the requirement, the criteria requiring hospitals to remain under 85 per cent capacity in order to perform non-elect -- or non-emergency surgery was justified from a public health perspective?

A. Ah, there were two sides of the coin. I think there was a need for us to have rapid surge capacity to deal with, you know, COVID was a transmission issue in the community, and us to have a buffer. But at the same time, you know, as we all know healthcare runs pretty ragged, and -- and there's

a lot of burden. And with all the slowdowns in healthcare there was a large degree of delayed care that required more hospitalization. So, it definitely put a drag on our ability to scale up as aggressively as possible.

MR. KITTREDGE: All right, and I guess at this point I would like to mark the collection of tweets that I've shown you as Exhibit E to the cross-examination. And let's call it collection of tweets. Counsel, do you have any ---

MR. HUNTER: You already have that as B.

MR. KITTREDGE: Pardon me?

MR. HUNTER: I think we already have that as B.

THE REPORTER: That's correct, Counsel.

MR. KITTREDGE: Oh right.

THE REPORTER: I've already marked it as B.

MR. HUNTER: And I have no objections.

MR. KITTREDGE: Okay, great.

All right, and I am going to turn over the questioning to my colleague Hatim Kheir.

Would you like to take a short break before that? I don't expect we'll be going on for all that much longer.

THE DEPONENT: No, I am good to keep going.

MR. KITTREDGE: Okay. Hatim, do you want to take over.

MR. KHEIR: Yes, thanks.

BY MR. KHEIR:

180. Q. Good morning, Dr. Chagla.

A. Good morning.

181. Q. So, I'll just have a few questions for you. So, just to begin, first I should add my names Hatim Kheir for the record.

In the course of my research, I found that since the start of the pandemic to now, there have been approximately 92,000 people hospitalized with COVID across Canada.

In your opinion, is that an accurate number?

A. Yeah, I don't have the number off the top of my head, but that seems appropriate for -- for what we've seen.

182. Q. So, I want to go through some comparisons of hospitalizations and deaths due to COVID and those due to the flu. Would you agree that using weights per

100,000 as opposed to absolute counts would be a reasonable way to compare those numbers?

A. Yeah, absolutely.

183. Q. So, you may want to pull up a calculator on your phone or computer as we go through some of the numbers.

But just as a preliminary point, would you agree that 38 million is a reasonable estimate of the population of Canada?

A. Yeah.

184. Q. Okay, so, if we wanted to find the rate of hospitalizations, we could take the number of hospitalizations, which we've agreed is approximately 92,000 and divide by the population being about 38 million. And then multiple it by 100,000. Would you agree that's a reasonable approach?

A. Yeah. Yeah.

185. Q. So, when I do that calculation, I get 242 hospitalizations due to COVID per 100,000 population. Is that what you get?

A. Correct, yeah.

186. Q. Okay. So, since the start of the pandemic to now there've been approximately 242 people hospitalized due to COVID for every 100,000 members of the population in Canada, right?

A. Yeah.

187. Q. Okay, I am going to show you a document, so just bear with me while I bring it up on my screen. Actually, first I will go to the top here. So, first of all do you see my screen? Did that work?

A. Yeah, it's a FluWatch from the public health agency of Canada.

188. Q. Okay. And are you -- are you familiar with these FluWatch documents?

A. Yeah, this is a lot of different surveillance networks that look at influenza rates across community, and self reported respiratory infection in the community.

189. Q. Okay. And so, I am just going to -- I am going to go down to page 8 here. And so, you here at the top there's a table where hospitalization rates per 100,000 for different age groups and different flu seasons, right?

A. Yeah.

190. Q. And so, it says for the 2018 to 2019 flu seasons, there were 45 hospitalizations per 100,000 for -- overall across the age groups, right?

A. Yeah.

191. Q. And looking at the previous years, would you agree it's comparable to previous years? It's not an

outlier?

A. No, no, I think that's the same across years.

192. Q. Okay. And in your experience would you agree that's a reasonable number in terms of trying to gauge the rate.

A. Yeah, again, FluWatch uses estimates. So, it's not perfect. You know, the COVID numbers are pretty precise numbers because they're literally the people that are being diagnosed with COVID that are being in the hospital. As compared to FluWatch which uses a bit of modelling to kind of get their numbers.

But, you know, they model based on sentinel networks. And so, would be, you know, accurate in that sense. They're -- they're just -- there is some error because it's not as perfect as saying x-number of cases, x-number of hospitalizations -- sorry, x-number of hospitalizations per 100,000.

193. Q. Right. In terms of trying to make comparisons, would you agree it's a reasonable number to work with?

A. Yeah, it's not unreasonable for sure. Again, this is their best estimate of flu activity in the community.

MR. KHEIR: Okay. I'd ask that

this exhibit be marked -- I believe it's exhibit F on the cross-examination.

MR. HUNTER: Fine. Fine.

MR. KHEIR: And we could call it FluWatch Report 2018 to 2019.

THE REPORTER: That will be Exhibit E. Counsel, yes, that's no problem.

MR. KHEIR: Okay. Thank you.

(WHEREUPON Exhibit E : FluWatch Report 2018 to 2019.)

BY MR. KHEIR:

194. Q. So, I am just going to take this down off my screen.

Okay, so, the number that we got for COVID, which was 242 hospitalizations per 100,000 it's about five times ---

A. Yeah ---

195. Q. --- the number we got for influenza, which was 45.

A. Yeah.

196. Q. Hospitalizations per 100,000.

Now, the number that we used for the rate of hospitalizations due to COVID that's based on two years of pandemic until now.

So, when we're comparing the numbers,

totalling one year of the flu, would you agree that to make a meaningful comparison it would make sense to compare it to two years of influenza?

A. The rate per 100,000 per year should be -- oh, I see what you mean. So, yeah, yeah, I see what you mean. So, yeah, a single year would be probably a better comparison if you're going to do absolute numbers for absolutely hospitalizations. Yes, I see what you mean.

197. Q. Okay. So, if we wanted to compare it to two years of the flu, we could double our rate for flue hospitalizations. So, we would get about 90 hospitalizations per 100,000?

A. Correct.

198. Q. So, when we -- when we compare those numbers then, the rate we calculated for COVID being 242 hospitalizations per 100,000, it's actually about two-and-a-half times the hospitalization rate we calculated for two years of influenza which was 90 hospitalizations per 100,000, right? Okay.

Are you aware of roughly how many people have died of COVID since the beginning of the pandemic across Canada?

A. I don't know the figure off the top of my head. I think we did pass 100,000 deaths at some

point, but I am not sure actually. I -- I don't know. I don't keep track of the numbers.

199. Q. Yes, that's fair. Here, I will show you -- I'll bring up the daily epidemiological reports. I'll just share my screen. Okay, you see that?

A. Yeah.

200. Q. Okay. So, can you identify this?

A. Ah, this is Canada epidemiologic update as of December 13th at 7:00 p.m. And total deaths of 29,941, including 15 deaths today.

201. Q. Okay. And as far as you're aware this is a -- this is an accurate number?

A. Yeah, this is the public health agency of Canada, so all provinces have to report to them.

MR. KHEIR: Okay. I'll just stop sharing my screen.

And before I forget, if we could have that marked as Exhibit F.

MR. HUNTER: Yes.

MR. KHEIR: This be -- be daily epidemiological summary for COVID-19.

(WHEREUPON Exhibit F : Daily Epidemiological Summary for COVID-19.)

BY MR. KHEIR:

202. Q. So, saying about 30,000 -- I think it was

29,000 and change, but about 30,000 in a population of 38 million. I get a rate of deaths of 79 deaths due to COVID per 100,000 population.

Is that what you get?

A. Yeah, I think so.

203. Q. I'll give you a moment if you want to just double check that.

A. Sorry, it's 29,000 deaths per 38 million population, times 100,000. I am 76; is that correct?

204. Q. Yes. So, I am going to -- and I apologize for bouncing around all these documents.

A. No ---

205. Q. But I am going to show you something else. Okay, so, do you see my screen?

A. Yes, this is the NASI Influenza Vaccine Statement from 2019, 2020.

206. Q. And I take it you may not have reviewed this particular document, but are you familiar with these -- these NASI statements?

A. Yeah, yeah, they put up statements for all different kinds of vaccines using the epidemiology and we see the vaccine information at the top.

207. Q. Okay. So, I am just going to scroll down to the first page here. And just that first paragraph in the introduction it -- it lists an estimate of 3,500

deaths related to influenza per year. Is that a reasonable estimate in your opinion?

A. Yeah, I think so. Yeah.

MR. KHEIR: Okay. And if we could have that marked Exhibit, I believe we're on G now. And we can -- we can call it the NASI Seasonal Influenza Vaccine Statement for 2019 to 2020.

MR. HUNTER: We can mark it, however I haven't seen a copy of that. So, if you could send me a copy before the re-exam that would be appreciated.

MR. KHEIR: Okay, will do.

(WHEREUPON Exhibit G : NASI Seasonal Influenza Vaccine Statement for 2019 to 2020.)

BY MR. KHEIR:

208. Q. So, if we're looking at an estimated 3,500 deaths due to flu every year in Canada, and we're looking at a population of about 38 million, I calculated that that would be about nine deaths due to flu per 100,000 population. Do you agree?

A. Sorry, I haven't calculated that. But I think that sounds about right. 3,500... yeah. Times 100,000. Yeah. Nine.

209. Q. Okay. So, the number that we calculated for the COVID death rate which was about 76 deaths to

COVID per 100,000 that's a -- it's about nine times the rate we got for influenza, which was nine deaths per 100,000, right?

A. Yeah.

210. Q. Okay. Now, just like with when we were comparing hospitalizations, we're looking at two years of COVID deaths. So, to make it a meaningful comparison we could compare it to two years of the flu. We could double our number to 18 deaths due to flu per 100,000, right?

A. Yeah.

211. Q. And so, in that case, the rate we calculated for COVID being 76 deaths per 100,000 it's actually about four-and-a-half times the rate we've calculated for two years of influenza being 18 deaths per 100,000, right?

A. Correct.

212. Q. Okay. Now, the numbers we've been looking at in terms of flu deaths and hospitalizations are associated with the seasonal influenza. But influenza, I understand, can also spread a pandemic, right?

A. Correct.

213. Q. And for example, there was an influenza pandemic in 1967 to '58, sometimes called the Asian

Flu.

A. Correct.

214. Q. Are aware of the death toll of the Asian Flu pandemic?

A. I am not sure.

215. Q. If I were to suggest to you it would be one to four million globally, would that be -- would that be a reasonable estimate?

A. I'd have to look at the actual estimates as reporting in the 1950's is, you know, largely not as great as it is in the digital era. So, point estimates are hard to -- to arrive in that sense as compared to -- you know, compared to 2021 data.

216. Q. That's fair. So, I am just going to show my screen again. Can you -- can you identify this document?

A. Yeah, World Health Organization Pandemic Influenza Management WHO interim guidance.

217. Q. And if I -- I am just going to go down to page 19 here. And there's a table in the middle of this page. It's titled characteristics of the past four influenza pandemics. Right?

A. Yeah.

218. Q. I'll zoom in. And now, specifically I -- I highlighted the row I was interested in. But it

suggests that the estimate attributable mortality worldwide for the Asian Flue was one to four million.

A. Yeah.

219. Q. In your opinion is that -- is that a reasonable estimate?

A. Again, presumably this is the World Health Organization, they've done their research. Again, these are estimated that are made from health records at the time and modelling. But it's probably the best estimate that could be made of it. I wouldn't say it's, you know, perfect, but it's probably as good as it's going to get in terms of a point estimate.

220. Q. Okay. So, I'll just stop sharing that again.

And so, if I were to suggest that the world population in around 1960 and 1957 was approximately 3 billion, do you accept that's a reasonable estimate?

A. I don't obviously know this off the top of my head. But I think that's what -- I presume we could look that up very quickly in terms of what the global population was at that point in time in history.

221. Q. So, if we -- if we want to calculate a population rate again for this mortality of the Asian Flu, and we're looking at -- we can look at first the

low end of the -- the estimate, it was one to four million. In a world population of about three billion I get about 33 deaths due to the Asian Flu per 100,000.

A. Yeah, okay. I am just trying to -- sorry, three one million. Lots of seroprevalence data, sorry. I don't think my calculator goes that high, but 33, yeah.

222. Q. Okay. And then on the high end of the rate being four million, I got 133 deaths per 100,000. Does that seem right to you, okay.

So, in that case the number that we came up with for COVID deaths per 100,000 which was 76 deaths, it falls within the range of estimated deaths. Or the estimated death rate, I should say, caused by the Asian Flu pandemic, right?

A. Yeah.

MR. KHEIR: Okay. And I suppose the -- the WHO Pandemic Influenza Risk Management Guide should be marked as Exhibit H.

THE REPORTER: That's correct, Counsel.

MR. KHEIR: Okay, thank you.

(WHEREUPON Exhibit H : WHO Pandemic Influenza Risk Management Guide.)

BY MR. KHEIR:

223. Q. Okay. And I am going to, once again, share my screen. Okay, do you see my screen?

A. Yeah.

224. Q. And I believe my colleague, Mr. Kittredge, already brought this document up. But can you just identify it for the record?

A. Ontario Health Plan for an Influenza Pandemic.

225. Q. Right. And it just says here it's Chapter 1, right?

A. M'hmm.

226. Q. And the document's dated March 2013?

A. Yeah.

227. Q. Okay. So, are you familiar with this document?

A. I have not read it, but I know this was generated, I think after 2009, after the H1N1 pandemic in terms of what to do for future pandemics.

228. Q. Okay. So, I am just going to take you to page 14 here. And well, you can see in the table and the text above it, that's providing context. They've essentially created or contemplated four different pandemic scenarios based on two -- two variables, right? The first variable is clinical severity.

A. M'hmm.

229. Q. And the second being transmissibility.

A. Yeah.

230. Q. Okay. And so, from that they generate four potential scenarios which, sorry, bear with me I'll just read for the record being low transmissibility, low clinical severity, high transmissibility, low clinical severity, low transmissibility, high clinical severity. And finally high transmissibility, high clinical severity, correct?

A. Yeah.

231. Q. Okay. And just going to the next page here. And they've essentially set out a table with those -- those four scenarios. One's -- it's on the next page, so if you need me to flip back and forth just ask.

And then they just included a fifth unknown category, right?

A. Right.

232. Q. Okay. And in this column here, you see they provide some examples of pandemics which would fall into the categories they've contemplated.

A. Right.

233. Q. Okay. And they -- they would place the 1957 influenza pandemic under the low transmissibility, high clinical severity, category?

A. Yes.

234. Q. Okay. And they also provide here in this table, characteristics that would place a pandemic into that category. And they -- they provided three -- three characteristics, right? Cumulative attack rate, the reproductive rate, and the case fatality rate. Right?

A. Yeah.

235. Q. And so, looking at these, these characteristics and the examples provided, and once again if you need me to -- to go the next screen just ask. But what category would you place the COVID pandemic in?

A. Ah, what was the -- can I see the last one there? So...

236. Q. Yes.

A. Ah, high transmissibility, high clinical severity. I am just trying to think of the case counts. Probably, I mean it -- it's hard right on the spot, but I would say either between high transmissibility, low clinical severity and high transmissibility, high clinical severity. But between one of the two.

237. Q. So, either -- sorry, high transmissibility, low clinical severity or ---

A. It ---

238. Q. --- high, high ---

A. --- high transmissible. High, high, yeah, exactly.

239. Q. Okay. Now, so, I just want to look at these -- these characteristics that are being presented.

And, you know, since -- since we're -- the rest of us here aren't medical experts, for our clarification, there's a footnote here explaining that cumulative attack rate. It refers to the percentage of people who are expected to become symptomatic at some point during the influenza pandemic, right?

A. Yeah.

240. Q. Now, to date, there have been about 1.8 million confirmed cases of COVID in Canada, right?

A. Correct.

241. Q. So, with a population of 38 million, that number would be far below that 21 per cent cut off. Right?

A. Yes, although, I would again with the earlier testimony was, you know, again is the confirmed -- the confirmed cases may not capture every symptomatic individual out there. And there may be a discrepancy here.

242. Q. So, given that you -- you've -- you've

testified you think that the -- the percentage of cases that we capture has -- has -- it has fluctuated throughout the pandemic.

A. M'hmm.

243. Q. Do you -- do you have an estimate in terms of this 1.8 million number, what that would compare to the actual number?

A. Yeah, I mean 1.8 on 3.33 38 million, there were some seroprevalence data-prevalence data, again, that suggested up to 15 per cent of the population was infected at any given time. So, -- or, sorry, at that kind of third wave.

So, I would suspect that would mean, I am just trying to do that, ah, 3.8 plus -- yeah, I mean 15 per cent as -- what I mean, that is 15 per cent. So, you know, I would say it has varied. But, you know, I would say somewhere between ten and 15 per cent. And, you know, the pandemic isn't over yet.

So, it's hard to kind of say at this point in time if that's going to be the end number as compared to these pandemics that have ended.

244. Q. Okay, but looking at, you know -- we're now two years in. It doesn't appear we've reached that 21 per cent benchmark, right?

A. Yeah, but I would not say that 21 per cent

is not reachable, even in the next few months with what's coming down the pipeline.

245. Q. Now, to fall into the low transmissibility, high severity category, it also states that the reproductive rate must be less than 1.6, correct?

A. Correct.

246. Q. Would you agree that the -- the reproductive rate for COVID is currently less than 1.6?

A. Yes. In Ontario I believe it sits at about 1.3 or 1.3 today. But, again, reproductive rates are hard to interpret just from a daily point estimate that's based on cases, which is based on the number of people that are diagnosed.

And, you know, these are baseline reproductive rates for a disease process in a susceptible population with no mitigation measures in place.

And so, you know, making direct comparisons to a 1.6, you know, if we were to let COVID run wild, basically, you know, the estimates for even the alpha variant, which was circulating I think in April were somewhere in the three to four range. And the delta variant in the six range. So, you may have a reproductive rate that is actually much higher.

247. Q. Now, the example provided for the high

transmissibility and high clinical severity rate is the 1918 Influenza Pandemic, right? The Spanish Flu.

A. M'hmm.

248. Q. So, given the examples and where we've talked about some of these characteristics fall, I am going to suggest that it would be -- it would be reasonable to place the COVID pandemic into either the high transmissibility, and low clinical severity, category as you indicated. Especially if we look at in terms of the cases capturing a wider -- or the actual case number being a much larger number than caught by the -- the deep laboratory confirmed case counts. Would that be reasonable?

A. Yeah, I -- again, the CFR .25 per cent, I am -- of the confirmed cases, and again -- again, this is where it gets difficult to -- to kind of tease out what the true CFR is. But if we were using, you know, 29,000 deaths, and I forget how many of the cases were confirmed in Canada now, you know, it would be -- yeah, again, I don't know the exact say far off the top of my head. So, I would have to kind of look it up based on current data.

249. Q. Would you agree that the pandemic certainly falls within the range of scenarios contemplated in 2013 when this document was issued?

A. Yeah, I think between -- again, the two that I have identified high transmissibility, low clinical severity, and high transmissibility and high clinical severity. And again, the big thing is -- is the case fatality rate, which -- which is the distinguishing between the two.

MR. KHEIR: Okay. At this point if we could take a 15-minute break.

MR. HUNTER: Yes.

OFF THE RECORD

(WHEREUPON A BRIEF RECESS WAS TAKEN)

ON THE RECORD

THE REPORTER: Back on the record at 11:53 a.m. Counsel.

DR. ZAIN CHAGLA, resumed,

CONTINUED EXAMINATION BY MR. KITTREDGE:

250. Q. Dr. Chagla, in preparing your Affidavit you've had the opportunity review the Affidavit of Dr. Kettner, didn't you?

A. Yes.

251. Q. And that Affidavit was prepared for a party that has since dropped out of this matter. But you address his Affidavit at paragraph, what is it, 4 (O) and 4 (P), I believe.

I am wondering if you can take me through

your reasoning here as you ---

MR. HUNTER: We'll just stop there for a second. As you've already stated that Affidavit -- Dr. Kettner's Affidavit was prepared for a different proceeding.

It is not in evidence in this proceeding. And in accordance with the Court Order that the matters be heard together, but not consolidated, Dr. Chagla and Ali (ph) prepared some paragraphs in response for use in that other proceeding.

Ontario is not relying on those paragraphs in this proceeding, because of course, Dr. Kettner's Affidavit is not in evidence. And therefore, I will refuse any questions related to Dr. Kettner's Affidavit.

MR. KITTREDGE: All right. I would just take -- I would take the position that the paragraphs dealing with Dr. Kettner's Affidavit are properly in evidence in the matter that we are continuing forward with. And that questions about Dr. Chagla's reasoning regarding his criticisms of Dr. Kettner's Affidavit are fair questions in this matter.

But am I to understand that you're going to refuse to allow me to ask any -- or instruct

your expert to -- not to answer any questions that I may ask about Dr. Kettner's Affidavit?

MR. HUNTER: That is correct.

(WHEREUPON Refusal NO. 1: To answer any questions asked regarding Dr. Kettner's Affidavit.)

MR. KITTREDGE: And if I was to show Dr. Chagla Dr. Kettner's Affidavit would you permit me to do that?

MR. HUNTER: No, because our view that would be an attempt to lead new evidence after cross examinations have commenced without leave of the Court.

MR. KITTREDGE: All right, well, I would take the position that it's proper for me to put any statement by any doctor in front of Dr. Chagla and ask him what he makes of it, whether that statement is in the form of an Affidavit prepared for the other party that was formally involved in this matter or not.

So ---

MR. HUNTER: You can put the statements to him, but I am not going to allow the -- I am not going to agree to allow the Affidavit in as evidence.

MR. KITTREDGE: Right ---

MR. HUNTER: If you want to put a statement to him, and ask him whether he agrees with it or not, by all means. But it is not evidence of Dr. Kettner that is in this proceeding.

MR. KITTREDGE: Right.

MR. HUNTER: Because he is not an expert that's been qualified in this proceeding.

MR. KITTREDGE: But you're not going to permit any questions asking Dr. Chagla to take me through his reasoning and his criticisms of Dr. Kettner's Affidavit as a whole?

MR. HUNTER: Well, the Affidavit is not there in the first place, so, what's the relevance of that?

MR. KITTREDGE: Well, if I show him the Affidavit, it would seem that ---

MR. HUNTER: I think you have my refusal.

MR. KITTREDGE: All right. In that case, I forwarded a copy of that Affidavit to pass along to Dr. Chagla.

Do you have any objections to marking it for identification?

MR. HUNTER: It can be marked as identification, yes. On the basis that it's been

refused in case there is any further arguments need to take place as a result of that.

MR. KITTREDGE: Okay, great.

(WHEREUPON Exhibit NO. I : Dr. Kettner's Affidavit.)

BY MR. KITTREDGE:

252. Q. Dr. Chagla, just before I go, I guess I'd like to say I have been following you on twitter since early in the pandemic, so it's been a pleasure to talk to you.

And thanks so much for your time today. As well as for everything you've done over the past two years with regards to COVID. It's appreciated.

A. Thanks. Thanks a lot.

MR. KITTREDGE: All right, and no further questions.

MR. HUNTER: We will have a few questions of re-examination. Can we just take a five-minute break.

MR. KITTREDGE: Sure.

MR. HUNTER: Come back, say at 12:05.

MR. KITTREDGE: Sounds good.

MR. HUNTER: So, a seven-minute break.

THE REPORTER: Very good, Counsel.

OFF THE RECORD

(WHEREUPON A BRIEF RECESS WAS TAKEN)

ON THE RECORD

THE REPORTER: Back on the record at 12:08 p.m., Counsel.

DR. ZAIN CHAGLA, resumed,

RE-EXAMINATION BY MR. HUNTER:

253. Q. Dr. Chagla, you were asked about some areas where you and Dr. Hodge had disagreed.

Do public health experts always agree on everything?

A. Clearly not. There's been a lot of discrepancy and it comes from different places of knowledge and different kind of clinical experiences. So, yeah, absolutely not -- not everyone agrees.

254. Q. And there's a wide range, often reasonable interpretations of even the same data, much less different data?

A. Yeah, absolutely. And again it's -- it's people's experience and what they see. And -- and how they interpret that data.

255. Q. And are you aware of what data Dr. Hodge used when he was giving his opinions in cross-examination?

A. I presumed it was the numbers that were

displayed, but I am not entirely sure.

256. Q. And you mentioned zero prevalence data prevalence data, first of all, can you just explain what zero prevalence data prevalence data is?

A. Sorry, seroprevalence data.

257. Q. Sero, sorry.

A. And this is -- yeah, this is using antibody data to describe, you know, better rates. It's not perfect, but it gives a sense of who has been infected over a set timeframe by using the antibodies in people's blood to get a sense.

So, it would pick up some of those people that would not have necessarily gotten tested, people that were asymptomatic, or very mildly symptomatic, had not noticed that they were infected. As compared to PCR tests which are kind of triggered by people to go get tested.

258. Q. And do you know if we have that data available for the whole province, throughout the whole pandemic?

A. There has been intermittent -- so, there has been a couple of studies done to -- provincial health laboratory through blood donors. And then there's been the Canada Immunity Taskforce, which has kind of had more national data looking at this.

259. Q. So, we don't have it for as many people as have PCR tests for?

A. No, no, as -- and again, it's not -- it's a lot of data where they've looked at things like blood donors or healthy volunteers and tried to get prevalence and model it out from there.

So, it's a -- you know, not like everyone has given a blood sample to be enrolled in this.

260. Q. And are we anywhere close to, or are we close, or are we getting close what so-called herd immunity based on the number of people who have been infected?

A. I mean, the fact that we have uncontrolled spread is probably telling in that sense that we haven't. You know, again, this disease is spreading. And especially with variants now that may evade immunity of it more, even having a set amount of immunity isn't necessarily a basis to stop things cold in the population as herd immunity would eventually do.

261. Q. And you were asked a number of questions about PCR testing.

A. M'hmm.

262. Q. Do we have better tools right now for determining if someone is capable of transmitting

COVID to others than a PCR test?

A. I mean, the gold standard we use in -- in studies is viral culture, but that's completely impractical and it's often just a reference standard for things like scientific testing. They're not really used in clinical practice. The reason being is, you know, growing the virus out needs special conditions, needs multiple days of incubation. So, they're pretty useless in a clinical context. We use them more for research or -- or to validate our PCR tests.

PCR is the gold standard and, you know, for other viral infections like Influenza and -- and other respiratory infections, other viral infections like hepatitis or HIV. You know, it's a -- it's used primarily as the gold standard diagnostic entity.

263. Q. I know you -- you had some questions about, you know, range of potential sensitivity or false positive rates. Has that changed throughout the pandemic?

A. Yeah, again, the initial data from China gave that 75 per cent PCR sensitivity. You know, PCR sensitivity is not only just the population you're testing, but is the assay itself. And so, how well it's been developed, and -- and you know some other

technical factors. So, you know, as assays have gotten better again, it's ranged higher rather than lower in terms of sensitivity.

264. Q. And so, just to be clear, so higher sensitivity, does that mean it's more accurate or less ---

A. Yeah, like, you know, again towards that 90 to 95 per cent range. The initial Chinese PCR's were a little bit off. But again, you know, with time it's -- repeating, find a better targets, that type of thing, you can -- you can get better assays as things progress.

265. Q. And so, you know, you were asked a lot of questions about percentages and such like. But I just want to understand the absolute numbers. You know, does thirty -- what if any impact, does 30,000 hospitalizations have on Ontario hospitals?

A. Yeah, I -- there are a lot. Right? I mean it took 891 ICU beds to cripple our healthcare system, to shutdown surgeries, to redeploy staff.

You know, 30,000 hospitalizations means people that are in hospital that need oxygen, that need care, that, you know, need clinical services to deal with them. Some of them need rehabilitation, some of them have secondary complications.

And so, you know, having zero of those would be fantastic. And we all realize that respiratory viruses lead to people being hospitalized. But the sheer number of people that have needed to be hospitalized from this virus in the last couple of years is -- is different than any other respiratory viruses in the past. And again that their healthcare bodies, they're real people that have to deal with them.

266. Q. And you were asked some questions about, you know, hospital and ICU capacity. You know, in your clinical practice, are you aware of any steps that have been taken to expand capacity during the pandemic?

A. I mean we've found beds. And we've bought ventilators, but we don't have the staff necessarily all the time for them. And so, you know, even to deal with kind of reinforcing our ICU's, we've had to retrain staff.

We've had to bring in agency staff, so third-party agencies rather than hiring them we've had to -- we've had to go through hiring fairs. We've really tried to blitz trying to get as many healthcare resources in, and particularly during the worst parts of our pandemic. Again, we had to shut down services

to just redeploy staff into the ICU, in order to offer more bodies.

267. Q. And are there any limits on our ability to do further or?

A. I mean it's not a secret that the healthcare human resources right now in the pandemic are probably one of the worse they've ever been for the fact that many staff are burnt out. Many nurses have left the profession. And so, you know, our ability to scale up even more is going to be difficult as time goes on.

268. Q. Now, you were asked a number of questions about whether different measures were, in your opinion justified on a public health basis.

Do public health practitioners always know with certainty, in advance, what's going to work?

A. No, and again, these -- these measures were made with transmission dynamics in mind. Some of them may not have been perfect, but -- but, you know, particularly the ones that targeted indoor measures were made to, you know, look at what would be the definable risks of COVID-19 in terms of people gathering, contacts, you know, the respiratory spread of the virus et cetera.

So, you know, no one -- we don't go in with randomized clinical trials to say this measure will

reduce COVID-19 by this much. We go in based on the assumptions that, you know, more people mixing, indoor spaces, poor ventilation, et cetera, increase the risk of transmission and -- and again, mitigating settings with those factors in mind, would likely decrease transmission and -- and lead to less -- less COVID cases.

269. Q. Now, you were askes a number of -- you were taken to an article you wrote in the Toronto Star about outdoor activity.

A. M'hmm.

270. Q. And you said outdoor activity is generally safe, and comparatively far safer. And then when you answered some questions, you spoke of mitigated outdoor activity, and outdoor activities being don appropriately.

So, what do you mean by those qualifiers?

A. Yeah, so, I mean again, you know, you're not going to get the benefits -- I mean, again, outdoor ventilation is appropriate, it does mitigate a lot of transmission. But, if for example, you're very, very close to each other, packed in a small space, if you're -- you know, we've seen kind of outdoor patios, for example, that have really been like three walls.

So, you know, it really is kind of a -- an

indoor space that looks like an outdoor space. Ah, ah -- you know, people are kind of, you know, very, very close to each other. If they're, you know, swapping drinks, or that type of thing, where there's saliva going back and forth. The outdoors isn't going to save you at that point, right?

You know, if you're -- if you're kind of breaking those barriers down, then -- then certainly, again, you know, the ventilation advantage of the outdoors is -- is turned off by the fact that you kind of broken down some of the barriers that lead to transmission.

271. Q. So, I'd like to talk to you a little bit now just about from what was put to you about COVID versus influenza.

A. M'hmm.

272. Q. First of all, you were asked some questions about the 1950's influenza pandemic. Do you know what, if any, public health measures were going on at that time to reduce the spread of influenza in the 50's?

A. I am not sure. I mean all I -- I was born and alive during the 2019 -- 2009 pandemic, but, yeah, I clearly don't know what life was like back in the 50's.

273. Q. And you also talked about influenza in 2019, 2020, so that would be the pandemic or at least before the pandemic in Canada. Were there significant public health measures in place to prevent influenza spread?

A. Outside of just encouraging people to get vaccinated, and stay home when sick, those are kind of the baseline measures, I think, for more respiratory viruses in the community.

274. Q. And do you know what impact, if any, the public health measures take into combat COVID-19 had on influenza after 2019, 2020?

A. We didn't have an influenza season in 2020, 2021. You know, it's just starting now because people are now engaging again it travels with them. But, yeah, from 2020 really that -- that influenza season shut down essentially when the lockdowns happened. And -- and really, you know, through last winter we didn't have an influenza season. There were just a handful of cases, nothing to declare a true influenza season.

275. Q. Okay. So, I am just going to take you to -- some of the exhibits my Friend took you to. I am going to start -- I am going to share my screen with the NACI advisory committee statement.

So, this is the exhibit my Friend took you

to. And he took you to that number about flu deaths.

A. M'hmm.

276. Q. Give me a second. And so, you notice there's a footnote 3, after that number he took you to?

A. Correct.

277. Q. And then if I just take you to the end notes, footnote 3 refers to a study by Schanzer, Sevenhuysen et al., about -- from estimating influenza deaths in Canada.

A. Correct.

278. Q. Let's actually go to that study. One second, I'll stop sharing. So, I'll just give you a minute to read the abstract of that study.

A. Okay.

279. Q. So, I am just going to suggest that this study was a regression modelling study, not an actual measuring of influenza positive patients.

A. Yes, again, as I think I mentioned in prior testimony a lot of our influenza data is -- is modelled. It's not -- it's not as accurate as COVID-19 data and we've been tracking every case in that sense.

280. Q. And also, this was data based from 1992 to 2009.

A. Correct.

MR. HUNTER: I'd like to mark the actual article as an exhibit.

MR. KITTREDGE: No objection.

(WHEREUPON Exhibit J : Schanzer and Sevenhuysen study estimating influenza data in Canada.)

BY MR. MR. HUNTER:

281. Q. And so, let's just -- one other thing on that point. If we go actually to the FluWatch study that my Friend's took you to. They took you to it about hospitalization rates. But they didn't mention what it said about death rates. Let me take a look at that. I'll share my screen.

Can you see the FluWatch study now?

A. Yeah, yeah, absolutely.

282. Q. And if you just look under the table you were taken to, how many ICU admissions and how many deaths related to flu did -- were reported for 2018/19?

A. A total 163 ICU admissions and 224 deaths were reported this season.

283. Q. I just want to say something, one other -- hang on one second, while Adobe decides to work for us. Can you see that now?

A. Yeah, yeah.

284. Q. Okay. So, just wanted to ask what they reported about the 2018, 19 influenza season. It's in the second bullet.

A. Ah, the 2019 -- 2018, 2019, influenza season was longer than previous five seasons, was characterized by two waves of influenza A activity, and influenza B situation, national season started week 43, October 21st, 27, 2018, and peaked in week 52 December 23rd to 29, 2018. And ended in week 21 May 19th to 25th, 2019.

285. Q. And do they say anything about the hospitalization rate? That's in the fifth bullet.

A. The annual season hospitalization rate was above average, compared to the previous five seasons. Adults 65 had the highest hospitalization, however the cumulative hospitalization rate shifted during the season, from children zero to four years of age, November to March. Adults 65plus of age, March onwards, likely due to the second wave of AH3N2.

286. Q. The last thing I want to take you to is the Ontario Health Plan that you were taken to. So, let's just put that up. Should be able to see that now. Just going to take you to the chart my Friend took you to.

So, here's the chart on pages 15 and 15 my

Friend took you to. I just want to make sure I understand some of the terms and how they're dealt with in public health practice.

So, first he asked you about the cumulative attack rate.

A. M'hmm.

287. Q. The percentage of people, it says in the note here, who are expected to become symptomatic at some point during the influenza pandemic.

Now, when you're trying to decide whether to impose various public health measures, do you look at the cumulative attack rate with those measures or the rate that you would have if you didn't take measures in deciding when you're higher or lower than this 21 per cent number?

A. Yeah, I mean I -- I think we take examples from what happens in the world, and we look at, you know, what the spread would look like. And again, we make proactive measures to deal with that.

So, again, you know, our -- our attack rate being, you know, less than 21 per cent is often -- the fact that we have less than 21 per cent is not necessarily the fact that this has not spread to 21 per cent of the population. It's the fact that public health measures have prevented it from spreading to

over 21 per cent of the population.

And, you know, that is the paradox of public health, when things actually work, they get reflected in lower numbers which is exactly what we want. And we don't necessarily measure what could have happened in that sense.

288. Q. And similarly with the other -- it's -- the other number were asked about, the reproductive number, R Num.

A. Yeah.

289. Q. Is there a different between this basic reproductive number that's referred to in this document for assessing the transmissibility of a disease, and the observed reproductive number in the community?

A. Yeah, absolutely. I mean, again, you know, the reproductive number right now in Ontario is very, very rough guide. And is in the context of a population that has 90 per cent immunity. When they talk about the basic reproductive number here, it is literally just you put the virus in the population, a pool that is completely susceptible and you look at, you know, the growth over time. And -- and again, you know, that is what the basic reproductive number is in that sense.

So, what our reproductive number for COVID-19 in the community, you know, again it's been less than 1.6 for sometime, thankfully, is not a reflection of COVID-19 having a reproductive number biologically on its own at less than 1.6. When you were to take COVID-19 put it in a pool, again, the estimates of the original COVID-19 strain are two to three. The estimate of the alpha strain is four. And the estimate of delta is six. And even Omicron we're not even sure yet what the estimate is.

So, you know, again it is much more than just, you know, what looking at daily case counts are and generating a model to say what the reproductive rate is. It is, you know, again a susceptible population in kind of letting it spread outwards in a uniform manner.

290. Q. Similarly, you talked about how the reproductive numbers change with the variants, has that affected the case fatality rate?

A. Ah, I mean more that get infected means that there is a bigger chance of dying. But it also means that more of the population has some protection through natural immunity as well as vaccine. So, yeah, absolutely.

I mean, again, what we've done has affected

the case fatality rate with therapeutics and other interventions that have gone on in the population if less people -- again, less high-risk people are infected. It -- it artificially lowers the case fatality rate. So, things like lockdowns, and vaccinations in nursing homes, for example, would take down the case fatality rate because you don't have your highest risk members of society dying in that sense.

291. Q. My question was actually just about the variants.

A. Oh.

292. Q. Alpha, Delta, and Omicron.

A. Yeah.

293. Q. Has that affected the case fatality at all?

A. Yeah, absolutely, absolutely. I mean I think Delta was an estimated -- sorry, Alpha was an estimated 1.5 times, I think it was in the Affidavit for -- based on the original Wuhan strain. Delta looks like it's much higher.

We're not sure about Omicron yet, because it's just so new. But the CFR has -- has increased with some of these variants of concern that have actually come out there. Especially Alpha and Delta as the big two.

MR. HUNTER: Thank you those are my questions. All right, are we off the record?

I hereby certify the foregoing to be the Cross Examination of DR. ZAIN CHAGLA, taken before me, via videoconference, on the 14th day of December, 2021.

CERTIFIED CORRECT: PROFESSIONAL COURT REPORTERS INC.

@zchagla

There's 5000 active cases of COVID in Peel. Add to that the undiagnosed probably closer to 30000. That's 2% of the population walking around with COVID.

Taking AZ gives 60-80% reduction in COVID, a reduction in transmission, and reduction in hospitalization/death

Surge in patients forces Ontario hospitals to put beds in 'unconventional spaces'

By Theresa Boyle Health Reporter

Sun., April 16, 2017 | 17 min. read

Article was updated Apr. 27, 2017

It's been a rough few months for Ontario hospitals. Wait times for patients admitted through ERs have hit peak levels; more patients have been admitted than discharged; and a number of hospitals have simply run out of space.

Frazzled administrators, forced to get creative in accommodating the overflow, have coined the term "unconventional spaces" to describe their solution. They have converted into temporary accommodations patient lounges, staff classrooms, offices — and in some cases even storage rooms.

Overcrowded hospitals are nothing new to Ontario. They typically experience patient surges every January and February when flu season peaks and when there is a rebound effect after the Christmas lull. Hospitals struggle with overcrowded emergency rooms across Canada and in other countries, too.

But there has been something different about this year's surge in Ontario, according to numerous hospital CEOs interviewed by the Star — a handful on the record, but most off.

It was bigger than in years past and caught many by surprise. Patient capacity at about half of Ontario's 145 hospital corporations exceeded 100 per cent and reached as high as 130 per cent, according to figures requested by the Star from the Ontario Hospital Association (OHA).

Hardest hit have been large urban hospitals, regional facilities and some community hospitals. Even some rural hospitals have been overwhelmed. They include hospitals throughout the Greater Toronto Area, Hamilton, Ottawa, London, Kingston, Windsor, Sudbury and Cornwall.

Many have been over capacity for weeks, even months. While the surge has somewhat abated in recent weeks, it appears that some of the intensified demand for hospital services won't subside any time soon.

To accommodate the overflow, hospitals have been forced to open at least 1,100 "unfunded beds," more than 250 of them in unconventional spaces, according to the OHA. The organization said these are conservative estimates because not all hospitals participated in a survey on capacity.

An unfunded bed is one that a hospital did not budget for and therefore did not receive provincial funding to operate. To cover the cost, a hospital must dip into funds raised for capital projects, equipment and research through, for example, fees on parking, private rooms and food vendors.

The OHA is still surveying hospitals to determine exactly how severe the overcrowding problem has become, how many unfunded beds remain open and what the total cost of operating them has been. The cost of operating one such bed for a single day is $450, at the low end.

Some hospitals have incurred deficits to accommodate the extra patients.

There are three main causes of the growing pressures, health-care leaders agree: a population that is growing, aging and showing up in the ER sicker than ever; a health system that is not robust enough outside of hospitals, such as in the long-term-care and home-care sectors; and five years of austerity funding with minimal increases to operating budgets from the province. When inflation is factored in, hospitals budgets have actually fallen in real dollars.

The OHA has told the province that hospitals cannot go on at this rate without significantly compromising front-line care, the Star has learned. The organization has asked the province to put an end to the austerity and come to the rescue with a significant infusion of cash — $850 million — in the budget, to be tabled April 27.

A highly placed government source, who wasn't authorized to speak publicly, said the province is well aware of pressures on the sector, though questions whether they are really as severe as are being made out.

The source said the province may announce in the budget that it will loosen the purse strings to free up more hospital beds and create more capacity throughout the entire health system. Improving health care outside of hospitals is the key to relieving pressures inside them, he said.

Since October, Hamilton Health Sciences has been struggling to care for more patients than it has beds. Its capacity peaked in February at 114 per cent, but remains high today.

Last Sunday, it was at 111 per cent capacity. There were 70 more patients in beds than the hospital had budgeted for.

Senior administrators and physicians meet daily to pore over "bed maps" to figure out where they can accommodate the overflow. When there is no more space for gurneys in ER hallways, they look to unconventional spaces, which can include patient sunrooms and recovery rooms normally dedicated to short-term stay for patients who have just had surgery.

"The whole system is under stress and Hamilton Health Sciences is no exception," said president Rob MacIsaac. "We are constantly operating on the edge. There is no slack left in the system. Zero."

Among the hospital's 1,391 in-patients last Sunday were 168 who had completed their acute-care hospital treatment and no longer needed to be there. Mostly frail seniors, they are known as "alternate level of care" or ALC patients because what they really need is

care outside an acute-care hospital.

Alternatives can include long-term-care homes, their own homes with home-care support, palliative care, rehabilitation facilities and complex continuing care facilities.

But there are shortages in these sectors too, especially for patients who are both physically and cognitively impaired. The hardest to place have multiple chronic physical ailments, dementia, behavioural problems and/or mental health problems.

When ALC patients can't be discharged, there are fewer beds available for those admitted to hospital from the emergency department. That makes for a particularly bad combination when there is a big influx of patients on that end too. Last Sunday, there were 40 patients admitted through the ER at Hamilton Health Sciences, waiting for beds.

The hospital has seen a 3 per cent increase in emergency department visits over the last year. The average acuity of patients — or intensity of nursing care they require — jumped 5 per cent over the same period.

"Circumstances overwhelm anything we can do internally. Fundamentally, there is no making up for lack of capacity with better processes," MacIsaac said.

Staff are stressed, patient satisfaction is suffering and the facility's budget is stretched thin, he noted.

The hospital was forced in February and March to cancel and reschedule 26 surgeries though it "moves heaven and earth" not to do that, MacIsaac explained.

Cancelling surgeries compromises its regional role in providing treatment for cancer, trauma, burns, stroke, cardiac care and pediatrics. The hospital serves a population of 2.5 million and its catchment area stretches out to Burlington, Oakville, Milton Niagara, Branford, Haldimand-Norfork and Kitchener-Waterloo.

"We are waiting on tenterhooks to see what our funding is. We are beside ourselves trying to figure out how we are going to manage," MacIsaac exclaimed.

People are often surprised to learn Ontario has very low numbers of hospital beds, compared to countries in the Organization for Economic Co-operation and Development. The province has 2.3 beds per 1,000 people, fewer than 31 OECD counties. Only Mexico, Chile and New Zealand have fewer.

But provincial policy-makers don't see that as a bad thing. On the contrary, it's by design and it's a point of pride, proof of a highly efficient system.

Ontario has purposely shrunk its hospital system. In 1990, there were 33,403 acute-care hospital beds, according to the OHA; today there are 18,571.

During that same period, the province's population jumped 36 per cent to 14 million.

Additional figures from the OHA and Canadian Institute for Health Information requested by the Star show that:

- The number of visits to Ontario hospital emergency departments jumped by 5.6 per cent to 6.3 million from 2012-13 to 2015-16. These patients are older and sicker than ever before.
- Ontario spends $1,427 per capita on hospitals. Of the 10 provinces, only Quebec spends less.
- The average length of stay for Ontario hospital patients fell to 5.7 days in 2014-15 from 6.9 days in 1995-96. That is the lowest of all provinces.

Advances in technology have contributed to shorter patient stays. Surgeries are less invasive than they used to be, allowing for faster recoveries. More procedures are done on an outpatient basis and more followup care is provided through home care.

Groups such as the Ontario Health Coalition argue that the province has gone too far in cutting hospital beds and want to see the sector built back up.

But policy-makers and health-care leaders see it differently. In their view, patients wouldn't need to rely on hospitals as much if they were kept healthy in the first place and received more health-care services in the community, where it is less expensive.

This has long been the vision for Ontario's publicly funded health system, the way to keep it affordable and sustainable. But getting there has not gone as smoothly as planned.

Said one GTA hospital president, who spoke on the condition of anonymity: "Hospitals have maximized their efficiencies, but things have not evolved as they should have over the last five years outside of acute care. We need more resources in the community."

Said the government source: "So what part of the system is good and what part is disorganized? I would say our hospital systems are pretty good and we have the data to prove it. Outside hospitals we are disorganized."

The source said that the province's ongoing measures to transform the health system, an effort known as Patients First, will take pressure off hospitals by improving health care outside of them.

"That is why Patients First is so important ... to organize the primary care, home and community and mental health care that are currently disorganized," he said.

OHA president Anthony Dale had a feeling last year that hospitals were heading into a tough winter. He had been watching the provincial ALC rate, which the government has been trying for years to lower.

The proportion of acute-care hospital beds occupied by ALC patients had fallen from a high of 19.6 per cent in 2008 to a level hovering between 13 and 15 per cent between 2011 and 2015.

But in July 2015, the ALC rate started to rise again — sharply. It went from 13.9 per cent in July 2015 to 16.5 per cent in November 2016.

By January this year, there were 3,121 ALC patients waiting in acute-care beds. A third of them were waiting to get into long-term-care homes.

At the same time, pressure was building in ERs because of flu season. By February, ER waits hit their highest levels since the province began measuring wait times nine years ago. Nine out of 10 patients waiting to be admitted from the ER waited 32.4 hours or less. The target for admitting all complex patients is eight hours.

"What caught us by surprise was the intensity of the flu surge," Dale said.

ER waits are a barometer of how well the health system is functioning, he explained. If there is a problem somewhere, it inevitably manifests in the ER.

"(ER waits) are often a warning sign of a system under stress and at the moment, the warning is flashing bright red," he said.

In recognition of this, the provincial government last November provided an extra $140 million to the sector on top of the $345 million announced in last year's budget. It was a much welcome "lifeline," Dale said.

The sector has asked for and received very little in the way of extra funding over the last five years. Hospital base operating budgets were frozen for four of those years and last year increased by 1.5 per cent. When inflation is taken into account, hospitals have actually seen real-dollar budget cuts for nine years.

Hospitals agreed to take less funding so that other sectors with greater need — namely home, community and long-term care — could get more.

At the same time the provincial government has been trying to cut its deficit.

But hospitals say they can no longer take a back seat to other health sectors. They are hoping the budget will include a 4.9 per cent increase in total operating and capital funding.

"While hospitals have been understanding and supportive of the need to spend elsewhere in the system, the hospital sector is now at a critical turning point," the OHA budget submission states.

"We can no longer say that funding others is a greater priority," it continues, warning that inflationary pressures may require diverting a significant amount of funds from front-line care.

Toronto resident Julie Devaney was surprised to see how busy the ER at Mount Sinai Hospital was at 1 a.m. on Jan. 28. The woman who has Crohn's Disease was taken there by her partner because she was suffering from a bowel obstruction.

Throwing up, barely verbal and in agonizing pain, she was deemed ill enough to admit. But she waited 18 hours in the ER to get a bed.

Devaney, 37, spent the first part of her wait in a busy hallway where she was hooked up to IV fluids. She remembers the scene as being chaotic. There were lots of people walking back and forth, it was noisy and at one point a shouting match broke out. Police were on hand to break it up.

"It was pretty intense. I felt extremely vulnerable," she said, recalling how she had to use a plastic bag that she brought from home to vomit into.

She was eventually moved into an ER treatment room where she was given pain medication and spent the rest of her wait.

Despite the commotion and long wait, Devaney was impressed by the doctors and nurses: "Staff were amazing and very comforting."

NDP health critic France Gelinas got a taste of the growing hospital capacity problem back in Nov. 2015 when her now deceased 93-year-old mother-in-law ended up in the emergency department of Sudbury's Health Sciences North with an infected foot.

Because the ER was full, her mother-in-law was moved into a storage room. Half of the room had been cleared for patient use. A bed sheet covered cleaning supplies in the other half. There was no window, washroom or sink. The elderly woman stayed there for eight hours while she was treated with IV antibiotics.

"When they saw it was me, they profusely apologized," Gelinas said of hospital brass. "They were doing the best they could. There was nowhere else to go."

She and her party have been leading the charge at Queen's Park in calling for more hospital funding.

"Hospitals need money to rebuild surge capacity," she said, charging that a broken home-care system and inadequate primary care are placing undue pressure on the sector.

Dr. Denis-Richard Roy, president of Health Sciences North, said there were 25 patients in the ER, waiting for beds on a recent day when he was interviewed.

"I have never seen it this bad before. It seems like the new normal," he remarked.

Roy said the waiting patients were lying on gurneys in hallways and occupying ER treatment rooms, preventing other patients from being seen there.

The hospital has operated within budget for the last five years but is facing a $7 million deficit in this current fiscal year, he said. Much of that is from overtime wages paid to nurses.

"It's a terrible situation. It is not something HSN can manage on its own, it's a system problem," he said.

Dr. Howard Ovens, the province's lead for emergency medicine, acknowledges hospitals are under tremendous pressure. But looking at the problem from a historical context brings valuable perspective, he said.

Overcrowding was much worse 20 years ago when the government of the day made massive cuts to hospitals and to nursing staff, he said, recounting how two high-profile deaths related to poor ER access resulted in coroners' inquests.

"When people say the sky is falling right now, I say, 'You haven't seen a sky fall,'" remarks Ovens, who until last month served as the chief of emergency medicine at Mount Sinai.

Funding constraints in recent years have indeed resulted in more stress and less resilience in the system, he said.

But hospitals have responded much better than they did in the past because they've learned from mistakes and instituted new measures such as a "pay-for-results" incentive system, he explained. Hospitals get financial bonuses when they accommodate ER patients in a timely manner.

In Ovens' eyes, the use of unconventional spaces, while far from ideal, is smart.

"We didn't use sunrooms in the '90s. We didn't put patients in closets. We used to say there was nothing we could do and leave people out in the waiting room indefinitely and ultimately some would die out there," he said.

"The fact we now go to extraordinary lengths to create capacity is good thing."

Perhaps the hardest hit hospital in Ontario has been the Cornwall Community Hospital, which has reported occupancy rates as high as 138 per cent.

Since Christmas, it has been operating at more than 100 per cent capacity.

"Being overcapacity isn't anything new for us. What is different this year is the extreme levels of occupancy and the length of time we have been in this state," said president Jeanette Despatie.

The hospital is using not only ER hallways to accommodate the overflow, but hallways in the hospital's medical and surgical units as well. Former clinical space that had been turned into offices has also been converted back into patient rooms.

"It is a very challenging environment to work in. It has compromised our ability to ensure we are providing the quality and safety we want for our patients," Despatie said.

She is particularly worried that there is no "surge capacity" to deal with a large-scale emergency such as a pileup on Hwy. 401: "We would be hard pressed to meet the needs of an immediate surge."

ALC rates in Cornwall are up noticeably this year, at 19 per cent of total patient days compared to 15 per cent least year. Eight ALC patients have been waiting more than 100 days to get into long-term care and one has been waiting more than a year.

"These patients are tougher to place in appropriate settings because they have mental health or behavioural challenges," Despatie explained.

These ALC patients also include seniors who cannot afford to pay higher fees for private or semi-private rooms in long-term care homes and are waiting for subsidized, ward-style rooms to open up.

Despatie said there has also been an increase in ALC patients waiting to be discharged home with home-care support.

In the recent past, the hospital had more success in discharging patients home with help from the province's Homes First program, which allotted more home-care hours for frail, ailing seniors, she noted.

But now that same cohort of patients — older and sicker — is finding itself back in hospital, too sick to return home and waiting for long-term care.

The province needs to find alternatives to long-term care, said another hospital president, warning that it will go broke if most aging baby boomers plan to spend their final years there.

Dr. Alan Drummond is an ER doctor at the Great War Memorial Hospital in Perth where there are 50 beds and nine ER stretchers.

It's not uncommon for him to arrive at work in the morning to see up to five elderly patients, who had been admitted the night before, waiting on stretchers with no prospect of being transferred to the wards for hours or even occasionally days, he said.

"I sometimes examine them in the hallway or the triage area because there is no other space," said Drummond, former head of the Canadian Association of Emergency Physicians.

Every time a stretcher is occupied by an admitted patient, those in the waiting room are denied access to a treatment area and so they wait too, he explained.

"I have sometimes wandered the hospital, found an available stretcher and brought it down myself to the back of the ER hallway to give me a couple of spaces to see people," he said.

The crowding that urban hospitals began seeing in the mid-1990s didn't reach small rural hospitals like his until the last five or six years, Drummond said.

"Even in Perth now we have ambulances that cannot off-load their patients. Paramedics have to wait in the hallways with their patients. No place to off-load," he remarked.

It can be demoralizing and leaves ER nurses "constantly on the fringe of burnout," Drummond said.

Hospital officials across the province end up spending an excess amount of time trying to figure out patient flow. In Perth, doctors can no longer easily transfer their sickest to tertiary hospitals in Kingston and Ottawa because they are also full, Drummond said.

"Kingston is so bad that it's usually a wasted call. We then spend hours on the phone trying to find a bed elsewhere or try to maintain critically ill patients in our own facility," he said.

"The point is that it is now endemic and chronic and affects rural communities just as much ass city hospitals."

The government source questions the accuracy of hospitals' peak occupancy rates, noting they can vary widely depending on the time of day they are measured. For example, if measured during the middle of the day, it's possible for one bed to show two patients — one that has just been discharged and another that has just been admitted.

The most accurate time to take a patient census is midnight, he said, adding that the sector and government are currently working out a mutually agreed-upon measurement protocol.

This source also pointed out that the province does not fund hospital beds, per se, but rather patient activity. In a well-managed hospital, there should be some spare beds, say in an older section, that could be put to use in flu season and closed again when ER activity slows.

"Some hospitals will occasionally use unconventional spaces and that is not good and needs to be fixed," he said, acknowledging the sector is under pressure.

Both the OHA and the government accept that the average annual occupancy rates for Ontario hospitals hovered between 91 and 93 per cent between 2012 and 2016.

The oft-cited ideal capacity rate for hospitals is 85 per cent. Anything above that leads to long waits and increased risk of transmission of infectious disease. As well, it leaves little wiggle room in the event of a big emergency.

The government source said the budget may include extra money to relieve overcrowded hospitals. The funds would go to hospitals and to sectors such as home and community care, in an effort to lower ALC rates.

But the source also said that a lasting long-term solution rests with creating more forms of "congregate" living arrangements where personal support workers would be available to assist the growing senior population. In the past, cultural and religious organizations did more to support their seniors through the creation of assisted-living and supportive housing facilities, he explained.

Society needs to return to those models with the encouragement of government subsidies, he said, adding that the budget may make some movement in that direction.

The time to beef up services outside hospitals is running short, health-care leaders agree. The oldest of the baby boomers turns 71 this year. Age 75 is when people enter their high health-care consuming years.

Introduction

Variants of concern (VOC) of SARS-CoV-2 emerged toward the end of 2020. These resulted in documented replacement of wildtype SARS-CoV-2, with concerns of transmissibility, virulence, and immune escape, and were subsequently classified by an alphabetical system by the World Health Organization.[1] Prior to the emergence of VOC, across countries, SARS-CoV-2 transmission and COVID-19 were disproportionately concentrated in neighborhoods of low socioeconomic status, which are characterized by a larger proportion of frontline essential workers, and higher density contact networks.[2,3] We created a retrospective cohort of neighborhoods in the City of Toronto and Region of Peel, two of the most populous and most affected per capita regions of Ontario,[4] stratified by income and essential work status, and noted the emergence of VOC through this population.

Methods

This cohort study was approved by the University of Toronto Health Sciences Research Ethics Board and participant consent was waived because this was a secondary analysis of preexisting health administrative data. This study followed the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) reporting guideline.

We performed a retrospective cohort study on the burden of COVID-19 and VOC characterizing by essential work and income status, using Statistics Canada 2016 Census (self-reported) data for neighborhood-level characteristics, using dissemination areas of approximately 400 to 700 persons. Neighborhoods in the City of Toronto and Region of Peel were stratified into ascending tertiles 1, 2, and 3, which represent 33% of the population ranked by income (where tertile 1 is the lowest income), and essential work status (where tertile 1 is the highest proportion of essential work) represented in **Figure 1**. Essential work status included the proportion of the working population engaged in essential services (manufacturing, utilities, trades, transport, equipment, agriculture, sales, services, and health). We excluded cases among residents of long-term care homes because they represented a different outbreak setting from community-level outbreaks and transmissions.

We used a public health reportable disease database of person-level data among laboratory-confirmed COVID-19 cases between February 3 and March 10, 2021, and the Statistics Canada 2016 Census data for neighborhood-level characteristics. Polymerase chain reaction (PCR)–positive tests with a cycle threshold less than 35 underwent secondary PCR for the N501Y variation, and genetic sequencing for positive results by centralized laboratories,[5] representing VOC cases. Of the samples positive for the N501Y mutation, 93% were clade B.1.1.7.[5] Self-reported race-based data among individuals diagnosed with COVID-19 were collected after June 2021 but were not available for analyses in this study. During the observation period, both regions had closed nonessential businesses, restaurants, fitness centers, and had limits to only interact with one's household.[6] Tertiles were compared for case growth during the study period with descriptive analysis conducted in R version 4.0.2 (R Project for Statistical Computing) from February to April 2021.

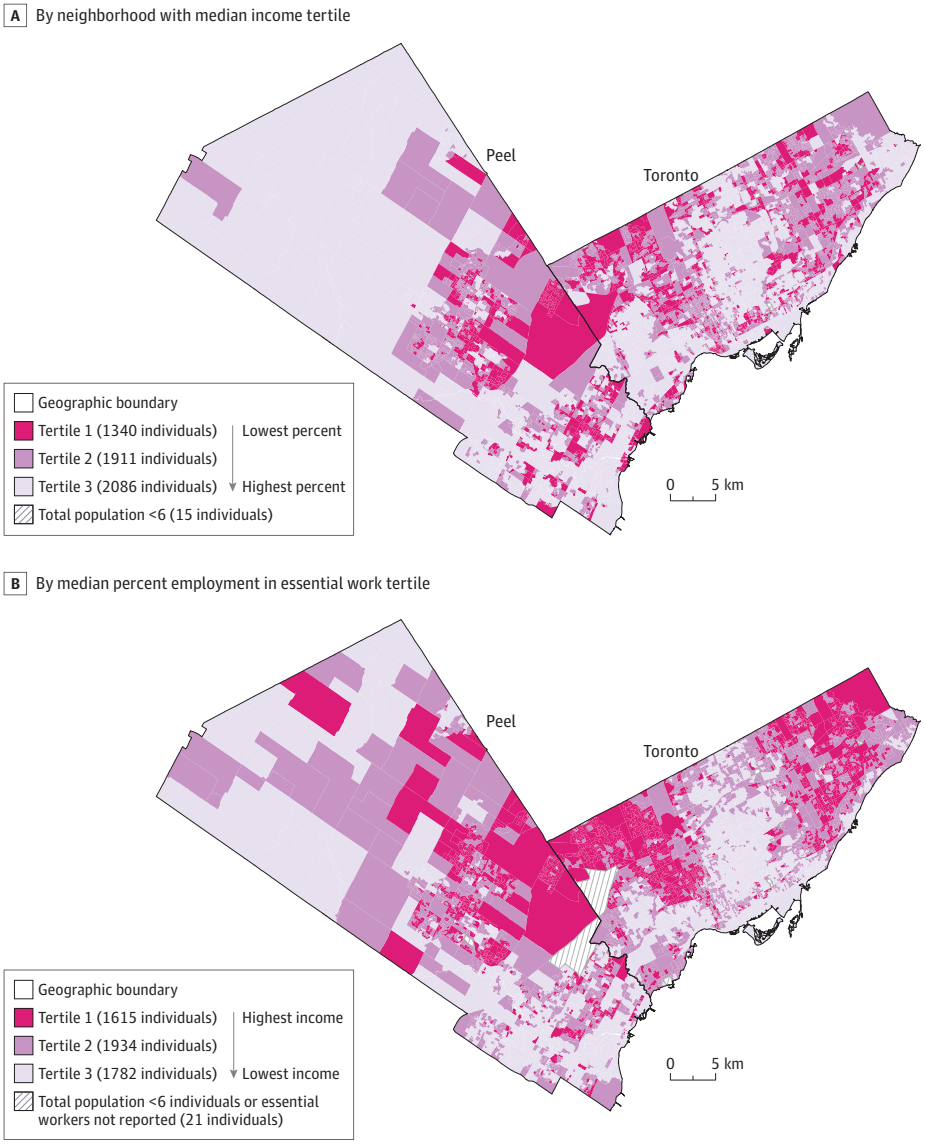
Results

A total of 19 912 COVID-19 cases were observed during the study period, of which 12 860 (64.6%) were screened for a VOC and 5084 (25.5%) screened positive. A similar pattern was observed with income tertiles. Of total cases within the study period, 8723 (43.8%) were in tertile 1, 7085 (35.6%) were in tertile 2, and 4104 (20.6%) were in tertile 3 (**Figure 2**A); whereas of VOC cases, 2228 (43.8%) were in tertile 1, 1757 (34.6%) were in tertile 2, and 1099 (21.6%) were in tertile 3 (Figure 2C).

When looking at essential work tertiles of total cases, 9597 (48.3%) were in tertile 1, 6504 (32.7%) were in tertile 2, and 3788 (19.0%) were in tertile 3 (Figure 2B). Among VOC cases in essential work tertiles, 2582 (50.8%) were in tertile 1, 1562 (30.8%) were in tertile 2, and 934 (18.4%) were in tertile 3 (Figure 2D).

Figure 1. Region of Peel and City of Toronto by Neighborhoods With Median Income Tertiles and Median Percentage Employment in Essential Work Tertiles



A, Median income tertiles were tertile 1: $33 819 (IQR, $29 337-37,054); tertile 2: $45 487 (IQR, $41 411-48,079); and tertile 3: $60 652 (IQR, $55 001-69,982). B, Median percentage employment in essential work tertiles were tertile 1: 63.2% (IQR, 59.4%-68.1%); tertile 2: 47.9% (IQR, 42.1%-52.0%); and tertile 3: 30.4% (IQR, 25.0%-35.3%).

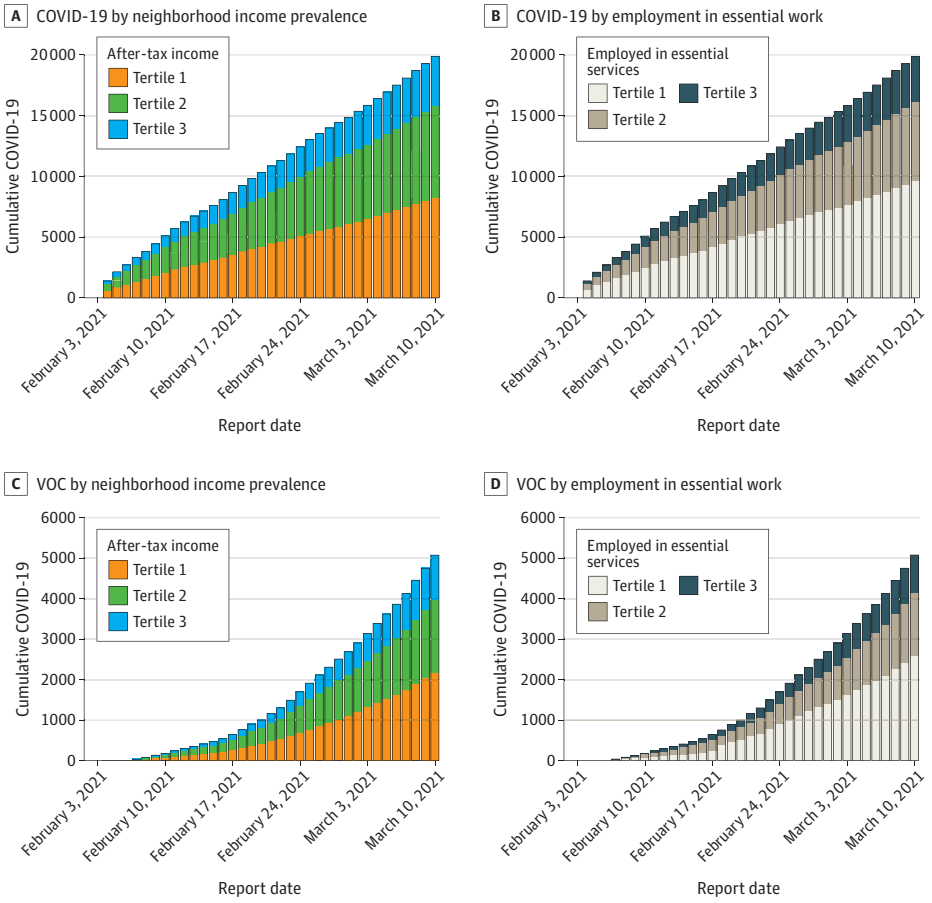
Figure 2. Cumulative COVID-19 Overall and Variants of Concern (VOC) Cases by Neighborhood-Level Prevalence of Income and by Essential Work in Toronto and Peel Regions, Canada



Discussion

These findings suggest that VOC of SARS-CoV-2, similar to wildtype SARS-CoV-2, are disproportionately associated with neighborhoods with lower income and a higher proportion of essential workers.[2] Notably, these analyses have some limitations. Use of ecological study design, rather than individual-level data on income and occupation for this analysis; and the potential for differential SARS-CoV-2 testing across tertiles, particularly less testing in low-income neighborhoods and essential work communities may result in underreporting both wildtype and VOC cases. Finally, not all samples were sent for VOC testing, and although testing was centralized, we cannot accurately ascertain if there were testing differences by region, with potential for a selection bias. Given the rapid mirroring of wildtype epidemics, these results suggest an association between essential work, income, and COVID-19 burden, which may be magnified by more transmissible variants. Reducing SARS-CoV-2 transmission and the associated morbidity and mortality necessitates tailored and equitable intervention strategies including vaccine prioritization and outreach services.

FluWatch

Public Health Agency of Canada | Agence de la santé publique du Canada

2018-19 Influenza Season (Aug 26, 2018 to Aug 24, 2019)

Overall Summary

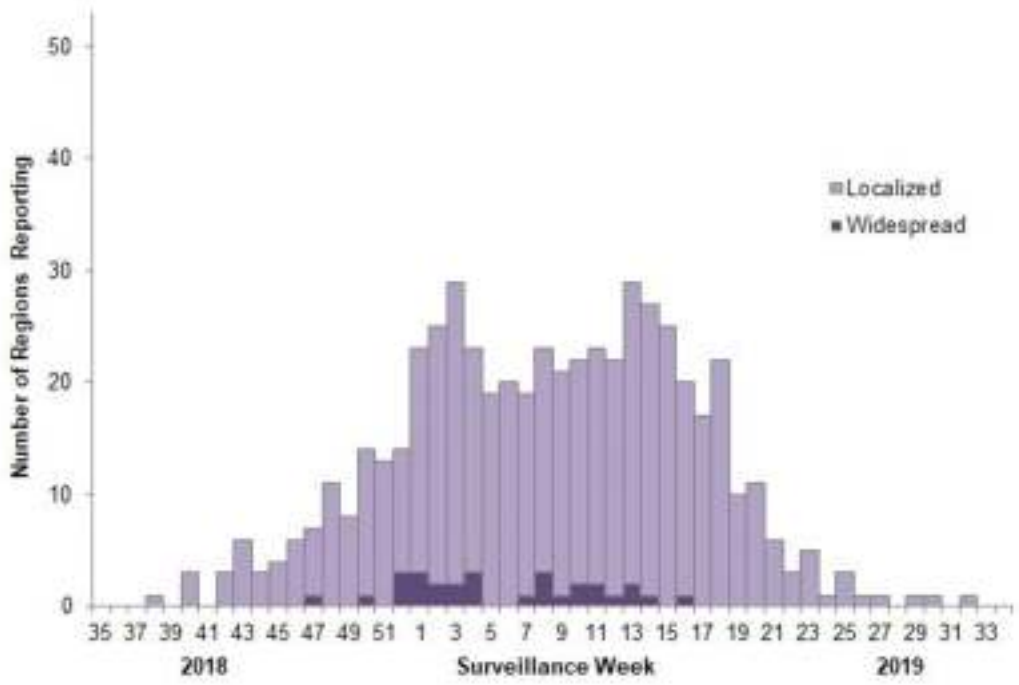
- During the influenza season, the FluWatch report is based on weekly data. This report is a summary of all of the data received for the 2018-19 influenza season and a comparison of these data to the previous five seasons.
- The 2018-19 influenza season in Canada was longer than the previous five seasons and was characterized by two waves of influenza A activity and very little influenza B circulation. The national season started in week 43 (October 21-27, 2018), peaked in week 52 (December 23-29, 2018) and ended in week 21 (May 19-25, 2019).
- A(H1N1) was predominant in the earlier part of the season (October to February) followed by a smaller wave of A(H3N2) circulation (March to April). Overall, A(H1N1) was the predominant strain nationally this season.
- Two waves of activity were observed in the number of reported outbreaks. The predominant subtype for typed outbreaks was A(H1N1) in the early part of the season (October to January), and A(H3N2) in the latter part of the season (Feburary onward).
- The annual seasonal hospitalization rate was above average compared to the previous five seasons. Adults 65 years of age and older had the highest overall hospitalization rate; however, the highest cumulative hospitalization rate shifted during the season from children 0-4 years of age (November to March) to adults 65 years of age and older (March onward), likely due to the second wave of A(H3N2).
- Overall, influenza vaccine coverage in the 2018-19 season (42%) was significantly higher than in the previous two seasons. Coverage was estimated at 34% for adults aged 18 to 64 years and 70% among seniors.
- Vaccine effectiveness studies in both the outpatient setting and adult inpatient setting observed good protection against A(H1N1) and little to no protection against A(H3N2) viruses relative to what is expected for influenza vaccine effectiveness.

Influenza/Influenza-like Illness (ILI) Activity (geographic spread)

Data on the geographic spread of influenza and influenza-like illness (ILI) are provided by all provinces and territories. All provinces and territories reported activity level data for each week of the 2018-19 influenza season.

- The number of surveillance regions reporting localized and widespread influenza activity peaked in week three and again in week 13 (Figure 1).
- Maps of the level of influenza activity reported by surveillance regions each week over the course of the season can be viewed here.

Figure 1 – Number of regions reporting widespread and localized influenza activity, Canada, weeks 2018-35 to 2019-34



Laboratory-Confirmed Influenza Detections

Data on laboratory-confirmed influenza detections are provided by 32 provincial, regional and some hospital laboratories. On average 99.6% of labs reported each week. During the 2018-19 season a total of 48,818 influenza detections were reported. Based on the seasonal thresholds for start and end of season (i.e. when the percentage of tests positive for influenza crossed 5%), the national influenza season started in week 43, peaked in week 52 and ended in week 21 (Figure 2).

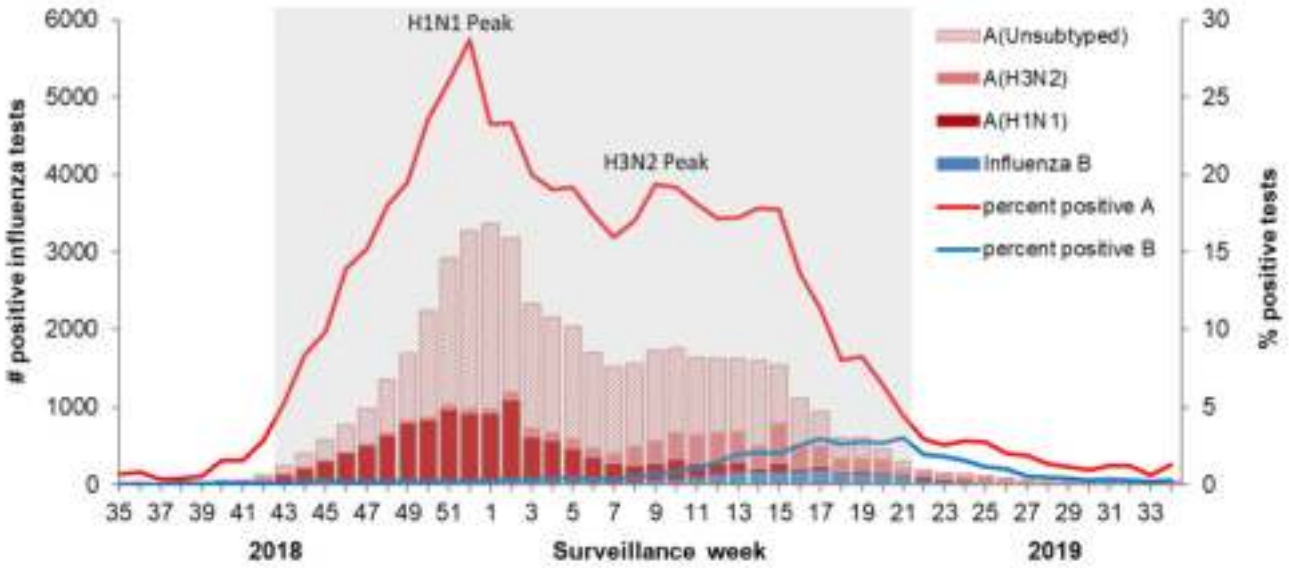
- Nearly all (95%) of influenza detections this season were influenza A. A(H1N1) was the predominant influenza strain and was the driver of the peak in percent positive detections in week 52. Among the 16,602 influenza A viruses that were subtyped this season, 69% were A(H1N1).
- The proportion of subtyped influenza A detections that were A(H3N2) began to increased markedly in mid-January (week three) and A(H3N2) became the predominant strain by week eight. This second more moderate wave of influenza A detections peaked in week nine and persisted near peak levels through to week 15.
- In the early part of the season (the A(H1N1) wave), influenza A activity was within the expected range; however, due to circulation of A(H3N2) in the latter part of the season, the overall proportion of detections of influenza A was higher compared to previous seasons.
- Compared to the last five seasons, the 2018-19 season started five weeks earlier than average; the number of weeks from the start of the season to the peak (10 weeks) was slightly longer than the average (nine weeks); and the length of the season (31 weeks) was six weeks longer than average (25 weeks).
- Canada observed the lowest cumulative total influenza B detections (5%) since the 2009 pandemic. Influenza B activity began to increase in week nine and peaked in week 17 but remained below previous seasonal values for the entire season.
- The distribution of influenza detections by type and subtype in provinces and territories was similar to the national distribution. The proportion of detections of influenza B was between zero and 5%. Among jurisdictions from which influenza A subtype information was provided, the proportion of A(H1N1) ranged from 62 to 100% of subtyped influenza A detections (Figure 3).

Detailed information on age and influenza type/subtype was received for 39,192 of laboratory-confirmed influenza cases. Among influenza A detections where subtype was identified (13,718), subtype distribution varied by age-group (Figure 4). A(H1N1) was the predominant subtype in all age groups except those 65 years of age and older, among

whom A(H3N2) was the predominant subtype (66%). Children less than five years of age had the highest proportion of A(H1N1) among subtyped influenza A detections (86%).

For more detailed weekly and cumulative influenza data, see the text descriptions for Figures 2 and 3 or the Respiratory Virus Detections in Canada Report.

Figure 2 – Number of positive influenza tests and percentage of positive tests, by type, subtype and report week, Canada, weeks 2018-35 to 2019-34



The shaded area indicates weeks where the positivity rate was at least 5% and a minimum of 15 positive tests were observed, signalling the period of seasonal influenza activity.

Data for week 14 excludes subtyping results from one jurisdiction due to batch reporting of subtype information. The results for week 14 should be interpreted with caution.

Figure 3 – Cumulative numbers of positive influenza specimens by type/subtype and province/territory, Canada, weeks 2018-35 to 2019-34

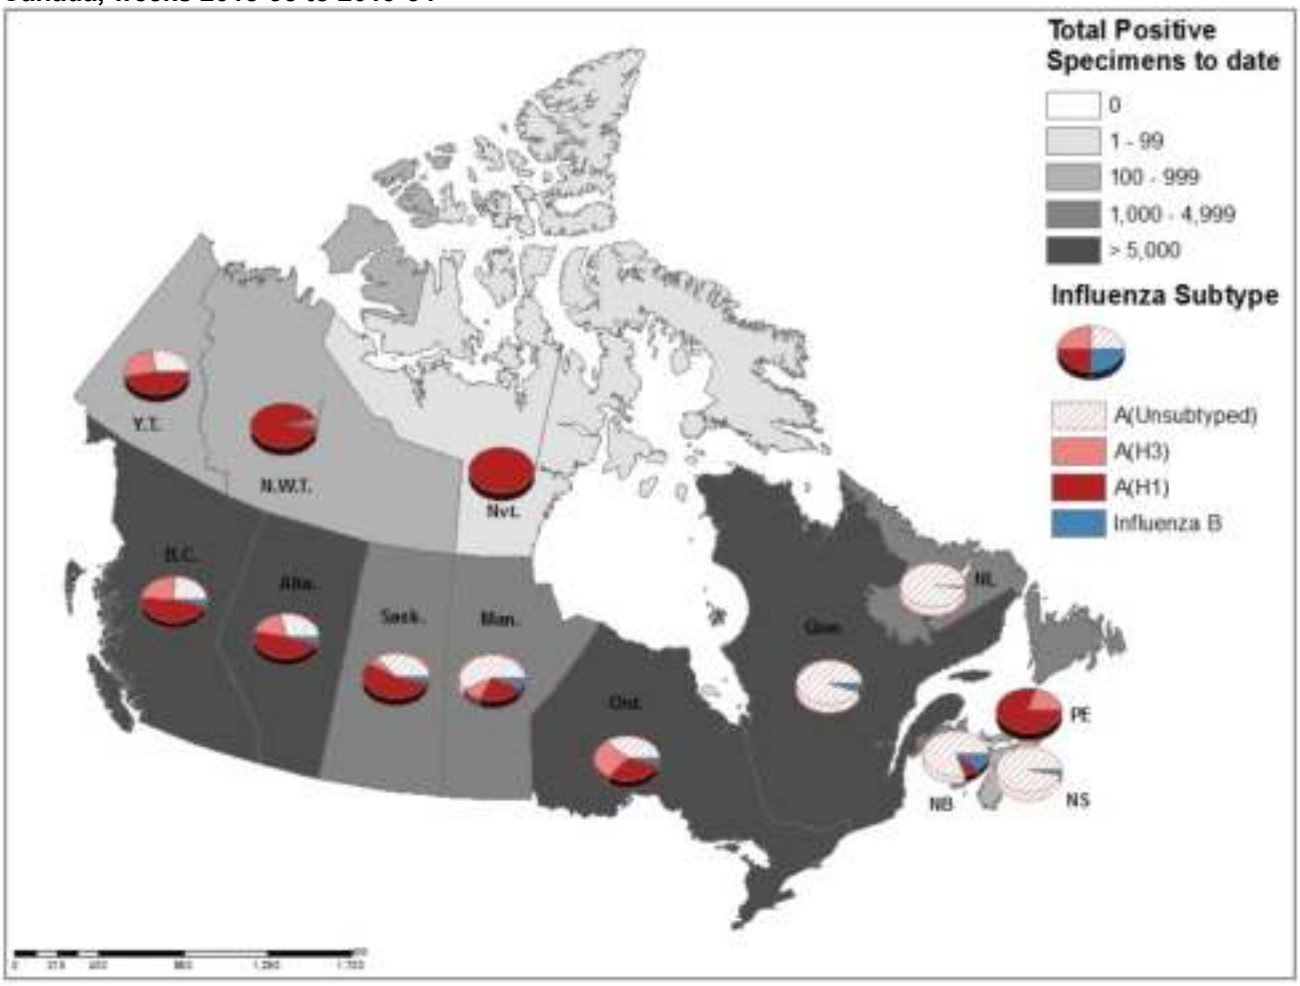


Figure 4 – Proportion of positive influenza A specimens by subtype and age-group reported through case-based laboratory reporting, Canada, weeks 2018-35 to 2019-34

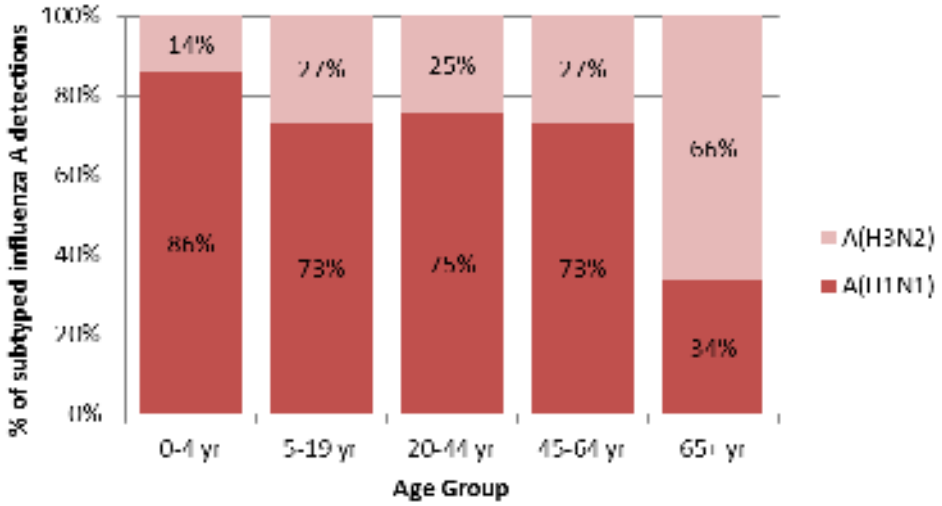


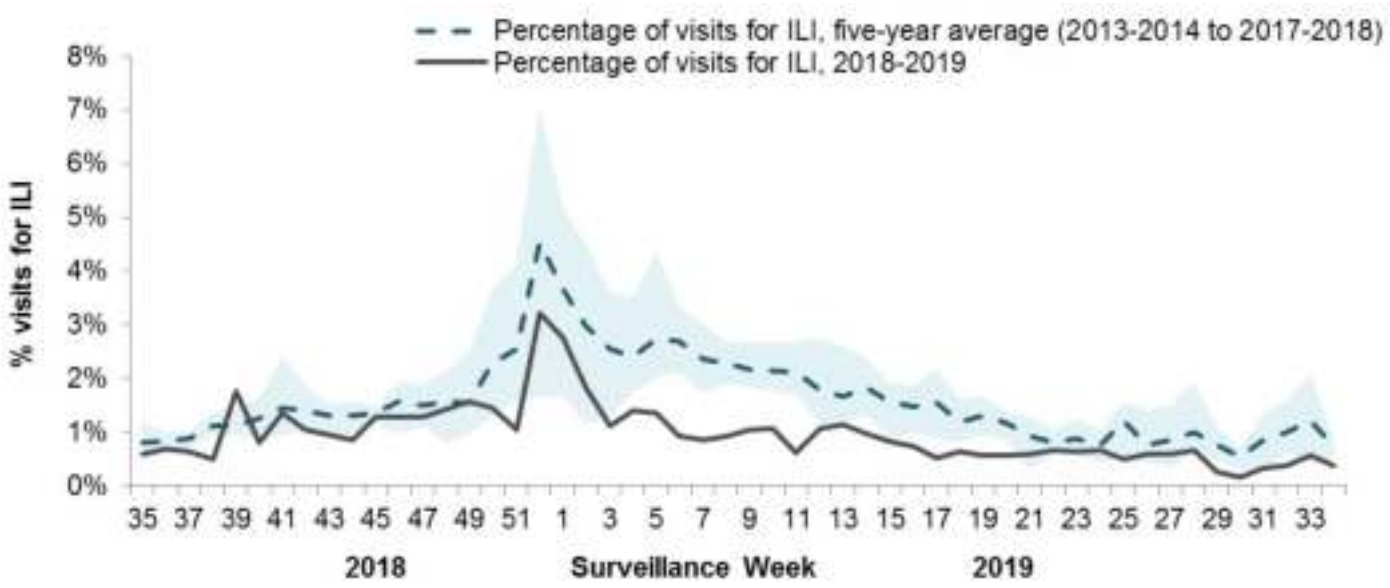
Syndromic / Influenza-like Illness Surveillance

Healthcare Practitioners Sentinel Syndromic Surveillance

On average, during the 2018-19 season, 106 healthcare practitioners across the country participated in influenza-like illness (ILI) surveillance for the FluWatch program. Each week these sentinel healthcare practioners report the proportion of patients in their practice who had ILI.

- Overall, ILI activity was below the five-year average for the majority of weeks this influenza season (range: 0.1% to 3.2%).
- 1.1% of all patient visits reported by sentinels were due to ILI this season (i.e. week 43 to week 21).
- The percentage of visitis for ILI reported by sentinels peaked in week 52 at 3.2%, consistent with the peak week of laboratory detections (Figure 5).
- For the majority of the season, the highest percentage of visits for ILI was reported among those less than 20 years of age. The lowest percentage of visits for ILI was reported among the 65+ year age group.

Figure 5 – Percentage of visits for ILI reported by sentinels by report week, Canada, weeks 2018-35 to 2019-34



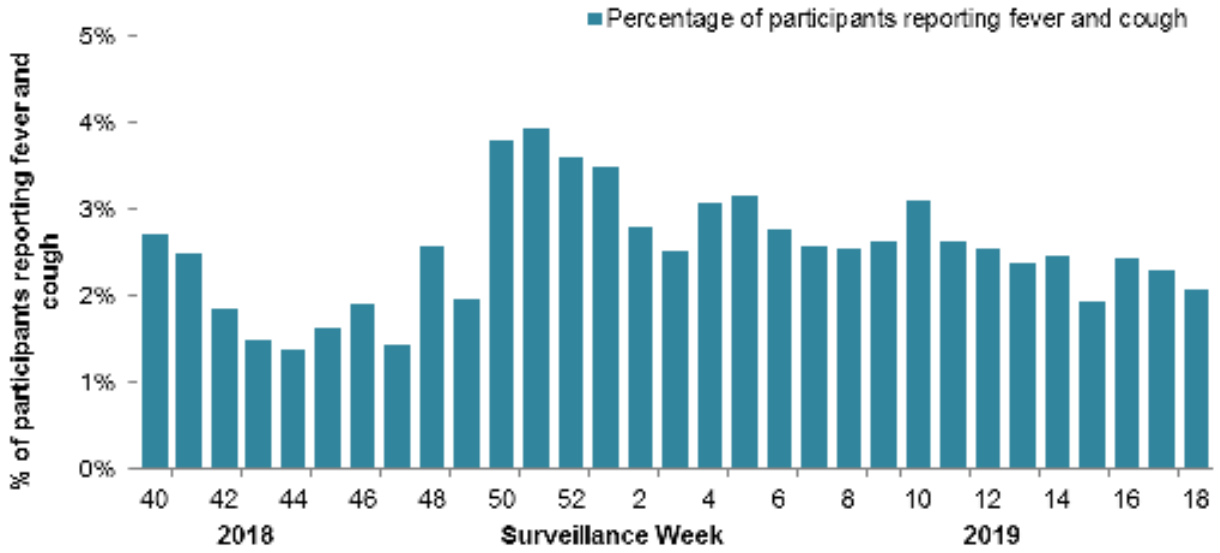
The shaded area represents the maximum and minimum percentage of visits for ILI reported by week from seasons 2013-2014 to 2017-2018

Participatory Syndromic Surveillance

FluWatchers are Canadians who report via a weekly online questionnaire if they have had symptoms of ILI in the preceding week. FluWatchers surveillance for the 2018-19 started in week 40 (October) and ended in week 18 (May). A total of 3,205 participants reported at least once this season, resulting in 64,728 completed questionnaires.

- The majority (75%) of FluWatchers particpants were adults 20-64 years of age. The age distribution of all FluWatchers participants this season was as follows:
  - 4% - 0 to 4 years of age
  - 15% - 5-19 years of age
  - 43% - 20 to 44 years of age
  - 33% - 45 to 64 years of age
  - 5% - 65 years of age and older
- 31% of FluWatchers reported experiencing cough and fever at least once this season.
- The percentage of FluWatchers reporting fever and cough peaked in week 51 with 3.9% of participants reporting cough and fever, consistent with the peak week of laboratory detections (Figure 6).
- A total of 1599 reports of cough and fever were reported by FluWatchers, of which 73% (1175) reported at least 24 hours off work or school, and 19% (306) reported a visit to a health care practitioner.
- A total of 46 tests for influenza and 15 positive tests were reported by FluWatchers.

Figure 6 – Percentage of FluWatchers participants reporting fever and cough, Canada, weeks 2018-40 to 2019-18



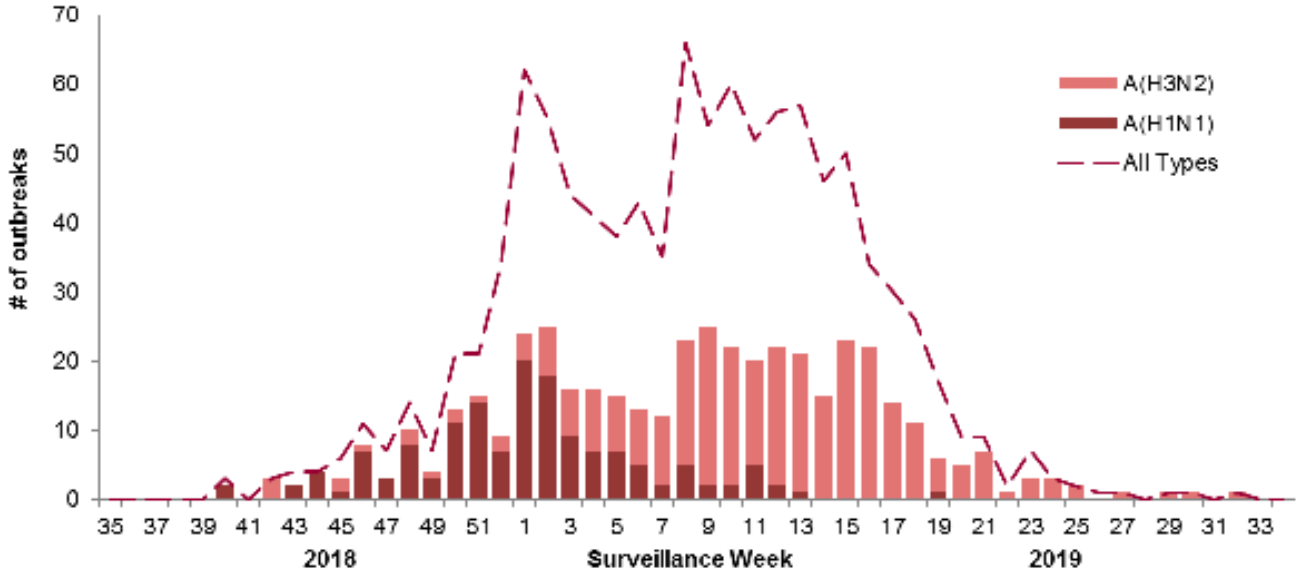
Influenza Outbreak Surveillance

Outbreak activity reports were provided by all provinces and territories each week this season. Not all provinces/territories conduct influenza outbreak surveillance in all the noted facilities. A total of 1038 laboratory-confirmed influenza outbreaks were reported (Figure 7).

- Two waves of activity were observed in the number of reported outbreaks.
- 62% (639) of reported outbreaks were in long-term care facilities (LTCF), 13% (138) were in acute care facilities, 3% (32) in schools and daycares and 22% (229) were in other settings (e.g. retirement homes, correctional facilities, etc.).
- Among the outbreaks for which influenza type (951) and subtype (446) were available, 98% (929) were associated with influenza A and 67% (298) were associated with influenza A(H3N2) respectively.
- Among the 220 outbreaks for which facility type was known and influenza A subtype was available:
    - 67% (173) of LTCF outbreaks were associated with influenza A(H3N2)
    - 65% (30) of acute care facility outbreaks were associated with influenza A(H3N2)
    - 85% (17) of school outbreaks were associatd with influenza A(H1N1).
- The predominant subtype for typed outbreaks was A(H1N1) from weeks 43 to two and A(H3N2) from weeks six to 29; between weeks three to five the number of A(H1N1) and A(H3N2) outbreaks was approximately equal.

In addition, a total of 180 outbreaks of influenza-like illness were reported; 112 occurred in LTCF, 62 in schools, five in acute care facilities, and one in a setting categorized as “other” (e.g. retirement homes, correctional facilities, etc.)

Figure 7 – Number of influenza outbreaks by report week (all types) and number of subtyped influenza A outbreaks by subtype and report week, Canada, weeks 2018-35 to 2019-34



Severe Outcomes Influenza Surveillance

Provincial/Territorial Influenza Hospitalizations and Deaths

Nine provinces and territories report influenza associated hospitalizations and deaths for all ages to FluWatch each week – Alberta, Manitoba, Saskatchewan, Newfoundland, Prince Edward Island, Nova Scotia, New Brunswick, Yukon and the Northwest Territories. The number of reporting provinces/territories varied over the course of the season. On average, seven provinces/territories reported each week.

A total of 3,657 influenza-associated hospitalizations were reported which corresponds to an annual seasonal hospitalization incidence of 45 hospitalizations per 100,000 population in the 2018-19 season (Table 1).

- 96% (3,525) were associated with influenza A.
- Among the 2,149 hospitalized cases for which the influenza subtype was available, the majority were associated with A(H1N1) (68%).
- Similar to the temporal pattern observed in laboratory detections, in the earlier part of the season (October to February) the majority (93%) of hospitalizations for which the influenza subtype was available were A(H1N1). In the latter part of the season (March to April) the majority (87%) of hospitalizations were A(H3N2).
- Overall, adults ≥ 65 years of age had the highest rate of hospitalizations (132 hospitalizations per 100,000 population); however, children 0-4 years of age had the highest cumulative hospitalization rate in the first part of the season from weeks 45 to 10, while adults ≥ 65 years of age had the highest cumulative rates in the second part of the season from weeks 10 to 29 which is likely due to the change in predominant subtype over time.
- This season's hospitalization rate (45 per 100,000 population) was slightly above the average compared to the previous five seasons (40 per 100,000 population), and notably higher than the annual seasonal hospitalization rates of the previous two A(H1N1) predominant seasons (25 and 34 per 100,000 population). The higher observed hospitalization rate relative to previous A(H1N1)-predominant seasons is likely due to the circulation of A(H3N2) in the latter part of the season.

Table 1 – Estimated annual seasonal incidence of influenza hospitalizations (per 100,000 population) by age group reported by participating provinces and territories[1], Canada, 2013/14 to 2018/19 influenza seasons

	Influenza Season (Predominant Influenza A Subtype)					
Age Groups (Years)	2013-14[2] (H1N1)	2014-15 (H3N2)	2015-16 (H1N1)	2016-17 (H3N2)	2017-18 (H3N2)	2018-19 (H1N1)
0-4	51	46	96	42	69	97
5-19	7	16	16	10	17	22
20-44	13	13	16	6	12	14
45-64	29	16	37	22	41	40
65+	41	207	68	143	268	132
Overall	25	45	34	34	64	45

1. Influenza-associated hospitalizations are reported by N.L., P.E.I, N.S., N.B., Man., Alb., Y.T. and N.W.T. Data provided by Sask is not included in these rates as only hospitalizations that require intensive medical care are reported by Sask. The annual seasonal hospitalization rate for a given season is calculated using the population by age-group in participating provinces and territories.
2. During the 2013-14 season N.B. did not report influenza-associated hospitalizations.
3. Highlighted boxes indicate the age group with the highest rate during the season.

A total of 613 ICU admissions and 224 deaths were reported this season.

- 97% (595) of reported ICU admissions and 98% (220) of reported deaths were associated with influenza A.
- Similar to the previous two A(H1N1)-predominant seasons, the highest proportion of ICU admissions was reported among adults 45-64 years of age (39%).
- The highest proportion of deaths was reported among adults ≥ 65 years of age (66%). This was approximately 20% higher than the number reported in the previous two A(H1N1)-predominant seasons and approximately 20% lower than the number reported in the previous three A(H3N2)-predominant seasons, likely as a result of the mixed A(H1N1) and A(H3N2) season.

Pediatric Influenza Hospitalizations and Deaths

Pediatric hospitalization data are provided by the Canadian Immunization Monitoring Program Active (IMPACT). IMPACT actively monitors pediatric influenza hospitalizations from 12 hospital sites in British Columbia, Alberta, Saskatchewan, Manitoba, Ontario, Quebec, Nova Scotia and Newfoundland.

A total of 1,352 pediatric hospitalized cases were reported this season. While the total number of hospitalized cases was above the five-year average (mean: 888; range: 593 to 1350) and the average of the last two A(H1N1)-predominant seasons (mean:1,032; range:714 to 1350), the number of hospitalized cases each week was within the expected range based on the minimum and maximum number of weekly cases observed in the previous five seasons.

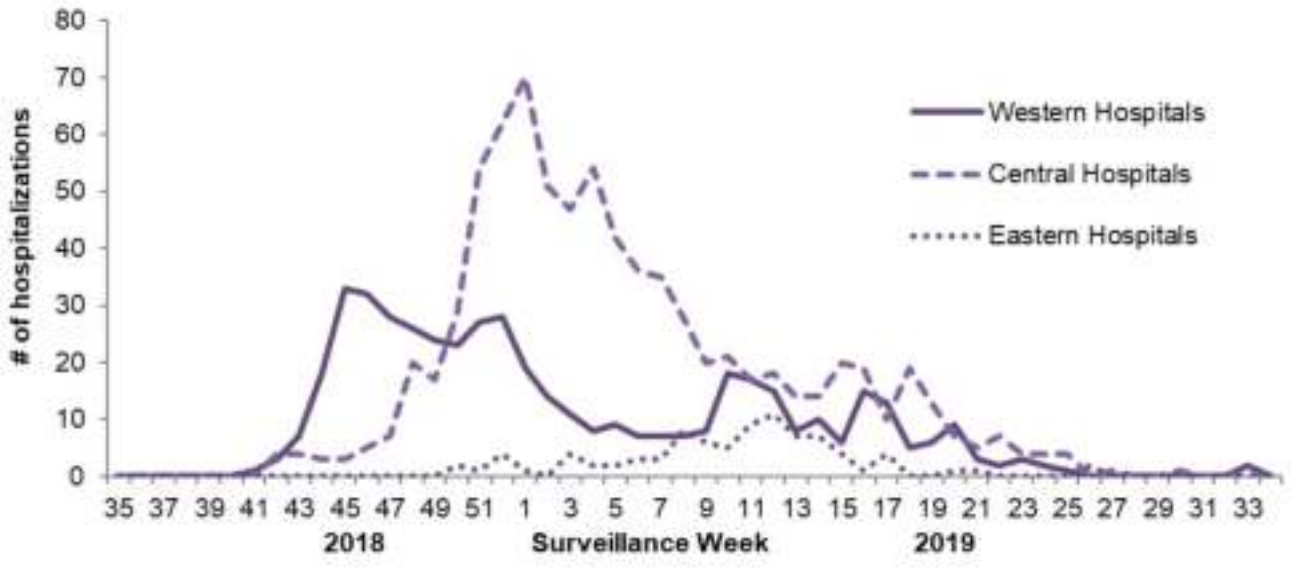
- Nationally, reports began earlier than previous seasons and peaked in week 52 consistent with the peak week of laboratory detections; however peaks varied by region, with an earlier peak in activity in sites in western Canada and a later peak of activity in sites in eastern Canada (Figure 8).
- More subtle peaks in activity can also be observed in western and central sites between weeks nine and 20 and in weeks 17 to 21 in eastern sites which may have resulted from the second wave of A(H3N2) activity and, along with this season's longer duration, may have contributed to the higher than average hospitalization counts.
- 91% (1,227) of pediatric hospitalized cases were associated with influenza A.
- Among the 402 pediatric hospitalized cases for which the influenza subtype was available, 80% (323) were associated with A(H1N1).
- 66% of pediatric hospitalized cases were among children under five years of age (Figure 9). This is consistent with the average proportion of hospitalized cases under five in the past five seasons (65%) and slightly less than the average of the two post-pandemic A(H1N1)-predominant seasons (71%) which were in 2013-14 and 2015-16.

Among the 1,352 pediatric hospitalized cases, a total of 271 (20%) ICU admissions and 10 (0.7%) deaths were reported. The proportion of hospitalized cases resulting in ICU admission was slightly above the average from the past five seasons (17%) and the last two A(H1N1)-predominant seasons (17%). The proportion of hospitalized cases

resulting in death was consistent with the average from the past five seasons (0.6%) and slightly above the average of the last two A(H1N1)-predominant seasons (0.4%).

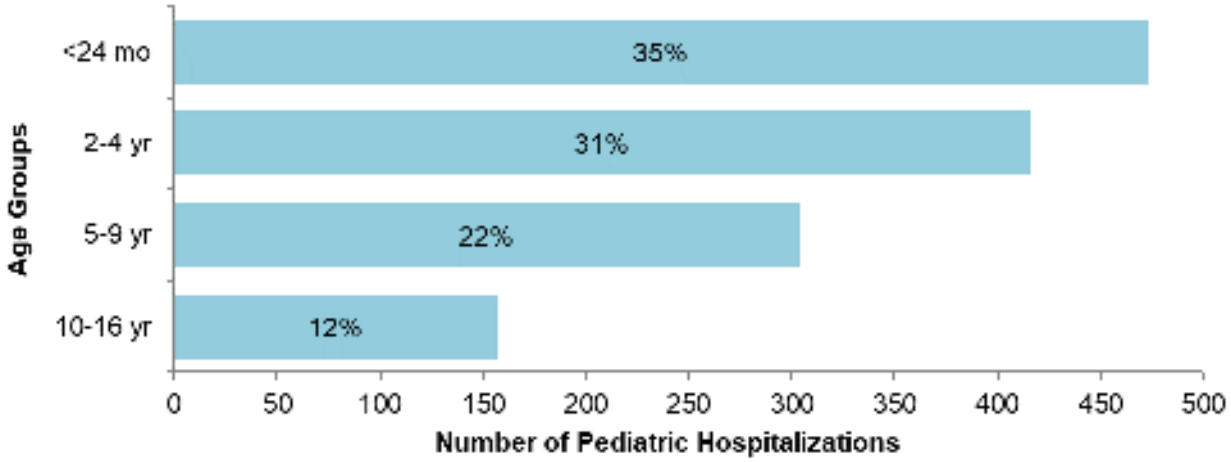
- 59% (161) of ICU admissions were among children under five years of age.
- 92% (248) of ICU admissions were associated with influenza A; 83% of the 111 cases for which the influenza A subtype was available were associated with A(H1N1).
- 80% (8) of deaths occurred in children two to four years of age.
- All deaths were associated with influenza A.

Figure 8 – Number of pediatric (≤16 years of age) hospitalizations reported by the IMPACT network, by region and by week of admission, Canada, weeks 2018-35 to 2019-34



Western hospitals consist of four sites in Vancouver, Calgary, Edmonton and Saskatoon. Central hospitals consist of 6 sites in Winnipeg, Toronto, Ottawa, Montreal and Quebec City. Eastern hospitals consist of 2 sites in Halifax & St. John's.

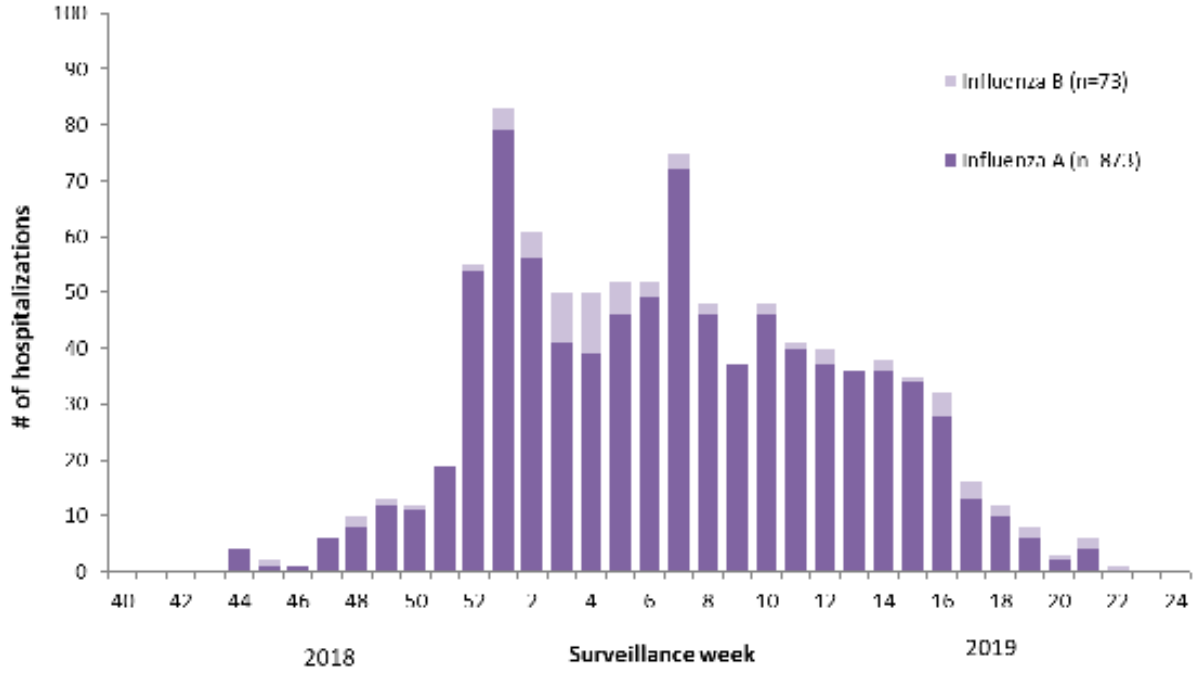
Figure 9 – Number and percentage of pediatric hospitalizations (≤16 years of age) with influenza by age-group reported by the IMPACT network, Canada, weeks 2018-35 to 2019-34



Adult Influenza Hospitalizations and Deaths

Surveillance of laboratory-confirmed influenza-associated adult (≥16 years of age) hospitalizations by the Canadian Immunization Research Network (CIRN) Serious Outcomes Surveillance (SOS) network began on November 1st (week 44) for the 2018-19 season and ended on June 1st (week 22). CIRN-SOS collects influenza hospitalization data from eight hospital sites in Ontario, Quebec, and Nova Scotia.

Figure 10 – Number of adult hospitalizations (≥16 years of age) with influenza reported by CIRN-SOS by surveillance week and influenza type, Canada, weeks 2018-44 to 2019-22



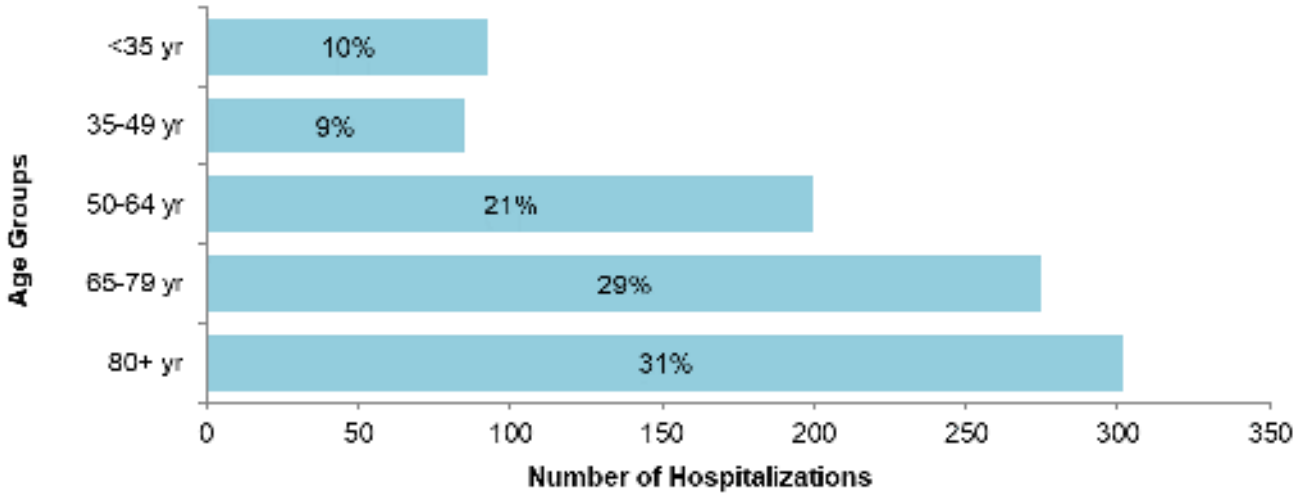
A total of 946 hospitalizations were reported by CIRN-SOS sentinels this season (age ≥16) (Figure 10):

- 92% (873) of hospitalizations were associated with influenza A.
- Among the 838 hospitalized cases for which the influenza subtype was available, 52% (439) were associated with A(H1N1).
- The highest proportion of hospitalized cases (31%) was among adults aged 80 years and over, followed by adults aged 65-79 years (29%) (Figure 11). The mean age of hospitalized cases was 67 years (range: 16 to 100).
- 89% of hospitalized cases reported at least one comorbid condition; vascular disorders were the most common comorbity (70% of all patients reporting a comorbidity) followed by cardiac disorders (43%).

A total of 137 (14%) ICU admissions and 65 (7%) deaths were reported.

- 95% (131) of ICU admissions were associated with influenza A.
- The majority of ICU admissions were among adults under the age of 65 (63%).
- The majority of deaths occurred among adults over the age of 65 (75%) with a mean age of 77 years.

Figure 11 – Number and percentage of adult hospitalizations (≥16 years of age) with influenza by age group reported by CIRN-SOS, Canada, 2018-19, weeks 2018-44 to 2019-22



Influenza Strain Characterizations

During the 2018-19 season, the National Microbiology Laboratory (NML) characterized 2,545 influenza viruses received from Canadian laboratories: 1,656 A(H1N1), 649 A(H3N2), 240 influenza B. Antigenic characterization is established by hemagglutination inhibition (HI) assay using cell-passaged vaccine reference viruses for A(H1N1) and influenza B, and the egg-passaged vaccine reference virus for A(H3N2). Over recent years, circulating strains of A(H3N2) have evolved, and are increasingly difficult to characterize by HI assay. Genetic characterization is established by sequencing the hemagglutinin gene of the influenza viruses to compare their genetic properties.

Influenza A(H3N2)

The influenza A(H3N2) component of the 2018-19 Northern Hemisphere influenza vaccine was an A/Singapore/INFIMH-16-0019/2016-like virus which belongs to the genetic group 3C.2a1.

All of the A(H3N2) viruses (649) were genetically characterized and 42% (378) of A(H3N2) viruses also grew to sufficient hemagglutination titer for antigenic characterization by HI assay (Table 2). Among all influenza A(H3N2) viruses genetically characterized, the most common subclade observed this season was 3C.2a1 (Figure 12). Of the A(H3N2) viruses characterized antigenically by HI assay (Figure 13-A):

- 56% (212) were characterized as A/Singapore/INFIMH-16-0019/2016-like by HI testing using antiserum raised against egg-propagated A/Singapore/INFIMH-16-0019/2016.
- 44% (166) of viruses showed reduced titer with ferret antisera raised against egg-propagated A/Singapore/INFIMH-16-0019/2016
- Among A(H3N2) viruses that showed reduced titer to A/Singapore/INFIMH-16-0019/2016, a greater proportion belonged to the genetic subclade 3C.3a. This is consistent with the genetic differences between subclades 3C.3a and 3C.2a1.

Table 2 – Genetic and antigenic characterization among characterized A(H3N2) viruses, Canada, weeks 2018-35 to 2019-34 (n=648)

Genetic clade	Genetic charaterization only	Antigenic characterization:		Total A(H3N2)
		Similar to A/Singapore/INFIMH-16-0019/2016	Reduced titer to A/Singapore/INFIMH-16-0019/2016	
Clade 3C.2a	20	17	3	40
Subclade 3C.2a1	242	132	16	390
Clade 3C.3a	8	63	147	218
Total	270	212	166	648

Influenza A(H1N1)

The influenza A(H1N1) component of the 2018-19 Northern Hemisphere influenza vaccine was an A/Michigan/45/2015-like virus.

Approximately 97% (1612) of the A(H1N1) viruses characterized were antigenically similar to A/Michigan/45/2015, while only 3% (44) of viruses showed reduced titer with ferret antisera raised against cell culture-propagated A/Michigan/45/2015 (Figure 13-B).

Influenza B

The recommended influenza B components for the 2018-19 Northern Hemisphere influenza vaccine were an B/Colorado/06/2017-like virus (Victoria lineage) and a B/Phuket/3073/2013-like virus (Yamagata lineage). The B/Colorado/06/2017-like virus was included in both the trivalent and quadrivalent vaccines. The B/Phuket/3073/2013-like virus was included in the quadrivalent influenza vaccine.

The majority of B viruses characterized, 70% (168), showed reduced titer with ferret antisera raised against cell culture-propagated B/Colorado/06/2017 (Figure 13-C). Sequence analysis showed that 96% (162) of viruses that showed reduced titer had a three amino acid deletion (162-164) in the hemagglutinin gene. Of the remaining B viruses characterized, 19% (46) were characterized as B/Colorado/06/2017-like (Victoria lineage) and 11% (26) were characterized as B/Phuket/3073/2013-like (Yamagata lineage).

Figure 12 – Distribution of genetic clades among characterized influenza A(H3N2) viruses, Canada, weeks 2018-35 to 2019-34

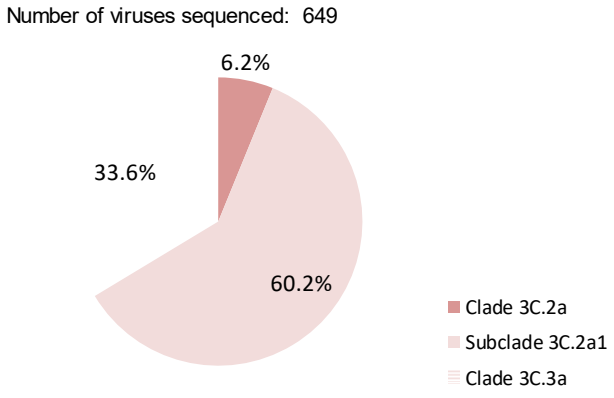


Figure 13 – Distribution of antigenic phenotypes among characterized influenza viruses, Canada, weeks 2018-35 to 2019-34

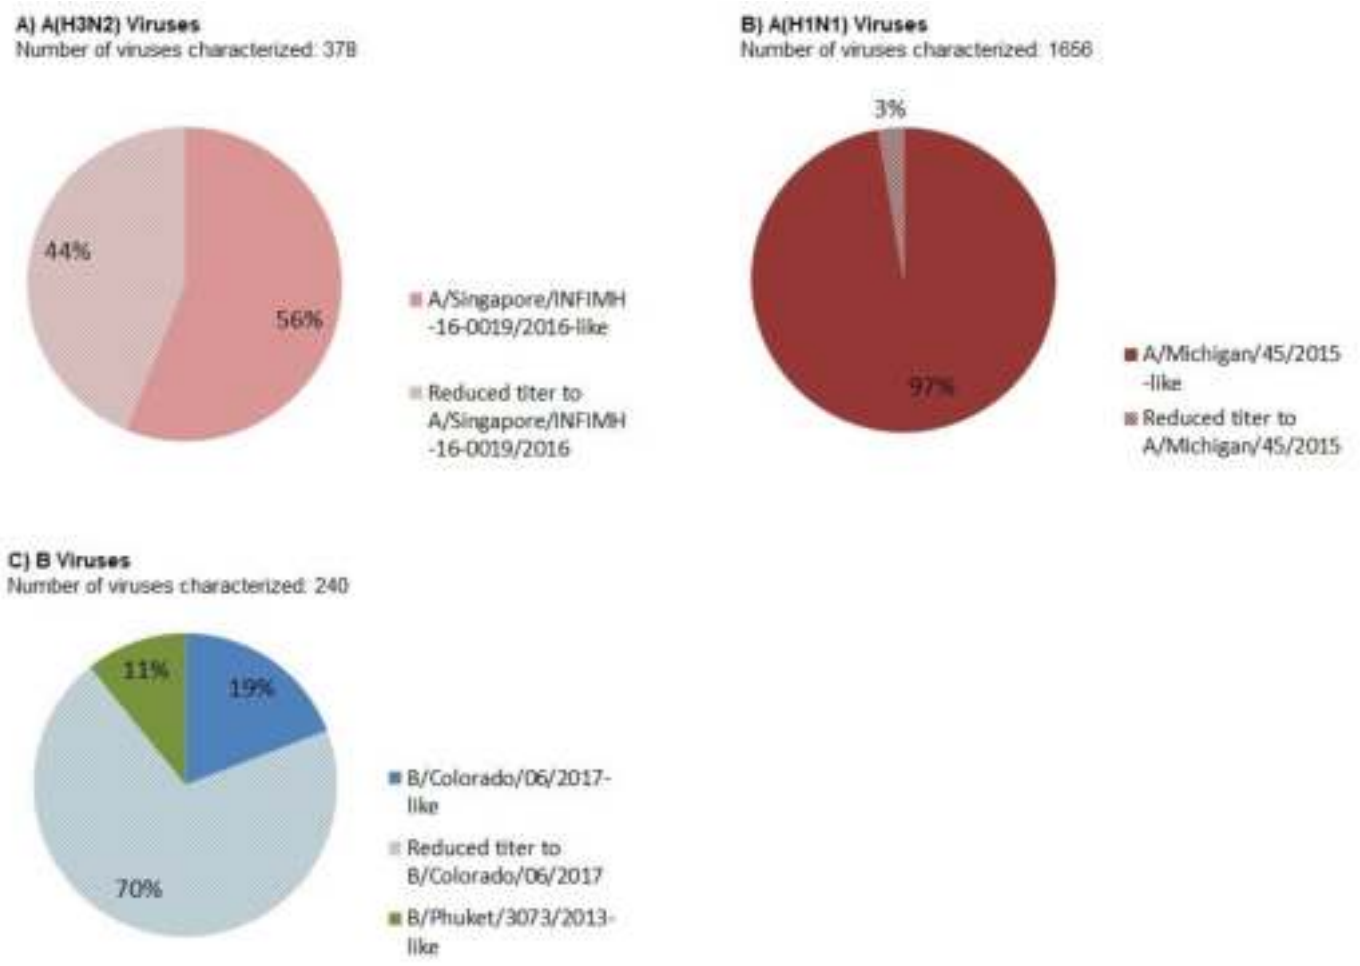

Antiviral Resistance

All influenza viruses characterized at the NML in the 2018-19 season were resistant to amantadine and sensitive to zanamivir. All influenza A(H3N2), all influenza B viruses, and all but four A(H1N1) viruses were sensitive to oseltamivir. The four A(H1N1) viruses resistant to oseltamivir had a H275Y mutation in the viral neuraminidase. The proportion of influenza viruses resistant to oseltamivir in 2018-19 is similar to recent seasons. Since the 2009 pandemic, nearly all circulating strains of influenza have been sensitive to oseltamivir and zanamivir. Widespread resistance to amantadine among influenza A viruses has been observed for more than 10 years.

Table 3 – Proportion of characterized influenza viruses resistant to antivirals by type and subtype, Canada, 2018-35 to 2019-34

Virus type and subtype	Oseltamivir		Zanamivir		Amantadine	
	# tested	# resistant (%)	# tested	# resistant (%)	# tested	# resistant (%)
A (H3N2)	222	0 (0%)	222	0 (0%)	135	135 (100%)
A (H1N1)	1084	4 (0.4%)	1082	0 (0%)	391	391 (100%)
B	142	0 (0%)	142	0 (0%)	NA[1]	NA[1]
TOTAL	1448	4 (0.3%)	1446	0 (0%)	526	526 (100%)

[1]NA: Not Applicable

Vaccine Monitoring

Vaccine monitoring refers to activities related to the monitoring of influenza vaccine coverage and effectiveness.

The quadrivalent vaccines used in the 2018-19 northern hemisphere influenza season contained:

- an A/Michigan/45/2015 (H1N1)pdm09-like virus;
- an A/Singapore/INFIMH-16-0019/2016 (H3N2)-like virus;
- a B/Colorado/06/2017-like virus (B/Victoria/2/87 lineage); and
- a B/Phuket/3073/2013-like virus (B/Yamagata/16/88 lineage).

The B/Colorado/06/2017-like virus was included in both the trivalent and quadrivalent vaccines.

Vaccine Coverage

The Seasonal Influenza Immunization Coverage Survey is an annual telephone survey conducted between January and February that collects information from Canadians on whether they received the annual seasonal influenza vaccine that season. Vaccine coverage is measured as the percentage of people who received the influenza vaccine in a specific influenza season. More detail on the methodology used for the coverage survey can be viewed here.

Overall, influenza vaccination coverage in the 2018-2019 season (42%) was significantly higher than the 2017-2018 season (38%) and the 2016-2017 season (36%). The vaccination rate was lowest among adults 18-64 years of age without any chronic medical condition (31%); however, coverage increased mostly among this subgroup when compared to the previous two seasons. Among high-risk groups, vaccination coverage rates for adults 18-64 years of age with a chronic medical condition (43%) and seniors 65 years of age and older (70%) remained steady over the past three seasons.

Table 4 – Influenza vaccine coverage among adults (≥ 18 years of age) by age group, gender and chronic disease[1], Seasonal Influenza Vaccination Coverage Survey, Canada, September 2018-February 2019

	Male		Female		Combined	
Age group (years)	Total	Vaccine Coverage (%)	Total	Vaccine Coverage (%)	Total	Vaccine Coverage (%)
All adults (≥18)	1568	36.6	2150	46.8	3726	41.8
18-64	1252	28.6	1640	39.9	2898	34.3
without chronic diseases	948	25.8	1171	36.1	2124	30.8
with chronic diseases	304	36.3	465	48.5	770	42.8
≥65	316	69.0	510	70.9	828	69.9

[1]Excluded from stratified analysis: eight people who did not disclose their gender and four people (18-64 years old) who did not disclose whether they had any chronic diseases.

Vaccine Effectiveness

The Canadian Sentinel Practitioner Surveillance Network (SPSN) provides estimates of the effectiveness of the seasonal influenza vaccine in preventing primary care visits for laboratory confirmed influenza among Canadians of all ages but primarily those from 20-64 years of age.

Based on data collected between November 1, 2018 and April 30, 2019, VE against any influenza, foremost driven by A(H1N1) viruses, was 56% (95% CI: 47 to 64%), and for A(H1N1) alone was 67% (95% CI: 58 to 75%) (Table 5). This substantial protection against A(H1N1) was observed in all age groups. Conversely, the SPSN reported little or no vaccine protection against A(H3N2) viruses, with an overall VE against medically-attended outpatient A(H3N2) illness of 17% (95% CI: -13 to 39). Overall, the A(H3N2) VE estimate for 2018-19 was lower than expected generally for

A(H3N2) vaccines (~30%), and similar to that observed by SPSN in the 2017-18 A(H3N2)-dominant season where VE was estimated at 14% (95% CI: -8 to 31).

More information on the SPSN including study methodology and available publications can be viewed here.

The Serious Outcomes Surveillance (SOS) Network of the Canadian Immunization Research Network (CIRN-SOS) provides estimates of the effectiveness of the seasonal influenza vaccine in preventing hospitalization for laboratory-confirmed influenza in adults.

Based on data collected between November 1, 2018 and June 1, 2019 among adult (≥16 years of age) hospitalized cases of influenza, VE against any influenza was 43% (95% CI: 28 to 55%), and for A(H1N1) alone was 68% (95% CI: 52 to 79%). CIRN-SOS also reported little or no vaccine protection against A(H3N2) viruses, with an overall VE against hospitalized cases of influenza A(H3N2) of 19% (95% CI: -35 to 51). The number of influenza B hospitalized cases was too low to calculate an adjusted VE estimate.

More information on the CIRN-SOS Network including study methodology and available publications can be viewed here.

Table 5 – Vaccine effectiveness estimates against primary care visits (SPSN - November 1, 2018, to April 30, 2019) and hospitalizations (CIRN-SOS - November 1, 2018 to June 1, 2019)

	SPSN (Primay Care Visits)†		CIRN-SOS (Adult Hospitalizations)	
	VE(%) (CI)*	N	VE(%) (CI)**	N
All Influenza	56 (47, 64)	3034	43 (28, 55)	1350
Influenza A	55 (46, 63)	2992	58 (43, 69)	1105
Influenza A H1N1	67 (58, 75)	2630	68 (52, 79)	562
Influenza A H3N2	17 (-13, 39)	1993	19 (-35, 51)	409
Influenza B	72 (27, 89)	1703	n/a***	140

† SPSN 2018-19 estimates are published and available here and here
CI: 95% confidence interval
*adjusted for age, province, specimen collection interval and calendar time (natural cubic spline with 3 equally spaced knots)
** VE for All Influenza, Influenza A, Influenza A/H1, and Influenza A/H3 was adjusted for age, pregnancy and current or past smoker.
VE for 16-49 and 50-64 age groups was adjusted for age, body mass index categories, pregnancy and medications prior to admission.
VE for 65-75 and >75 age groups was adjusted for age, Frailty index prior to admission; and current or past smoker.
***Sample size was too small to calculate an adjusted estimate

COVID-19 daily epidemiology update

Updated: December 13, 2021, 7 pm EST

Summary of COVID-19 cases across Canada and over time. Contains detailed data about the spread of the virus over time and in different regions of the country. Includes breakdowns by age and sex or gender. Provides an overview of hospitalizations and deaths, testing, variants of concern and exposures.

Key updates as of December 13, 2021, 7 pm EST

Cases today	Total cases
4,233	1,840,919

Active cases	Total resolved
36,844	1,774,134

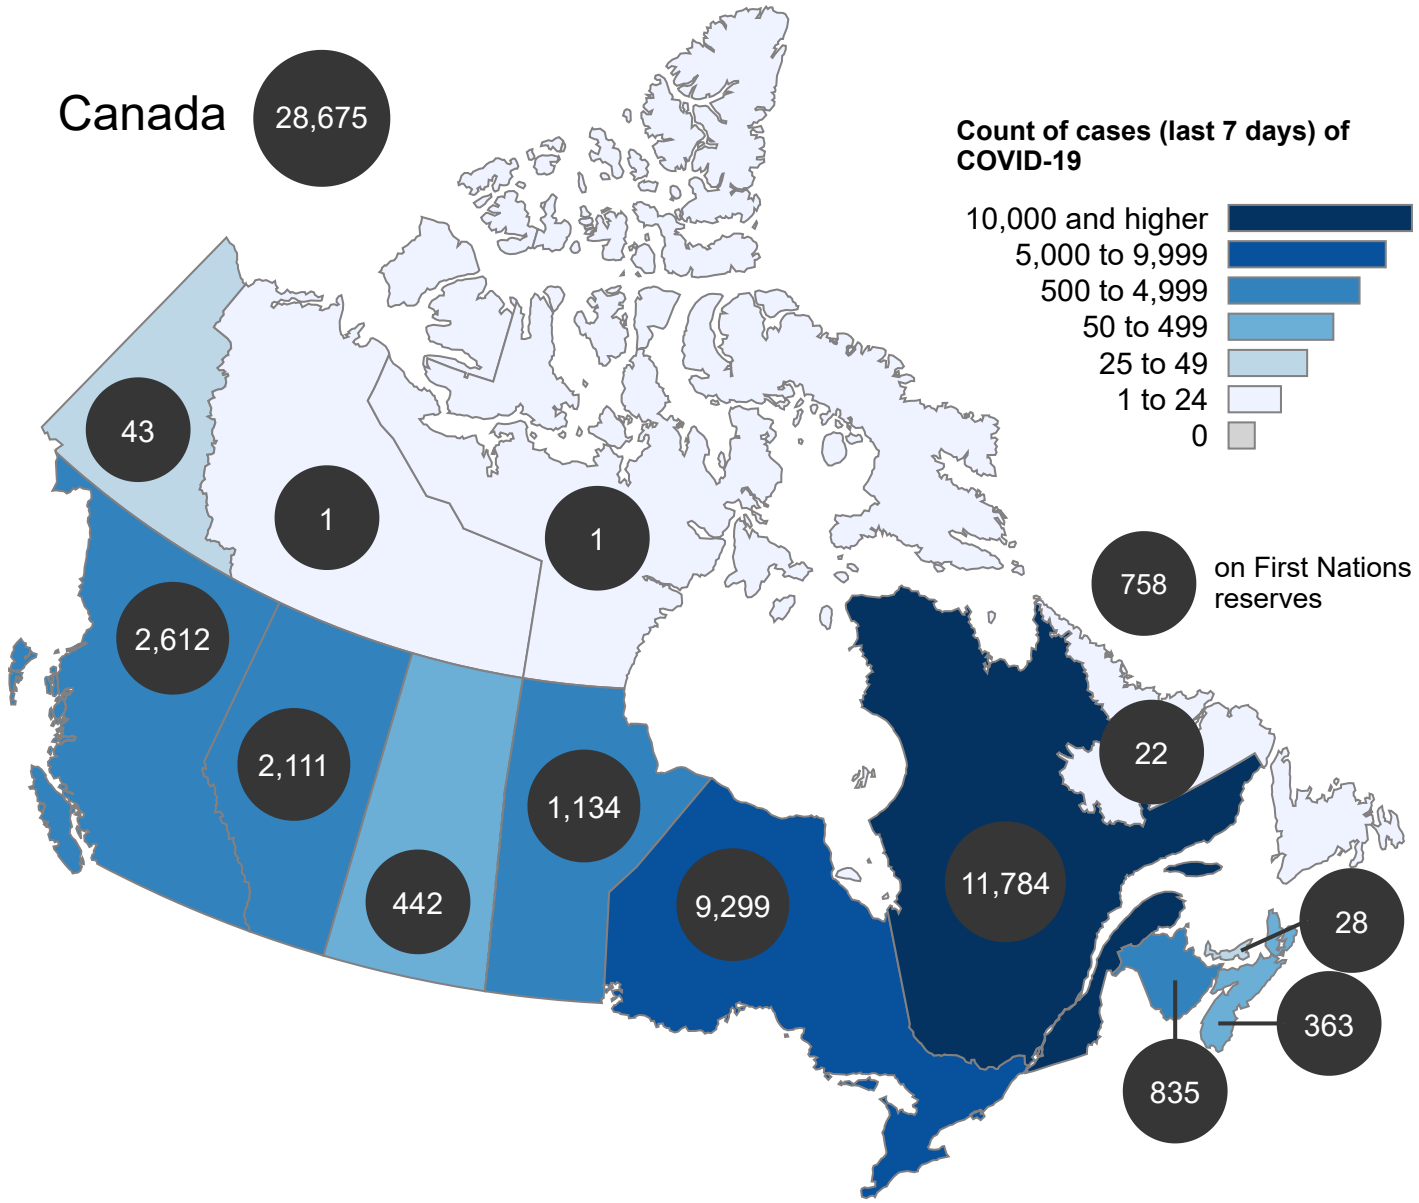
Deaths today	Total deaths
15	29,941

Total tests performed	Daily percent positive (last 7 days)	Daily tests per 100,000 population (last 7 days)
50,147,977	4.1%	269

- We update these sections Monday to Friday at 7:00 PM EST: Key updates, Current situation and National overview. Laboratory data represents specimens received by labs up to December 11, 2021 to allow time to process results.
- We update these sections every Friday: Epidemic curve, Demographics, How people were exposed, and Severe illness and outcomes.
- Of the 12 jurisdictions reporting updates, no new cases were reported in 2 provinces and territories in the past 24 hours.
- Of the 12 jurisdictions reporting updates, no new deaths were reported in 6 provinces and territories in the past 24 hours.

Current situation

Figure 1a. Count of cases (last 7 days) of COVID-19, by province/territory as of December 13, 2021



The count of cases (last 7 days) of COVID-19 in **Canada** was **28,675** as of December 13, 2021.

This information is based on data our provincial and territorial partners published on cases, deaths, and testing daily, and are current as of the day they are published. Today's numbers are current as of December 13, 2021, 2021, 7 PM EST. For the most up to date data for any province, territory or city, please visit their website. The number of cases or deaths reported on previous days may differ slightly from those on the provincial and territorial websites as these websites may update historic case and death counts as new information becomes available.

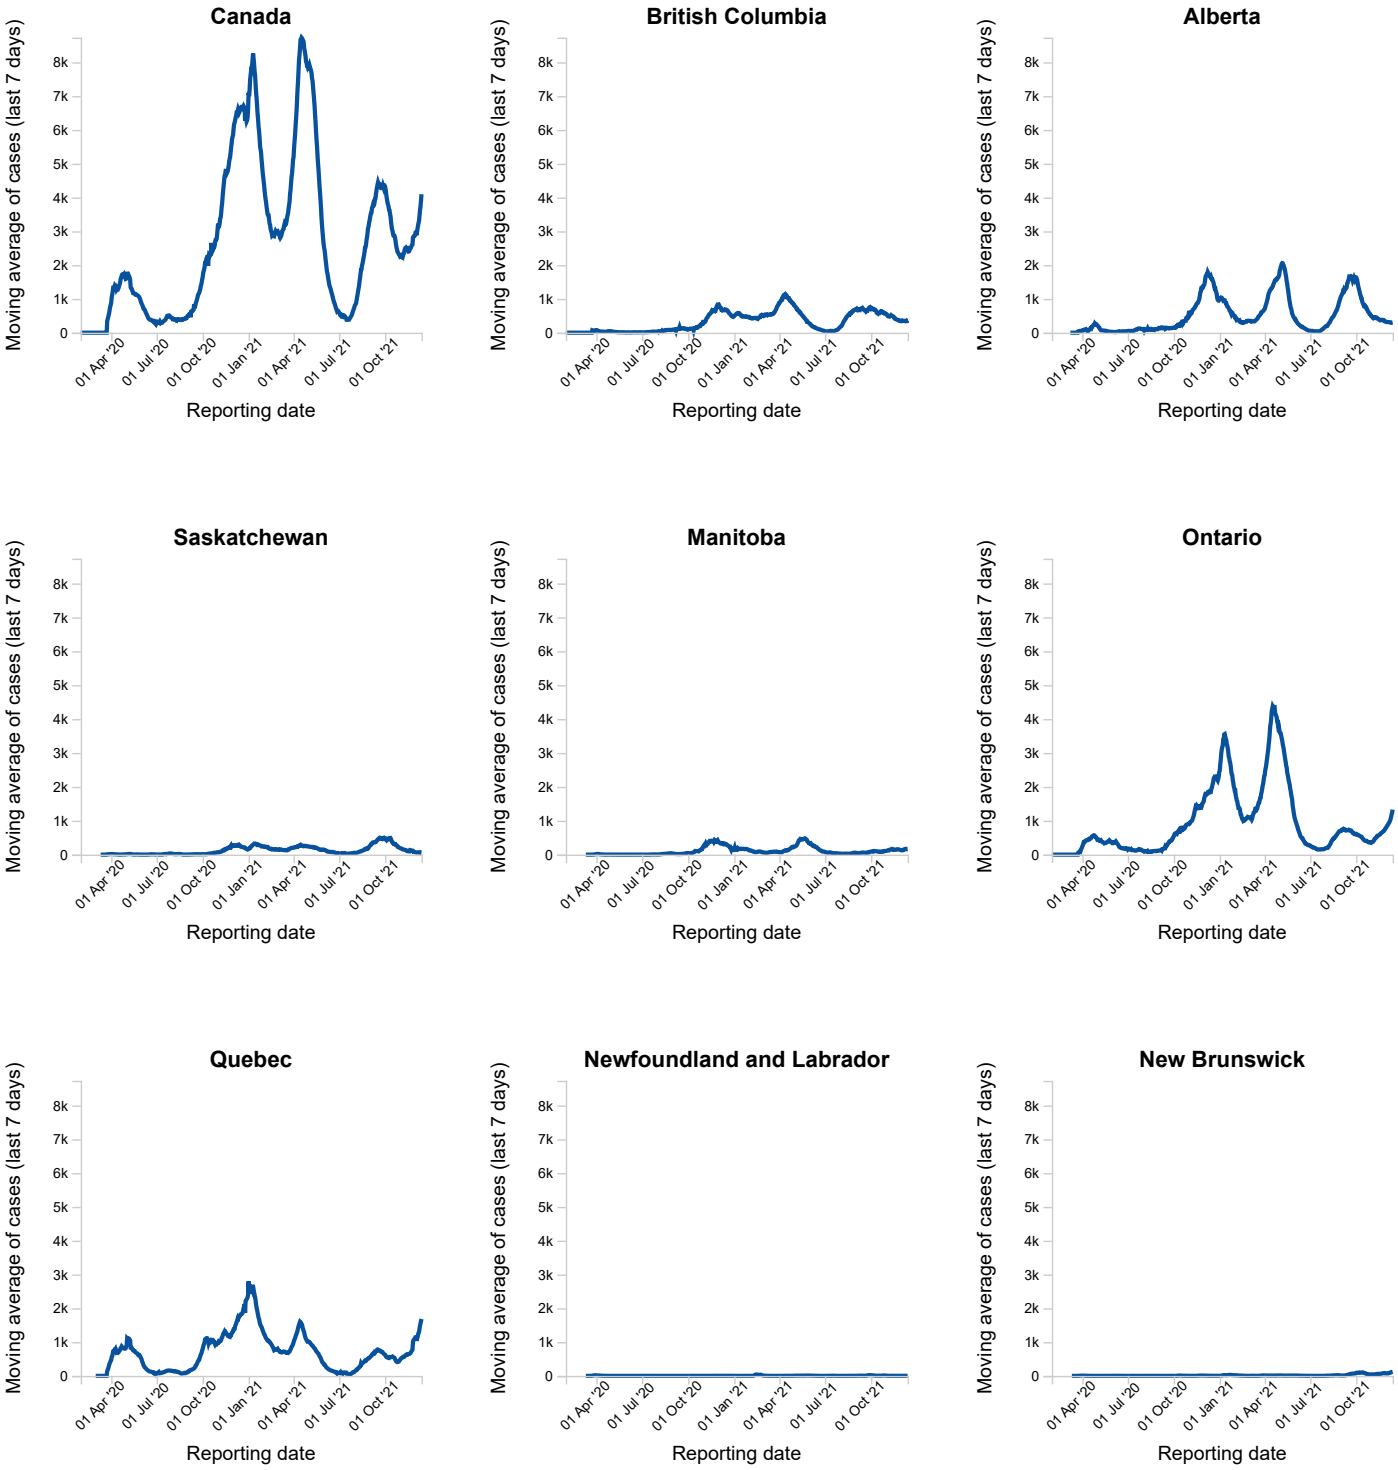
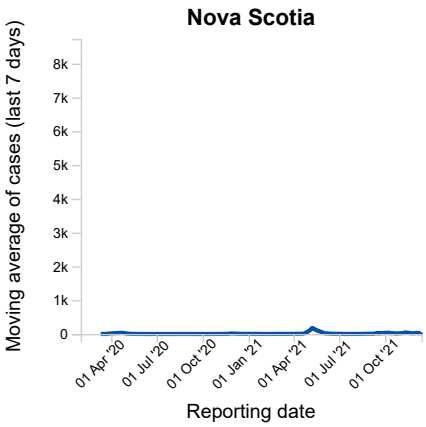
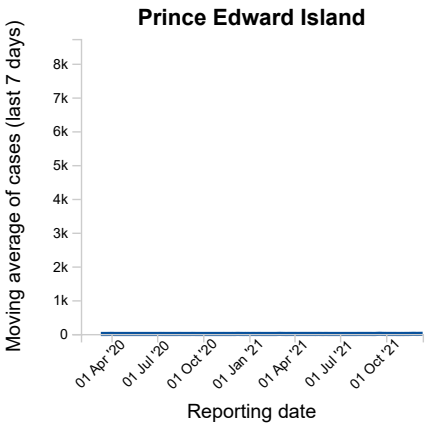
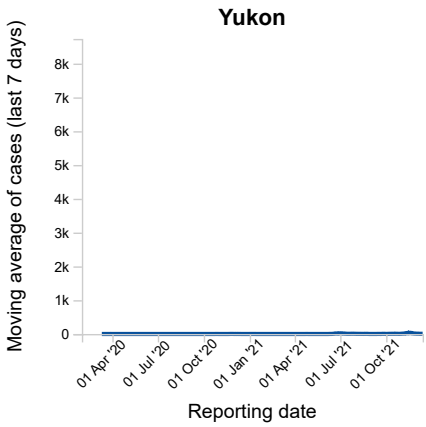
Figure 1b. Moving average of cases (last 7 days) of COVID-19 in Canada as of December 13, 2021, 7 pm EST

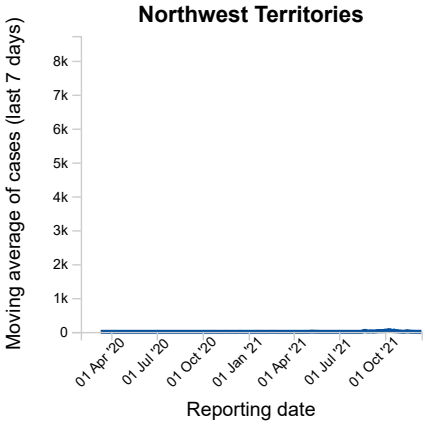
The figures below show cases over time. The range of dates (January 31st, 2020 - present date) is the same for each figure. This allows you to compare the provinces and territories on the same timescale.

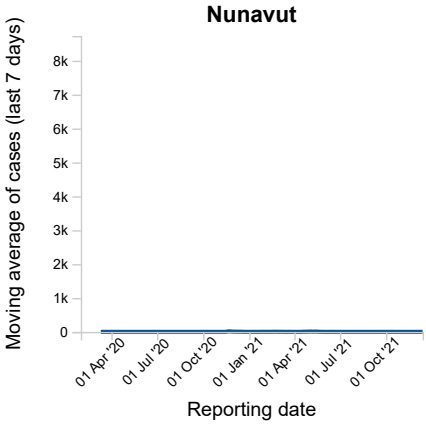












a. This information is based on data from our provincial and territorial partners. Data about cases was last updated on December 13, 2021. Laboratory data includes specimens received by labs up to December 11, 2021. For the most up to date data for any province, territory or city, please visit their web site.
b. The 7-day moving average is the total of the daily numbers for the previous 7 days (up to and including the day of the last update), divided by the number of days for which data is available. We go back and update the moving averages as provinces and territories submit more data. We calculate the national 7-day moving average by summing the 7-day moving average from the provinces and territories then dividing by the national population if a rate is calculated.

Downloadable data (in .csv format).

Note: Out of the total number of people tested, 76 were repatriated travellers, of which 13 were cases.

National overview

There have been over **50,147,977** COVID-19 tests performed in Canada or **1,311,192 tests per 1 million people**. For information about testing trends, please see the Detailed weekly epidemiological report (PDF).

Table 1. Daily* change in the number of cases, deaths and tests performed, by province or territory, as of December 13, 2021, 7 pm EST

Location	New cases	New deaths	Tests performed
British Columbia	349	5	12,412
Alberta	202	3	N/A
Saskatchewan	35	0	1,191
Manitoba	152	1	2,397
Ontario	1,536	1	38,477
Quebec	1,628	3	34,065

Nunavut	0	0	11
Canada	**4,233**	**15**	**96,223**

* The new cases, deaths and tests reflect the difference between a province or territory's current report and their last report. Some provinces and territories do not update daily.

N/A means that no daily update was provided by the province or territory.

COVID-19 variants in Canada

All viruses, including COVID-19, change over time. These changes are called mutations, and result in variants of the virus. Not all mutations are of concern. Most do not cause more severe illness. However, some mutations result in variants of concern or variants of interest.

A variant of concern has mutations that are significant to public health. Before a variant of interest is considered one of concern, scientists and public health professionals must determine if the mutations result in an actual change in the behaviour of the virus. For example, it might:

- spread more easily
- cause more severe illness
- require different treatments, or
- reduce vaccine effectiveness

There are several variants of interest that have mutations similar to variants of concern, but we don't yet know if they pose a higher risk to public health.

The Public Health Agency of Canada (PHAC) works with provincial and territorial partners and the Canadian COVID-19 Genomics Network (CanCOGeN) to sequence a percentage of all positive COVID-19 test results. Sequencing reveals the genetic code of the virus, which tells us which variant is involved in a specific case of COVID-19. We report the proportion of COVID-19 variants in Canada every week.

We collect evidence to determine if new variants meet the definition for a variant of concern or a variant of interest. Many variants are being tracked across Canada and around the world. Variants of concern now represent a majority of COVID-19 cases in Canada.

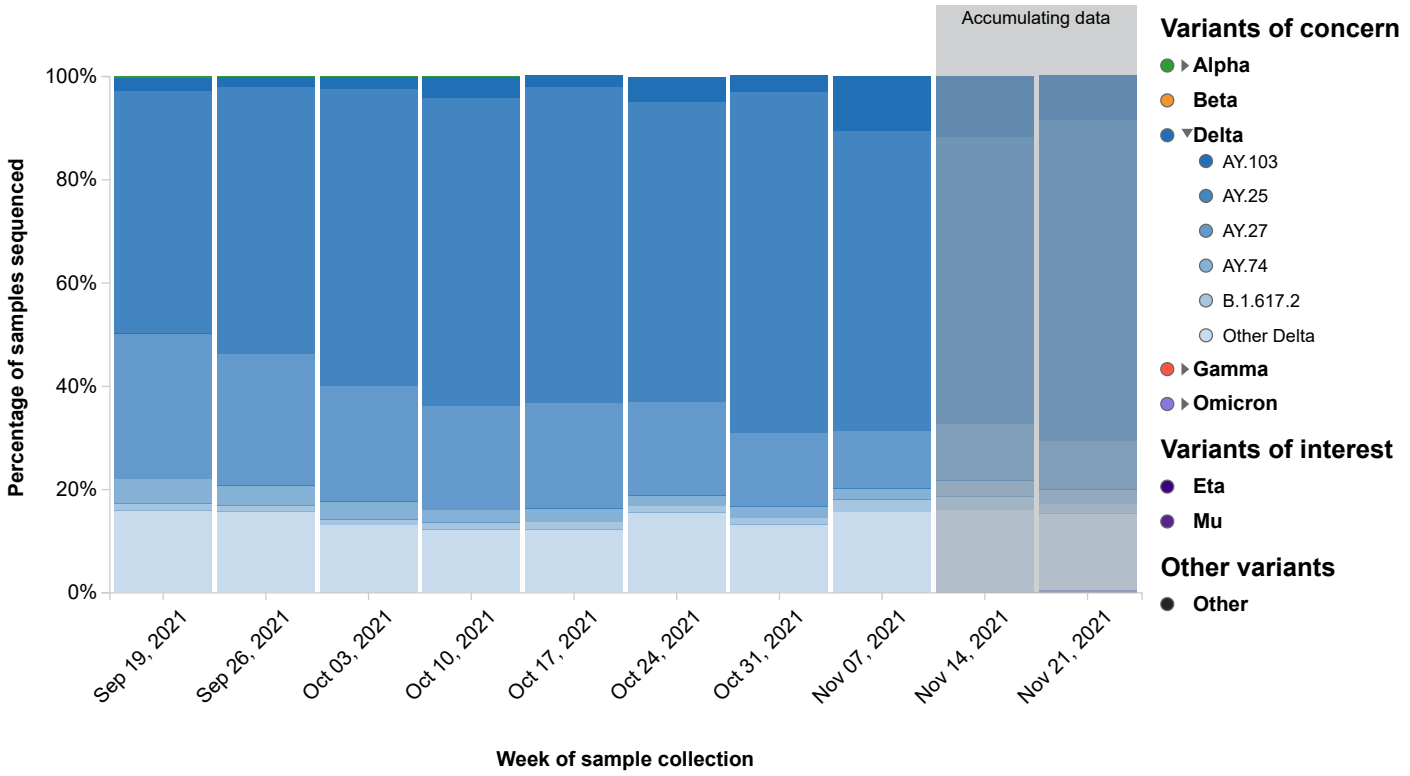
Current variants of concern in Canada include:

- Alpha (B.1.1.7)
- Beta (B.1.351)
- Gamma (P.1)
- Delta (B.1.617.2)
- Omicron (B.1.1.529)

New variants will continue to appear. We must remain vigilant and take all available measures to limit spread.

Figure 2. Weekly variant breakdown Updated: December 10, 2021, 4 pm EDT

The graphic shows the percentage mix of COVID-19 variants detected in Canada through whole genome sequencing, by week of sample collection. You can see the numbers for each date by hovering over, tabbing to, or long-pressing any of the bars. To see a specific variant or variant grouping, click or press return. Repeat to restore the complete graph. Sublineages or offshoots for some variants can be revealed or hidden by clicking on the name of the variant in the legend.



This information is based on whole genome sequencing from surveillance testing in all provinces and territories. In addition to sequencing done by the National Microbiology Laboratory in Winnipeg, data is included from provincial and territorial laboratories.

Sequencing takes from 1 to 3 weeks to complete, so the proportions for recent weeks may change as more data are added. Surveillance in each province or territory is organized and prioritized according to local needs and may change from time to time. Because of differences in local sampling and reporting, the percentages illustrate trends rather than precise measurements.

Weekly variant breakdown

Percentage of COVID-19 cases identified through whole genome sequencing, presented by variant and by week of sample collection.

Detailed case information

The tables and figures below reflect detailed case information provided to the Public Health Agency of Canada (PHAC) by health authorities in the provinces and territories. This data is updated every week. It may change as we get more information about cases.

Updated: December 10, 2021, 7 pm EST

Epidemic curve

As of December 10, 2021, 7 pm EST, PHAC has received detailed case report data on 1,811,673 cases. Both exposure and symptom onset date were available for 1,338,828 (73.9%) cases [1].

The shaded area on the far right of Figure 3 represents a period of accumulating data. This is the period of time (1 to 2 weeks) before the latest cases are reported to PHAC. This delay is a result of the time required to seek health care, get tested and receive results. It also takes time for public health authorities to gather information on cases. We update this information as it becomes available.

Figure 3. COVID-19 cases (n=1,811,673 [1]) in Canada by date [2] as of December 10, 2021, 7 pm EST (total cases)

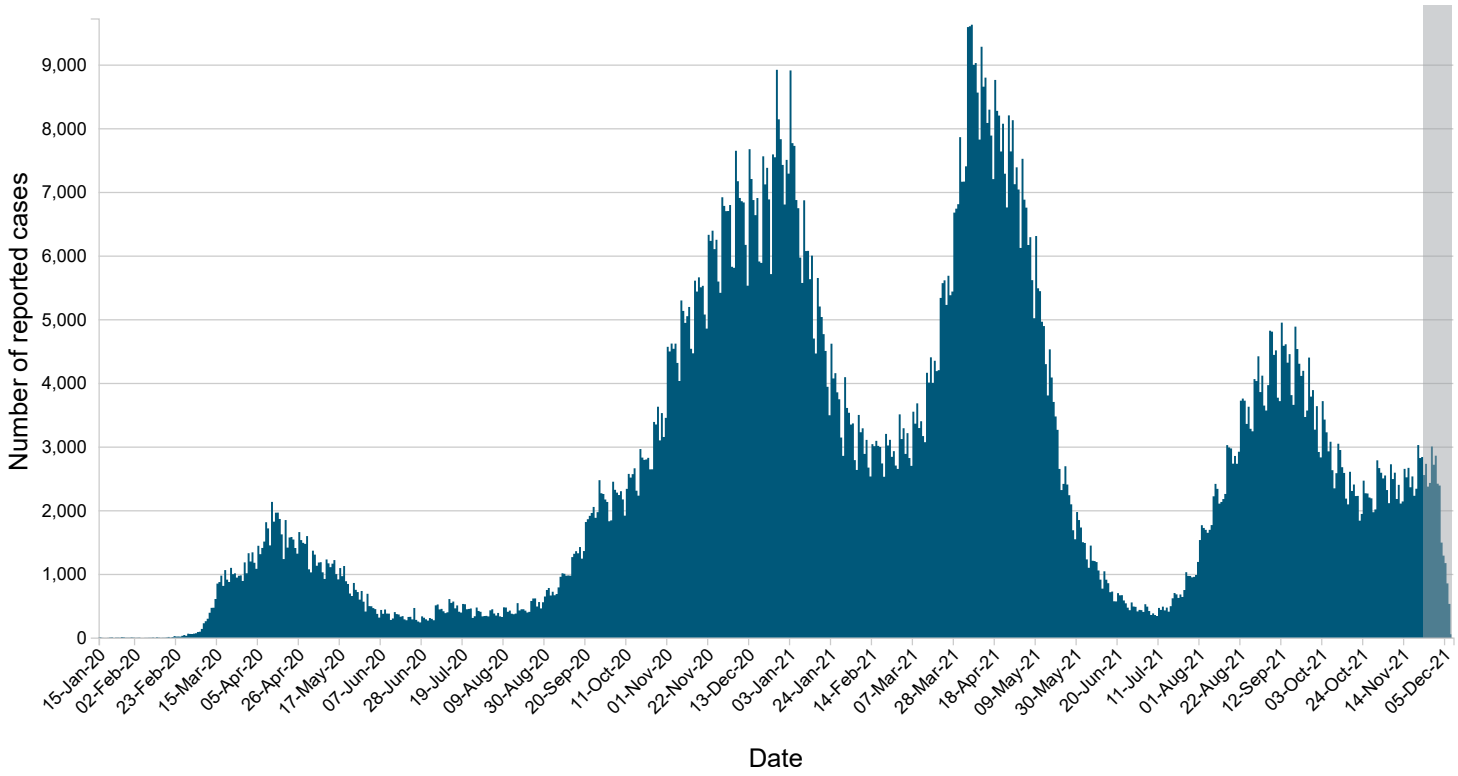

Figure 3. COVID-19 cases (n=1,338,828 [1]) in Canada by date [2] as of December 10, 2021, 7 pm EST (by exposure)

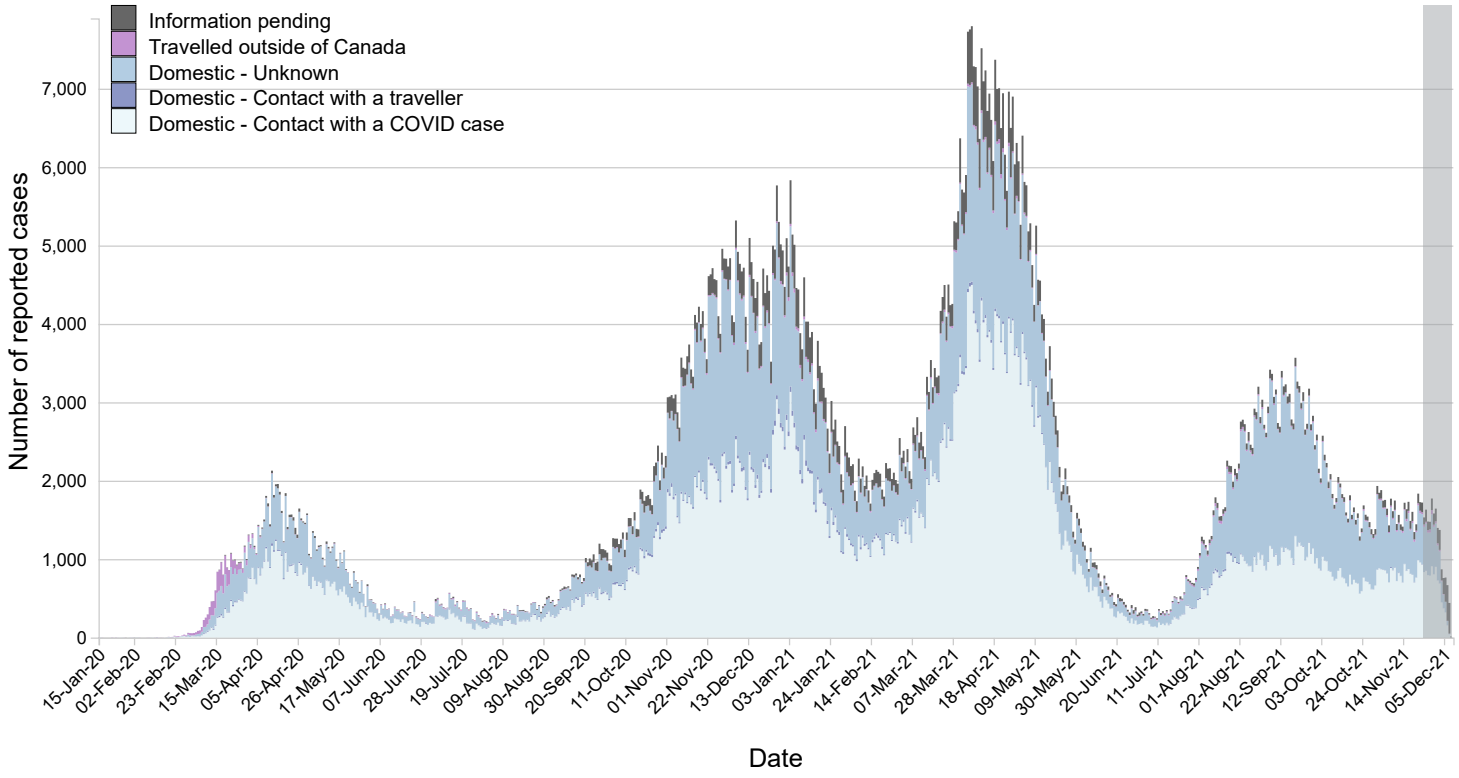

Figure 3. COVID-19 cases (n=1,748,330 [1]) in Canada by date [2] as of December 10, 2021, 7 pm EST (by age - 10 year groups)

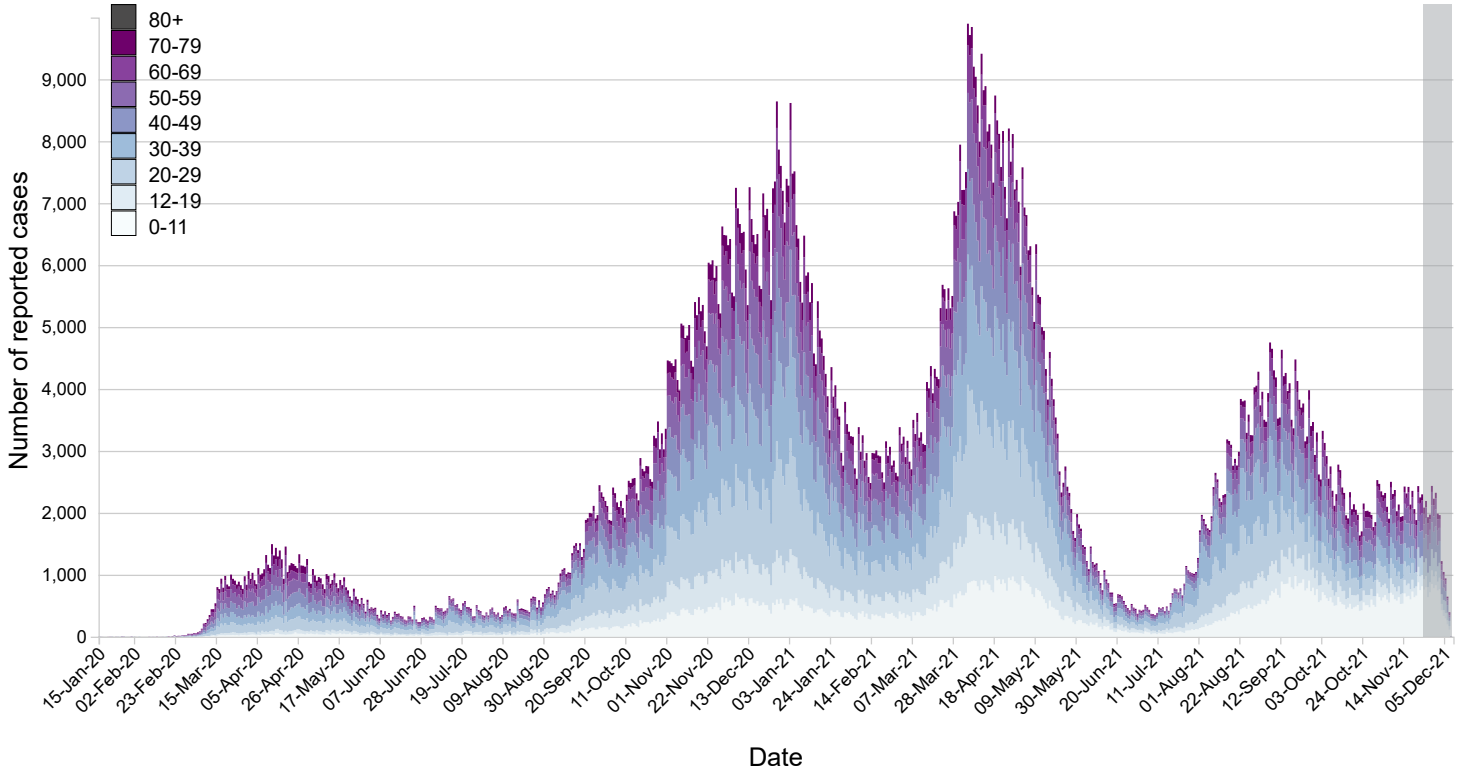

Figure 3. COVID-19 cases (n=1,748,330 [1]) in Canada by date [2] as of December 10, 2021, 7 pm EST (by age - 20 year groups)

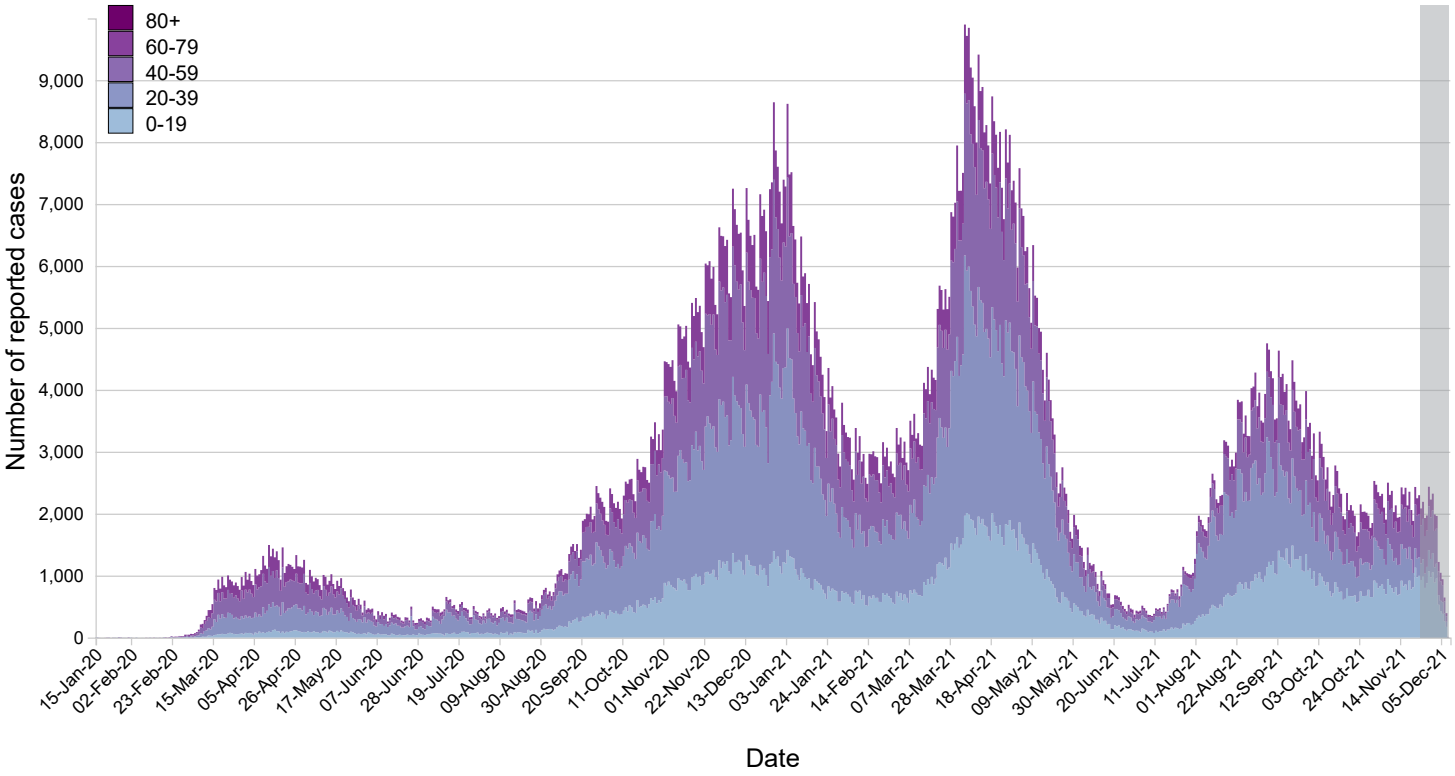


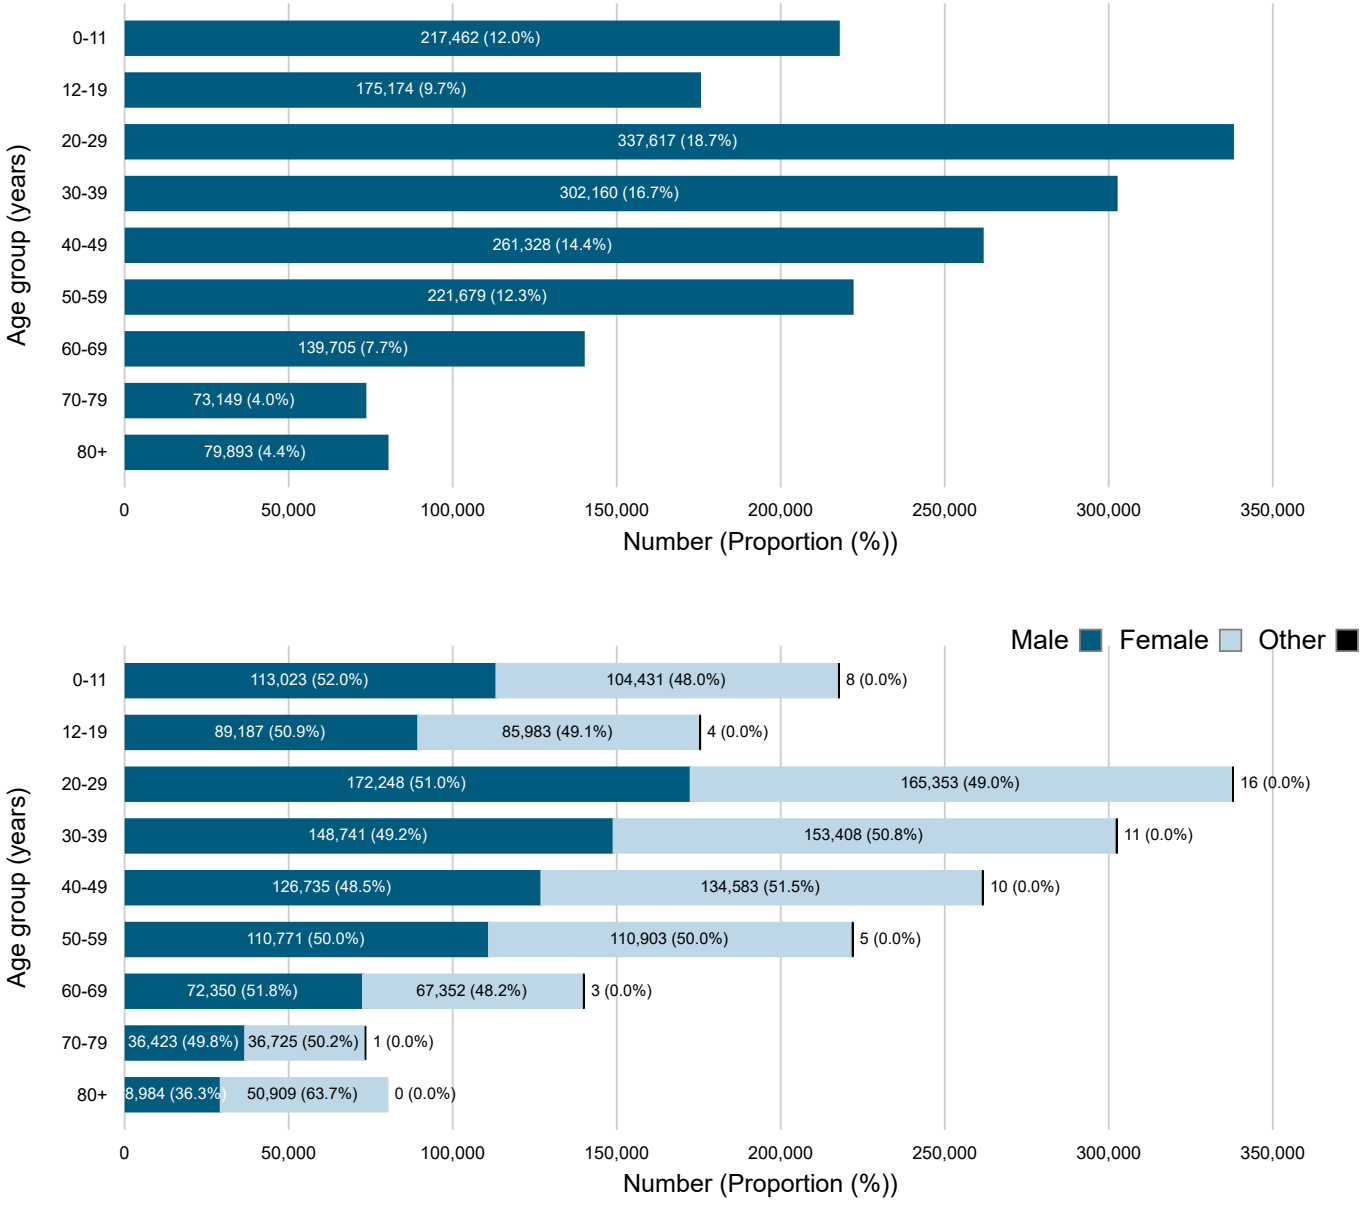
This figure may underestimate the total number of cases among returning travelers. Exposure history is not available for all cases and jurisdictions have not all consistently reported exposure history to PHAC throughout the pandemic.

Demographics

We have detailed case report data from 1,811,673 cases. We know the age of patients in 99.83% of cases, and both age and gender in 99.81% of cases.

Of the cases reported in Canada so far, 50.3% were female and 35.4% were between 20 and 39 years old (Figure 4).

Figure 4. Age distribution of COVID-19 cases (n=1,808,669 [1]) in Canada as of December 10, 2021, 7 pm EST [4]



Age by gender [4] distribution of COVID-19 cases (n=1,808,669 [1]) in Canada, December 10, 2021, 7 pm EST

Age group (years)	Number of cases with case reports (percentage)	Number of male cases (percentage)	Number of female cases (percentage)	Number of other cases (percentage)
0-11	217,462 (12.0%)	113,023 (12.6%)	104,431 (11.5%)	8 (13.8%)
12-19	175,174 (9.7%)	89,187 (9.9%)	85,983 (9.5%)	4 (6.9%)
20-29	337,617 (18.7%)	172,248 (19.2%)	165,353 (18.2%)	16 (27.6%)

80+	79,893 (4.4%)	28,984 (3.2%)	50,909 (5.6%)	0 (0.0%)
Total	1,808,167 (100%)	898,462 (100%)	909,647 (100%)	58 (100%)

How people were exposed [3]

In Canada, detailed case report data were provided for 1,811,673 cases. We have exposure history for 1,338,828 (73.9%) cases. The probable exposure setting of these cases [1] are:

- any exposure that occurred in Canada: **1,236,455 (92.4%)**, including
  - from contact with a known COVID case: **712,467 (53.2%)**
  - from contact with a traveller: **9,581 (0.7%)**
  - from an unknown source: **514,407 (38.4%)**
- currently unknown (information pending): **89,809 (6.7%)**
- travelled outside of Canada: **12,564 (0.9%)**

Cases following vaccination

Data extracted on December 03, 2021 for cases from December 14, 2020 up until November 20, 2021.

While the COVID-19 vaccines are effective, there is still a small percentage of the population who are vaccinated that will still be infected with COVID-19 if they are exposed to the virus that causes it. This means that even with high vaccine effectiveness, a small percentage of the population who are vaccinated against COVID-19 will still get sick and some may be hospitalized or even die as a result of their illness. It is also possible that a person could be infected just before or just after vaccination and still get sick. It typically takes about two weeks for the body to build protection after vaccination, so a person could get sick if the vaccine has not had enough time to provide protection.

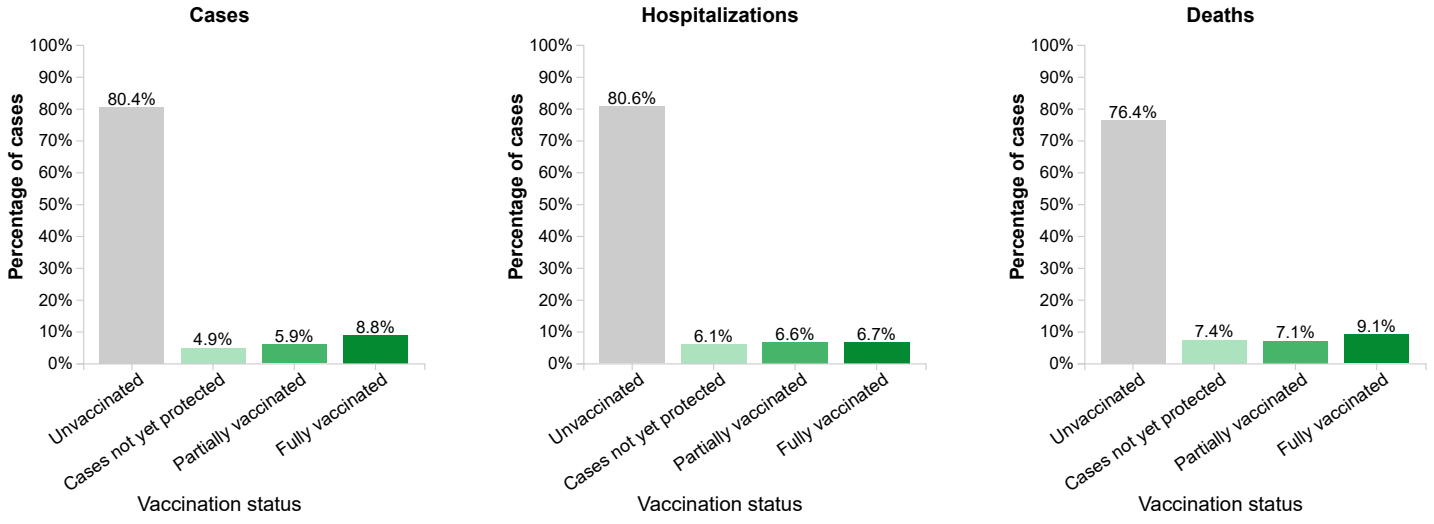
Cases reported since the start of the vaccination campaign, as of November 20, 2021

Since the start of the vaccination campaign on December 14, 2020, PHAC received case-level vaccine history data for 79.0% (n=873,512) of COVID-19 cases aged 12 years or older.

Of these cases:

- 702,434 (80.4%) were unvaccinated at the time of their episode date
- 42,876 (4.9%) were not yet protected by the vaccine, as their episode date occurred less than 14 days after their first dose
- 51,277 (5.9%) were only partially vaccinated, as their episode date occurred either 14 days or more after their first dose or less than 14 days after their second dose
- 76,925 (8.8%) were fully vaccinated, as their episode date occurred 14 days or more after their second dose

Figure 5. Distribution of confirmed COVID-19 cases reported to PHAC by vaccination status as of November 20, 2021



Characteristics and severe outcomes associated unvaccinated, partially vaccinated and fully vaccinated confirmed cases reported to PHAC, as of November 20, 2021

Status	Cases	Hospitalizations	Deaths
Unvaccinated	80.4%	80.6%	76.4%
Cases not yet protected	4.9%	6.1%	7.4%
Partially vaccinated	5.9%	6.6%	7.1%
Fully vaccinated	8.8%	6.7%	9.1%

Among the twelve jurisdictions that have reported case-level vaccine history data to PHAC, a total of 23.2 million people have received at least one dose of the COVID-19 vaccine as of November 20, 2021.

Of these people:

- 23.0 million achieved partial vaccination status, of which 51,277 (0.22%) were diagnosed with COVID-19 while partially vaccinated
- 21.9 million achieved full vaccination status, of which 76,925 (0.35%) were diagnosed with COVID-19 while fully vaccinated

Based on detailed case information reported to PHAC from provinces and territories, cases following vaccination were reported more frequently among females and those aged 60 years and older (Table 2). This may be the result of higher vaccination coverage in Canada among females and those aged 60 years and older due to the prioritization of older age groups and healthcare workers as part of the vaccine rollout.

Table 2. Characteristics and severe outcomes associated unvaccinated, partially vaccinated and fully vaccinated confirmed cases reported to PHAC, as of November 20, 2021

		Unvaccinated (n=702,434)	**Cases not yet protected** (n=42,876)	**Partially vaccinated** (n=51,277)	**Fully vaccinated** (n=76,925)	**Total cases** (n=873,512)
Gender*	Male	359,198 (82.1%)	20,629 (4.7%)	24,000 (5.5%)	33,890 (7.7%)	437,717 (100%)
	Female	341,713 (78.7%)	22,188 (5.1%)	27,208 (6.3%)	42,957 (9.9%)	434,066 (100%)
Hospitalizations		39,637 (80.6%)	2,977 (6.1%)	3,230 (6.6%)	3,310 (6.7%)	49,154 (100%)
Deaths		7,790 (76.4%)	751 (7.4%)	724 (7.1%)	933 (9.1%)	10,198 (100%)

Source: Detailed case information received by PHAC from provinces and territories, since December 14, 2020

Note:

- Twelve of thirteen provinces and territories have reported case-level vaccine history data to PHAC as part of the national COVID-19 dataset. Ten provinces and territories have reported case-level vaccine history data to PHAC since August 2021. A data cut-off of November 20, 2021 was used to account for routine reporting delays associated with vaccine history information.
- *Cases with missing gender were excluded. Where available, gender data was used; when gender data was unavailable, sex data was used. Reliable data on gender diverse respondents are unavailable due to small counts.

Fully vaccinated individuals diagnosed with COVID-19 were significantly protected from severe outcomes. Compared to unvaccinated cases, fully vaccinated cases were 80% less likely to be hospitalized and 68% less likely to die as a result of their illness (Table 3).

Table 3. Risk of severe outcomes among fully vaccinated cases compared to unvaccinated cases as of November 20, 2021

Severe Outcome	Adjusted* Odds Ratio (95% CI)
Hospitalizations	0.20 (0.19 - 0.21)
Deaths	0.32 (0.29 - 0.35)

*Adjusted for 10-year age groups and month of episode date

Source: Detailed case information received by PHAC from provinces and territories

Note: Due to the nature of the dataset (i.e. confirmed cases of COVID-19 in Canada), the odds of severe outcomes among cases following vaccination only considers vaccinated individuals that contracted COVID-19. It does not reflect the protection conferred by the vaccines to prevent COVID-19 infection.

Data for this analysis is extracted from the COVID-19 national data set, which contains detailed case-level information received by PHAC from all provinces and territories. Note that a data cut-off of November 20, 2021 was used to account for any reporting delays associated with vaccine history information. There are currently twelve jurisdictions reporting case-level vaccine history data to PHAC as part of the national COVID-19 dataset.

PHAC monitors cases following vaccination using the following categories:

Unvaccinated cases: include those who were unvaccinated at the time of their episode date.

Cases not yet protected from vaccination include those whose episode date occurred less than 14 days after their first dose of the vaccine.

Partially vaccinated cases include those whose episode date occurred 14 days or more after their first vaccine dose or less than 14 days after their second dose of the vaccine.

Fully vaccinated cases include those whose episode date occurred 14 days or more after their second dose of a two dose vaccine series or those whose episode date occurred 14 days or more after one dose of a one-dose vaccine.

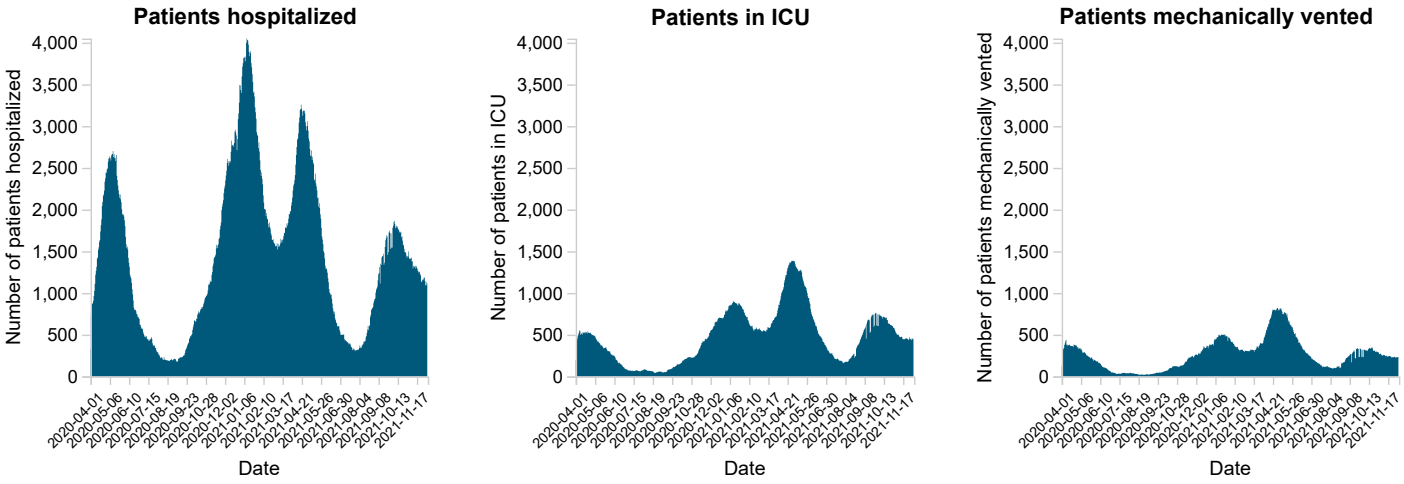
Note: When symptom onset date is unavailable or the case is asymptomatic, episode date uses the following dates as a proxy for classification: laboratory specimen collection date, or laboratory testing date.

For more information on cases following vaccination, please see the Weekly epidemiology report (PDF) available on the Government of Canada's COVID-19 data trends page.

Severe illness and outcomes

Hospital use

Figure 6. Daily number of hospital beds and ICU beds occupied by COVID-19 patients as of December 6, 2021



Between November 29, 2021 and December 6, 2021:

- the number of **hospital beds** occupied by COVID-19 patients **decreased** from **1,164** to **1,116** beds.
- the number of **ICU beds** occupied by COVID-19 patients **decreased** from **470** to **445** beds.
- the number of **COVID-19 patients who were mechanically vented decreased** from **238** to **228**.

Hospitalizations and deaths to date

We have detailed case report data on 1,811,673 cases, and hospitalization status for 1,318,820 (72.8%) of them:

- **93,472** cases **(7.1%)** were hospitalized, of whom:
  - **18,147 (19.4%)** were admitted to the ICU
  - **2,128 (2.3%)** needed mechanical ventilation

The provinces and territories provided detailed case report forms for **29,737** deaths related to COVID-19.

Figure 7a. Age and gender [4] distribution of COVID-19 cases hospitalized in Canada as of December 10, 2021, 7 pm EST (n=93,375 [1])

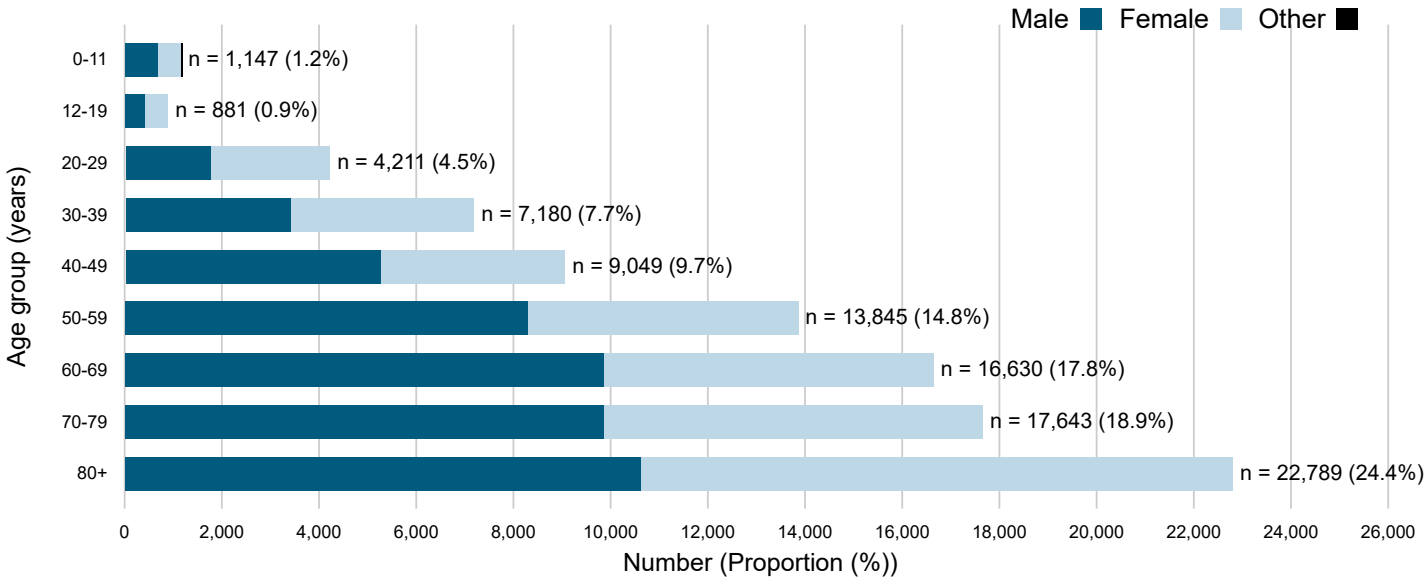


Figure 7b. Age and gender [4] distribution of COVID-19 cases admitted to ICU in Canada as of December 10, 2021, 7 pm EST (n=18,126 [1])

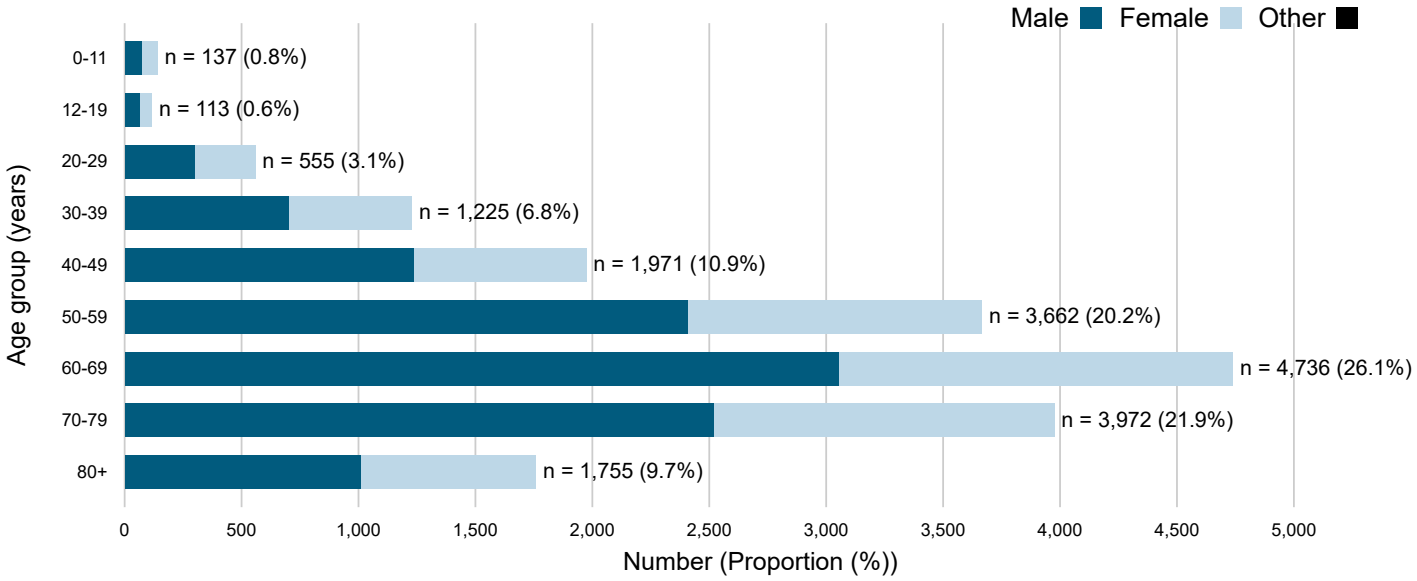

Figure 7c. Age and gender [4] distribution of COVID-19 cases deceased in Canada as of December 10, 2021, 7 pm EST (n=29,678 [1])

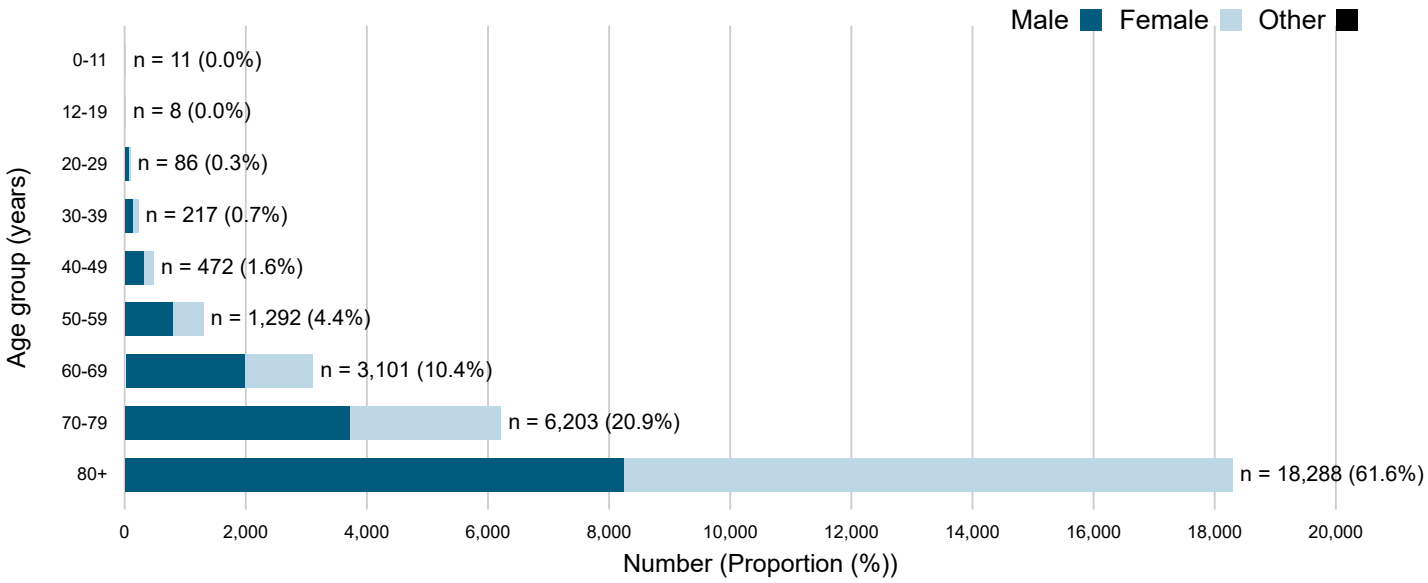

Data note: Figure 7 includes COVID-19 cases hospitalized, admitted to ICU, and deceased for which age and gender information were available. Therefore, some COVID-19 hospitalizations, ICU admissions, and deaths may not be included in Figure 7.

Age and gender [4] distribution of COVID-19 cases hospitalized in Canada as of December 10, 2021, 7 pm EST (n=93,375 [1])

Summary of the NACI Seasonal Influenza Vaccine Statement for 2019–2020

L Zhao[1], K Young[1], I Gemmill[2,3] on behalf of the National Advisory Committee on Immunization (NACI)*

Abstract

Background: Many different influenza vaccines are authorized for use in Canada and new evidence on influenza and vaccines is continually emerging. The National Advisory Committee on Immunization (NACI) provides annual recommendations regarding the use of seasonal influenza vaccines to the Public Health Agency of Canada (PHAC) for the upcoming influenza season.

Objective: To summarize NACI recommendations regarding the use of seasonal influenza vaccines for the 2019–2020 influenza season, including conclusions from reviews of evidence on 1) a new split virus quadrivalent inactivated influenza vaccine and 2) the comparative effectiveness and immunogenicity of subunit and split virus inactivated influenza vaccines in adults 65 years of age and older.

Methods: For both topics, the NACI Influenza Working Group developed a predefined search strategy to identify all eligible studies, assessed their quality, summarized and analyzed the findings and, according to the NACI evidence-based process, proposed recommendations and identified the grade of evidence that supported them. In light of the evidence, the recommendations were then considered and approved by NACI.

Results: NACI concluded that the new split virus quadrivalent inactivated influenza vaccine has a safety and immunogenicity profile comparable to the quadrivalent inactivated influenza vaccines already authorized for adults and children 5 years of age and older (Grade B Evidence). Therefore, NACI recommended that this new vaccine may be considered among the quadrivalent inactivated influenza vaccines offered to adults and children five years of age and older (Discretionary NACI Recommendation). However, NACI concluded that the evidence is not sufficient (Grade I Evidence) to support specific recommendations on the differential use of subunit and split virus inactivated influenza vaccines in adults 65 years of age and older.

Conclusion: NACI continues to recommend that an age-appropriate influenza vaccine should be offered annually to anyone six months of age and older who does not have contraindications to the vaccine, with focus on the groups for whom influenza vaccination is particularly recommended. This includes people at high risk of influenza-related complications or hospitalization, people capable of transmitting influenza to those at high risk, people who provide essential community services and people in direct contact with poultry infected with avian influenza during culling operations.

Introduction

Influenza, together with pneumonia, ranks among the top 10 leading causes of death in Canada (1). Although the burden of influenza can vary from year to year, it is estimated that there are an average of approximately 12,200 hospitalizations (2) and 3,500 deaths (3) related to influenza per year.

The National Advisory Committee on Immunization (NACI) provides annual recommendations regarding seasonal influenza vaccines to the Public Health Agency of Canada (PHAC). For the 2019–2020 influenza season, NACI updated the abbreviations it uses for the different types of influenza vaccines available in Canada. NACI also reviewed evidence from two literature reviews: one on studies relevant to a new split virus quadrivalent inactivated influenza vaccine (Afluria® Tetra, Seqirus) and one on the comparative effectiveness and immunogenicity of subunit and split virus inactivated influenza vaccines in adults 65 years of age and older. Complete details can be found in the *Statement on Seasonal Influenza Vaccine for 2019–2020* (4) and related publications.

The objective of this article is to summarize this annual seasonal influenza statement.

Updated influenza vaccine abbreviations

The abbreviations used by NACI have been updated to better describe the defining features of the various types of influenza vaccines. The new and corresponding former abbreviations are listed in **Table 1**.

Methods

To prepare the *Statement on Seasonal Influenza Vaccine for 2019–2020*, the Influenza Working Group identified two literature reviews and, following review and analysis of the information, proposed recommendations according to the NACI evidence-based process (5). NACI critically appraised the available evidence and approved the specific recommendations brought forward.

Use of Afluria Tetra influenza vaccine

The Influenza Working Group conducted a systematic review to inform the development of the NACI guidance on the use of Afluria Tetra in Canada. Five electronic databases (MEDLINE, Embase, Scopus, ProQuest Public Health Database and ClinicalTrials.gov) were searched from inception to

Table 1: New National Advisory Committee on Immunization (NACI) abbreviations for influenza vaccines

Influenza vaccine category	Formulation	Type	New NACI abbreviation[a]	Former NACI abbreviation
Inactivated influenza vaccine	-	-	IIV	IIV
	Trivalent	-	IIV3	TIV
		Standard dose[b], unadjuvanted, IM administered	IIV3-SD	Standard-dose TIV
		Adjuvanted[c], IM administered	IIV3-Adj	ATIV or adjuvanted TIV
		High dose[d], unadjuvanted, IM administered	IIV3-HD	High-dose TIV
	Quadrivalent	-	IIV4	QIV
		Standard dose[b], unadjuvanted, IM administered	IIV4-SD	Standard-dose QIV
Live attenuated influenza vaccine	-	-	LAIV	LAIV
	Trivalent	Nasal spray	LAIV3	Trivalent LAIV
	Quadrivalent	Nasal spray	LAIV4	Quadrivalent LAIV

Abbreviations: IIV, inactivated influenza vaccine; IIV3, trivalent inactivated influenza vaccine; IIV3-Adj, adjuvanted trivalent inactivated influenza vaccine; IIV3-HD, high-dose trivalent inactivated influenza vaccine; IIV3-SD, standard-dose trivalent inactivated influenza vaccine; IIV4, quadrivalent inactivated influenza vaccine; IIV4-SD, standard-dose quadrivalent inactivated influenza vaccine; TIV, trivalent inactivated influenza vaccine; QIV, quadrivalent inactivated influenza vaccine; -, not applicable
IM, intramuscular; LAIV, live attenuated influenza vaccine; LAIV3, trivalent live attenuated influenza vaccine; LAIV4, quadrivalent live attenuated influenza vaccine; -, not applicable
[a] The numeric suffix denotes the number of antigens contained in the vaccine ("3" refers to the trivalent formulation and "4" refers to the quadrivalent formulation). The hyphenated suffix "-SD" is used when referring to IIV products that do not have an adjuvant, contain 15 µg hemagglutinin (HA) per strain and are administered as a 0.5 mL dose by intramuscular injection; "-Adj" refers to an IIV with an adjuvant (e.g. IIV3-Adj for Fluad or Fluad Pediatric); and "-HD" refers to an IIV that contains higher antigen content than 15 µg HA per strain (e.g. IIV3-HD for Fluzone High-Dose)
[b] 15 µg HA per strain
[c] 7.5 µg (in 0.25 mL) or 15 µg (in 0.5 mL) HA per strain
[d] 60 µg HA per strain

August 22, 2017 to identify relevant literature on the efficacy, effectiveness, immunogenicity and safety of Afluria Tetra or the trivalent Afluria (1.5% sodium taurodeoxycholate [TDOC]) in adults and children aged six months and older. The use of 1.5% TDOC as a splitting agent was incorporated in the manufacturing process for Afluria and for the new Afluria Tetra after a safety signal in the 2010 Southern Hemisphere influenza season in Australia showed that Afluria made with less than 1.5% of TDOC was associated with an increased rate of fever and febrile seizures in children less than five years of age (6). Two reviewers independently screened the titles and abstracts of records retrieved from the search and eligible full-text articles for inclusion. Two reviewers extracted data from eligible studies and appraised the methodological quality of these studies using the criteria outlined by Harris et al. (7). A narrative synthesis of the extracted data was performed.

Comparative effectiveness and immunogenicity of subunit and split virus inactivated influenza vaccines in adults 65 years of age and older

A rapid review was performed to inform NACI on potentially important differences between subunit and split virus inactivated influenza vaccines in older adults. Three electronic databases (MEDLINE, Embase and ClinicalTrials.gov) were searched to identify relevant literature published between January 1, 2007 and October 13, 2017 on the effectiveness and immunogenicity of subunit and split virus inactivated influenza vaccines (unadjuvanted, standard dose) in adults 65 years of age and older. A manual search of the reference lists of included articles was performed because of the small number of records retrieved in the initial database search. A single reviewer screened the retrieved records and performed data extraction and quality appraisal of eligible studies. A narrative synthesis of the extracted data was performed.

Results

Use of Afluria Tetra influenza vaccine

Based upon a review of two randomized controlled trials of Afluria Tetra and two of Afluria (1.5% TDOC), NACI concluded that Afluria Tetra is safe and has immunogenicity non-inferior to comparable vaccines in adults and children five years of age and older. No direct evidence on the efficacy or effectiveness of Afluria Tetra was available. Furthermore, no evidence for any outcome was available on the use of Afluria Tetra for children less than five years of age, and Afluria Tetra is not authorized for use in this age group in Canada. Fever and febrile seizure were not identified as concerns for both Afluria Tetra and Afluria (1.5% TDOC) in two studies looking at children five years of age and older.

NACI recommends that Afluria Tetra may be considered among the quadrivalent inactivated influenza vaccines offered to adults and children five years of age and older (Discretionary NACI Recommendation, Grade B Evidence).

Complete details of the findings of literature review, and rationale and relevant considerations for the recommendation, can be found in the NACI *Supplemental Statement on Afluria Tetra* (6).

Comparative effectiveness and immunogenicity of subunit and split virus inactivated influenza vaccines in adults 65 years of age and older

Eight studies that assessed either vaccine effectiveness or immunogenicity of subunit compared with split virus inactivated influenza vaccines were identified. These studies did not show statistically significant differences in vaccine effectiveness or immunogenicity. Furthermore, the quality of the included studies was a concern. Based upon a review of these studies, NACI concluded that the evidence is not sufficient (Grade I Evidence) to support specific recommendations on the differential use of subunit and split virus inactivated influenza vaccines in adults 65 years of age and older.

The detailed findings of this review can be found in the *NACI Literature Review on the Comparative Effectiveness and Immunogenicity of Subunit and Split Virus Inactivated Influenza Vaccines in Adults 65 Years of Age and Older* (8).

Summary of NACI recommendations for the use of influenza vaccines for the 2019–2020 influenza season

NACI continues to recommend influenza vaccination to anyone six months and older who does not have contraindications to the vaccine. Vaccination should be offered as a priority to people at high risk of influenza-related complications or hospitalization, people capable of transmitting influenza to those at high risk of complications, and others as indicated in **Table 2**.

Recommended influenza vaccine options by age group and by dosage and route of administration by age are summarized in **Tables 3** and **4**, respectively.

Table 2: Groups for whom influenza vaccination is particularly recommended (4)

People at high risk of influenza-related complications or hospitalization:

- All pregnant women[a]
- Adults and children with the following chronic health conditions:
  - cardiac or pulmonary disorders (includes bronchopulmonary dysplasia, cystic fibrosis, and asthma)
  - diabetes mellitus and other metabolic diseases
  - cancer, immune compromising conditions (due to underlying disease, therapy or both)
  - renal disease
  - anemia or hemoglobinopathy
  - neurologic or neurodevelopmental conditions (includes neuromuscular, neurovascular, neurodegenerative and neurodevelopmental conditions and seizure disorders [for children, includes febrile seizures and isolated developmental delay], but excludes migraines and psychiatric conditions without neurological conditions)
  - morbid obesity (body mass index [BMI] of 40 and over)
  - children 6 months to 18 years of age undergoing treatment for long periods with acetylsalicylic acid, because of the potential increase of Reye's syndrome associated with influenza
- People of any age who are residents of nursing homes and other chronic care facilities
- Adults 65 years of age and older
- All children 6–59 months of age
- Indigenous peoples

People capable of transmitting influenza to those at high risk:

- Health care and other care providers in facilities and community settings who, through their activities, are capable of transmitting influenza to those at high risk
- Household contacts, both adults and children, of individuals at high risk, whether or not the individual at high risk has been vaccinated:
  - household contacts of individuals at high risk
  - household contacts of infants less than six months of age, as these infants are at high risk but cannot receive influenza vaccine
  - members of a household expecting a newborn during the influenza season
- Those providing regular child care to children 6–59 months of age, whether in or out of the home
- Those who provide services within closed or relatively closed settings to people at high risk (e.g. crew on a ship)

Others:

- People who provide essential community services
- People who are in direct contact with poultry infected with avian influenza during culling operations

[a] The risk of influenza-related hospitalization increases with length of gestation (i.e. it is higher in the third than in the second trimester)

Table 3: Recommendations on choice of influenza vaccine type for individual-level decision making[a] by age group (4)

Recipient by age group	Vaccine types available for use	Recommendations on choice of influenza vaccine
6–23 months	• IIV3-SD • IIV3-Adj • IIV4-SD	• Quadrivalent influenza vaccine should be used, given the burden of influenza B disease in this age group and the potential for lineage mismatch between the predominant circulating strain of influenza B and the strain in a trivalent vaccine • If a quadrivalent vaccine is not available, any of the available trivalent vaccines should be used
2–17 years	• IIV3-SD • IIV4-SD • LAIV4	• Either IIV4-SD or LAIV4 should be used for children without contraindications, including those with non-immune compromising chronic health conditions, given the burden of influenza B disease in this age group and the potential for lineage mismatch between the predominant circulating strain of influenza B and the strain in a trivalent vaccine • If IIV4-SD or LAIV4 is not available, IIV3-SD should be used • IIV4-SD should be used for children for whom LAIV is contraindicated, such as in children with: - severe asthma - medically attended wheezing in the seven days prior to vaccination - current receipt of Aspirin or Aspirin-containing therapy - immune compromising conditions • LAIV4 may be given to children with: - stable, non-severe asthma - cystic fibrosis who are not being treated with immunosuppressive drugs (e.g. prolonged systemic corticosteroids)
18–59 years	• IIV3-SD • IIV4-SD • LAIV4	• Any of the available influenza vaccines should be used in adults without contraindications • IIV should be used for adults for whom LAIV is contraindicated, such as in: - pregnant women - adults with any of the chronic health conditions identified in Table 2, including immune compromising conditions - HCWs
60–64 years	• IIV3-SD • IIV4-SD	• Any of the available influenza vaccines should be used
65 years and older[b]	• IIV3-SD • IIV3-Adj • IIV3-HD • IIV4-SD	• When available, IIV3-HD should be used over IIV3-SD, given the burden of influenza A (H3N2) disease and the evidence for better efficacy compared with IIV3-SD in this age group • There is insufficient evidence to make comparative individual-level recommendations on the use of IIV3-Adj or IIV4-SD over IIV3-SD or between IIV3-Adj, IIV3-HD and IIV4-SD

Abbreviations: HCW, health care worker; IIV, inactivated influenza vaccine; IIV3-Adj, adjuvanted trivalent inactivated influenza vaccine; IIV3-HD, high-dose trivalent inactivated influenza vaccine; IIV3-SD, standard-dose trivalent inactivated influenza vaccine; IIV4-SD, standard-dose quadrivalent inactivated influenza vaccine; LAIV4, quadrivalent live attenuated influenza vaccine

[a] Recommendations for individual-level decision making are intended for individuals wishing to protect themselves from influenza, or vaccine providers wishing to advise individual patients about preventing influenza

[b] The recommendations on influenza vaccine for individuals 65 years of age and older presented here are for individual-level decision making. For public health program–level decision making (i.e. provinces/territories making decisions for publicly funded immunization programs), NACI recommends that any of the available influenza vaccines be used, as there is insufficient evidence (cost-effectiveness assessments have not been performed) to make comparative public health program–level recommendations on the use of the available vaccines

Table 4: Recommended dose and route of administration, by age, for influenza vaccine types available for the 2019–2020 influenza season (4)

Age group	Influenza vaccine type (route of administration)				Number of doses required
	IIV3-SD[a] or IIV4-SD[b] (Intramuscular)	IIV3-Adj[c] (Intramuscular)	IIV3-HD[d] (Intramuscular)	LAIV4[e] (intranasal)	
6–23 months	0.5 mL[f]	0.25 mL	–	-	1 or 2[g]
2–8 years	0.5 mL	–	–	0.2 mL (0.1 mL per nostril)	1 or 2[g]
9–17 years	0.5 mL	–	–	0.2 mL (0.1 mL per nostril)	1
18–59 years	0.5 mL	–	–	0.2 mL (0.1 mL per nostril)	1
60–64 years	0.5 mL	–	–	–	1
65 years and older	0.5 mL	0.5 mL	0.5 mL	–	1

Abbreviations: IIV3-Adj, adjuvanted trivalent inactivated influenza vaccine; IIV3-HD, high-dose trivalent inactivated influenza vaccine; IIV3-SD, standard-dose trivalent inactivated influenza vaccine; IIV4-SD, standard-dose quadrivalent inactivated influenza vaccine; LAIV4, quadrivalent live attenuated influenza vaccine; - , not applicable

[a] Agriflu (six months and older), Fluviral (six months and older), Influvac (three years and older)

[b] Afluria Tetra (five years and older), Flulaval Tetra (six months and older), Fluzone Quadrivalent (six months and older)

[c] Fluad Pediatric (6–23 months) or Fluad (65 years and older)

[d] Fluzone High-Dose (65 years and older)

[e] FluMist Quadrivalent (2–59 years)

[f] Evidence suggests moderate improvement in antibody response in infants, without an increase in reactogenicity, with the use of full vaccine doses (0.5 mL) for unadjuvanted inactivated influenza vaccines (9,10). This moderate improvement in antibody response without an increase in reactogenicity is the basis for the full dose recommendation for unadjuvanted inactivated vaccine for all ages. For more information, refer to *Statement on Seasonal Influenza Vaccine for 2011–2012* (11)

[g] Children six months to less than nine years of age receiving seasonal influenza vaccine for the first time in their life should be given two doses of influenza vaccine, with a minimum interval of four weeks between doses. Children six months to less than nine years of age who have been properly vaccinated with one or more doses of seasonal influenza vaccine in the past should receive one dose of influenza vaccine per season thereafter

Conclusion

NACI continues to recommend annual influenza vaccination for all individuals aged six months and older (noting product-specific age indications and contraindications), with particular focus on people at high risk of influenza-related complications or hospitalization. This includes all pregnant women; people capable of transmitting influenza to those at high risk; people who provide essential community services; and people in direct contact during culling operations with poultry infected with avian influenza. For the 2019–2020 influenza season, NACI recommends that the new Afluria Tetra influenza vaccine may be considered among the quadrivalent inactivated influenza vaccines offered to adults and children five years of age and older. NACI concluded that there is insufficient evidence at this time to support specific recommendations on the differential use of subunit and split virus inactivated influenza vaccines in adults 65 years and older.

Executive summary

Influenza pandemics are unpredictable but recurring events that can have consequences on human health and economic well-being worldwide. Advance planning and preparedness are critical to help mitigate the impact of a pandemic. This WHO guidance document, *Pandemic Influenza Risk Management*, updates and replaces *Pandemic influenza preparedness and response: a WHO guidance document*, which was published in 2009. This revision of the guidance takes account of lessons learnt from the influenza A(H1N1) 2009 pandemic and of other relevant developments.

The influenza A(H1N1) 2009 pandemic was both the first of the 21st century and the first since WHO had produced pandemic preparedness guidance. The experience of Member States during the pandemic varied, yet several common factors emerged. Member States had prepared for a pandemic of high severity and appeared unable to adapt their national and subnational responses adequately to a more moderate event. Communications were also demonstrated to be of immense importance: the need to provide clear risk assessments to decision-makers placed significant strain on ministries of health; and effective communication with the public was challenging. These, and other areas with improvement potential, were identified by the Review Committee on the Functioning of the International Health Regulations (2005) in relation to Pandemic (H1N1) 2009.

The influenza A(H1N1) 2009 pandemic provided a wealth of additional information to the established and growing body of knowledge on influenza viruses at the human–animal ecosystem interface. Other notable developments since the publication of the 2009 guidance include the adoption by the Sixty-fourth World Health Assembly of the Pandemic Influenza Preparedness Framework for the sharing of influenza viruses and access to vaccines and other benefits. In addition, risk management of acute public health events that have the potential to cross borders and threaten people worldwide continues to improve as a result of the International Health Regulations (2005) and States Parties' obligations on capacity strengthening.

This guidance can be used to inform and harmonize national and international pandemic preparedness and response. Countries should consider reviewing and/or updating national influenza preparedness and response plans to reflect the approach taken in this guidance. The roles and responsibilities of WHO relevant to pandemic preparedness, in terms of global leadership and support to Member States, are also articulated. This document is not intended to replace national plans, which should be developed by each country.

New in the 2013 guidance

Emergency Risk Management for Health

The approach taken in this 2013 guidance applies the principles of all-hazards emergency risk management for health (ERMH) to pandemic influenza risk management. The objectives of emergency risk management for health are to: strengthen capacities to manage the health risks from all hazards; embed comprehensive emergency risk management in the health sector; and enable and promote multisectoral linkage and integration across the whole-of-government and the whole-of-society. This guidance therefore aligns more closely with the disaster risk management structures already in place in many countries and underscores the need for appropriate and timely risk assessment for evidence-based decision-making at national, subnational and local levels.

Risk-based approach

This guidance introduces a risk-based approach to pandemic influenza risk management and encourages Member States to develop flexible plans, based on national risk assessment, taking account of the global risk assessment conducted by WHO. To support implementation, content on the application of assessments of risk and severity have been strengthened.

Approach to global phases and uncoupling global phases from national actions

In response to lessons learnt from the influenza A(H1N1) 2009 pandemic, a revised approach to global phases is introduced in this guidance. The phases, which are based on virological, epidemiological and clinical data, are to be used for describing the spread of a new influenza subtype, taking account of the disease it causes, around the world. The global phases have been clearly uncoupled from risk management decisions and actions at the country level. Thus, Member States are encouraged as far as possible to use national risk assessments to inform management decisions for the benefit of their country's specific situation and needs.

PIP Framework

The Pandemic Influenza Preparedness Framework for the sharing of influenza viruses and access to vaccines and other benefits, commonly known as the PIP Framework, brings together Member States, industry, other stakeholders and WHO to implement a global approach to pandemic influenza preparedness and response. Its key goals include:

- to improve and strengthen the sharing of influenza viruses with human pandemic potential; and
- to achieve, *inter alia*, more predictable, efficient and equitable access for countries in need of life-saving vaccines and medicines during future pandemics.

The Framework was developed by Member States and became effective on 24 May 2011, when it was adopted by the Sixty-fourth World Health Assembly.

1. Introduction

The influenza A(H1N1) 2009 pandemic was the first to occur since WHO had produced preparedness guidance. Guidance had been published in 1999, revised in 2005 and again in 2009 following advances in the development of antivirals and experiences with influenza A(H5N1) infections in poultry and humans. The emergence of the influenza A(H1N1)pdm09 virus provided further understanding of influenza pandemics and requirements for pandemic preparedness and response. The report of the Review Committee on the Functioning of the International Health Regulations (2005) in relation to Pandemic (H1N1) 2009 concluded: "The world is ill-prepared to respond to a severe influenza pandemic or to any similarly global, sustained and threatening public-health emergency" (*1*).

The Review Committee recommended that WHO should revise its pandemic preparedness guidance to support further efforts at the national and subnational level. Revisions recommended included: simplification of the pandemic phases structure; emphasis on a risk-based approach to enable a more flexible response to different scenarios; reliance on multisectoral participation; utilization of lessons learnt at the country, regional and global level; and further guidance on risk assessment. The Review Committee's report reflected the broad experiences of Member States during the influenza A(H1N1) 2009 pandemic – and the key point that previous pandemic planning guidance was overly rigid. Member States had prepared for a pandemic of high severity and appeared unable to adapt their responses adequately to a more moderate event. Communications also proved to be of immense importance during the influenza A(H1N1) 2009 pandemic, within the health and non-health sectors and to the public. Provision of clear risk assessments to decision-makers placed significant strain on ministries of health, and effective communication with the public was challenging.

This 2013 guidance is based on the principles of all-hazards emergency risk management for health (ERMH), thereby aligning pandemic risk management with the strategic approach adopted by WHO, in accordance with World Health Assembly resolution 64.10.[1] Commensurate with this approach, this guidance promotes building on existing capacities – in particular those under the International Health Regulations (2005) (*2*) (IHR [2005]) core capacities, in order to manage risks from pandemic influenza. Certain aspects of implementation of ERMH for national pandemic preparedness may therefore be linked with the core capacity strengthening activities required by the IHR (2005). This guidance can therefore be used as a model to illustrate how the mechanisms required for response to and recovery from pandemic influenza can be applied, as appropriate, to the management of all relevant health emergencies.

A risk-based approach to pandemic influenza management is emphasized and Member States are encouraged to develop flexible plans, based on national risk assessments. This guidance also places pandemic planning in the whole-of-society context. This 2013 revision therefore (1) reflects the approach taken at national level where pandemic influenza planning often rests with national disaster management authorities and (2) introduces or promotes all-hazards ERMH at Ministry of Health level, including mechanisms for wider national engagement.

This guidance also summarizes the roles and responsibilities of WHO relevant to pandemic preparedness, in terms of global leadership and support to Member States.

[1] WHA Resolution 64.10 in 2011, urges Member States to (1) integrate all-hazards health emergency and disaster risk management programmes (including disaster risk reduction) into national or subnational health plans; and (2) institutionalize capacities for coordinated health and multisectoral action to assess risks, proactively reduce risks, and prepare for, respond to, and recover from, emergencies, disasters and other crises.

2. WHO global leadership

WHO is responsible for providing leadership on global health matters, shaping the health research agenda, setting norms and standards, articulating evidence-based policy options, providing technical support to Member States and monitoring and assessing health trends. WHO promotes health as a shared responsibility, involving equitable access to essential care and collective defence against transnational threats.

As the directing and coordinating authority for health within the United Nations (UN) system, WHO has a mandate for global pandemic influenza risk management, (*3*, *4*) which is reflected at all levels of the Organization. Key mechanisms by which WHO fulfils this obligation are summarized below.

2.1 Coordination under the International Health Regulations (2005)

The IHR (2005) are binding upon 196 States Parties[2] and provide a global legal framework to prevent, control or respond to public health risks that may spread between countries.

Convening of an Emergency Committee, declaration of a Public Health Emergency of International Concern and issuance of IHR (2005) temporary recommendations

The IHR (2005) provide the regulatory framework for the timely and effective management of international public health risks. In addition, the Regulations provide a basis for collective global action for certain rare events of particular importance. Such serious events that endanger global public health are specified by the Regulations as public health emergencies of international concern. The term Public Health Emergency of International Concern (PHEIC) is defined in the IHR (2005) as "an extraordinary event which is determined to constitute a public health risk to other States through the international spread of disease and to potentially require a coordinated international response". This definition implies a situation that: is serious, sudden, unusual or unexpected; carries implications for public health beyond the affected State's national border; and may require immediate international action.[3]

---

[2] Non-Member States of WHO can notify the Director-General of their acceptance of the IHR (2005) which enters into force for them three months after the said notification. Two non-Member States have made such notifications.

[3] Article 12 Determination of a public health emergency of international concern

1. The Director-General shall determine, on the basis of the information received, in particular from the State Party within whose territory an event is occurring, whether an event constitutes a public health emergency of international concern in accordance with the criteria and the procedure set out in these Regulations.
2. If the Director-General considers, based on an assessment under these Regulations, that a public health emergency of international concern is occurring, the Director-General shall consult with the State Party in whose territory the event arises regarding this preliminary determination. If the Director-General and the State Party are in agreement regarding this determination, the Director-General shall, in accordance with the procedure set forth in Article 49, seek the views of the Committee established under Article 48 (hereinafter the "Emergency Committee") on appropriate temporary recommendations.
3. If, following the consultation in paragraph 2 above, the Director-General and the State Party in whose territory the event arises do not come to a consensus within 48 hours on whether the event constitutes a public health emergency of international concern, a determination shall be made in accordance with the procedure set forth in Article 49.
4. In determining whether an event constitutes a public health emergency of international concern, the Director-General shall consider:

The responsibility of determining whether an event is within this category lies with the WHO Director-General and requires the subsequent convening of a committee of health experts – the IHR Emergency Committee. This committee advises the Director General on the recommended measures to be promulgated on an emergency basis, known as temporary recommendations. Temporary recommendations include health measures to be implemented by the State Party experiencing the PHEIC, or by other States Parties, to prevent or reduce the international spread of disease and avoid unnecessary interference with international traffic.

The Emergency Committee also gives advice on the determination of the event as a PHEIC in circumstances where there is inconsistency in the assessment of the event between the Director-General and the affected country/countries. The Emergency Committee continues to provide advice to the Director-General throughout the duration of the PHEIC, including any necessary changes to the recommended measures for control and on the determination of PHEIC termination. WHO maintains an IHR roster of experts and the members of an IHR Emergency Committee are selected from this roster and/or WHO expert advisory panels and committees. At least one member of the Emergency Committee should be an expert nominated by a State Party within whose territory the event arises, and such States Parties are invited to present their views to the Emergency Committee.

Provision of information and support to affected States Parties

The IHR (2005) also provide a mandate to WHO to perform public health surveillance, risk assessment, support States Parties and coordinate the international response to significant international public health risks. After preliminary assessment, WHO is obliged by the IHR (2005) to obtain verification of event reports from States Parties.[4] If verification is sought, including in the context of potential pandemic influenza, States Parties are required to respond to WHO within a prescribed time period and include available relevant public health information. The regulatory requirement to respond to requests for verification by WHO aims to provide early identification of any public health event that may constitute a PHEIC. WHO

(a) information provided by the State Party;
(b) the decision instrument contained in Annex 2;
(c) the advice of the Emergency Committee;
(d) scientific principles as well as the available scientific evidence and other relevant information; and
(e) an assessment of the risk to human health, of the risk of international spread of disease and of the risk of interference with international traffic.

5. If the Director-General, following consultations with the State Party within whose territory the public health emergency of international concern has occurred, considers that a public health emergency of international concern has ended, the Director-General shall take a decision in accordance with the procedure set out in Article 49.

[4] IHR Article 10 – Verification

1. WHO shall request, in accordance with Article 9, verification from a State Party of reports from sources other than notifications or consultations of events which may constitute a public health emergency of international concern allegedly occurring in the State's territory. In such cases, WHO shall inform the State Party concerned regarding the reports it is seeking to verify.
2. Pursuant to the foregoing paragraph and to Article 9, each State Party, when requested by WHO, shall verify and provide:
   (a) within 24 hours, an initial reply to, or acknowledgement of, the request from WHO;
   (b) within 24 hours, available public health information on the status of events referred to in WHO's request; and
   (c) information to WHO in the context of an assessment under Article 6, including relevant information as described in that Article.
3. When WHO receives information of an event that may constitute a public health emergency of international concern, it shall offer to collaborate with the State Party concerned in assessing the potential for international disease spread, possible interference with international traffic and the adequacy of control measures. Such activities may include collaboration with other standard-setting organizations and the offer to mobilize international assistance in order to support the national authorities in conducting and coordinating on-site assessments. When requested by the State Party, WHO shall provide information supporting such an offer.
4. If the State Party does not accept the offer of collaboration, WHO may, when justified by the magnitude of the public health risk, share with other States Parties the information available to it, whilst encouraging the State Party to accept the offer of collaboration by WHO, taking into account the views of the State Party concerned.

is also obligated to provide event information to States Parties regarding public health risks, whenever that information is necessary for them to protect their populations.

When WHO intends to make information available to other States Parties, it has an obligation to consult with the country experiencing the event. WHO may also make information related to an arising influenza pandemic available to the public, if other information about the event is already in the public domain, and if a need exists for public availability of information that is authoritative and independent. Under the IHR (2005), WHO must offer assistance to States Parties in assessing or controlling public health events occurring within their territories. This support can be in the form of technical advice and guidelines, specialized materials, deployment of international teams to affected areas, and coordination of international support from various sources.

Measures adopted by States Parties in relation to travel or trade

The IHR (2005) seek to limit the public health measures taken in response to disease spread to those "that are commensurate with and restricted to public health risks, and which avoid unnecessary interference with international traffic and trade". To achieve this objective, WHO regularly issues advice on trade and travel measures related to public health events where such measures are likely or relevant. While the IHR (2005) do not prevent States Parties from implementing specific trade and travel related measures, they do require States Parties to inform WHO of these measures and the justification for their introduction when they will result in significant interference, defined in the IHR (2005) as resulting in delays to movement of international travellers, baggage, cargo, containers, conveyances, goods, and the like, of greater than 24 hours. In addition to providing other States Parties with information on these measures, WHO can request the implementing State Party to reconsider their application.

2.2 Pandemic phases

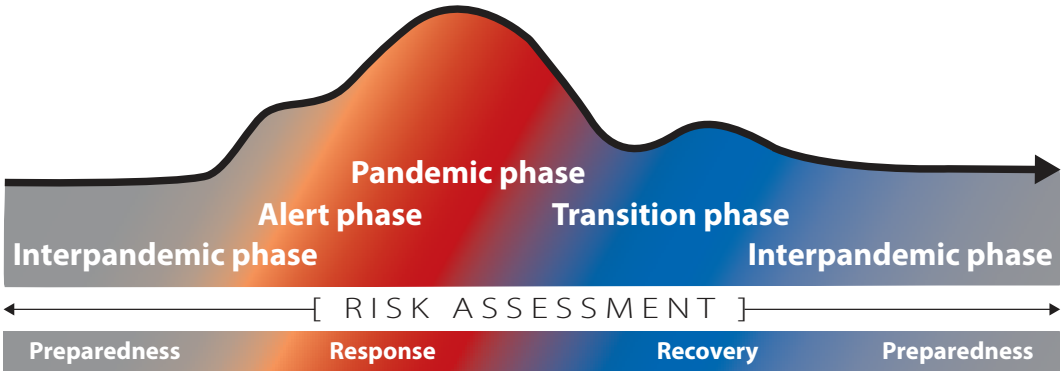
The pandemic influenza phases reflect WHO's risk assessment of the global situation regarding each influenza virus with pandemic potential that is infecting humans. These assessments are made initially when such viruses are identified and are updated based on evolving virological, epidemiological and clinical data. The phases provide a high-level, global view of the evolving picture.

The global phases – interpandemic, alert, pandemic and transition – describe the spread of the new influenza subtype, taking account of the disease it causes, around the world. As pandemic viruses emerge, countries and regions face different risks at different times. For that reason, countries are strongly advised to develop their own national risk assessments based on local circumstances, taking into consideration the information provided by the global assessments produced by WHO. Risk management decisions by countries are therefore expected to be informed by global risk assessments, but based on local risk assessments.

The risk-based approach to pandemic influenza phases is represented in **Figure 1** as a continuum, which also shows the phases in the context of preparedness, response and recovery, as part of an all-hazards approach to emergency risk management. Both WHO guidance and international standards exist that describe formats and conduct of such risk assessment (see **Section 4.2**). One of the underlying principles of this guidance is to acknowledge that emergency risk management at country level needs to be sufficiently flexible to accommodate different consequences within individual countries, for example, different severities and different numbers of waves of illness.

The global phases will be used by WHO to communicate the global situation. They will be incorporated into IHR (2005) related communications to National IHR Focal Points, in Disease Outbreak News releases and various other public and media interactions, including through social media channels.

Figure 1. The continuum of pandemic phases[a]



[a] This continuum is according to a "global average" of cases, over time, based on continued risk assessment and consistent with the broader emergency risk management continuum.

Interpandemic phase: This is the period between influenza pandemics.

Alert phase: This is the phase when influenza caused by a new subtype has been identified in humans.[5] Increased vigilance and careful risk assessment, at local, national and global levels, are characteristic of this phase. If the risk assessments indicate that the new virus is not developing into a pandemic strain, a de-escalation of activities towards those in the interpandemic phase may occur.

Pandemic phase: This is the period of global spread of human influenza caused by a new subtype. Movement between the interpandemic, alert and pandemic phases may occur quickly or gradually as indicated by the global risk assessment, principally based on virological, epidemiological and clinical data.

Transition phase: As the assessed global risk reduces, de-escalation of global actions may occur, and reduction in response activities or movement towards recovery actions by countries may be appropriate, according to their own risk assessments.

The global phases and their application in risk management are distinct from (1) the determination of a PHEIC under the IHR (2005) and (2) the declaration of a pandemic. These are based upon specific assessments and can be used for communication of the need for collective global action, or by regulatory bodies and/or for legal or contractual agreements, should they be based on a determination of a PHEIC or on a pandemic declaration.

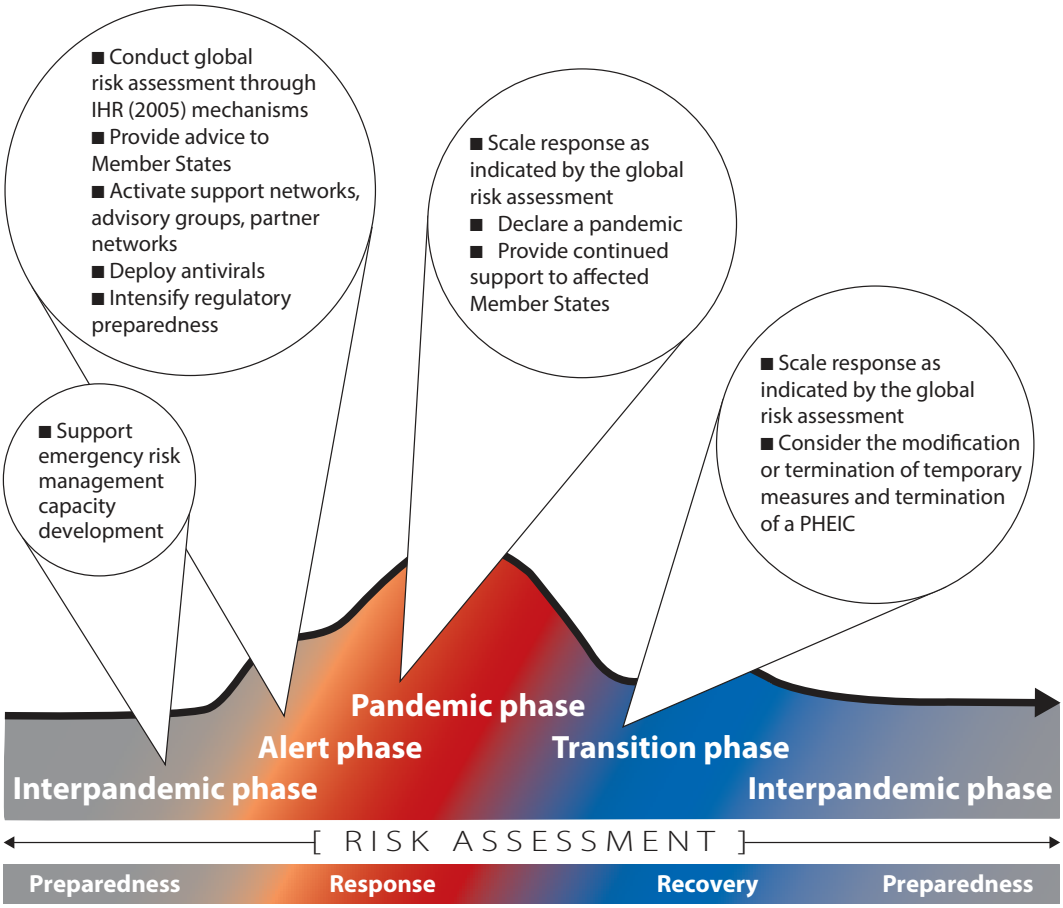
Determination of a PHEIC: The responsibility of determining a PHEIC lies with the WHO Director-General under Article 12 of the IHR (2005). The determination leads to the communication of temporary recommendations, see **Section 2.1**.

Declaration of a pandemic: During the period of spread of human influenza caused by a new subtype, and appropriate to the situation, the WHO Director-General may make a declaration of a pandemic.

While the determination of a PHEIC and/or declaration of a pandemic may trigger certain regulatory actions by WHO and Member States, actions at national level should be based on national/local risk assessments and be commensurate with risk.

[5] The IHR (2005) Annex 2 includes "human influenza caused by a new subtype" among the four specified diseases for which a case is necessarily considered "unusual or unexpected and may have serious public health impact, and thus shall be notified" in all circumstances to WHO.

Figure 2. The continuum of pandemic phases with indicative WHO actions



Actions by WHO occur throughout the phases continuum; their nature and scale at any point in time will be in line with the global risk assessment. Indicative actions by the Organization are illustrated in **Figure 2**. For further examples of WHO actions, see **Section 3.2**.

National actions: The nature and scale of national actions at any point in time will be in line with the current national risk assessments, taking into consideration the global risk assessment. The uncoupling of national actions from global phases is necessary since the global risk assessment, by definition, will not represent the situation in individual Member States. For further information on suggested national actions, see **Section 5**.

2.3 Pandemic Influenza Preparedness Framework

The Pandemic Influenza Preparedness Framework for the sharing of influenza viruses and access to vaccines and other benefits – widely known as the PIP Framework – brings together Member States, industry, other key stakeholders and WHO to implement a global, Member State-developed approach to pandemic influenza preparedness and response (*5*). The Framework aims to improve the sharing of influenza viruses with pandemic potential and to achieve, *inter alia*, more predictable, efficient and equitable access for countries in need of life-saving vaccines and medicines during future pandemics. The PIP Framework became effective on 24 May 2011, when it was adopted by the Sixty-fourth World Health Assembly. The Framework has three core components, described below.

Virus sharing

Member States share PIP biological materials[6] to ensure ongoing global monitoring and risk assessment and the development of safe and effective influenza vaccines. Standard Material Transfer Agreement 1 establishes the rights and obligations of Global Influenza Surveillance and Response System (GISRS)[7] laboratories when transferring PIP biological materials within GISRS and to parties outside GISRS.

Benefit sharing

Member States and WHO aim to ensure that benefits arising from the sharing of PIP biological materials are made more accessible and available to countries based on public health risk and need. Various key points are as follows:

- Standard Material Transfer Agreement 2 are binding contracts between WHO and all recipients of PIP biological materials outside of GISRS, which include: influenza vaccine, diagnostic and pharmaceutical manufacturers; biotechnology firms; and research and academic institutions. Non-GISRS recipients must assess benefits they can commit, or consider committing, to the PIP benefit-sharing system based on their nature and capacity.
- Partnership contribution: An annual contribution to WHO by influenza vaccine, diagnostic and pharmaceutical manufacturers who use WHO GISRS. The Framework specifies that the contribution will be used to improve global pandemic influenza preparedness and response.
- Other benefits: As listed under Section 6 of the PIP Framework, other benefits include laboratory and surveillance capacity building; regulatory capacity building; and the establishment of antiviral and interpandemic vaccine stockpiles.

Governance and review

The Framework puts in place an oversight mechanism with three pillars.

- The World Health Assembly to oversee implementation of the PIP Framework.
- The WHO Director-General to promote implementation.
- The Advisory Group to provide guidance to the Director-General, monitor PIP Framework implementation and report thereon annually to the Director-General.

WHO acts as the secretariat for implementing the PIP Framework and works with private and public partners to facilitate achieving results as efficiently as possible.

---

[6] For the purposes of the PIP Framework and its annexed Standard Material Transfer Agreements and terms of reference and the Influenza Virus Tracking Mechanism, "PIP biological materials" include human clinical specimens; virus isolates of wild-type human H5N1 and other influenza viruses with human pandemic potential; and modified viruses prepared from H5N1 and/or other influenza viruses with human pandemic potential developed by WHO GISRS laboratories, these being candidate vaccine viruses generated by reverse genetics and/or high growth reassortment. Also included in "PIP biological materials" are RNA extracted from wild-type H5N1 and other human influenza viruses with human pandemic potential and cDNA that encompass the entire coding region of one or more viral genes.

[7] GISRS monitors which influenza viruses are circulating in humans around the world throughout the year. GISRS comprises WHO Collaborating Centres; National Influenza Centres; H5 Reference Laboratories; and Essential Regulatory Laboratories. The major technical roles of GISRS are to: monitor human influenza disease burden; monitor antigenic drift and other changes (such as antiviral drug resistance) in seasonal influenza viruses; obtain suitable virus isolates for updating of influenza vaccines; and detect and obtain isolates of new influenza viruses infecting humans, especially those with pandemic potential. WHO also develops logistics management capacity to ensure that public health laboratories have access to protocols, tests and diagnostic reagents necessary to identify non-seasonal influenza virus infections. (See http://www.who.int/influenza/gisrs_laboratory/en/index.html, accessed April 2013.)

Member States' responsibilities

Under the Framework, Member States are responsible for (1) ensuring the timely sharing of influenza viruses with human pandemic potential with GISRS; (2) contributing to the pandemic influenza benefit-sharing system, including by working with relevant public and private institutions, organizations and entities so they make appropriate contributions to this system; and (3) continuing the support of GISRS.

2.4 Pandemic vaccine production

WHO issues biannual recommendations on the composition of seasonal influenza vaccines. Since 2004, WHO has also been reviewing vaccine candidate viruses for A(H5N1) and other influenza subtypes with pandemic potential. This process is undertaken in consultation with WHO Collaborating Centres for Influenza, National Influenza Centres, WHO H5 Reference Laboratories and key national regulatory reference laboratories. It is based on surveillance conducted by GISRS. The recommendations and availability of vaccine viruses are announced in a public meeting and simultaneously on the WHO web site (*6*). They are also communicated to influenza vaccine manufacturers via the International Federation of Pharmaceutical Manufacturers and Associations and the Developing Country Vaccine Manufacturers Network.

A critical action of WHO during an emerging pandemic is the selection of the pandemic vaccine strain and determination of when to move from seasonal to pandemic vaccine production. As soon as there is credible evidence to suggest that an influenza virus with pandemic potential has acquired the ability to sustain human-to-human transmission, WHO will expedite the process of review, selection, development and distribution of vaccine viruses for pandemic vaccine production, as well as vaccine potency testing reagents and preparations, involving all stakeholders as necessary. The efficiency of this process depends on the timely sharing of viruses and clinical specimens with WHO via GISRS and the WHO Collaborating Centres for Influenza.

The decision to recommend a move to pandemic vaccine production will be taken in collaboration and consultation with relevant technical advisory bodies including the Strategic Advisory Group of Experts on Immunization (SAGE) and GISRS, with due consideration to applicable requirements under the IHR (2005), including advice from an IHR Emergency Committee, should one be convened. WHO will then announce its recommendations on whether and when to move production to pandemic vaccine and the virus strain that should be used in the pandemic vaccine.

The decision to revert to seasonal vaccine production will be based on the formal recommendation for the composition of influenza vaccines, which is based on the virological and epidemiological information provided by GISRS and on the advice of relevant technical advisory bodies.

3. Emergency risk management for health

3.1 Principles of Emergency Risk Management for Health

Health and the systems that support it are vulnerable to loss and disruption from a variety of acute hazards including: (1) health events, such as pandemic influenza, chemical spills and nuclear contamination; (2) hazards secondary to emergencies and disasters, such as cholera outbreaks following floods; as well as (3) system destabilizers, such as earthquakes or acute energy shortages. Management of the risk associated with such hazards is central to the protection and promotion of public health.

To a varying extent, risk is managed within existing health systems and via programmes focused on specific hazards. However, some functional components of hazard-specific preparedness and response systems are common to all hazards and can therefore be consolidated into a comprehensive system of emergency risk management for health (ERMH). The objectives of ERMH are to:

- strengthen country and community capacities to manage the health risks from all types of hazards (7).
- ensure that the essential components required in a comprehensive emergency risk management programme are in place in the health sector.
- link and integrate these components into (1) health systems, (2) multisectoral disaster management systems, and (3) other mechanisms across the whole of society, including relevant risk management within non-health sectors.
- enable the health sector to advocate for and strengthen the health aspects of national and international policies and frameworks related to emergency and disaster risk management, particularly in the reduction of risk and health impact from all hazards.

The emergency risk management for health continuum describes the range of measures to manage risks through prevention and mitigation, and preparing for, responding to and recovering from emergencies.[8] Risk management measures for any health emergency, including pandemic influenza should be made on the basis of national and local risk assessment, taking account of the global assessment produced by WHO as appropriate.

Emergency risk management for health is based on the principles listed below.

Comprehensive risk management: A focus on assessment and management of risks of emergencies rather than events.

All-hazards approach: Use, development and strengthening of elements and systems that are common to the management of risks of emergencies from all sources.

Multisectoral approach: Recognition that all elements of government, business and civil society have capacities relevant to ERMH.

[8] For the purposes of risk management for pandemic influenza, three main groups of measures are used – preparedness, response and recovery. Prevention and mitigation are important in the context of comprehensive ERMH. They are reflected in both preparedness and response activities to be considered in national Pandemic Influenza Risk Management, Section 5.

Multidisciplinary approach: Recognition of the roles of many disciplines in health required to manage the health risks of emergencies through risk assessment, mitigation, prevention, preparedness, response, recovery and capacity strengthening.

Community resilience: Utilization of capacities at community level for risk assessment, reporting, providing basic services, risk communication for disease prevention and long-term community care and rehabilitation.

Sustainable development: Recognition that development of country and community capacities in health and other sectors requires a long-term approach to protect health and build resilience.

Ethical basis: Consideration of ethical principles throughout health emergency risk management activities.

3.1.1 Ensuring ethical Emergency Risk Management for Health

Management of an influenza pandemic, as with any urgent public health situation, requires certain decisions that balance potentially conflicting individual and community interests. For example, during the influenza A(H1N1) 2009 pandemic, countries experienced pressures on critical services that required prioritization (*8*) and impacted at the individual level. In addition, questions about social distancing measures, forced isolation and quarantine arose, together with debates on mandatory vaccination of health-care workers.

Ethics do not provide a prescribed set of policies; rather, ethical considerations will be shaped by the local context and cultural values. Nevertheless, it is important that any emergency measures that limit individual rights and civil liberties are necessary, reasonable, proportional, equitable, non-discriminatory and in full compliance with national and international laws (**Annex 3**) (*9*).

3.1.2 Emergency Risk Management for Health throughout the whole-of-society

A pandemic will affect the whole of society. No single agency or organization can effectively prepare for a pandemic in isolation, and uncoordinated preparedness of interdependent public and private organizations will reduce the ability of the health sector to respond. A comprehensive, coordinated, whole-of-government, whole-of-society approach to pandemic preparedness is required (**Annex 4**).

In the absence of effective planning, the effects of a pandemic at country level could possibly lead to social and economic disruption, threats to the continuity of essential services, lower productivity, distribution difficulties and shortages of supplies and human resources. It is therefore essential that all organizations – private and public – plan for the potential disruptions that a pandemic may cause. Business continuity planning should be considered for all essential service providers (**Annex 5**).

3.2 Emergency Risk Management for Health: essential components

The six categories of ERMH essential components are: policies and resource management; planning and coordination; information and knowledge management; health infrastructure and logistics; health and related services; and community emergency risk management capacities. A summary of the essential components in each of the categories is provided in **Table 2**.

WHO has been mandated by a series of World Health Assembly resolutions to provide Member States with guidance and technical support regarding pandemic influenza (*3*, *4*). Some of these obligations are specific to pandemic influenza and others overlap with the Organization's responsibilities in all health emergencies. Examples of the various functions, which are fulfilled at all levels of WHO, are provided for each category of essential component.

Table 2. Essential components in each category

Categories	Essential components
Policies and Resource Management	• Policies and legislation
	• Capacity development strategies
	• Monitoring, evaluation and reporting
	• Financing
	• Human resources
Planning and Coordination	• Coordination mechanisms
	• ERMH units in Ministry of Health
	• Prevention and mitigation planning and coordination
	• Preparedness and response planning and coordination
	• Recovery planning and coordination
	• Business continuity management
	• Exercise management
Information and Knowledge Management	• Risk assessments
	• Early warning and surveillance
	• Research for ERMH
	• Knowledge management
	• Information management
	• Public communications
Health infrastructure and logistics	• Logistics and supplies
	• Safer, prepared, and resilient health facilities
Health and related services	• Health-care services
	• Public health measures
	• Specialized services for specific hazards
Community ERMH capacities	• Local health workforce capacities and community-centred planning and action

3.2.1 Policies and resource management

Appropriate policies, plans, strategies and legislation form the basis of effective governance of ERMH. Policies and legislation should use an all-hazards approach, i.e. one that recognizes that risk management measures for hazard-specific emergencies have common elements and should cover the ERMH continuum through prevention and mitigation, preparedness, response and recovery.

Legislation should clearly articulate procedures for declaring and terminating a national public health emergency, based on national risk assessment. It should also define emergency management structures across the government national emergency/disaster management authority and should articulate the precise roles, rights and obligations of different organizations during a health emergency, based on an ethical framework to govern policy development and implementation. National legislation should be consistent with legally binding international agreements and conventions. Policies specific to the health sector should be compatible with legislation and should include defined roles and responsibilities, procedures and standards of implementation of ERMH. Policies and mechanisms to finance all ERMH activities need to be considered.

This category of essential components also includes the management of human and material resources. A human resource plan should be developed and should contain the staffing requirements for the management of health emergencies and define the competencies needed.

These plans should also specify the roles, responsibilities and authorities of the responders with written terms of reference for each specific function.

Capacity development is central to ensure that the health workforce is well equipped to implement ERMH. These efforts should be systematic and start with a thorough capacity assessment and analysis of training available for different target groups. Based on these analyses, training programmes that are appropriate, effective and efficient should be developed and instigated within educational institutions and as continuing professional development for the workforce.

Role of WHO in supporting policies and resource management

- Provide support to assess, strengthen and maintain core capacities in order to meet IHR (2005) obligations (*10*).
- Provide technical support to document the disease burden and economic impact of seasonal influenza and develop a national vaccine policy, if indicated.
- Advise on ethical frameworks to govern policies.
- Provide support and guidance to strengthen workforce capacities, e.g. health-care worker training.
- Strengthen GISRS and other laboratories to increase influenza diagnostic and surveillance capabilities and provide technical support, capacity building and technology transfer for influenza vaccines and diagnostics.
- Promote the increase of global production capacity for pandemic vaccines in developing countries, though the Global Action Plan for Influenza Vaccines (GAP) (*11*).

3.2.2 Planning and coordination

The health sector should be properly represented at all levels of government in any emergency/disaster risk management coordination forum to ensure that health needs are identified and technical advice provided to other sectors. One of the roles of these fora will be to develop and strengthen appropriate command and control systems across the national disaster management authority, within each government ministry and at subnational levels. Another important role of these fora is to ensure that the most current evidence is available to inform policy decisions.

In addition, an operational entity within the Ministry of Health or related institution should be responsible for coordinating and supervising emergency risk management implementation throughout the health sector, with stakeholder involvement. Similar entities should be in place at all subnational and local administrative levels.

Prevention and mitigation actions for any risk should be determined following a detailed risk assessment and be included in ERMH programmes at the national and subnational levels. The implementation of prevention, mitigation and preparedness measures should be coordinated with relevant technical departments inside the Ministry of Health and with the whole of government, business and civil society (**Annex 4**).

Effective coordination should be integral to all aspects of the response, starting with the initial risk assessment and including: the development of short- and long-term action plans; the assignment of resources to priority needs; and the provision of urgent community care and support. Incident management systems may be considered to facilitate the coordination under a common management structure. ERMH processes should be well documented in contingency plans and should include standard operational procedures that are appropriately disseminated, regularly updated and exercised.

Recovery needs to be an integral part of response planning and should be done in parallel with other risk management actions, i.e. well in advance of an emergency. Sufficient attention should be given to recovery planning for the health sector.

Role of WHO in planning and coordination

- Consistent with the whole-of-society, whole-of-government approach required for robust risk management for pandemic influenza, advocate collaboration and coordinate prioritized activities with organizations of the UN system, bilateral development agencies, nongovernmental organizations, the private sector and stakeholders in non-health sectors.
- Establish joint initiatives for closer collaboration with national and international partners in (1) early detection, reporting and investigation of influenza outbreaks of pandemic potential and (2) coordination of research on the human–animal ecosystem interface.
- Collaborate with the animal health sector, e.g. the Food and Agriculture Organization of the United Nations and the World Organisation for Animal Health, on preparedness, prevention, risk assessment and risk reduction mechanisms to decrease exposure of humans to influenza viruses at the human–animal ecosystem interface.
- Promote agreements for international technical assistance, resource mobilization and fair sharing of influenza products such as through the UN prequalification programme, Essential Medicines List and the PIP Framework (*5*, *12*, *13*).
- Provide guidance and/or technical support to Member States in the preparation of pandemic influenza risk management plans and in identifying priority needs and response strategies and assessing preparedness.
- Facilitate regional/cross-border collaborations.

3.2.3 Information and knowledge management

Information and knowledge management encompasses technical guidance for risk management, communications and early warning and surveillance, which are highlighted below, as well as risk assessment, (see **Section 4.1**) research for emergency risk management and information management.

3.2.3.1 Technical guidance

Practitioners should be provided with practical technical guidance on all aspects of ERMH. These guidelines should include clinical and operational aspects of the event. Continuity of health-care provision strategies should be periodically updated, as well, to reflect new research findings and lessons learnt from past health emergency events.

3.2.3.2 Communication

Effective and efficient communication is critical throughout the ERMH continuum and include information dissemination within the health sector, between health and other sectors and, crucially, with the public.

In risk communication, national and local government authorities provide information to the public in an understandable, timely, transparent and coordinated manner before, during and after a health emergency. The objectives are to develop and maintain public trust in local and national health systems and to convey realistic expectations about capacities for health emergency risk management. Risk communication also promotes the effective exchange of information and opinion among science, public health and veterinary experts, which facilitates assessment, implementation and coordination of risk management activities.

A communications strategy involves processes to collect, develop and distribute information in a timely manner and procedures to ensure that formats are appropriate to the target audiences. The strategy should take into account behavioural aspects of how people react to and act on advice and information they receive, not only from authorities but also from sources such as mass and social media. Public understanding of hazards and risks is complex, context-dependent and culturally mediated, thus communications strategy development may benefit from community participation (*14*).

ERMH plans and activities across all hazards should use the principles of risk communication to build the capacity to understand and anticipate public concerns and develop effective and responsive dialogue mechanisms. This can be achieved through an emergency communications committee that has developed and tested standard operating procedures to ensure streamlined, expedited dissemination of information for decision-making and public communication.

3.2.3.3 Early warning and surveillance

Accurate, timely information is one of the most valuable commodities during a health emergency or disaster. This information serves as the evidence base for critical decisions at all levels of administration and defines the messaging for public communication and education. An effective system, with minimal data sets of information required throughout the management of an emergency, should be developed and tested in preparation for a response.

The systems required for early warning and surveillance should be robust and enable the capture of data required for assessment of severity, the implementation of protocols for operational research, including efficacy studies on interventions applied, and assessments of national impact based on criteria such as workplace and school absenteeism, regions affected, groups most affected and essential worker availability.

Role of WHO in information and knowledge management

- Provide guidance and/or technical support to Member States on identifying priority needs and response strategies to inform preparedness planning.
- Facilitate development of national guidelines for relevant activities such as targeted vaccination campaigns, laboratory biosafety and safe specimen handling/shipping.
- Promote public health research priorities relevant to all resource settings for pandemic, non-seasonal and seasonal epidemic influenza over the medium- to long-term period via the WHO Public Health Research Agenda for Influenza.[9]
- Provide support and guidance on capacity building for health systems (*15*), infection prevention and control in health-care settings (*16*), surge capacity and national vaccine deployment (*17*).
- Assess and monitor the type and pathogenicity of circulating influenza viruses through information provided through GISRS.
- Provide technical guidance and advice to support Member States to develop effective and responsive pandemic communications, including risk communication and behavioural interventions messaging (*18*, *19*).
- Provide guidance, technical support and tools for detection, investigation, rapid risk assessment and reporting (*20*).

[9] The WHO Public Health Research Agenda for influenza has five thematic streams: (1) reducing the risk of emergence of pandemic influenza; (2) limiting the spread of pandemic, non-seasonal and seasonal epidemic influenza; (3) minimizing the impact of pandemic, non-seasonal and seasonal epidemic influenza; (4) optimizing the treatment of patients; and (5) promoting the development and application of modern public health tools. The research agenda also aims to facilitate discussion and coordination among researchers, donors and public health experts. See http://www.who.int/influenza/resources/research/about/en/index.html, accessed February 2013.

- Provide technical support and information to national authorities:
  - to enhance surveillance and collection of clinical, virological and epidemiological data to facilitate assessment of the extent of human-to human transmission and the epidemiological situation;
  - on risk assessment of clusters of influenza-like illness; and
  - on interventions to reduce the spread of influenza disease.
- Define standards for initial case investigations and for routine sentinel surveillance.
- Establish and refine global case definitions for reporting by countries of human cases of influenza caused by viruses with pandemic potential.
- Coordinate and disseminate relevant public health messages through channels such as the WHO web site, published materials, press conferences and the media.
- Provide regular and timely feedback on the results of the analysis of data reported by Member States to WHO.
- Periodically reassess and modify recommended interventions in consultation with appropriate partners, including those outside the health-care sector, on the acceptability, effectiveness and feasibility of interventions.
- Provide principles and update guidance for appropriate: infection prevention and control; laboratory biosafety; clinical management in health-care facilities and home-based care; use of antivirals; and use of seasonal and pandemic vaccines.

3.2.4 Logistics and infrastructure

Effective management of health emergencies requires access to and management of adequate infrastructure and logistics, the most important of which involve transportation, telecommunications, stockpiling and distribution of medicines and supplies, and establishment of temporary health facilities. To ensure that logistic support will be available during health emergencies, the Ministry of Health should consider making advance arrangements with government departments responsible for transport, communications, public works and the armed forces together with external agencies, such as nongovernmental organizations, UN agencies and private companies. The type and quantity of supplies and medicines will be determined by the nature of the hazard. The most critical supplies for pandemic influenza are those needed to prevent and treat the disease and its complications while maintaining critical non-influenza health services.

The Ministry of Health or the central coordinating body could also consider identifying, supporting, training and deploying operational and logistics response teams.

Role of WHO in supporting health infrastructure and logistics

- Manage the WHO strategic global stockpile of antivirals and vaccines and develop standard operating procedures to ensure rapid deployment of the WHO global "stockpile" of pandemic vaccines, based on existing pandemic vaccine deployment guidelines.
- Develop logistics management capacity to ensure that public health laboratories have access to protocols, tests and diagnostic reagents to be able to identify non-seasonal influenza virus infections (*21*).

3.2.5 Health and related services

Regardless of the nature of a health emergency challenge faced, health and related services will need to be provided to the affected population to save lives, manage public health, prevent secondary effects and maintain essential non-hazard-related emergency services. While many

of these health services do not differ from services provided in non-emergency situations, their organization and delivery may change significantly during a health emergency. This will require thoughtful planning beforehand. Health services related to triage, emergency care and maintenance of non-influenza acute care are among the many specified services requiring effective planning for implementation during a pandemic. Examples include activating contingency plans for health and laboratory facilities to deal with potential staff shortages, adjust triage systems as required and implementing mortuary management procedures as necessary.

In addition to service provision and public health measures, this essential component also includes identifying priorities and response strategies for public and private health-care systems triage and surge capacity. Surge capacity should be planned in advance for different scenarios with predetermined procedures for mobilizing staff on short notice. Mechanisms for ensuring adequate human resources for long-term events, such as an influenza pandemic should be considered, including planning for staffing of alternative care facilities for cohorting influenza patients, based on national plans. It is also important to consider ensuring that health-care workers have the opportunity for rest and recuperation.

Role of WHO in supporting health and related services

- Provide advice and technical guidance on organization and delivery of health and related services, e.g. laboratory services, blood services, non-pharmaceutical measures and mass casualty management systems.
- Utilize existing clinical networks to review clinical information and effectiveness and safety of clinical interventions.
- Provide advice on measures for controlling international disease spread through temporary recommendations issued under IHR (2005).
- Support health system capacity assessments for emergency risk management (*22*).

3.2.6 Community capacities

Community capacities are a vital component of ERMH. The community-based health workforce is a crucial front line for ERMH activities and has the language and cultural skills to implement effective local ERMH activities, including social mobilization. This workforce may include appropriately trained and accredited community health workers, trained volunteers, community-based organizations that promote health, health education and social mobilization, and those from key sectors (water, sanitation, hygiene, agriculture, food security, shelter and education) that contribute to promoting health. Developing local action plans based on national plans for any hazard is also an important consideration for strengthening community capacities.

Role of WHO in supporting community capacities

- Promote the role played by the community-based health workforce in emergency risk management and advocate for scale-up of this vital resource (*23*).
- Advise on strengthening community-based health workforce programmes, including recruitment, training, supervision, evaluation, deployment and retention (*24*).
- Provide guidance on training community health workers (*25*).
- Provide advice and guidance on community capacity building activities during pandemic influenza (*15*).

4. National pandemic influenza risk assessment

4.1 Influenza viruses and pandemics

Influenza, a viral respiratory disease, can cause high morbidity and mortality in humans and is known to affect some animal species. Clinical disease can range from mild to severe and in some cases result in death. While influenza B remains a human disease, influenza A viruses are found in human, avian and some mammalian species. An influenza pandemic occurs when an influenza A virus to which most humans have little or no existing immunity acquires the ability to cause sustained human-to-human transmission leading to community-wide outbreaks. Such a virus has the potential to spread rapidly worldwide, causing a pandemic.

At the genetic level, pandemic influenza viruses may arise through: (1) genetic reassortment: a process in which genes from animal and human influenza viruses mix together to create a human–animal influenza reassortant virus; (2) genetic mutation: a process in which genes in an animal influenza virus change allowing the virus to infect and transmit easily in humans.

Influenza pandemics are unpredictable but recurring events that can have significant global consequences. Since the 16th century, influenza pandemics have been described at intervals ranging between 10 and 50 years with varying severity and impact. Characteristics of the past four pandemics are summarized in **Table 3**.

Table 3. Characteristics of the past four influenza pandemics (*26*)

Pandemic year of emergence and common name	Area of origin	Influenza A virus sub-type (type of animal genetic introduction/ recombination event)	Estimated reproductive number (*27*, *28*)	Estimated case fatality	Estimated attributable excess mortality worldwide	Age groups most affected (*29*)
1918 "Spanish flu"	Unclear	H1N1 (unknown)	1.2–3.0	2–3% (*30*)	20–50 million	Young adults
1957–1958 "Asian flu"	Southern China	H2N2 (avian)	1.5	<0.2%	1–4 million	All age groups
1968–1969 "Hong Kong flu"	Southern China	H3N2 (avian)	1.3–1.6	<0.2%	1–4 million	All age groups
2009–2010 "influenza A(H1N1) 2009"	North America	H1N1 (swine)	1.1–1.8 (*31*)	0.02% (*32*)	100 000–400 000 (*33*)	Children and young adults

In June 2009, WHO declared the first influenza pandemic of the 21st century after the emergence of the new A(H1N1)pdm09 virus subtype. This virus was first isolated from humans in Mexico and the United States of America in April 2009. Within a few weeks, the virus had spread rapidly, and there was sustained human-to-human transmission worldwide. The triple-reassortant virus contained a unique combination of gene segments from avian, swine and human influenza viruses. Risk factors for severe influenza A(H1N1)pdm09 disease were similar to those for seasonal influenza, e.g. pregnancy and many chronic medical illnesses, although younger age groups were more affected than usual.

Prior to 2009, much of the focus on influenza viruses with pandemic potential was on the avian influenza subtype A(H5N1). A human outbreak of avian influenza A(H5N1) was detected

in 1997 in Hong Kong SAR, China. This was the first recognized instance in which a highly pathogenic avian influenza virus had been transmitted to humans and resulted in serious illness. Since its widespread re-emergence in 2003–2004, this avian virus has resulted in millions of poultry infections and over 600 human cases. On rare occasions, human-to-human transmission of influenza A(H5N1) has occurred – most often to a family or other household member acting as a caregiver. However, none of these events has so far resulted in sustained community-level transmission.

Most animal influenza viruses do not cause disease in humans. However, viruses circulating in animals or derived from viruses circulating in animals have caused infections in humans, including avian and swine viruses and reassortants, notably of the H1, H3, H5, H7 and H9 subtypes. Most of these human infections have been mild and the viruses have not spread further to other people. In contrast, the influenza A(H1N1)pdm09 virus, which is thought to have originated in swine, would be an example of a swine influenza virus that was able to spread easily among people and cause disease.

Humans generally acquire these infections through direct contact or close exposure to infected animals or contaminated environments. Control of influenza among animals is therefore essential both to reduce the risk of human infection and the potential for pandemic strains to evolve and to prevent or reduce the economic consequences. Successfully meeting this challenge requires long-term commitment from countries and strong coordination between animal and human health authorities and practitioners.

Experience with the emergence of such a variety of different influenza strains that transmit from animals to humans illustrates the highly unpredictable nature of influenza viruses such that assumptions about where the next influenza virus with pandemic potential will emerge, or what its characteristics will be, cannot easily be made. This uncertainty underscores that planning should not focus only on avian influenza but should be based on broad and robust surveillance and evidence-based risk assessment.

4.2 National risk assessments

Risk assessment is a sy*stematic process for gathering, assessing and documenting information to assign a level of risk (20*). Risk assessment aims to determine the likelihood and consequences of events that impact public health at global, national, subnational and local levels. It provides the basis for taking action to manage and reduce the negative consequences of risks to public health.

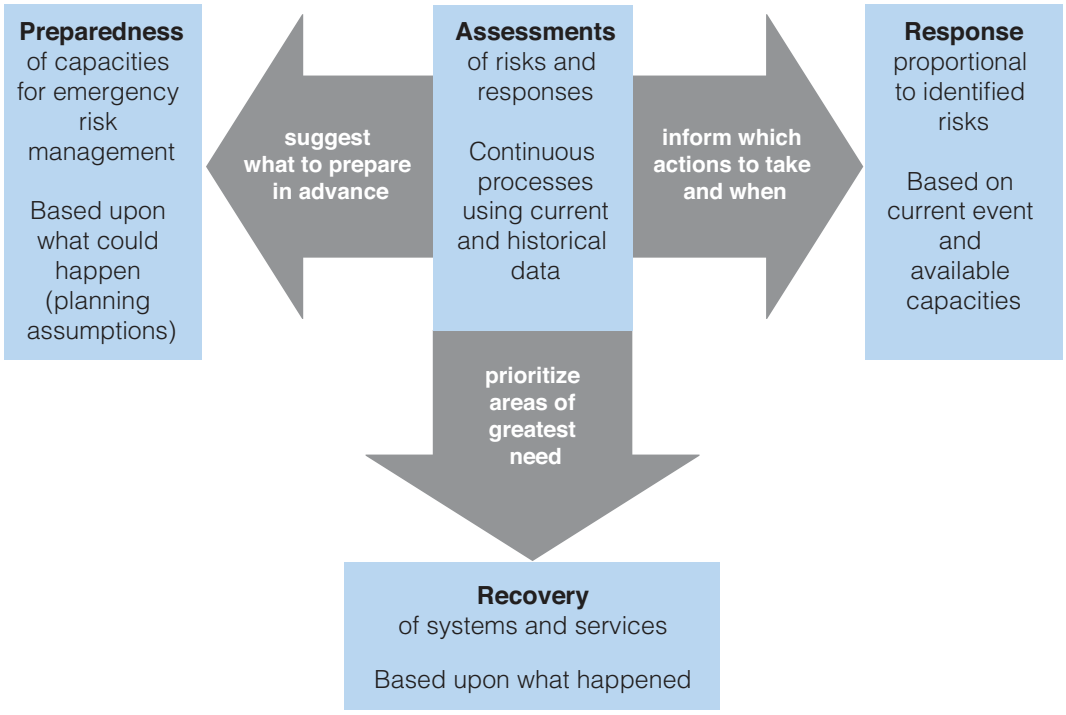
Use of risk assessment (*35*) promotes an understanding of the risks and attendant uncertainties of pandemic influenza and their potential influence on sustained health and other development objectives. It also facilitates the communication of risks and uncertainties. Risk assessment allows the provision of evidence-based information for policy-makers.

In an all-hazards approach, risk assessments can be performed to identify and prioritize preparedness, including mitigation and prevention, activities, response and recovery programmes, as illustrated in **Figure 3**.

For each influenza virus with pandemic potential, WHO will conduct global risk assessments in collaboration with the affected Member State(s), to inform decision-making for risk management (*36*). While WHO will communicate these global assessments and the uncertainties that surrounds them throughout the event, each Member State is strongly advised to assess national risk related to pandemic influenza in the context of their local experience, resources and vulnerabilities. Member States are also encouraged to share their risk assessments through networks or multilateral arrangements and to utilize regional resources for risk assessment.

At any point in a pandemic, one or many Member States may be responding to a national-level epidemic, while other Member States may not be affected for some months to come.

Figure 3. Pivotal role of risk assessment in preparedness, response and recovery actions



Consequently, each Member State is encouraged to conduct its own risk assessments, which will determine the timing, scale, emphasis, intensity and urgency of the actions required at their national and local levels. More information on suggested national actions is provided in **Section 5**.

National pandemic influenza risk assessment should involve a multidisciplinary team representative of the whole of government, together with stakeholders, and linked to relevant decision-makers. Since pandemic risk assessment has similar components across the whole of society, it should be conducted collaboratively with stakeholders at national, subnational and local levels.

A risk assessment considers hazard, exposure and context coupled with risk characterization. A hazard assessment relevant to pandemic influenza includes: identifying influenza viruses of concern; reviewing key virological and clinical information about each influenza virus; and ranking them by pandemic potential and possible consequences.

An exposure assessment seeks to define the groups of individuals known to have been, or likely to be, exposed to an influenza virus of concern and to delineate the susceptibility of these groups in terms of immunity and disease severity. This process incorporates epidemiological and susceptibility factors such as travel history, incubation period and estimation of potential for transmission.

These two assessments are then complemented by a context assessment. A context assessment is an evaluation of the environment in which the event takes place. It examines factors that affect risk, including: social; technological and scientific; economic; ethical; and policy and political factors, see **Table 4**.

Table 4. Factors to consider in context assessments

Factor	Examples
Social	• population size and characteristics such as distribution of high-risk groups
	• behaviours
	• impact of seasonal influenza
	• impact on lifestyle, e.g. acceptability and applicability of any social distancing recommendations
Technical and scientific	• ability to implement surveillance and mitigation activities
	• the likelihood that all suspect cases can be identified
	• the availability of mechanisms to reach specific high risk groups
	• the availability and acceptability of effective preventive measures and of treatment or supportive therapies
Economic	• direct and indirect financial costs including:
	• household income
	• hospitalization costs
	• potential impacts on tourism and trade
Ethical	• privacy issues
	• use of unlicensed products
	• transparency
	• unequal risk burden
	• potential requirements for the protection of critical infrastructure
Policy and political	• likely response of key stakeholders and media
	• government capacity to participate in risk management efforts
	• the country's recent experience with influenza
	• past and ongoing emergencies with implications for future hazards, vulnerabilities and capacities.

Once the hazard, exposure and context assessments are conducted, the risk can be characterized. Risk characterization seeks to organize the assessments into a determination of likelihood and impact of each risk. In the context of pandemic influenza, risk characterization employs these assessments to evaluate whether a particular influenza virus has pandemic potential and the degree to which such an event will impact on society, and, consequently, the urgency and scale of risk management actions to be implemented.

Throughout the risk assessment process, the uncertainty for each part of the assessment should be recorded and shared by the evaluating team. This documentation should include an overview of the basis for each assessment to ensure ongoing consistency in risk assessment processes.

Risk assessment is a continuous process throughout the risk management continuum. Member States are encouraged to conduct risk assessments at the national, subnational and local levels, in order to prioritize the development of risk management programmes tailored to the hazards present.

4.3 Assessment of pandemic severity

Gauging the severity of an influenza pandemic – a critical component of overall pandemic risk assessment – is an important consideration for WHO and Member States in planning for and responding to a pandemic. Early information about severity can help support decision-making at global and country levels. As a pandemic spreads from country to country, data derived from existing influenza disease and virological surveillance, coupled with field investigations and other data sources, can be used to adjust global and national responses. Some of these data-collection processes are provided through existing WHO guidance and related resources (*37*).

Early assessments in countries first affected by human infection with a new influenza subtype will inform the global community. However, each country's context and pandemic-influenza-related severity will differ, requiring careful evaluation not only of the data reported but the capacities, demographics and other features of the country in which the observations are made. In addition, continual severity assessments will be necessary over the course of a pandemic since the accuracy and precision of severity-related information will change.

Severity assessments should be conducted at the community, national and global level. Each of these assessments will enable refinement of risk assessments at the other levels. As when conducting other components of risk assessments, a country may measure a severity parameter directly, do so with the assistance of an external partner or rely on applicable information from others. For example, during the influenza A(H1N1) 2009 pandemic, informal networks of experts in epidemiology, clinical medicine, virology and mathematical modelling shared preliminary information with WHO to enable a global assessment of severity.

To be useful, the severity assessments should be done when public health decisions are needed. To that end, a risk assessment, incorporating severity, should provide as much information as possible to answer the following key questions about an emerging pandemic.

- How rapidly are new cases accruing?
- What groups of people (e.g. age groups or groups at risk of severe outcomes) will become severely ill and die?
- What types of illnesses and complications are being seen?
- Is the virus sensitive to antiviral agents?
- How many people will become ill?
- What will be the impact on the health-care sector, including such factors as health-care utilization and impact on the health-care work force?

Operationally, these questions will help guide decisions regarding vaccine production and strategy for usage, antiviral use, mobilization of health-care resources, school closures and other social distancing strategies.

The data that answer each of these key questions will be considered in the context of three indicators. Each of these indicators will contain information derived from a variety of different types of data, including virological, epidemiological, and clinical. The data will be grouped into the following indicators to help make them more accessible and understandable to the public and policy makers.

Transmissibility: Reflects the ease of movement of the virus between individuals, communities, and countries. The factors that will go into describing transmissibility include both virological factors and epidemiological observations. As with all of the indicators, the values of each of the observations or measurements that are used to reflect transmissibility will be interpreted in the context where they are made as they will be influenced by social and climatic factors.

Seriousness of Disease: A pandemic virus that has a high level of clinical severity can result in a disproportionate number of persons with serious or grave illness, some of whom will die in the absence of effective treatment or adequate clinical management. However, the severity or virulence of a virus will also depend on the presence of underlying medical conditions that predispose individuals to severe illness, as well as age. An infection is likely to be much more severe for some segments of a population than others and descriptions of the groups at risk will be part of this indicator.

Impact: If the health-care sector is impacted at a high level it may not be able to accommodate the stress on its resources. The impact on the health sector will also be influenced by public concern and health-care policies put in place in response to the event. As such, assessing

impact will aid in understanding how these issues interact with inherent characteristics of the virus and the way it behaves.

As appropriate, some of these data may also be communicated directly to policy-makers and planners. Examples of representative parameters informing each indicator are provided in **Annex 6**. WHO will communicate with its geographically and technically diverse group of staff, networks and external experts to help interpret the available qualitative and quantitative data. The severity assessments must be flexible in order to accommodate unforeseen characteristics of the pandemic as it evolves (e.g. a new indicator could be included or a known one excluded).

Any severity assessment plan has inherent limitations. Assessments are dependent upon the data available. Data first must be sought, then found, collected, shared, analyzed and communicated. Resource availability and competing interests may impede any of these steps and the ways in which these steps proceed will affect the validity of the data. Even under the best operational circumstances, data must accumulate over time before accuracy can be achieved. Case-fatality ratio, a commonly sought and communicated severity-related parameter, is well reported to have significant variability over the course of a pandemic and is not useful in the very early stages of an event because it is likely to be inaccurate and misleading (*38*, *39*). In these very early stages, the proportion of known cases requiring mechanical ventilation, for example, might be used instead of case-fatality ratio.

Severity varies within a population owing to a variety of risk factors (*40*). Population risk factors in terms of community resilience have not been carefully studied. However, antecedent general health status, availability of resources, including health-care services and medications, and cultural dynamics that affect transmission and care-seeking are likely to be relevant and will complicate comparisons between populations. As such, WHO will attempt to interpret the observations described above in the context in which they are made and project how they might affect subsequently affected Member States whose context is different. To do this, it will be necessary to communicate a wide variety of data to describe the full profile of the event. These considerations further increase the need for severity assessments to occur in the context of robust risk assessments. Further information on the representative parameters for core severity indicators is provided in **Annex 6**.

5. National pandemic influenza risk management

Individual countries may be exposed to the pandemic influenza virus at different times, have different case and case fatality rates, surveillance and response capacities, and vulnerabilities. They may experience different numbers and severities of waves of illness arising from the pandemic virus. Therefore, flexibility must be embedded in planning such that movement between the groups of activities below can be done with agility to reflect the national situation and meet local needs. For example, activities in the recovery period may need to be supplemented, as necessary, by response actions, should there be a subsequent pandemic wave. Mechanisms must be in place to enable this flexibility and for national emergency response procedures to be implemented – as guided by national risk assessment – irrespective of the global phase.

The following national actions are grouped by the six categories of essential components of ERMH (**Table 2**) and are indicative of actions to be considered following risk assessments. The degree of implementation should be commensurate with the degree of risk, national priorities and needs. These suggested national actions are intended to build on the progress made in developing and strengthening existing systems.

5.1 Policy and Resource Management

Preparedness activities to be considered

Based on national/local risk assessments, resources and needs:

- Review or develop national pandemic risk management programmes, including preparedness activities and response plans, and establish, as needed, the full legal authority and legislation required to sustain and optimize pandemic preparedness, capacity development and response efforts across all sectors.
- Perform forecasts of the national economic impact of a pandemic and cost-effectiveness of preparedness to advocate for funding and to aid risk management planning.
- Integrate pandemic risk management plans into existing national emergency risk management programmes.
- Establish goals and priorities for the use of pandemic influenza vaccines and antiviral drugs.
- Explore ways to provide drugs and medical care free of charge (or cover by insurance) to encourage prompt reporting and treatment of human cases caused by a non-seasonal influenza virus or virus with pandemic potential.
- Strengthen and maintain capacities to detect, assess, notify and report events, the capacity to respond promptly and effectively and the capacities at designated points of entry relating to the identification and management of pandemic risks in accordance with IHR (2005) Annex 1A and 1B.2.
- Advise subnational and local governments on best practices in pandemic planning and implement a quality control system to regularly monitor and evaluate the operability and quality of local and regional plans.
- Develop procedures for access to and timely allocation of resources for preparedness, capacity development and intervention implementation at national and subnational levels, including activities to be fulfilled by humanitarian, community-based or nongovernmental organizations.

- Create a national roster of experts to provide high-level technical advice in areas such as ethics, risk assessment, infection prevention and control, respiratory diseases and emergency management.
- Assess existing capacities and identify priorities for pandemic risk management at national and subnational levels.
- Develop strategies, plans and training to enable all health-care workers, including community-level workers, to respond during influenza outbreaks and throughout a pandemic (*24*).
- Develop occupational health policies for essential services workers and develop guidance and policies to enable workers to stay home when ill.

Response activities to be considered

Based on national/local risk assessments, resources and needs:

- Prioritize and guide the allocation and targeting of additional human and material resources to achieve the goals of pandemic risk management plans.
- Assess whether international assistance is required to meet humanitarian needs. Alternatively, consider providing resources and technical assistance to countries experiencing outbreaks of influenza with pandemic potential (*41*).

Recovery activities to be considered

Based on national/local risk assessments, resources and needs:

- Review the lessons learnt about policies and resource management and revise national and subnational pandemic risk management plans; encourage stakeholders across all public and private sectors to do likewise.

5.2 Planning and coordination

Preparedness activities to be considered

Based on national/local risk assessments, resources and needs:

- If not already in place, consider appointing a cross-governmental, multi-agency national pandemic risk management committee. Suggested activities of this committee could include the following:
  - Develop, exercise (*42*) and periodically revise national and subnational pandemic risk management plans in close collaboration with all relevant public and private partners. Review subnational pandemic plans against the national plan and involve subnational and local representatives in testing interoperability.
  - Provide the key assumptions, guidance and relevant information to promote development of pandemic business continuity plans and strategies for public and private sector workplaces (**Annex 5**).
  - Lead and coordinate multisectoral resources to mitigate the societal and economic impact of a pandemic (**Annex 4**).
  - Consider planning for containment measures (**Annex 7**).
- Planning and coordination activities of the Ministry of Health entity responsible for ERMH could include the following activities:
  - Identify, brief regularly and train key personnel to be mobilized as part of a multisectoral expert response team for influenza outbreaks of pandemic potential.

— Encourage collaboration with neighbouring countries on aspects of pandemic preparedness planning that may have regional or cross-border implications through information sharing, participation in regional and international initiatives, exercises and coordination of responses to address trans-border issues including interoperability of plans.

Response activities to be considered

Based on national/local risk assessments, resources and needs:

- Update leadership and other relevant sectors on global and national pandemic influenza risk assessments.
- Provide the key assumptions, guidance and relevant information to public and private sectors to facilitate implementation of their pandemic business continuity plans.
- Finalize preparations for an imminent pandemic by activating national and subnational command and control systems.
- Activate pandemic contingency planning arrangements for the health sector and all sectors deemed critical for the provision of essential services.
- Switch to pandemic working arrangements.
- Respond, if possible, to requests for international assistance by offering resources and technical assistance to countries with ongoing pandemic activity.
- Collaborate with neighbouring countries on information sharing.
- Provide regular updates on the evolving situation to WHO and other partners to facilitate response coordination.
- Review and, if necessary, revise pandemic risk management plans to manage possible future pandemic wave(s).
- Evaluate the resources and capacities needed to monitor and respond to subsequent waves.

Recovery activities to be considered

Based on national/local risk assessments, resources and needs:

- Review the lessons learnt about planning and coordination across all sectors and share experiences with the international community. Review and, if necessary, revise pandemic risk management plans to manage a possible future pandemic.

5.3 Information and knowledge management

5.3.1 Technical guidance

Preparedness activities to be considered

Based on national/local risk assessments, resources and needs:

- Develop and disseminate guidance on all aspects of pandemic response including: clinical management; prevention and control of health-care associated infections; surveillance throughout the pandemic; public health measures; surge capacity; and management of non-influenza acute care patients.
- Anticipate the need for rapid revision and dissemination of guidance, e.g. new laboratory protocols as the diagnostics for the new strain become available.
- Develop and test guideline dissemination mechanisms.
- Develop case-finding, treatment and management protocols/algorithms.

- Provide guidance to health-care workers to test and report cases of suspected pandemic influenza infection in patients with respiratory illness, especially those who have travelled to an affected country/countries or their close contacts.

Response activities to be considered

Based on national/local risk assessments, resources and needs:

- Update, if necessary, national guidance and recommendations on the use of planned interventions taking into account information from affected countries.
- Update, if necessary, laboratory protocols for virus detection, identification, shipping and sharing with WHO Collaborating Centres for Influenza.
- To the extent possible, use standardized protocols to monitor safety, efficacy and supply of pharmaceutical interventions.
- Revise case definitions and diagnostic and treatment protocols/algorithms, as required.

Recovery activities to be considered

Based on national/local risk assessments, resources and needs:

- Communicate to the public and other stakeholders the lessons learnt about the effectiveness of policy and technical guidance during the pandemic and how the gaps that were discovered will be addressed. Evaluate guidance dissemination mechanisms and work with professional associations towards improvement. In addition, analyse data collected during the event for dissemination and consider revising the national risk assessment algorithms.

5.3.2 Communications

Preparedness activities to be considered

Based on national/local risk assessments, resources and needs:

- Develop effective strategies to inform, educate and communicate with individuals and families to improve their ability to take appropriate actions before, during and after a pandemic.
- Identify appropriate spokespeople.
- Identify communications channels and assess their ability to reach all target population groups. Develop protocols and provide training to spokespeople for each communication channel.
- Pre-test messages through each medium, including social media, and test communications procedures through exercises.
- Build effective relations with key journalists and familiarize them with influenza and pandemic related issues.
- Develop communication strategies to support the implementation of non-pharmaceutical interventions including restrictions on mass gatherings and school closures.

Response activities to be considered

Based on national/local risk assessments, resources and needs:

- Provide regular briefing updates to all spokespeople to ensure that the information conveyed is consistent and up-to-date.
- Conduct frequent and pre-announced public briefings through popular media outlets such as the web, television, social media and radio to counter panic and dispel rumours.

- Activate mechanisms to ensure the widest possible dissemination of information. Topics likely to require regular communication include :
  - What is known and not known about the virus, the state of the outbreak, use and effectiveness of measures and likely next steps.
  - What is known and not known about the pandemic disease, including transmission patterns, clinical severity, treatment and prophylaxis options.
  - The importance of compliance with recommended measures to stop further spread of the disease.
  - Societal concerns, such as the disruption to travel, border closures, school closures and the impact on the economy or society in general.
  - Sources of emergency medical care, resources for dealing with urgent non-pandemic health-care needs, and resources for self-care of medical conditions.
  - Any changes to the status of the pandemic.
  - The ongoing need for vigilance and disease-prevention efforts to prevent any upswing in disease levels.
  - Advice for travellers.
- Ensure effective communication of public health measures to reduce the spread of pandemic influenza, e.g. hand and respiratory hygiene, reduction of unnecessary travel and overcrowding of mass transport systems, self-isolation for sick individuals, except their nominated caregiver, and minimization of contact with others.
- Gather feedback from the general public, vulnerable populations and at-risk groups on attitudes towards the recommended measures and barriers affecting their willingness or ability to comply.
- Update communications strategies as feedback from the general public and stakeholder organizations is collected and analysed.

Recovery activities to be considered

Based on national/local risk assessments, resources and needs:

- Publicly acknowledge the contributions of all communities and sectors to the pandemic effort. Review the lessons learnt about communications and revise in readiness for the next major public health event. Communicate that the event may be over but that a second (or subsequent) wave(s) is/are possible and that the pandemic virus will revert to a seasonal pattern and be present as one of the circulating viruses for some time to come.

5.3.3 Early warning and surveillance

Preparedness activities to be considered

Based on national/local risk assessments, resources and needs:

- Ensure that mechanisms are in place for meeting obligations under IHR (2005) to detect, assess, notify and report events. Such mechanisms include the capacities to respond promptly and effectively and requisite capacities at designated points of entry relating to the identification and management of pandemic risks in accordance with IHR (2005) Annex 1A and 1B.2.
- Develop or strengthen national surveillance to collect up-to-date virological, epidemiological and clinical information on trends in human seasonal influenza infections to aid estimates of additional capacities needed to detect increases in pandemic activity.

- Enhance virological and epidemiological surveillance to detect and investigate unusual cases/clusters of influenza-like respiratory illness or deaths associated with non-seasonal influenza viruses, identify potential animal sources of human infection; and assess the risk of human-to-human transmission.

Response activities to be considered

Based on national/local risk assessments, resources and needs:

- Undertake a comprehensive assessment of the earliest national cases of pandemic influenza.
- Ensure that, as required under the IHR (2005), any notification is followed by ongoing communication to WHO of timely, accurate and sufficiently detailed public health information on the event, including, where possible, case definitions, laboratory results, source and type of risk, number of cases and deaths, conditions affecting the spread of the disease and the public health interventions employed.
- Collect and analyse available data to evaluate the virological, epidemiological and clinical characteristics of the national epidemic.
- Modify national case definitions and update clinical and laboratory algorithms for diagnosis, as necessary.
- Collect specimens for testing and virological characterization using protocols and procedures developed in collaboration with WHO.
- Document the evolving national epidemic including population susceptibility, changes in epidemiological and clinical features, geographical spread, trends and impact.
- Collect more detailed epidemiological and clinical data as time and resources permit.
- Maintain adequate virological surveillance to detect antigenic and genetic changes and changes in antiviral susceptibility and pathogenicity (*43*, *44*).
- Continue to update the health sector and other relevant ministries and decision-makers on new information or other changes that affect disease status, signs and symptoms, case definitions, protocols and algorithms.
- Activate the surveillance activities required to detect subsequent pandemic waves.
- Monitor and assess national impact using criteria such as workplace and school absenteeism, regions affected, groups most affected and essential worker availability.

Recovery activities to be considered

Based on national/local risk assessments, resources and needs:

- Review and revise situation monitoring and assessment tools for subsequent waves of disease, the next pandemic and other public health emergencies. In addition, resume seasonal influenza surveillance programmes incorporating the pandemic virus subtype as part of routine surveillance.

5.4 Health infrastructure and logistics

Preparedness activities to be considered

Based on national/local risk assessments, resources and needs:

- Develop pandemic risk management plans throughout the health sector, including for health facilities, laboratories and other allied health services.
- Plan for the increased need for antibiotics, antipyretics, hydration, oxygen and ventilation support within the context of national clinical management strategies.

- Develop mechanisms and procedures to select, procure, stockpile, distribute and deliver antivirals, essential pharmaceuticals, personal protective equipment, diagnostics tests and vaccines, when available and based on national goals and resources. Consider whether these mechanisms are adequate to conduct containment measures (**Annex 7**).
- Develop a deployment plan to deliver pandemic influenza vaccines to national and subnational distribution points within 7 days from when the vaccine is available to the national government and develop a mass vaccination campaign strategy (*17*).

Response activities to be considered

Based on national/local risk assessments, resources and needs:

- Implement vaccine procurement plans.
- Implement distribution and deployment plans for antivirals, vaccines and other pharmaceuticals, other medical supplies and personal protective equipment, according to national plans.
- Monitor essential health-related resources such as: medical supplies; antivirals, vaccines and other pharmaceuticals; health-care worker availability; hospital occupancy/availability; use of alternative health facilities; laboratory material stocks; and mortuary capacity.
- Deploy pandemic vaccine when available in accordance with national plans, priorities and vaccine availability.

Recovery activities to be considered

Based on national/local risk assessments, resources and needs:

- Restock medications and supplies and service and renew essential equipment in preparation for possible subsequent waves of pandemic virus-induced disease or other health emergencies. In addition, review the status of, and replenish, national and local stockpiles.

5.5 Health and related services

5.5.1 Health services

Preparedness activities to be considered

Based on national/local risk assessments, resources and needs:

- Consider policy and needs of an in-country approach to antivirals and vaccination, including mechanisms for evaluating effectiveness and monitoring for adverse events.
- Estimate and prioritize requirements for antiviral treatment or prophylaxis and vaccination during a pandemic.
- Consider capacity and resources for stockpiling essential medicines and equipment.
- Assess health system capacity to detect and contain outbreaks of pandemic influenza disease in hospital settings (*45*).
- Develop mechanisms to monitor uptake, compliance, safety and effectiveness of mitigation measures and share findings with the international community and WHO.

Response activities to be considered

Based on national/local risk assessments, resources and needs:

- Implement national plans for antivirals and/or vaccine campaigns according to priority status and availability, in accordance with the evidence or modify/adapt antiviral and vaccine strategies based on monitoring and surveillance information.

- Enhance infection prevention and control practices in health-care and laboratory settings and issue personal protective equipment as needed in accordance with national plans.
- Activate alternative strategies for case isolation and management as needed.
- Address the psychological impacts of the pandemic, especially on the health workforce, and provide social and psychological support for health-care workers, patients and communities.
- Reassess the capacity to implement mitigation measures to reduce the spread of pandemic influenza.
- Consider vaccination of health-care workers, when available and based on national goals and policies.
- Conduct ongoing evaluations of antiviral effectiveness, safety and resistance, and vaccine coverage, effectiveness and safety, throughout their deployment, according to national plans, mechanisms and procedures.

Recovery activities to be considered

Based on national/local risk assessments, resources and needs:

- Conduct a thorough evaluation of all the specific responses and interventions used, including: (1) antiviral effectiveness, safety and resistance; (2) vaccine coverage, effectiveness and safety, and share findings with the international community.
- Begin rebuilding essential services in preparation for subsequent waves of disease and/or other health emergencies.
- Work to increase seasonal influenza vaccine coverage levels of all groups at high risk, in accordance with national policy.

5.5.2 Public health-related measures

Preparedness activities to be considered

Based on national/local risk assessments, resources and needs:

- Identify the range of non-pharmaceutical interventions that might be recommended and develop protocols and communications to support their implementation.
- Develop a framework to facilitate decision-making for activation and de-escalation of specific measures, such as school closures or cancellation or restriction of mass gatherings based on appropriate risk assessment criteria.
- Plan for actions relating to temporary recommendations issued under IHR (2005), especially measures to slow the spread of disease.

Response activities to be considered

Based on national/local risk assessments, resources and needs:

- Assess and determine whether cancellation, restriction or modification of mass gatherings is indicated.
- Implement social distancing measures, as indicated in national plans, such as school closures and other societal-level disease control measures including adjusted working patterns.

Recovery activities to be considered

Based on national/local risk assessments, resources and needs:

- Conduct a thorough evaluation of the effectiveness of the individual, household and societal measures implemented and update guidelines, protocols and algorithms accordingly.

5.6 Community capacities

Preparedness activities to be considered

Based on national/local risk assessments, resources and needs:

- Develop guidance and plans to provide necessary support for prevention, treatment and infection prevention and control for ill persons isolated at home and their household contacts.
- Develop plans and mechanisms to enable increased access to treatment and care for community members.
- Develop public health education campaigns, including creating messages and feedback mechanisms targeted towards hard-to-reach, disadvantaged or minority groups.

Response activities to be considered

Based on national/local risk assessments, resources and needs:

- Initiate public health education campaigns in coordination with other relevant authorities on individual-level infection control measures.
- Implement appropriate individual/household medical and non-medical disease control measures for suspect cases and their contacts in households.
- Advise household contacts to minimize their level of interaction outside the home and to isolate themselves at the first symptoms of influenza.
- Advise individuals to stay home when ill.
- Provide infection control guidance for household caregivers taking into account relevant WHO guidance.

Recovery activities to be considered

Based on national/local risk assessments, resources and needs:

- As needed, provide psychosocial services to facilitate individual and community-level recovery.

Annexes

Annex 1. Guidance revision process

The content of this WHO guidance document, *Pandemic influenza risk management*, has been largely based on *Pandemic influenza preparedness and response: a WHO guidance document*, which was published in 2009. The draft content was reviewed by a WHO Internal Steering Committee, comprising technical experts in influenza, multisectoral collaboration for influenza, risk management, event management, communications, influenza at the human–animal ecosystem interface, antivirals, vaccine research and emergency risk management for health, and assessed for relevance and continued applicability to the risk management of pandemic influenza.

Throughout the revision process, the Internal Steering Committee met four times, with significant e-mail correspondence between meetings. Members of the Internal Steering Committee were invited to provide inputs and updates to relevant sections of the document, according to their expertise.

During 11–12 April 2013, an external Peer Review Group meeting was convened to: (1) consider the revised guidance in relation to emergency risk management for health as well as recommendations from the report of the Review Committee on the Functioning of the International Health Regulations (2005) in relation to Pandemic (H1N1) 2009; and (2) provide feedback, comment and input on the draft guidance.

The peer reviewers' comments were noted, and taken into account in a revised draft of the document. The revised draft was sent to the peer reviewers for acknowledgement of the changes requested and inclusion of additional comments, then finalized for Member State engagement.

Declaration of interests

All external peer reviewers acknowledged herein completed and submitted a WHO Declaration of Interest for WHO Experts form. These declarations of interest were assessed and presented to the Peer Review Group meeting. The Chair of the Peer Review Group formally declared no interests. Of the 16 other external peer reviewers who participated in the review of this guidance document, three declared interests. The peer reviewers with declared interests are listed below, together with a short description of the interests concerned.

Peer reviewers with declared interests

Dr Nick Phin

At the time of the Peer Review Group meeting, Dr Nick Phin was about to undertake a retrospective review of clinical and safety data on patients given aqueous zanamivir during the influenza A(H1N1) 2009 pandemic and the 2010–2011 influenza season as part of the compassionate use programme. The research is being led by Public Health England with some sponsorship from GlaxoSmithKline. This sponsorship consists of £25 000 for a short-term researcher post and £25 000 to reimburse the resources used by hospitals to identify and provide the data. As the review is retrospective and there is no specific information on the use of medicines included in this project, no conflict of interest was determined.

Professor Lone Simonsen

In 2011, Professor Simonsen provided consulting services in the area of influenza and respiratory syncytial virus disease burden modelling and methodological issues with observational study designs to GlaxoSmithKline and BioCryst for US$ 10 000 and in 2012 received less than US$ 5000 to participate in expert panels for GlaxoSmithKline, Merck, AstraZeneca and Novartis. As no specific information on burden modelling is included in this guidance, no conflict of interest was determined.

Dr Benjamin Cowling

Dr Benjamin Cowling was paid US$ 2000 for consultation work on influenza treatment and prevention strategies for Crucell NV in 2012. He was also the principal investigator and account-holder for an investigator-initiated trial of influenza vaccine supported by significant funding from MedImmune in 2009–2010. This was vaccine-specific research. As there are some references to vaccines and vaccine policy throughout this guidance, it was felt this research could constitute a conflict of interest and therefore Dr Cowling was excluded from discussions on vaccine-related issues.

Annex 2. Planning assumptions

Planning for a future influenza pandemic is challenging in part because important features of the next pandemic are not known. In this situation, assumptions relating to the epidemiology of influenza are needed to make decisions in public health planning, as well as estimating required resources.

This Annex provides some planning assumptions to be considered by national authorities in developing a pandemic influenza risk management strategy. These assumptions are based on information known at the time of publication about seasonal influenza, avian influenza and past influenza pandemics. These data should not be taken as predictive of features of the next pandemic. The characteristics and impacts of past pandemics have varied between and within countries. These differences are most likely attributable to both the characteristics of the pandemic virus and the local ability to respond to the disease.

It is not the intention of this Annex to provide a comprehensive review of the epidemiology of influenza. However, it will be updated as new scientific data become available that significantly change these assumptions. Key references are provided for readers to review the existing literature.

A2.1 Modes of transmission

Assumptions

Modes of virus transmission of pandemic influenza are expected to be similar to those of seasonal influenza: via the large droplet or contact (either direct or indirect) route, with a contribution by particle airborne route, or a combination of both.

The relative contribution and clinical importance of potentially different modes of transmission of influenza are unknown. However, epidemiological patterns suggest that the spread of the virus is mostly through close contact via the droplet or contact route.

Implications

- To decrease viral transmission, good hand hygiene, isolation of ill people and the use of personal protective equipment are important measures when caring for people with influenza.
- An airborne precaution room is not indicated for routine care. However, health-care workers should wear eye protection, a gown, clean non-sterile gloves and particulate respirators during aerosol-generating procedures.

Scientific basis

- Droplet and contact transmission appear to be major routes of transmission for seasonal influenza (Brankston G et al, 2007; Bridges CB et al, 2003).
- However, data are insufficient to determine the relative importance of the different modes of transmission. In addition, there is lack of standardization and consensus about the technical definition (i.e. particle size) of an aerosol versus a droplet (Tellier R, 2006; Lemieux C et al, 2007, Lindsley W, 2012).
- Relative heat and humidity affect the efficiency of transmission of influenza via aerosol. (Hanley BP, 2010). Some have reported the lack of aerosol transmission at 30 °C, while transmission via the contact route was equally efficient at 30 °C and 20 °C. (Lowen AC et al, 2007; Lowen AC et al, 2008).
- Certain procedures performed in health-care settings can create aerosols. Some of these procedures have been associated with a significant increase in the risk of disease transmission and have been termed “aerosol-generating procedures associated with pathogen trans-

mission" (WHO, 2007). These procedures include intubation, cardiopulmonary resuscitation, bronchoscopy, autopsy and surgery where high-speed devices are used (WHO, 2007).

A2.2 Incubation period and infectivity of pandemic influenza

Assumptions

- Incubation period: 1–3 days.
- Latent period: 0.5–2 days.
- Duration of infectiousness: about 5 days in adults and possibly longer in children.
- Basic reproduction number (R0): 1.1–2.0.

Implications

- The incubation period and the duration of infectiousness are useful for planning purposes with regard to: length of isolation for cases; development of a definition for contacts of cases; and the length of quarantine for contacts.
- A relatively short incubation period would make it difficult to stop the spread of pandemic influenza by contact tracing and quarantine.
- Viral shedding before symptoms develop would make it difficult to stop the spread of pandemic influenza solely by screening and isolating clinically ill persons.

- Once the pandemic begins, it will be important for countries to undertake surveillance and special studies to assess the incubation period and the duration of infectiousness of the pandemic virus.

Scientific basis

- An early study using Australian maritime statistics suggested that the mean incubation period of the 1918 pandemic influenza was 32.71 hours (1.4 days). (McKendrick and Morison as reviewed by Nishiura, 2007).
- A meta-analysis of 56 volunteer studies (Carrat et al, 2008) found that:
  - an increase in the average total symptoms score was noted by day 1 after inoculation, total scores peaked by day 2 and returned to baseline values by day 8;
  - viral shedding increased sharply between 0.5 and 1 day after challenge and consistently peaked on day 2 (mean generation time 2.5 days) and the average duration of viral shedding was 4.8 days;
  - viral shedding curves and total symptom score curves showed similar shapes, although viral shedding preceded illness by 1 day.
- Longer durations of viral shedding are not rare. As reviewed by Carrat et al, in one study subgroup, five participants (20%) shed influenza B virus 8 days after inoculation, while another study also reported 9 days of shedding for influenza A(H3N2).
- Reasonable estimates of the basic reproduction number (R0): for past pandemic viruses as well as seasonal influenza viruses converge between 1.5 and 2.0 (Ferguson NM et al, 2005; Ferguson NM et al, 2006; Colliza V et al, 2007; Vynnycky E et al, 2007) and for A(H1N1)2009 ranged from 1.1-1-8 (Fraser et al, 2009; Lessler et al, 2010; Opatowski, et al 2011).
- The incubation period of influenza A(H5N1) human cases (7 days or fewer; mostly 2–5 days) appears to be longer than that of seasonal influenza. In clusters in which limited human-to-human transmission has probably occurred, the incubation period appears to be approximately 3–5 days, although in one cluster it was estimated to be 8–9 days (WHO writing committee, 2008).
- Patients with influenza A(H5N1) disease may have detectable viral RNA in the respiratory tract for up to three weeks; data, however, are limited. (Reviewed by WHO writing committee, 2008; and Gambotto et al, 2007).

A2.3 Symptom development and clinical attack rate

Assumptions

- About two-thirds of people with pandemic influenza are expected to develop clinical symptoms.
- Uncomplicated clinical symptoms of pandemic influenza are expected to be similar to those of seasonal influenza: respiratory symptoms; fever and abrupt onset of muscle ache and headache or backache.
- Averaged overall (across all age groups), population clinical attack rates are expected to be 25% to 45%.

Implications

- Existing clinical criteria for influenza-like illness can serve as the basis for pandemic disease surveillance. However, countries are encouraged to monitor closely the evolution of clinical characteristics of pandemic influenza and to facilitate refinement of a clinical case definition.
- Since clinical presentations of influenza are usually nonspecific, pandemic surveillance should be supported by laboratory diagnosis. This step is critical to confirm and describe comprehensively the first cases in each country.
- Because the number of ill persons may overwhelm existing health-care capacities, countries should plan for rapid scale up of health-care capacity and prioritization of limited resources.
- Wide variations in clinical attack rates among different age groups and localities have been observed with previous pandemics. Countries are encouraged to estimate clinical attack rates based on their own data and experiences.

Scientific basis

- A pooled analysis of 522 persons who were voluntarily infected with influenza reported the proportion of symptomatic infection (any symptoms) as 66.9% (95% CI: 58.3, 74.5). No significant differences were noted according to the virus type or the initial infectious dose (Carrat et al, 2008).
- A modelling study using 1957 pandemic data from the United Kingdom estimated that 60–65% of infected individuals experienced clinical symptoms (Vynnycky E et al, 2008).
- An analysis of an influenza outbreak experience in an isolated island, Tristin da Cunha, in 1971 suggested that almost all susceptible persons developed symptomatic illness (Mathews JD et al, 2007).
- During the 1918 pandemic in the United States of America, influenza-like illness rates averaged 28%, with a low of 15% and a high of 50% (Frost WH, 1919). These data were derived from house-to-house surveys.

- In one report, age-specific serological attack rates for the 1957 pandemic averaged 40%, with a low of 5% and a high of 70%. In contrast, a 20% serological attack rate was reported for the 1968 pandemic (Stuart-Harris CH, 1970).
- A retrospective questionnaire survey from one USA city revealed the overall clinical attack rate during the 1968 pandemic was 39%; and it was similar among all age groups (Davis LE et al, 1970). Another serological survey found that about 25% (range of 21% to 27%) of children tested positive for antibodies to the influenza strain that circulated in 1968 (Chin J et al, 1974).
- Clinical attack rates calculated from an estimated basic reproduction number (R0): between 1.5 and 2.0; range from approximately 25% to 45% (Ferguson NM et al, 2005; Ferguson NM et al, 2006; Germann TC et al, 2006; Colliza V et al, 2007; Halloran ME et al, 2008).
- Clinical attack rates from A(H1N1)pdm 2009 were estimated to be 7% to 15% (Fraser C et al, 2009) with a secondary attack rate from 7–13% (Cauchemez S et al, 2009, WHO writing group 2009).
- Gastrointestinal symptoms have been observed among patients with influenza A(H5N1) but have varied by clades (WHO writing committee, 2008).

A2.4 Dynamics and impact of a pandemic

Assumptions

- An influenza pandemic can begin at any time of the year and in any place in the world; it is expected to spread to the rest of the world within several weeks or months.
- The duration of a pandemic wave is expected to be from several weeks to a few months but will likely vary from country to country; within a single country, variations may be seen by community.
- Most communities are expected to experience multiple waves of different magnitudes of a pandemic.
- Increased hospitalizations, excess mortality and secondary complications are expected to vary widely among countries and communities. Vulnerable populations are expected to be affected more severely.
- Workplace absenteeism is expected to be higher than the estimated clinical attack rate.

Implications

- Each county should develop and strengthen its capacity to detect the early emergence of a potential pandemic event and to respond rapidly.
- Countries should guide their local governments and communities to develop their own pandemic influenza risk management plans.
- Actions during the post-peak periods between pandemic waves should be considered in overall pandemic risk management plans.
- Countries are encouraged to further estimate and prepare health-care needs based on their own resources and experiences, with particular concern to vulnerable populations.
- In a series of waves as experienced with 20th century pandemics, an early wave may lead to depletion of stocks of consumables, such as personal protective equipment and pharmaceuticals, before later waves.
- Countries are encouraged to further estimate excess workplace absenteeism during a pandemic based on their own contexts and to guide all sectors to develop business continuity plans for high and possibly fluctuating levels of absenteeism throughout the pandemic.

Scientific basis

- Early reports and later analysis of epidemiological evidence suggest that milder epidemic waves (in Europe in April and May, 1918 and in the USA in the (Northern Hemisphere) Spring of 1918 preceded the most severe pandemic wave in (Northern Hemisphere) Autumn 1918 (Frost WH, 1919; Olson SR et al, 2005).
- A review of data from the North Denmark region indicated three waves with the third in December 2010-January 2011 being the most severe (Orsted et al, 2013)
- An influenza virus A(H1N1) resistant to oseltamivir was first reported from Norway in January 2008 and then spread throughout much of the Northern Hemisphere during the next two months (WHO, 2008). It was subsequently detected in the Southern Hemisphere during the influenza season of 2008.
- Excess mortality data from 1918–1920 show that population mortality varied more than 30-fold across countries (Murray CL et al, 2006).
- Variation among countries ranged from a low of 0.20% (Denmark) to a high of 4.39% (India).

- Variation within countries ranged from 2.12% to 7.82% in India and from 0.25% to 1.00% in the USA.
- During the 1918 pandemic in the United States of America, there were marked and consistent differences in morbidity and mortality among persons of different economic status: the lower the economic level, the higher the attack rate. This relationship persisted even after adjustments were made for factors such as race, sex, age and other conditions (Sydenstricker E, 1931).
- A multinational analysis of the 1968 pandemic showed very different epidemic patterns in the six countries studied (Viboud C et al, 2005).
  - In the USA, a large epidemic was observed in 1968–1969, followed by a milder wave in 1969–1970, late in the winter season.
  - In Canada, the two epidemic patterns were similar in amplitude and timing.
  - In other countries (Australia, France, the United Kingdom and Japan), the first epidemic was mild, followed by a much more intense epidemic in the next season.
- A simulation study in the United Kingdom estimated that, overall, about 16% of the workforce is likely to be absent due to school closures during a pandemic. This estimate rises for sectors with a high proportion of female employees, such as health and social care (Sadique MZ et al, 2008).

Annex 3. Ethical considerations

Preparedness planning for an influenza pandemic involves balancing potentially conflicting individual and community interests (*9*). In emergency situations, the enjoyment of individual human rights and civil liberties may have to be limited in the public interest. However, efforts to protect individual rights should be part of any policy. Measures that limit individual rights and civil liberties must be necessary, reasonable, proportional, equitable, non-discriminatory and in full compliance with national and international laws.

Ethics do not provide a prescribed set of policies; rather, ethical considerations will be shaped by the local context and cultural values. The principles of equity, utility/efficiency, liberty, reciprocity and solidarity are especially helpful in the context of influenza pandemic preparedness planning.

For example, the principle of utility suggests that resources should be used to provide the maximum possible health benefits, often understood as "saving most lives". Utility considerations include the following:

For individual benefit:

- the likelihood that an individual with pandemic influenza disease will experience a medical benefit if provided antiviral or adjuvant treatment;
- the likelihood that an individual at risk of infection will become infected/ill if influenza-specific antiviral prophylaxis is not provided.

For community benefit:

- the likelihood that an infected individual will infect other persons if not given access to antivirals (for treatment or prophylaxis) and infection control measures;
- the overall reduction in disease burden expected to result from the intervention;
- the potential value of giving priority to:
  - essential health-care workers,
  - other workers who provide life-saving services,
  - workers who provide critical services necessary for society to function as normally as possible; such policies should be developed with great care, given the danger that decisions favouring certain categories of workers may be perceived as unfair and undermine public trust.

Another important principle, which may sometimes conflict with utility considerations, is equity. Considerations of equity in use of antivirals may lead to giving priority to:

- the worst-off (in terms of severity of illness);
- vulnerable and disabled populations;
- uninfected persons who are at high risk of developing severe complications and death if they become infected.

Regardless of the criteria selected to govern the allocation of therapeutic and preventive measures, certain basic elements will be important in all plans; for example, those which:

- Facilitate access to the highest level of treatment possible given available resources, with careful attention to the needs of all populations.
- Provide health-care workers with clear and transparent screening and treatment protocols in line with the latest guidance from WHO or relevant national health authorities.

- Incorporate mechanisms that:
  - ensure that the guidelines and protocols are followed;
  - enable health-care workers to inform health authorities when clinical experience suggests the need for revisions of protocols;
  - enable health-care workers to (1) take part in the process of updating guidelines and protocols as the pandemic progresses, and (2) propose prioritization criteria for maintenance of a functioning health-care system in a crisis situation;
  - ensure a fair balance of treatment for pandemic influenza patients and patients with other serious conditions;
  - enable prioritization protocols for non-influenza patients and their access to the general health-care infrastructure;
  - identify the pandemic influenza patients who will receive hospital-based versus home-based care and criteria for early discharge (potentially even if still infectious).

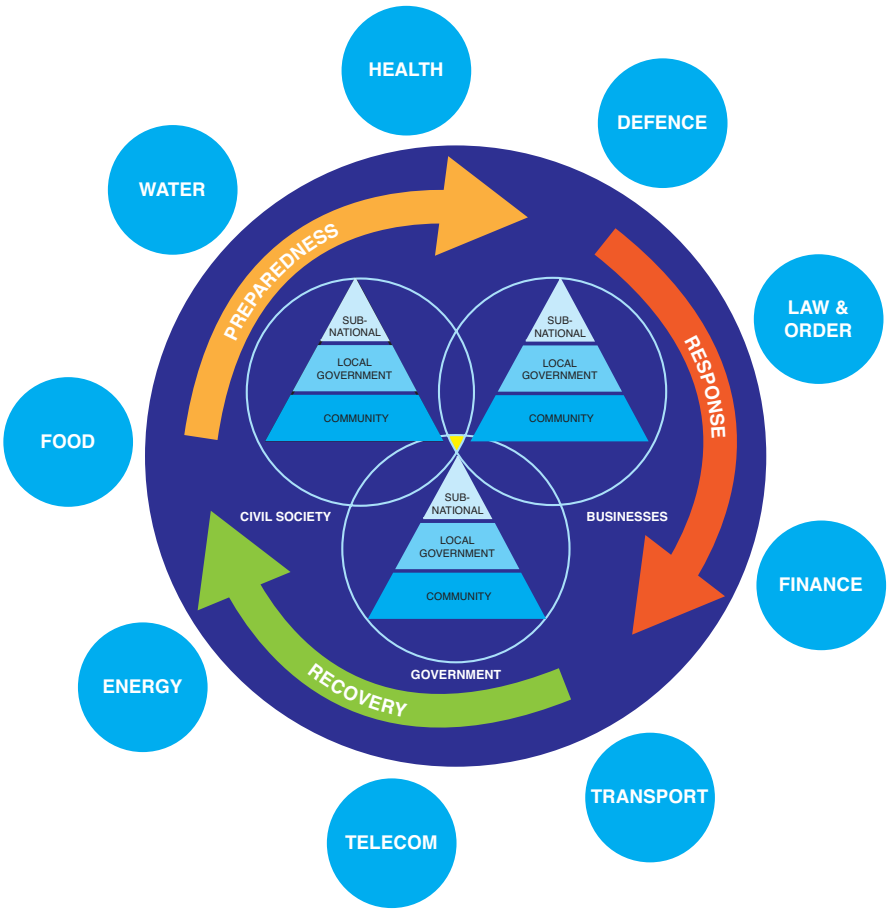
As part of pandemic influenza planning, policy-makers are encouraged to establish a fair process for setting priorities and promoting equitable access to services and supplies that: (1) involves civil society and other major stakeholders in the decision-making process so that decisions about the criteria to be used in allocating scarce resources are made in an open, transparent and inclusive manner and (2) incorporates clear, pre-established mechanisms for revising decisions based on new evidence when appropriate. An open, trusted process will strengthen solidarity and enhance the whole-of-society approach to pandemic risk management.

Annex 4. Whole-of-society approach

An influenza pandemic will test the resilience of nations, businesses, and communities, depending on their capacity to respond. No single agency or organization can prepare for a pandemic on its own. Inadequate or uncoordinated preparedness of interdependent public and private organizations will reduce the ability of the health sector to respond during a pandemic. A comprehensive approach to pandemic risk management is required.

As illustrated in F**igure 4**, the whole-of-society approach encompasses three major groups in society – governments, business and civil society – at the global, national, subnational, local and community levels. The nine circles around the disaster management continuum of mitigation, prevention, preparedness, response, and recovery represent nine key essential areas: health, defence, law and order, finance, transport, telecommunications, energy, food and water.

Figure 4. Whole-of-society approach (*46*)



All sectors of society should be involved in pandemic risk management. A concerted and collaborative effort is required by government ministries, businesses and civil society to sustain essential infrastructure and mitigate impacts of pandemic influenza on health, the economy and the functioning of society.

All levels – global, national, subnational, local and community – should prepare for a pandemic. The global and national levels should provide leadership and strategic planning while the local level should prepare to take specific actions. All organizations should incorporate pandemic preparedness into existing crisis and continuity management systems. As the impact and

duration of pandemic waves are unpredictable, and may continue for multiple seasons, local communities should develop flexible plans to support the full spectrum of their potential needs.

A4.1 Role of government

In national pandemic influenza risk management, the government is the natural leader for overall pandemic coordination and communication efforts. The national government should help other public and private agencies and organizations by providing guidance, planning assumptions and making appropriate modifications to the laws or regulations at all levels and sectors to enable appropriate pandemic response. These efforts are supported by WHO and other United Nations Organizations under the IHR (2005) (10). As part of their capacity building activities under the IHR (2005), governments globally have been assessing and revising their national legislation and regulations to ensure they can fully comply with their obligations. These activities include intersectoral collaboration and ERMH at all governmental levels.

Leadership should be based on strong political will and engagement with all stakeholders and sectors with good coordination and command and control mechanisms between the Ministry of Health, national public health authorities and non-health sectors. Emergency management roles, responsibilities and mechanisms also need to be clarified, communicated and tested, with particular attention to sustainability of response capacity and decision-making roles (*47*).

Pandemic risk management is a whole-of-government responsibility. All ministries should work with the Ministry of Health within the national coordination system to ensure a consistent approach to preparedness and business continuity planning. Plans that encompass a variety of scenarios should be developed from risk-based assumptions generated by the Ministry of Health and should be tested for compatibility. In addition, pandemic risk management processes need to take place at the national, subnational, local and community levels; central government should stipulate which level is responsible for specified activities. The central government should also provide guidance to local authorities on preparedness planning; conduct training to ensure effective dissemination at all levels; and design and implement exercises to test plans and encourage community mobilization. Throughout the whole of government, roles, responsibilities, designated leads and chains of command should be clearly mapped. Standard operating procedures can help generate common understanding and coordinated implementation (*46*).

All ministries are responsible for ensuring their respective sectors are well prepared to respond to and recover from pandemic influenza; examples of ministry-specific activities are provided below.

- **Ministries of Transportation** should plan to minimize infection risks and staff absences in vital transportation, airports and sea ports, and loading and unloading facilities, to enable continued supply of medicines and food. Mechanisms for communication and education of public transport users should be considered well in advance.
- **Ministries of Finance** should plan to maintain essential cash, credit, banking, payment, international funds transfers, salary, pension and regulation services in the face of significant absenteeism; systemic resilience to pandemic risk should be tested. National-level financial planning for pandemic risk management is also a task for the national emergency committee and the Ministry of Finance and the mechanisms to draw down emergency funding for interventions should be tested prior to a pandemic.
- Ministries of Justice should consider how to maintain all essential legal and administrative operations during a pandemic. Measures should also be considered to minimize the spread of infection in prisons and other institutions under their authority. Plans for infection control and risk reduction in facilities should be tested in conjunction with the Ministry of

Health plans to ensure that messaging is consistent and that public health principles are upheld.

- **Ministries of Defence** should consider which military assets could be released and mobilized in the event of a pandemic, based on Ministry of Health planning assumptions and risk assessment.
- **Ministries of Education** should have a key role in the surveillance and reduction of influenza risk to communities. Surveillance of absenteeism in schools can be used as a proxy indicator of community transmission. Linking of school surveillance systems with the Ministry of Health is therefore vital to ensure that school-based interventions, including closures, are guided by public health principles.
- **Ministries of Energy** should ensure that key providers within the energy sector have well-developed and well-exercised preparedness plans. Alternative plans for energy supplies, in case of major disruptions, should be evaluated.
- **Ministries of Communication** should have the responsibility to ensure that communications channels remain open at times of crises. As the formal partner to the Ministry of Health in disseminating information, the Ministry of Communication should be closely involved in the development of a national communications plan across the government.
- **Ministries of Agriculture and Animal Health** should have a key role in the surveillance and monitoring of non-seasonal influenza viruses and on preparedness, prevention, risk assessment and risk reduction mechanisms to decrease exposure of humans to influenza viruses at the human–animal ecosystem interface.
- In addition to leading the health sector response, **Ministries of Health** should provide planning assumptions and technical input for the development of plans by other sectors, provide public education and other communication messages and provide advice on reducing risk of infection in essential workers.

A4.2 Role of business

In many countries, essential services are provided by a mix of public and private providers. It is therefore vital that, along with public agencies, private essential goods and service providers undertake pandemic risk management activities. At a national level, the business sector should be represented in the national planning committee, to ensure a consistent planning approach and establish formal communication channels.

The continuity of activities by businesses involved in medical supplies and services, e.g. manufacturers, distributors and providers, is critical to pandemic risk management. Other business sectors also have important roles. For example, human resource surveillance systems in larger businesses to monitor absenteeism can provide valuable information for national risk assessment and the retail sector can use strategies to reduce population density in shopping areas. Businesses have an obligation to protect their employees during any health emergency; the provision of accurate and timely communication messages developed on the national communication plan, personal protective equipment and training is encouraged.

A4.3 Role of civil society

In many countries, national and international civil society and community-based organizations will have a key role in providing community-based services to meet the needs of vulnerable populations. It is therefore critical that these organizations have planned how to maintain or expand their essential services during a pandemic. In addition, community-based organizations can translate scientific and government messages and recommendations, which otherwise may be met with mistrust or scepticism by parts of society. Community leaders can build public confidence, disseminate information and identify people at risk. Governments should

therefore involve civil society and local communities in developing pandemic risk management plans. Governments should also work with local and international humanitarian agencies and organizations to identify how the basic needs of vulnerable populations will be met in a pandemic. The adoption of this whole-of-society approach will clarify responsibilities, identify gaps and avoid duplication in planning and implementation.

Throughout the UN system, agencies, funds, programmes and partners support pandemic risk management efforts, in particular assisting countries and promoting multisectoral and whole-of-society approaches, facilitating and enhancing regional and global synergies and establishing norms for effective work (48). The overarching objectives through which this work has been pursued are captured in the UN System and Partners Consolidated Action Plan for Animal and Human Influenza, which identifies specific outputs and activities of the UN system and partners under seven strategic objectives, namely: animal health and biosecurity; sustaining livelihoods; human health; coordination of national, regional and international stakeholders; communication: public information and supporting behaviour change; continuity under pandemic conditions; and humanitarian common services support (49). The UN system also works to ensure continuity of its essential operations during pandemics and to maintain staff health and safety to ensure a timely, consistent and coordinated response across the UN system to a possible global threat (*50*).

A4.4 Critical interdependencies among essential services

Although there are variations between countries, key essential services are: health, defence, law and order, finance, transport, telecommunications, energy, food and water (**Figure 4**). Public and private providers of these essential services are interdependent and rely on the goods and services of other sectors in order to sustain their operations. Pandemic plans should take into account potential failures generated by interdependencies. These include failures of individual businesses or small numbers of businesses representing the sole providers of an essential good or service. Interdependencies need to be identified by each individual essential service provider. Issues that need to be clarified in the process of identifying interdependencies include:

- critical goods and services necessary for the organization to provide its essential service/s;
- key interdependencies for each critical good or service;
- the impact of the loss or reduction of any of the critical goods or services to the customers/beneficiaries;
- critical employee groups;
- the impact of the loss or reduced availability of critical employee groups; and
- likely points of failure.

The health-care sector always faces especially severe challenges during a pandemic. Health-care institutions depend on goods and services that are delivered by the following sectors:

- transport for the movement of supplies, personnel and patients;
- telecommunications to support patient care, provide teletriage and maintain business processing;
- energy to power facility, clinical and security systems;
- water for health-care facilities, pharmaceutical operations and sanitation services;
- pharmaceuticals, including consumables, for treatment of patients; and
- finance to ensure the supply chain.

Flexible business continuity plans should be developed for multiple scenarios ranging from some delays/interruptions to significant interruptions to essential services, with corresponding action plans.

Annex 5. Business continuity planning

Business continuity plans, which document business continuity management processes, are at the heart of preparing all levels and groups of society for an emergency; pandemic risk management should be an integral part of any establishment's business continuity management. Business continuity plans should be based on risk assessment of the potential effects of a pandemic on the ability to maintain or expand operations. The risk assessment should include consideration of vital components outside the specific organization, such as the resilience of supply chains for essential goods and services. The plans can be used to manage business interruptions, including significant absences of staff or disruption of supplies.

Business continuity plans should be based on explicit assumptions that characterize the parameters of a pandemic and its potential impacts. Public health authorities should communicate planning assumptions and guidance to other sectors of society.

Regardless of the type of the organization, business continuity plans should include the following actions :

- Identify the critical functions that need to be sustained.
- Identify the personnel, supplies and equipment vital to maintain critical functions.
- Consider how to deal with staff absenteeism to minimize its impact on critical functions.
- Provide clear command structures, delegations of authority and orders of succession.
- Assess the need to stockpile strategic reserves of supplies, material and equipment.
- Identify units, departments or services that could be downsized or closed.
- Assign and train alternative staff for critical posts.
- Establish guidelines for priority of access to essential services.
- Train staff in workplace infection prevention and control and communicate essential safety messages.
- Consider and test ways of reducing social mixing (e.g. telecommuting or working from home and reducing the number of physical meetings and travel).
- Consider the need for family and childcare support for essential workers.
- Consider the need for psychosocial support services to help workers to remain effective.
- Consider and plan for the recovery phase.
-

Annex 6. Representative parameters for core severity indicators

Indicator	Representative parameters
Transmissibility	**From initial investigations** • Number of symptomatic cases of influenza/influenza-like illness per week • Basic reproduction number (R0): the average number of secondary cases generated from one case at the start of the epidemic • Generation time: the mean delay between the time of infection of an index case and the times of infection of secondary cases infected by the index case • Serial interval: the average length of time between symptom onset of individual cases and the persons they infect • Secondary attack rate: the proportion of individuals exposed to a known case who become infected, e.g. in a household where a case is discovered • Clinical attack rate (CAR): the proportion of the population that is symptomatically infected in a given time period. CAR is relatively simple to measure since it does not rely on detection of asymptomatic individuals. CARs can be calculated for different age groups, different settings (e.g. school, workplace) and different risk groups (e.g. pregnant women) • Spatial distribution of cases: mapping of countries/regions in which the virus has been detected in a given time period **From later investigations** • Attack rate: the proportion of the population that become infected in a given time period (e.g. as obtained from population serologic studies) • Incidence proportion: the proportion of people who develop new disease during a specified time period • Prevalence: the proportion of people who have disease at a specific time • Mode of transmission, particularly if new modes or previously uncommon modes of transmission (e.g. faecal–oral) are important
Seriousness of disease	**From initial investigations: molecular** • Sensitivity to available antiviral medicines • Presence of genetic markers that have been associated with increased risk of severe disease • Pre-existing immunity in the population, as measured by the level of cross-reactive antibodies **From initial investigations: clinical** • Case-fatality ratio (CFR): the proportion of symptomatic cases that die. Estimations of CFR are particularly difficult at the early stages of a pandemic. Since reliable case-fatality ratios will only be available in later stages of a pandemic, other parameters that may be of use are: — the proportion of cases of pneumonia that are influenza positive from sentinel surveillance that uses a representative sampling system — the ratio of hospital admissions and deaths attributed to respiratory causes to total admissions at the sentinel site — the proportion of hospital admissions attributed to respiratory causes that require mechanical ventilation or die — the proportion of influenza admissions, intensive-care admissions and deaths with pre-existing medical conditions **From later investigations** • Number of deaths attributed to influenza • Crude disease-associated mortality rate: the number of persons in a given population who die of the illness, expressed in terms of confirmed or suspected cases • The proportional distribution of cases by clinical illness (i.e. the proportions of cases that are asymptomatic/have mild illness/severe illness/die – the “clinical severity pyramid”) • The number of cases of influenza-associated pneumonia and death compared with previous seasons or pandemic events based on comparisons with historical surveillance data

Indicator	Representative parameters
Impact	**From initial investigations** • Daily hospitalization rate: the number of persons in a given population who are hospitalized each day, expressed in terms of confirmed or suspected cases • The proportion of emergency department visits attributed to pandemic influenza • The proportion of emergency department visits that require hospitalization • The proportion of hospitalized cases that require admission to an intensive-care unit or require mechanical ventilation • The proportion of all hospital beds occupied by patients with pandemic influenza • The percentage of overall laboratory capacity directed to influenza testing **Potential societal impact parameters from other sectors** • Interruption of critical infrastructure and services • Work and school absenteeism • State of tourism • Sales of core capital (privately held land, livestock) • Gross Domestic Product • Border, travel and trade actions by countries • Nature of public perception

Annex 7. Containment measures

Before the presence of human infection with a new influenza subtype is identified, the clinical syndrome associated with a new influenza subtype is likely to be similar to that caused by currently circulating seasonal viruses. It will therefore be very difficult to recognize an emerging pandemic sufficiently early to achieve containment at source, given current capacities for detection and intervention (51). Evidence supporting containment at source is extremely limited, with theoretical evidence only. Modelling studies suggest that containment may be possible in certain near-ideal scenarios characterized by low to moderate transmissibility (basic reproduction number, R_0 ≤1.7); very early detection of initial cluster/outbreak (within 15–21 days); a non-urban pandemic epicentre with limited size (*52*), density and mobility; access to well-trained response workers within a highly organized response infrastructure; a short period of communicability and low rate of asymptomatic illness; and antiviral drug susceptibility.

However, even in these near-ideal situations, it is unlikely that this approach would be feasible given the large amount of resources (antiviral drugs, geographical cordon, health-care personnel) that would need to be mobilized (53). The data from theoretical modelling studies are based on mass use of neuraminidase inhibitors within a defined "containment zone" coupled with movement restrictions (geographical cordon) and targeted at a population of 500 000 people. Moreover, the experience in 2009 was that obtaining initial data on the R0, communicability and rate of asymptomatic illness associated with influenza A(H1N1)pdm09 was challenging, thus data in a future pandemic would be unlikely to be available within the timescale that would make this approach feasible.

Nevertheless, measures that have been associated with containment such as social distancing, hand/respiratory hygiene and judicious use of antiviral drugs may be effective in mitigating the impact of outbreaks of a new influenza subtype in individual countries. These measures are most likely to be successful and are better supported by data demonstrating effectiveness when implemented in specific local (smaller scale) circumstances, e.g. households and closed or semi-closed institutions. Although there is no evidence of any wider population-level containment effect, these measures may reduce the spread and overall impact of the pandemic and could be considered as part of a country's national preparedness plan, depending on available resources.

Court File No.: CV-21-00013361-0000

ONTARIO
SUPERIOR COURT OF JUSTICE

B E T W E E N :

WELLANDPORT UNITED REFORMED CHURCH

Applicant

- and -

THE ATTORNEY GENERAL OF ONTARIO

Respondent

AFFIDAVIT OF DR. JOEL KETTNER

I, JOEL KETTNER, of the City of Winnipeg in, Province of Manitoba, **MAKE OATH AND SAY:**

BACKGROUND

1) I am an epidemiologist and former Chief Medical Officer of Health of Manitoba.

2) I have been informed by counsel and I understand and affirm my duty to this court as an expert witness. I have completed Form 53 under the *Courts of Justice Act*, which is attached to this Affidavit.

3) I have been asked by counsel for the Applicants to addresses the following questions.

   a) What is the ordinary or absolute risk for exposure to and transmission of SARS-CoV-2 in a church service that is near full seated capacity (leaving aside church programs and activities outside of the worship service in the church sanctuary)?

   b) What is the comparative risk between an ordinary church service with no safety plan (social distancing, self-screening, masks, hygiene measures, etc.) and a church service

that follows public health measures including distancing between households, but does not otherwise implement a capacity limit?

c) What is the comparative risk between a church that follows public health advice and gathers at 30% of seated capacity and the same church gathering at 15% of seated capacity?

d) What is the comparative risk between a church gathering of 10 people and a church gathering at 15% of seated capacity (in either case, following public health measures)?

e) What is the comparative risk between attending a church gathering under the circumstances described in 2-4, above, and doing other activities permitted under Ontario Regulation 82/20 (Rules for Areas in Stage 1)? Assume both have a written safety plan as described in Schedule 1, section 5 of Regulation 82/20.

QUALIFICATIONS

4) I currently hold a position as geographic full-time associate professor in the Department of Community Health Sciences at the College of Medicine at the University of Manitoba. I hold Canadian Royal College Fellowship certifications in Public Health and Preventive Medicine as we as General Surgery. I obtained a Master of Science in Epidemiology from the London School of Hygiene and Tropical Medicine at the University of London in the United Kingdom.

5) During my time as Manitoba's Chief Medical Officer of Health, I led the Province's public health responses to several outbreaks including the SARS Coronavirus-1 and the H1N1 pandemic influenza.

6) Following the SARS-01 outbreak, I was part of the Canadian delegation to the World Health Organization ("WHO") special meeting in Geneva to develop the fourth edition of the International Health Regulation which introduced the concept, definition and expectations of countries during a public health emergency of international concern.

7) I played a leading role at the WHO Pan American Health Organization special H1N1 meeting in Washington D.C. In addition to a plenary presentation describing Manitoba's

experience with the first wave of H1N1, I led a working group to develop guidance for the prevention and treatment of H1N1 in low resourced parts of the world. At that same meeting, I collaborated as an author of the first comprehensive review article of H1N1 influenza published in the New England Journal of Medicine.

8) Following my tenure as Chief Medical Officer of Health of Manitoba, I have undertaken a number of relevant roles and responsibilities including that of scientific director of the Public Health Agency of Canada's National Collaborating Centre for Infectious Diseases, medical director of the International Centre for Infectious Diseases in Winnipeg, board director of the Canadian Public Health Association, and president of the Public Health Physicians of Canada.

9) Specific relevant roles at the University of Manitoba have included director of the Medical College undergraduate program in Community Health Sciences and director of the Master in Public Health program. I continue to teach public health and epidemiology at the undergraduate, graduate and pos-graduate levels. During this current COVID-19 pandemic, I have been active in organizing learning events and providing expert opinion and dialogue in a variety of consultative, academic and public platforms.

10) A copy of my curriculum vitae is attached at **Exhibit "A"**.

OPINION

11) The answers to these questions are of fundamental importance. This is because the starting point for all public health decisions, especially about the need for emergency response and powers, is risk assessment. Estimates of the magnitude of a public health threat and the distribution of its impacts enable the determination of priorities and rational considerations of intervention options. It is incumbent on public health decision-makers to optimize the balance of benefits and harms of their strategies and to be guided by public health perspective and ethics. The public health perspective is population-based.

12) The public health perspective considers all causes and all consequences of all diseases and injuries and should never be overly focused on just one disease at the expense of others. The public health perspective considers equity and fairness, always with the goal of reducing

disparities of health amongst communities. To achieve this requires partnering with others to establish policies that reduce the unequal and unfair distribution of social, economic, educational, and other determinants of health. The public health perspective requires the least intrusive and harmful means necessary to achieve optimal benefit. It is incumbent upon public health government officials to demonstrate transparently that any restrictions of autonomy are minimal and are proportionate to the severity of the threat. That is why risk assessment of the threat is the starting point of effective and ethical public health process.

13) This bears repeating with other words. To meet these expectations, public health officials and their governments are required to show that the severity of a threat has justified the use of restrictive interventions; they are required to show how the effectiveness and benefits of the interventions will sufficiently outweigh the harms; and that there are no alternative strategies that would be more effective, less harmful, and/or less restrictive. Perhaps most relevant, public health actions should not be equal ("one size fits all") for every geographic area or community, for every type of setting, for every occupation, or for every person regardless of age, health condition, or other risk factors.

Best Practices regarding public health emergencies

14) Section 7.0.1 (3) of the *Emergency Management and Civil Protection Act* ("the Act") states that an emergency can be declared only if the Lieutenant Governor in Council or the Premier is of the opinion that there is a "danger of major proportions that could result in serious harm" and one of the following exists:
    a) Resources normally available to the Government "cannot be relied upon without the risk of serious delay".
    b) The resources normally available to the Government "may be insufficiently effective to address the emergency".
    c) "It is not possible without the risk of serious delay to ascertain" whether the resources normally available to Government can be relied upon.

15) In public health emergencies, premiers and other elected leaders look to their senior public health officials – including their chief medical officer of health or chief public health officer - to provide advice regarding the level of threat and the need for emergency powers. The

starting point for a decision of such consequence is a comprehensive and reasonable risk assessment. In a public health emergency, the advice from public health professionals is expected to be based on valid and reliable data, relevant information, objective scientific evidence, best estimates, and critical reasoning.

16) The Act does not specify what information and advice will be used by the premier to form their opinion, but general guidance is provided by section 7.0.2. (1):

> The purpose of making orders under this section is to promote the public good by protecting the health, safety and welfare of the people of Ontario in times of declared emergencies in a manner that is subject to the *Canadian Charter of Rights and Freedoms* 2006, c. 13, s. 1 (4).

17) Public health legislation and practice across Canada addresses this issue in various ways, but the principles are similar. Like any medical advice – for an individual or a community – public health leaders are expected to assess the magnitude of the threat and to weigh up the pros and cons of alternative interventions, whether these are preventive or therapeutic.

18) The foundation for all public health advice, actions, and communications is risk assessment. It is not only a starting point; it is an essential part of ongoing surveillance, monitoring, and adjustments to strategies, policies, regulations, and advice.

19) Ontario's *Hazard Identification and Risk Assessment Guidelines (2019)*[1] states:
"The purpose of HIRA is to assess the potential risk of hazards with the capacity to cause a disaster. This helps set priorities for prevention, mitigation, preparedness, response and recovery." The HIRA allows for the assessment of risk based on hazards, exposure, vulnerability, capacity and resilience. The core questions are:

a) What risks can lead to a disaster?
b) What impacts could occur over a range of scenarios?
c) Are there scenarios in which the level of risk is unacceptable or unmanageable?
d) What are the impacts, relative to each hazard?
e) What existing measures prevent or mitigate the risk?

[1] https://www.emergencymanagementontario.ca/english/emcommunity/ProvincialPrograms/HIRA/Guidelines/main.html#StepFour

20) The Guideline specifies several principles and practical approaches to assessing risk, interpreting risk, and using risk assessment to make appropriate and fair decisions with respect to responding to the risk (hazard, threat). The following are excerpts of particular relevance to the facts and opinions of my report.

- The Guideline uses a "whole-of-society" approach to risk.
- Ultimately, how risk is measured is determined by values and assumptions that should be transparent.
- There is no one correct way to express risk. However, a good risk analysis, will be extremely clear about:
    - Its purpose
    - Why particular metrics were chosen, and
    - Limitations of the analysis

21) Regarding the application of risk assessment to emergency management, the Guideline specifies seven ethics:

1. **Transparency:** Emergency Management has a duty to serve the public; including their right to obtain key information that benefits its safety and security.
2. **Professionalism:** A professional obligation to provide the public with competent practice.
3. **Comprehensiveness:** Emergency Management is proactive, includes an all-hazard approach, all 'pillars', and partners from all parts of society.
4. **Risk-based:** Sound risk management principles should be used in assigning priorities.
5. **Respectfulness:** The equal dignity of all people must be respected, along with their customs and culture, and their right to the necessities of life.
6. **Resilience:** Emergency Management aims to strengthen the resiliency of citizens, organizations, communities, systems and society.
7. **Equity:** It is vital to provide appropriate care to all citizens of Ontario, consistent with their needs. Equity ensures a fair distribution of supports and resources.

22) As described in step four of the guidelines section of the Ontario Hazard and Identification Risk Assessment Program[2], considerations of extraordinary public health interventions requires clear descriptions of quantitative estimates of likelihoods (probabilities) of events and the level of severity of the consequences of those events. Epidemiological descriptors to

[2] https://www.emergencymanagementontario.ca/english/emcommunity/ProvincialPrograms/HIRA/Guidelines/main.html

assess the threat of any potential hazard should include specific probabilities – whether in the form of rates, ratios, or proportions –not only crude numbers (numerators without denominators). For effectiveness of interventions, this includes measurements and estimations of quantifiable outcomes, including benefits and harms. These estimates are fundamental to the process of determining that public health interventions are proportionate to the threat and are reasonably necessary.

23) This report focuses on risk assessment, threat assessment, and demonstrates how basic surveillance and basic epidemiology should be used to estimate quantitatively the absolute and relative levels of the risk and consequences of transmission of COVID-19 in the settings of churches and other places of worship. To demonstrably justify restrictions of activities in churches and other settings, it is incumbent upon governments and public health leaders to obtain, analyze, and use relevant data reasonably and transparently.

24) A quantitative assessment of the threat posed by church services could not be found on Public Health Ontario websites. The assessments in this report were based on information publicly available on websites of Public Health Ontario, Niagara Health Region, Health Canada, and the World Health Organization.

Framework to describe the sequence and to estimate the probabilities of transmission and outcomes for COVID-19 in any setting, including factors for the probability of occurrence of each stage.

25) Requirement #1. A person attending church is infectious on the day of attendance. For purposes of the following explanation, an infected person at church will be described as a "case". (Technically, they would not be considered or counted as a case until they have a positive PCR test for SARS-CoV-2.)
    a) The probability of requirement #1 is a function of the incidence of the disease in the community and the average duration of being infectious.
        i) Note that this probability is usually estimated using reported cases diagnosed by a positive PCR test and does not include infections not identified as cases.
        ii) The degree of infectiousness – from highest to lowest - is a function of the following states.
            (1) During symptoms (symptomatic)

(2) Just before symptoms (pre-symptomatic)

(3) Infections in which no symptoms occur (asymptomatic)

b) Because of the variations of degree of infectious between these three states, the probability of each of these three states should be considered separately.

26) Requirement #2. There is a high-risk exposure between the infected person and an uninfected contact.

a. Classification of exposures as high-risk or low-risk is primarily determined by the three considerations:

i. closeness of the contact to the case,

ii. duration of the contact, and

iii. barriers between the case and the contact.

27) Requirement #3. Transmission has occurred. Contact becomes infected and will be identified as a case after a positive PCR test.

28) Outcomes of infections resulting from transmission (requirement #3): a case may have no symptoms, mild symptoms or severe symptoms. The probability of severe illness or death is a function of many factors including

a) Age (severe illness correlates with increasing age, especially over the age of 70).

b) Pre-existing serious health conditions

i) Immune system dysfunction (e.g. malignancy, medications)

ii) Organ dysfunction (e.g. chronic lung or heart disease)

iii) Neuromuscular dysfunction (e.g. multiple sclerosis)

iv) Cognitive dysfunction (e.g. dementia)

v) Metabolic disorders (diabetes, severe obesity)

c) Living setting, social and economic conditions (e.g. poverty, congregate living arrangements)

d) Access to care

e) Health care directive (e.g. comfort care only, no life-prolonging treatment)

What is the ordinary or absolute risk for exposure to and transmission of SARS-CoV-2 in a church service that is near full seated capacity (leaving aside church programs or activities outside of the worship in the church sanctuary)?

29) The framework described above is used to estimate the answer to this question.

Incidence rate of new cases

30) There are several options for selecting the appropriate population and period to estimate the incidence rate that would most apply to the attendees of a specific church. The following compares the incidence rates between different geographic boundaries and time periods for the of relevance to Wellandport United Church.

Niagara region

31) The population of the Niagara region as of the last (2016) census was 447,888.[3]

32) The total accumulated COVID-19 cases from March 14, 2020 until April 29, 2021 was 13,704.[4]

33) The incidence rate of new cases since March 14, 2020 was 13,704/447,888 = 3.1 cases per 100 people per 380 days = 1 new case per 12,420 persons per day.

34) The total cases from January 1, 2021 to April 29, 2021 = 9,760[5]

35) The incidence rate of new cases from January 1, 2021 to April 29, 2021 = 9760/447,888 = 2.2 cases per 100 people per 119 days = one new case per 5461 persons per day. This incidence rate in 2021 is about twice the incidence rate from March, 2020.

Welland municipality

36) Population of Welland municipality as of the last 2016 census was 52,293.[6]

[3] https://www.niagararegion.ca/about-niagara/statistics/population-and-maps.aspx
[4] https://niagararegion.ca/health/covid-19/statistics/statistics.aspx
[5] https://niagararegion.ca/health/covid-19/statistics/statistics.aspx
[6] https://www.niagararegion.ca/about-niagara/statistics/population-and-maps.aspx

37) Total accumulated COVID-19 cases since March 14, 2020 until April 29, 2021 = 1,853.[7]

38) The incidence rate of new cases since March 14, 2020 until April 29, 2021 = 1,853/52,293 = 3.5 cases per 100 persons per 380 days = 1 new case per 10,857 persons per day.

39) Total cases January 1, 2021 to April 29, 2021 for Welland only were not found. Using the incidence rate from total cumulative cases since March 2020 would probably underestimate the incidence rate of 2021, as shown by the data for the Niagara region. This is because the incidence rate in Niagara in 2021 has been about twice that of the incidence rate since March, 2020. There is no known reason why this comparison would not be similar for Welland municipality.

40) To obtain an estimate of the expected number of Welland cases, assuming a similar ratio as that of the Niagara region, one can pro-rate the Welland total cases by using the Niagara region proportion of total accumulated cases that occurred in 2021 (9760/13704 = 0.71). Using this assumption, it can be estimated that the incidence of new cases in Welland from January 1, 2021 to April 29, 2021 = 0.7*1,853 = 1,297. Based on this pro-ration, the estimated incidence of new cases in Welland from January 1, 2021 – April 29, 2021 = 1,297/52,293 = 2.5 new cases per 100 persons per 119 days = 1 new case per 4,760 persons per day. This is similar to the Niagara region rate for 2021 of one new case per 5,461 per day. At 1 per 4760 new cases per person per day, in a population of 52,293, this reflects an average daily case count of 11. Because it is not know the distribution of attendees from outside the Welland municipality – and to work with more intuitive rounded and estimated numbers – it seems reasonable to use one new case per 5000 per day as an incidence estimate for calculating the estimated prevalence of infectious attendees at church services in the Welland municipality.

[7] https://niagararegion.ca/health/covid-19/statistics/statistics.aspx

Using community incidence rates to estimate transmission risk at church

41) We can use these data to estimate the probability of *requirement #1* in the framework above, namely that a person will be infectious on the day of their church attendance.

42) The first assumption is that the incident rate of COVID-19 for Wellandport Church attenders is similar to others in the municipality of Welland and the region of Niagara.

43) The second assumption is that empirical observations regarding symptom patterns, natural history of COVID-19 infections, infectiousness, and transmission characteristics are similar for Wellandport Church attendees as other people, groups, and places in which they have been studied.

44) In epidemiologic terms, the probability of a church attendee being infectious on the day of attendance is called the point (in time) prevalence. This probability is then multiplied by the number of attendees to determine the best estimate of the number of people that would be infectious at the time of the service. I will use 500 as an estimate of the number of attendees.

45) There are two possible states for a person that is infectious – symptoms or no symptoms. To reiterate from earlier, an infectious person may be pre-symptomatic and is soon to get symptoms or asymptomatic and will never get symptoms. These distinctions are important because in comparison to asymptomatic infections, infectiousness is considered to be about ten times higher in the pre-symptomatic or symptomatic stage in comparison to people who are infected but do not have symptoms. Note that a person cannot know if they are infected by COVID without a test, whether they have symptoms or not.

46) What follows is an analysis of the probabilities of infectiousness and transmission for the three states of symptoms – asymptomatic, pre-symptomatic or symptomatic. Before getting into the details, it may help to provide some perspective.

47) For a symptomatic case, it is reasonable to consider that the significant infectious days are about two days before symptoms and about ten days after symptoms begin. Therefore, for each symptomatic infection, there are two infectious pre-symptom days and 10

infectious symptomatic days. The probability of any one of these days coinciding with a day of attendance at church means that the incidence rate must be multiplied accordingly to estimate the probably of an infectious state on any one day.

48) The duration of infectiousness for asymptomatic infections is difficult to estimate, but it would be reasonable to assume that it is no more than the 10-day period estimated of symptoms.

Case is asymptomatic (never will get symptoms)

49) Estimates of the proportion of infections that are asymptomatic are quite variable as are the duration of infectiousness. The most recent scientific briefing of the World Health Organization[8] estimated the proportion of infections that are asymptomatic at 16%. The same document estimated that "between 0% and 2.2% of people with asymptomatic infection infected anybody else". More recent data are available but these have not resulted in an update to the World Health Organization scientific brief on this subject.

50) Therefore, the probability of a person having an asymptomatic infection on the day of the service can be estimated as (1/5000) *0.16 *10= 1 in 3,000. Even assuming a 1% probability of transmission during a two hour service (rather than throughout the whole period of infectiousness that was assessed in the WHO referenced studies), the frequency of transmissions associated with an asymptomatic infection via a high-risk exposure (prolonged contact, no distancing, no barrier) would be in the order of one per 300,000 persons. In a service attended by 500 people, the probability of a transmitted infection per service is 1/300,000 multiplied by 500 = one in 600 services or about once in every two years.

Case is symptomatic.

51) Public Health Ontario's Synthesis *COVID-19 Overview of the Period of Communicability – What we Know so Far (Feb 8, 2021)* concluded "There are differences in the findings across included studies due to different designs and sample size; however, there were primary epidemiological studies identified that indicated individuals can be infectious up to 3–5 days

[8] https://apps.who.int/iris/bitstream/handle/10665/333114/WHO-2019-nCoV-Sci_Brief-Transmission_modes-2020.3-eng.pdf?sequence=1&isAllowed=y

prior to symptom-onset and epidemiological, live virus and modelling studies that indicated the period of communicability is approximately 8–10 days after symptom-onset, with infectiousness highest just before or after the time of symptom-onset."[9] The most recent scientific briefing of the World Health Organization estimated that between 0.8% - 15.4% of people with symptoms infected anybody else[10]. More recent data are available but these have not resulted in an update to the World Health Organization scientific brief on this subject.

52) Using these estimates of an incidence of 1 per 5000 persons per day, 10 days of symptomatic infectiousness, and 8% probability of transmission (in two hours, rather than the whole period of infectiousness), the probability of transmission at a church service from a symptomatic infectious attendee via a high-risk exposure (prolonged contact, no distancing, no barrier) is estimated at = 1/5000*10*.08 = 1 in 6000. In a service of 500 people, that equates to a 10% probability of one transmission to one person at each service or, equivalently, one transmission from a symptomatic person every 10 services – without public health measures.

Case is pre-symptomatic (period before symptoms begin)

53) The infectious period duration in the pre-symptomatic phase is estimated as 1-3 days by a World Health Organization scientific brief[11] and up to 3-5 days by a Public Health Ontario review[12]. Public Health Ontario uses two days as their guide for case and contact management[13]. *Public Health Ontario's Risk Assessment Approach for COVID-19 Contact Tracing*[14] states "Exposures are only considered to have occurred if the contact was with the case during the case's period of communicability which is generally defined as 2 days (48

[9] https://www.publichealthontario.ca/-/media/documents/ncov/covid-wwksf/2021/03/wwksf-period-of-communicability-overview.pdf?la=en
[10] https://apps.who.int/iris/bitstream/handle/10665/333114/WHO-2019-nCoV-Sci_Brief-Transmission_modes-2020.3-eng.pdf?sequence=1&isAllowed=y
[11] https://apps.who.int/iris/bitstream/handle/10665/333114/WHO-2019-nCoV-Sci_Brief-Transmission_modes-2020.3-eng.pdf?sequence=1&isAllowed=y page 6

[14] https://www.publichealthontario.ca/-/media/documents/ncov/main/2020/09/covid-19-contact-tracing-risk-assessment.pdf?la=en

hours) before the onset of the case's symptoms." For this reason, a period of two days has been used in estimating the probability of exposure to an infectious pre-symptomatic person attending a service.

54) Given the probability of a new infection as one in 5000 per person per day and using two days as the period of infectiousness in the pre-symptomatic phase, the probability of infectiousness on the day of the service is one in 2500. Using 8% as the probability of transmission in one day (high-risk exposure: close contact without distancing or barrier protection), the probability of transmission would be (1/2500)*.08 = about one in 30,000. In a service of 500 people, the probability of one transmission at any one service is one in 60 (1.7%). In other words, there would be a transmission from a pre-symptomatic case once in every 60 services – in the absence of public health measures. This is equivalent to about one per year.

High-risk exposure to a contact.

55) Public Health Ontario divides exposures into two categories – low risk and high risk. This definition is for operational purposes to guide decisions for contact tracing. Based on this assessment, high risk exposure contacts are directed to self-isolate (i.e. quarantine). Low-risk exposure contacts are advised to self-monitor. Self-monitoring means to "follow guidance on core public health measures recommended for everyone at all times". In other words, the probability of transmission from a low-risk exposure is considered low enough that no additional public health measures are deemed necessary. They are advised to follow the guidelines for everyone.

56) Public Health Ontario describes a number of factors to consider in categorizing the exposure to a case as a low-risk exposure or high-risk exposure, but the essence of the categorizing is based on whether any of the following three conditions have been met:
    a) More than two-meter distancing,
    b) Face-to-face exposure less than 15 minutes, or
    c) Masks worn properly by case and contact.

57) If any one of these three conditions are met, the exposure would – according to a reasonable interpretation of the described protocols of Public Health Ontario - be expected to be classified as low-risk. Inversely, a high-risk exposure would be identified if none of these three conditions were met.[15]

58) The estimates that have been made for the prevalence of an infectious attendee and the probability of transmission (without public health measures in place) would, of course, be much lower in the presence of protective interventions. If adhered to, any exposures would be classified as low-risk rather than high risk. Even in the situation of low-risk exposures to an identified infectious case, public health would not direct contacts to self-isolate or to be tested. They would only be advised to self-monitor and to self-isolate and get tested only if they developed symptoms.

Outcomes of infections resulting from transmission

59) Having estimated the probabilities and frequencies of infection and transmission, the next, and perhaps most important question is about the frequency of serious outcomes.

60) Case may have no symptoms, mild symptoms or severe symptoms. The probability of severe illness or death is a function of many factors including

a) Age (severe illness correlates with increasing age, especially over the age of 70).
b) Pre-existing serious health conditions
    i) Immune system dysfunction (e.g. malignancy, medications)
    ii) Organ dysfunction (e.g. chronic lung or heart disease)
    iii) Neuromuscular dysfunction (e.g. multiple sclerosis)
    iv) Cognitive dysfunction (e.g. dementia)
    v) Metabolic disorders (diabetes, severe obesity)
c) Living setting, social and economic conditions (e.g. poverty, congregate living arrangements)
d) Access to care

[15] https://www.health.gov.on.ca/en/pro/programs/publichealth/coronavirus/docs/contact_mngmt/management_cases_contacts.pdf

e) Health care directive (e.g. comfort care only, no life-prolonging treatment)

61) Most of these risk factors – other than age and personal care home residents – have not been quantified in sufficient detail for organizations to assess quantitively the personal risks of its members. But they do provide some useful guidance regarding whom should be considered for additional measures of focused protection, including frequency, duration, and other risk reductions as considered appropriate

62) The table below provides some Ontario-specific data on the frequency of hospitalizations and deaths, in relation to numbers of cases, stratified by age groups.

63) The association with age is striking, showing the very low rates of severe illness and death amongst younger adults and children.

Ontario Data, Definitions, and Policies

Ontario COVID Severity Data

64) The following table contains cumulative information of age-specific rates of cases, hospitalization, and deaths[16].

January 15 2020 to April 9, 2021

Age group	Population	Cases	Case rates	Hosp	Pop-hosp rate	Deaths	Pop mort. rate	Case-hosp. rate	Case-fatality	Hosp dth rt
0 to 09	1,518,527	19,308	1.3%	126	0.01%	1	0.0001%	1.3%	0.01%	1%

[16] https://www.publichealthontario.ca/en/data-and-analysis/infectious-disease/covid-19-data-surveillance/covid-19-data-tool?tab=ageSex

65) Average mortality rates for the whole population do not provide as much information as age-stratified or age-specific mortality rates. This is especially true when the deadliness of a disease varies significantly with age or health status. The table shows the trend from youngest age group to the oldest. For example, the COVID population mortality rate for Ontarians over 90 has been about 2% (1 death per 50) per year. Compare this to the mortality rate of 0.04% (one death per 2,500) for Ontarians age 60-69. Stated another way, 2,499 out of 2,500 people in their 60's did not die this past year from COVID-19. Compare this with 49 out of 50 people aged over 90 years.

66) Case-fatality ratios use the same numerator as mortality rates, namely deaths associated with the disease of interest. The denominator, however, for case-fatality ratios, is the number of cases. In other words, it is a measure of the "deadliness" of getting an infection - or, at least one that has been counted as a case (usually because of a positive lab test).

67) The case-fatality ratio, using the same dataset, has been about 2% (1 in 50) overall; i.e. 7511 deaths/378,339 cases. An average case-fatality ratio for the whole population does not, however, provide as much information as age-stratified or age-specific fatality ratios. The table shows the significant trend from the youngest age group to the oldest.

68) The highest death per case ratio is, predictably, in those over the age of 90 – about 30%. From another perspective, 2 out of 3 have survived their diagnosis. For those aged 60-69 case fatality is 2%. 98% have survived their diagnosis.

69) There have been two deaths in under-20's. That equates to an under-20 age-specific population mortality rate of one per million and case-fatality rate of about one per 10,000 cases.

70) The probability of severe illness or death from COVID-19 infection transmitted during religious event is a function of the age and health status of congregation members, focused protection strategies in the place of worship and risk-based policies for attendance.

Ontario definitions and policies regarding outbreaks

71) According to Ontario Public Health, "Outbreak-associated cases in this report include all cases directly linked to an outbreak as determined by the local public health unit but may not reflect where the case acquired the infection."[17]

72) "Definitions of outbreaks, including the number of cases, vary across settings. In addition, due to variations in data entry processes across public health units, some outbreaks included in this report may not have met the criteria included in an outbreak definition (i.e. size or duration of outbreak). Further there is no provincial outbreak definition for several setting types classified within the other settings category; as such, there may be variation in declaring outbreaks by public health unit."[18]

Ontario information on outbreaks, including churches and other settings.

73) At time of writing, the most recent Enhanced Epidemiological Summary of COVID-19 outbreaks and cases in Ontario was posted in March, 2021[19]. It covers the period February 16, 2020 to December 26, 2020. During these last 10 months of 2020, there were 4151 reported outbreaks. Of these, 23 (0.6 %) were associated with places of worship. Of the 39,774 cases associated with outbreaks, 221 (0.6%) were associated with places of worship.

74) The average number of cases per outbreak for all outbreaks was 39,774/4151= 10. This is the same average number of cases per outbreak associated with places of worship, 221/23. The median age for all outbreak-associated cases was 54 years; the median age for place of worship outbreak-associated cases was 40 years, i.e. 14 years younger.

75) Five of the place of worship outbreak-associated cases were hospitalized; this is 5/221 = 2.3% of all outbreak-associated cases compared to 8.7% hospitalization for all Ontario outbreak-associated cases. This is 5/3,460 outbreak-associated hospitalizations, equating to

[17] https://www.publichealthontario.ca/-/media/documents/ncov/epi/covid-19-settings-based-outbreaks-epi-summary.pdf?la=en page 2.
[18] https://www.publichealthontario.ca/-/media/documents/ncov/epi/covid-19-settings-based-outbreaks-epi-summary.pdf?la=en page 2.
[19] https://www.publichealthontario.ca/-/media/documents/ncov/epi/covid-19-settings-based-outbreaks-epi-summary.pdf?la=en

0.1% of all outbreak-associated hospitalizations. There were no deaths associated with places of worship outbreaks. 0% of 3,681 outbreak-associated deaths compares with 9.3% deaths of all outbreak-associated cases. This large difference is explained by the comparison with hospitalizations and deaths in congregate care facilities outbreaks, accounting for 88.7% and 98.5% of hospitalizations and deaths, respectively.

76) These numbers do not include secondary cases associated with outbreaks. These numbers do not include non-outbreak associated cases that were attributed to transmission at a place of worship. No data on these parameters were found.

77) In addition to identifying retrospectively where cases may have acquired their infections, prospective investigation can be more accurate to determine secondary cases and to identify the frequency of serious consequences (hospitalizations and deaths) associated with exposure in a particular setting. This type of information was not found in the "enhanced case and management strategy that will help contain the spread of COVID-19"[20]. After case and contact follow-up on more than 440,000 cases[21], a more accurate estimate of the frequency of transmissions in places of worship and all settings could have been ascertained to guide rational decisions about risk and policies. This is an example of the importance of ongoing risk assessment to inform and guide policy, including constant reassessment of the need for continuation of restrictive policies – looking at each setting and its specific levels of risks and need.

Specific questions

What is the ordinary or absolute risk for exposure to and transmission of SARS-CoV-2 in a church service that is near full seated capacity (leaving aside church programs or activities outside of the worship in the church sanctuary)?

78) Calculating the probabilities using incidence data for the Welland municipality, a reasonable estimate of the absolute risk to one person of getting infected during one service without public health measures in place is about one in 300,000 from an

[20] https://www.ontario.ca/page/case-and-contact-management-strategy
[21] https://www.publichealthontario.ca/-/media/documents/ncov/epi/covid-19-daily-epi-summary-report.pdf?la=en

asymptomatic person, one in 30,000 from a pre-symptomatic person and one in 6,000 from a symptomatic person.

79) In one service, the probability of transmission from an attendee without symptoms, is estimated at one in 30,000 (the contribution from asymptomatic attendees is negligible). In a service of 500 people, the probability of one transmission at that service is one in 60 (1.7%) = 30,000/500. In other words, there would be a transmission from an asymptomatic or pre-symptomatic case once in every 60 services. This estimate is in the absence of public health measures.

80) Using these estimates, the probability of transmission at one church service because of a high-risk exposure (prolonged contact, no distancing, no barrier) to a symptomatic case is about one in 5000 attendees. In a service of 500 people, that equates to a 10% probability of one transmission to one person at each service or one transmission from a symptomatic person every 10 services. This is the estimated probability without screening or other public health measures.

What is the comparative risk between an ordinary church service with no safety plan (social distancing, self-screening, masks, hygiene measures, etc.) and a church service that follows public health measures including distancing between households, but does not otherwise implement a capacity limit?

81) To answer this question, it is assumed that all factors of consideration are equal between the two services except for the effective implementation and compliance with recommended public health measures (self-screening for symptoms or required self-isolation, distancing, masks, hand-washing, building ventilation) in one service.

82) In essence, the answer comes down to the comparison of the frequency of high-risk exposures during the service. Public Health Ontario describes a number of factors to consider in categorizing the exposure to a case as a low-risk exposure or high-risk exposure, but the essence of the categorizing is based on whether any of the following three conditions have been met:

a) More than two-meter distancing,
b) Face-to-face exposure less than 15 minutes, or
c) Masks worn properly by case and contact.

83) If any one of these three conditions are met, the exposure would be expected to be classified as low-risk. Inversely, a high-risk exposure would be identified if none of these three conditions were met.[22]

84) Public Health Ontario has not provided estimates of the difference in transmission rates between high-risk and low-risk exposures, but it would not be unreasonable to assume at least an order of magnitude. Regardless of the magnitude, the probabilities of transmission would be significantly lower than those estimated without public health measures in place.

What is the comparative risk between a church that follows public health advice and gathers at 30% of seated capacity and the same church gathering at 15% of seated capacity?

85) Everything else being equal, the only factor of significance which may affect the risk would be the ability to social distance between members that are not of the same household. However, even in that case, the proper use of masks and/or the avoidance of prolonged face-to-face exposures (>15 minutes) would ensure that any exposure to a case would be expected to be classified as low-exposure and would not result in a directive to self-isolate.

What is the comparative risk between a church gathering of 10 people and a church gathering at 15% of seated capacity (in either case, following public health measures)?

86) The answer to this question is the same as that for question 3. Everything else being equal, the only factor of significance which may affect the risk would be the ability to social distance between members that are not of the same household. However, even in that case, the proper use of masks and/or the avoidance of prolonged face-to-face exposures (>15 minutes) would ensure that any exposure to a case would be expected to be classified as low-exposure and would not result in a directive to self-isolate.

[22] https://www.health.gov.on.ca/en/pro/programs/publichealth/coronavirus/docs/contact_mngmt/management_cases_contacts.pdf

What is the comparative risk between attending a church gathering under the circumstances described in 2-4, above, and doing other activities permitted under Ontario Regulation 82/20 (Rules for Areas in Stage 1)? Assume both have a written safety as described in Schedule 1, section 5 of Regulation 82/20.

87) The variations of people, space, and activities in other settings and the lack of detailed data make it difficult to compare risks in a valid way.

88) Comparing the numbers of reported outbreaks in 2020, there were 23 associated with places of worship, 49 in recreational fitness centres, 122 in bars/restaurants/nightclubs and 141 in retail.[23]

89) Comparing the numbers of cases associated with outbreaks, there were 221 in places of worship, 411 in recreational fitness centres, 471 in bars/restaurants/nightclubs and 508 in retail.

90) As a proportion of all outbreaks, places of worship constitute 23/4151 = 0.6%.

91) As a proportion of all cases associated with outbreaks, places of worship constitute 221/39,774 = 0.6%.

92) Although Public Health Ontario has not shown the number of total cases associated with places of worship, it does report on the total number cases associated with "other recreation" settings, which include places of worships and other venues for weddings and funeral. Assuming that all of these cases were associated with places of worship, the proportion of all cases on May 1, 2021 = 2261/466,733 = 0.5%, or 1 in 200 of all Ontario cases.[24]

93) Another way to estimate the risk of transmission is to consider the exposure time of all Ontarians attending a place of worship. 1/3 of Ontarians over the age of 15 attend a religious service at least once per month[25]. The population of Ontario ≥ 15 years is 12

[23] https://www.publichealthontario.ca/-/media/documents/ncov/epi/covid-19-settings-based-outbreaks-epi-summary.pdf?la=en
[24] https://covid-19.ontario.ca/data/likely-source-infection#obSetting
[25] https://www.statcan.gc.ca/sites/default/files/6493-eng.pdf

million[26]. If (1/3 of 12 million =) 4 million people attend an average of 1.5 hours per service and one service per month, the number of "person-hours" of exposure per attender is 12*1.5 = 18 per year. The total hours of exposure per year of all Ontario attenders = 4 million*1.5*12 = 72 million person-hours of exposure. Using this denominator for all accumulated cases that could be associated with exposure to a place of worship until the end of April (more than a year of time), the rate of transmission per hour of exposure to a service of worship is 2261/72 million = one transmission per 32,000 person-hours of exposure. Even if the actual infection rate is ten times the identified case rate, the transmission rate would be one per 3,200 hours of exposure – or one per 2000 services.

Summary and conclusions

94) The purpose of this report has been to estimate the risks associated with attendance at church services in Ontario, in particular the Wellandport United Reformed Church.

95) Using data from official sources, including the Public Health Ontario and the World Health Organization, estimates have been made of the probability of transmission of COVID-19 in church services with attendees from with current rates of infections similar to that of the Niagara health region.

96) Input estimates were used that would if anything overestimate - not underestimate the risk. Furthermore, the estimates used were under the assumption that neither symptom screening nor public health measures were in place.

97) The overall probability of transmission of infection from symptomatic infections occurring at any one service of 500 attendees without screening or other public health measures is estimated at 10% - or one per 10 services.

[26] https://www150.statcan.gc.ca/t1/tbl1/en/tv.action?pid=1710000501&pickMembers%5B0%5D=1.7&pickMembers%5B1%5D=2.1&cubeTimeFrame.startYear=2020&cubeTimeFrame.endYear=2020&referencePeriods=20200101%2C20200101

98) The overall probability of transmission from non-symptomatic infections occurring at any one service – with effective screening of symptomatic persons – is estimated at about 2% - or one in 50 services.

99) The number of people or percentage seating capacity at services should not impact on these estimates as long as high-risk exposures can be avoided and screening, distancing, barriers (masks), and duration of close contact can be maintained, in addition to other factors such as ventilation.

100) It appears that outbreaks from churches constitute less than one percent of all outbreaks and less than one percent of all cases associated with outbreaks.

SWORN BEFORE ME by video conference, in accordance with O. Reg, 431/20 under the *Commissioners for Taking Affidavits Act*, RSO 1990, c. C17, on May 4, 2021, the affiant being in Winnipeg, Manitoba, and the Commissioner being in Ottawa, Ontario.

ONTARIO
SUPERIOR COURT OF JUSTICE

BETWEEN:

WELLANDPORT UNITED REFORMED CHURCH

Applicant

- and -

THE ATTORNEY GENERAL OF ONTARIO

Respondent

ACKNOWLEDGEMENT BY DR. JOEL KETTNER

1. My name is Joel Kettner. I live in Winnipeg, Manitoba.

2. I have been engaged by or on behalf of the Wellandport United Reformed Church to provide evidence in relation to the above-noted court proceeding.

3. I acknowledge that it is my duty to provide evidence in relation to this proceeding as follows:
   a. to provide opinion evidence that is fair, objective and non-partisan;
   b. to provide opinion evidence that is related only to matters that are within my area of expertise; and
   c. to provide such additional assistance as the court may reasonably require, to determine a matter in issue.

4. I acknowledge that the duty referred to above prevails over any obligation which I may owe to any party by whom or on whose behalf I am engaged.

Estimating Influenza Deaths in Canada, 1992–2009

Dena L Schanzer , Claire Sevenhuysen, Brian Winchester, Teresa Mersereau

Published: November 27, 2013 • https://doi.org/10.1371/journal.pone.0080481

Abstract

Background

Poisson regression modelling has been widely used to estimate the disease burden attributable to influenza, though not without concerns that some of the excess burden could be due to other causes. This study aims to provide annual estimates of the mortality and hospitalization burden attributable to both seasonal influenza and the 2009 A/H1N1 pandemic influenza for Canada, and to discuss issues related to the reliability of these estimates.

Methods

Weekly time-series for all-cause mortality and regression models were used to estimate the number of deaths in Canada attributable to influenza from September 1992 to December 2009. To assess their robustness, the annual estimates derived from different parameterizations of the regression model for all-cause mortality were compared. In addition, the association between the annual estimates for mortality and hospitalization by age group, underlying cause of death or primary reason for admission and discharge status is discussed.

Results

The crude influenza-attributed mortality rate based on all-cause mortality and averaged over 17 influenza seasons prior to the 2009 A/H1N1 pandemic was 11.3 (95%CI, 10.5 - 12.1) deaths per 100 000 population per year, or an average of 3,500 (95%CI, 3,200 - 3,700) deaths per year attributable to seasonal influenza. The estimated annual rates ranged from undetectable at the ecological level to more than 6000 deaths per year over the three A/Sydney seasons. In comparison, we attributed an estimated 740 deaths (95%CI, 350–1500) to A(H1N1)pdm09. Annual estimates from different model parameterizations were strongly correlated, as were estimates for mortality and morbidity; the higher A(H1N1)pdm09 burden in younger age groups was the most notable exception.

Interpretation

With the exception of some of the Serfling models, differences in the ecological estimates of the disease burden attributable to influenza were small in comparison to the variation in disease burden from one season to another.

Introduction

Regression modelling is widely used to estimate the disease burden attributable to seasonal and pandemic influenza [1], with this approach recently endorsed by the World Health Organization (WHO) [2], along with a caution not to compare the number of laboratory-confirmed deaths from the 2009 pandemic with estimates of the number of seasonal influenza deaths. Applying these statistical methods to Canadian data has allowed us to study the full burden of seasonal or pandemic influenza on not only mortality [3], [4], but also admissions to hospital [5], visits to emergency departments [6], and workplace absenteeism [7], thereby gaining a better understanding of the relative risks of severe disease that age and health status poses.

The emergence of a novel influenza A H1N1 strain in the spring of 2009 has resulted in a renewed interest in better understanding the reliability of annual estimates of the number of deaths attributable to influenza [8], [9] amid concerns that methods that assume that all excess deaths are due to influenza are falsely including some deaths which were actually due to other respiratory viruses or environment causes [8], [10], [11]. Much of the concern is directed towards Serfling-style [12] regression models where the seasonality of the weekly baseline is described by a cyclical or sinusoidal function (sine and cosine terms). This baseline is

estimated by excluding weeks with influenza activity from the estimation process and then extrapolating the baseline to periods with influenza activity. In addition, it has been noted that some applications of this method have resulted in substantially different estimates of excess all-cause mortality [8]. It is only relatively recently that weekly virological surveillance, such as the Respiratory Viral Detection Surveillance System (RVDSS) of the Public Health Agency of Canada [13] has been available to provide a measure of the weekly level of influenza activity nationally. With the availability of a proxy variable for the weekly level of influenza activity, all weeks can be included in the analysis and the regression model can then simultaneously estimate the seasonal baseline and the number of deaths directly associated with the weekly level of influenza activity. Still, the choice of model parameterization could affect the annual estimates of the number of deaths attributable to influenza.

This study aims to provide annual estimates of the mortality and hospitalization burden attributable to seasonal influenza and the 2009 A/H1N1 pandemic for Canada and discuss issues related to the robustness of these estimates to the choice of statistical model. We applied a variety of Serfling and Poisson regression models incorporating over-dispersion to all-cause mortality and then compared the annual estimates of the number of deaths attributable to influenza. We also estimated and compared the annual estimates for mortality and morbidity stratified by age group, underlying cause of death, hospital discharge status, and primary reason for admission, with the hypothesis that disease severity might be similar enough to induce a strong degree of correlation between these annual measures of disease burden.

Methods

Sources of data

1.1 Mortality data. Records of deaths occurring in Canada from 1992 to 2009 were obtained from the Canadian Vital Statistics database, Statistics Canada [14], [15] and aggregated to weekly counts stratified by age group and underlying cause of death. Underlying cause of death was coded to the International Classification of Disease [16], [17] version 9 (ICD-9) from 1992 to 1999, and starting in 2000, version 10 (ICD-10). The categories of interest were: respiratory deaths (ICD-9: 460-519 and ICD-10: J00-J99); circulatory deaths (ICD-9: 390-459 and ICD-10: I00-I99) and a third category of ‘other causes’ which included all other causes of death (including external causes). Population denominators for the calculation of rates were obtained from Statistics Canada census and inter-census estimates [18].

For the 2009 pandemic, a total of 428 laboratory-confirmed deaths were reported to the Public Health Agency of Canada [19], though not all of these deaths were certified as due to laboratory-confirmed influenza (J09, J10) as the underlying cause of death [15]. These measures of the pandemic mortality burden were considered in assessing the uncertainty in the estimate of the number of deaths attributable to the pandemic.

1.2 Morbidity data. Hospital discharge records from patients admitted to an acute care hospital with a respiratory condition identified in any of the diagnostic fields were extracted from the Canadian Institute of Health Information (CIHI) patient-specific Hospitalization Database (HMDB) [20] for the period September 1994 to March 2010. The HMDB contains all separations (discharge or death) from an acute care hospital anywhere in Canada. Data was abstracted from the patient chart using ICD-9, or ICD-10-CA (Canadian version) [21]. At the 3 character ICD-10 code level used in this study, the ICD-10-CA is consistent with codes used in other countries [22]. The conversion from ICD-9 to ICD-10-CA occurred on a province-by-province basis from 2001 to 2006. Admissions were stratified by age, primary and secondary diagnostic category and discharge status and aggregated to weekly values. An additional subcategory of pneumonia and influenza admissions (ICD-9: 480-487, ICD-10 J09-J18) was also considered. Primary respiratory admissions are defined as admissions with a respiratory condition listed as the primary reason for admission/length of stay. Secondary respiratory admissions are those admissions for other causes with a respiratory condition as a contributing diagnosis.

1.3 Virological data and proxy variables for influenza activity. Respiratory virus identifications for influenza A and B and respiratory syncytial virus (RSV) were obtained from the RVDSS, Public Health Agency of Canada [13]. The RSVDSS compiles weekly data from selected laboratories on the number of tests performed and the number positive for influenza, respiratory syncytial virus (RSV), and other respiratory viruses. Specimens are generally submitted to laboratories by clinicians in the course of clinical care, and by clinicians participating in one of our provincial influenza surveillance programs. The predominant testing methods used for influenza detection have varied considerably over the study period and by laboratory. Panel tests were often used.[23]–[25] Though viral identification data has traditionally been used as the proxy variable for influenza activity and has performed well in this capacity [4], once circulation of a novel strain with pandemic potential was announced in late April of 2009, testing increased sharply as did the number of positive tests, and then varied in response to public health needs over the pandemic period. In many jurisdictions, the percent positive remained elevated over an unusually long period of time. As a result, viral identification data was no longer a good measure of the relative level of influenza activity over the pandemic period. Fortunately, with the conversion of hospitalisation coding to ICD-10, patients with laboratory-confirmed influenza were identifiable by the J09 and J10 codes. In addition, the use of J09/J10 (influenza virus identified) admissions to represent the level of influenza activity under ICD-10 coding has improved the model fit in other studies as well as providing better face validity [5], [6]. In order to use a longer study period these two data sources were combined; that is the weekly number of influenza positive tests (prior to the 2007/08 season) and the weekly number of admissions to hospital with laboratory-confirmed influenza for the 2007/08 influenza season through to March 2010 were combined. The splice was positioned to correspond to the ‘flu year’ to ensure separate multipliers for the two data sources.

1.4 Ethics Statement. This study was conducted in accordance with the principles expressed in the Declaration of Helsinki Declaration. Data provided by Statistics Canada was collected under the Statistics Canada Act. Data collected by the Canadian Institute of Health Information was provided to the Public Health Agency of Canada and the use of this data was in accordance with data sharing agreements. Data provided by the Public Health Agency of Canada was collected under the Public Health Agency of Canada Act and used in agreement with policy and regulations related to the publication of information related to public health. Identifying formation was not available to this study and most of the data has been previously published. Hence, ethics approval was not required.

1.5 Data Access. Access to the data used in this study is available from the data custodians (Statistics Canada, Canadian Institute of Health Information and the Public Health Agency of Canada) as per their data access arrangements. A dataset containing weekly mortality (all cause) and the weekly number of influenza and RSV positive tests has been made available as Table S1 with the description in Table S2.

Analysis

2.1 Poisson regression model. Stratified weekly deaths and admissions were modelled as a function of viral activity, seasonality, and trend using Poisson regression models similar to previously published estimates of the influenza burden in Canada[4], [5], [7]. The regression model was fit using SAS 9.1 [26] PROC GENMOD with a Poisson distribution, linear link function and dispersion parameter specified by:

$$NDEATHS = \sum_{m=1}^{12} \beta_{1,m} Mon_m + \beta_2 \cos(2\pi t/52.177457) + \beta_3 \sin(2\pi t/52.177457) + \sum_y \beta_{4,y} FY_y + \beta_5 Holiday + \beta_6 Dec25 + \beta_7 Jan1 + \beta_8 RSVproxy + \beta_9 FluBproxy + \sum_y \beta_{10,y} FY_y FluAproxy + \varepsilon$$

where ***NDEATHS*** represents the weekly number of deaths (or admissions) for the category of interest (for example age group). The monthly indicator variables (Mon_m) and the sinusoidal terms (with t=week) are included to account for seasonality. FY_y is a set of indicator variables for each influenza season, y ('flu' year) starting in September, with an exception for the 2009 pandemic where the 'flu' year was defined as May 2009 – March 2010. The β_4 parameters account for a general trend with more flexibility than the linear, quadratic and cubic trend terms used in the Serfling model below. The variables ***Holiday*** and ***Dec25*** were included in the hospital admission model to account for a reduction in admissions over holidays, and the last week of December (that includes December 25th, or Christmas day). The variable ***Jan1*** is an indicator variable for the first week of January, a week when a pronounced spike in respiratory admissions and deaths is often seen. The $\beta_{8,}$ $\beta_{9,}$ and $\beta_{10,\,y}$ parameters are multipliers for the proxy variables for RSV, influenza B and influenza A respectively. Separate annual multipliers for each flu season are necessary for any meaningful discussion of the annual estimates. Unfortunately, statistical power was insufficient to estimate the annual effects of RSV or influenza B. The ***FluAproxy*** is a combination of laboratory positive tests and admissions to hospital with laboratory-confirmed influenza as described above. The ***FluBproxy*** is the percentage of laboratory tests positive for influenza B. Various alternative parameterizations of the Poisson regression model were included in the sensitivity analysis. In the Week-of-Year Baseline model, all seasonal variables were replaced by a week-of-year indicator variable (53 seasonal parameters). In the Simple Serfling-like Poisson model seasonality and trend terms were replaced by the sinusoidal seasonality (2 seasonal parameters) and linear, quadratic and cubic trend terms as specified for the Serfling model below. The dispersion parameter was included in the model estimation to account for additional variation due to events not captured by the choice of explanatory variables and usually results in larger confidence intervals. A linear link function was used to specify that the weekly number of influenza deaths (or admissions) should be proportional over the year/season to the number of confirmed cases.

Influenza-attributed deaths were calculated as the difference between model-predicted deaths and the model-predicted deaths under the hypothetical absence of influenza, with the latter referred to as the seasonal baseline. Equivalently, the annual estimate can also be calculated by summing the proxy variable over the year/season and multiplying by the corresponding estimated parameter. The former (sum of weekly estimates) is easier to visualise, while the latter approach of working with estimated parameters ensures that the correlation structure induced by the regression model is accounted for. Hence, only disease burden estimates corresponding to an estimated parameter were reported, and confidence intervals for estimates of influenza-attributed rates were calculated from the coefficient of variation of the corresponding multiplier parameter.

2.2 Serfling regression model. The percentage of weekly laboratory tests positive for influenza A or B from the RVDSS and the percentage of deaths due to an influenza-like illness (ILI) or influenza (ICD-9: 487, ICD-10:J09, J10 or J11) at various arbitrary threshold levels were used to identify weeks for exclusion from the Serfling models specified by:

where t represents time or week. (Serfling-style models still use regression as the statistical procedure to estimate the parameters. However, these models are characterized by the exclusion of observations during periods of influenza activity.)

The Serfling model was only used in the sensitivity analysis. The annual number of deaths attributable to influenza was calculated for the Serfling models by summing the weekly excess (actual less estimated baseline) over a period that only included the excluded weeks. Both positive and negative 'excesses' were included in the sum in order to avoid biasing the estimate upward. For each Serfling model we reported the number of excluded weeks per season, the annual number of excess deaths and the annual baseline for the full year, averaged over 17 seasons (1992/93-2008/April 2009).

2.3 Cross-Validation and Sensitivity Analysis. The Poisson model described above was used to calculate annual estimates of the influenza disease burden by categories of interest. These annual estimates were plotted in scatter plots and as a time-series, and the correlation coefficient was used to summarize the disparity between two annualized time-series. Annual estimates for the burden attributed to influenza B were not specifically reported, as only one influenza B multiplier parameter was used for whole study period (and annual estimates calculated from such a model would be perfectly correlated with the annualized proxy variable).

For the sensitivity analysis for all-cause mortality, selected thresholds for the Serfling model and various parameterizations of the Poisson regression model were used to assess the impact of model choice on the point estimate of influenza mortality and its standard error. All parameters included in the main Poisson model described above were statistically significant (with p-values from the type 3 analysis often less than 0.0001).

Results

The average number of deaths attributable to seasonal influenza over the 17 seasons prior to the 2009 pandemic was estimated at 3,500 (95% CI 3,200 - 3,700) for an average crude mortality rate of 11.3 (95% CI, 10.5 - 12.1) deaths per 100,000 population per year. These estimates were based on the impact of influenza activity on all-cause mortality. The annual estimates ranged from undetectable to an average of more than 6000 deaths per year over the three A/Sydney seasons (Table 1). Between May and December 2009, an estimated 740 deaths (95%CI, 350-1500) were attributed to the pandemic strain, for a crude mortality rate of 2.2 (95%CI, 1.0 - 4.5) per 100,000 population. The average number of admissions to hospital attributable to seasonal influenza over the 15 seasons prior to the 2009 pandemic was estimated at 12,200 (95%CI, 10,800 - 13,600). The effect of influenza B on hospital admissions was not statistically significant. The annual estimates of respiratory admissions and deaths attributable to seasonal influenza were closely correlated (correlation coefficient of 0.82, see Figure1a, b), as were the mortality estimates from the death and hospitalization databases (correlation coefficient of 0.83, Figures1c, d). The pandemic was a notable exception with a relatively high morbidity burden compared to the mortality burden.

Table 1. Estimated Annual Number of Deaths and Hospital Admissions Attributed to Influenza, Canada.

1. Pandemic Mortality Burden

Of the 428 deaths with laboratory-confirmed A(H1N1)pdm09 reported to the Agency, 73% were in persons under 65 years of age and 72% were certified as due to influenza as the underlying cause of death. We estimated that 561 (95% CI, 347-775) deaths certified as due to an underlying respiratory cause were attributable to the pandemic. An additional 179 deaths certified as due to other causes were attributed to the pandemic, though this estimate was not statistically significant and the confidence intervals are quite wide. We assumed that the pandemic did not result in fewer deaths from circulatory or other causes, and as a result, set the lower 95% confidence interval (CI) for all-cause deaths attributed to influenza to the lower 95% CI from the respiratory underlying causes model. The resulting estimate is 740 deaths for a rate of 2.2 (95% CI, 1.0, 4.5) deaths per 100,000 population. (For any subsequent analysis, such as for a meta-analysis to assess the pandemic burden on a global scale, the model estimated standard error (coefficient of variation is 0.543) should be used.) The lower 95%CI at 1.0 deaths/100,000 population is close to the figure for deaths certified through ICD-10 coding as due to laboratory-confirmed influenza of 0.9 (Table 2). For persons under 65 years of age, the 216 deaths certified as due to influenza is in good agreement with the 254 (95%CI 192-315) deaths estimate to be attributable to A(H1N1)pdm09.

Table 2. A(H1N1)pdm09 Associated Mortality Rates per 100,000 Population, Canada, May – Dec 2009.
https://doi.org/10.1371/journal.pone.0080481.t002

Early reports of laboratory-confirmed A(H1N1)pdm09 associated deaths to the Agency suggested that most deaths (73%) had occurred among persons under the age of 65 years of age. However, the results of the regression models suggest that this early estimate was too high as under-ascertainment of the role of influenza was more significant for persons 65 years of age or older (Table 2).

2. Annual Estimates of Mortality and Morbidity by Epidemiological Characteristics

Estimates of respiratory and circulatory influenza-attributable deaths were closely correlated (Figure 2a, b), though with the conversion from ICD-9 to ICD-10, the proportion of influenza-attributable deaths coded to other causes increased (Figure 2a, c). Annual estimates of influenza-attributed admissions were correlated by reason for admission (primary versus secondary respiratory

r=0.77, Figure 3a), as were in-hospital deaths (Figure 3b). During the pandemic, most influenza-attributable respiratory admissions had a diagnosis of pneumonia or influenza, though for seasonal influenza, annual estimates for pneumonia and influenza versus other respiratory conditions were closely correlated (*r*=0.91) (Figure 3c). By broad age groups, annual estimates of influenza-attributed hospital admissions were strongly correlated between persons aged 20–64 years and persons 65 years of age or older (Figure 4a). However, the annual disease burden in persons under the age 20 years was a poorer predictor of the burden in adults (Figure 4b). Annual estimates by discharge status (discharged alive versus deceased) for persons aged 65 years or older, were also strongly correlated (*r*=0.94, Figure 4c).

Figure 2. Comparison of the annual estimates of the number of deaths attributable to influenza by underlying cause of death (respiratory, circulatory, and other causes).
a) Annual time-series with influenza season identified on the x-axis. b) Scatter graph with a linear trend shown in solid black. Annual estimates based on respiratory and circulatory underlying causes are highly correlated, while in c) a comparison of respiratory to other causes shows a significant change with the conversion from ICD-9 to ICD-10 (denoted by an x). Open symbols indicate that the estimate was not statistically significant (95% CI includes 0). The A(H1N1)pdm09 estimates are indicated with a red square.
https://doi.org/10.1371/journal.pone.0080481.g002

Figure 3. Comparison of annual estimates of the number of hospital admissions attributable to influenza by reason for admission.
Open symbols indicate that the estimate was not statistically significant (95% CI includes 0). The A(H1N1)pdm09 estimates are indicated with a red square. A linear trend line is shown in solid black.
https://doi.org/10.1371/journal.pone.0080481.g003

Figure 4. Comparison of annual estimates of the number of admissions attributable to influenza by age groups.

Sensitivity Analysis

In applying different parameterizations of Poisson regression models to the weekly time-series of all-cause mortality, we found minimal differences in the average number of deaths attributed to influenza and the annual estimates were closely correlated (*r* >0.9 for comparisons of models with annual multipliers) (Table 3 and Figure 5a). Model results using a multiplicative Poisson regression model (log link) rather than an additive model or the negative-binomial distribution in place of the Poisson distribution produced almost identical results (not shown).

Figure 5. Sensitivity Analysis of selected models to estimate the mortality burden attributable to influenza.
a) Poisson regression and Serfling model estimates of influenza-attributable deaths by influenza season. Three parameterizations of the Poisson regression model are shown in solid lines and 4 choices of thresholds for periods of influenza activity for the Serfling model are shown with dashed lines. Serfling models use regression to estimate a cyclical baseline, but exclude weeks with influenza activity. b) Average Number of Deaths (all cause) by Week with the Estimated Baselines for Selected Models. Despite an additional 150–200 deaths occurring in week 1, the averages of the weekly baseline for the full model (dashed line) and the Simple Serfling-like Poisson model (solid red) for January through mid-March were similar. Use of 53 indicator variables – 1 for each week of the year to account for seasonality resulted in a similar weekly baseline (dotted line). The Serfling baseline for a 10% influenza positive threshold is shown in green. The average weekly number of deaths attributed to influenza is shown on the secondary y-axis.
https://doi.org/10.1371/journal.pone.0080481.g005

Table 3. Sensitivity Analysis of the Poisson Regression Models for the Estimation of the Annual Number of Deaths Attributed to Seasonal Influenza.
https://doi.org/10.1371/journal.pone.0080481.t003

Though the annual estimates from various Serfling models were closely correlated with the results from the Poisson models (r>0.8) they tended to be lower. The source of this difference seems to stem from an over-estimation of the cyclical baseline over the winter months which had been excluded due to influenza activity. We found that excluding fewer weeks (from 33 to 6) increased the estimated baseline (Table 4). Still, simply adding the ***FluAproxy*** variable with individual multipliers for each season (Simple Serfling-like Poisson model) resulted in estimates that were similar to estimates from other Poisson regression models. This effect on the estimated baseline is illustrated in Figure 5b, where all-cause deaths and estimated baselines were averaged by week over the study period.

Table 4. Sensitivity Analysis of Serfling Models for the Estimation of the Annual Number of Deaths Attributed to Seasonal Influenza.

Discussion

Influenza-attributable deaths are deaths that occur in people for whom an influenza infection contributed to the actual death, or at least the time of death, regardless of whether or not influenza was identified as the underlying cause of death. Because of the limitations of an ecological study design, these models have been be given much scrutiny [1], [8], [11], [27], [28]. Some of these reviews have identified poor correlation in published annual estimates of influenza mortality rates, while other studies have found reasonable agreement. Unlike most ecological studies, the peak period of influenza activity in temperate regions occurs over a relatively short period of time, with over 50% of the cases occurring within a 4–5 week period each year[29]. Though influenza was attributed to only 2% of deaths annually, 14–19% of the weekly deaths at the peak for the three A/Sydney seasons (1997/98-1999/00), and up to 10% in other seasons were attributed to influenza. As an ecological study, there is no gold standard for the best model – and the most appropriate model may vary from country to country depending on data availability or unusual events. The short duration and intense effect of influenza on many endpoints provides a unique opportunity to use weekly data to estimate the impact and to use validation and cross-validation techniques at the annual level to assess the internal and external consistency of the annual estimates.

As a measure of external consistency, we assessed the correlation between the annual mortality estimates by cause of death and the annual morbidity estimates by age, reason for admission, and discharge status. Most estimates of the disease burden attributable to influenza were well correlated with only a few exceptions. A notable exception is that the severity of an influenza season among persons under the age of 20 years was found to be a relatively poor predictor of the severity among adults (Figure 4b). The proportion of all deaths that were coded to causes other than cardio-respiratory conditions increased from 54% to 60% with the conversion to ICD-10. However, the conversion had a much larger impact on the proportion of influenza-attributed deaths that were coded to other causes, which increased from 23% to 49% (Figure 2b) for seasonal influenza. Despite the labels of influenza-attributed ‘cardiovascular’ or ‘other causes’, the analysis of in-hospital deaths indicates that the attribution to influenza is limited to patients with a diagnosis of respiratory condition regardless of the certified underlying cause of death. The implication is that the use of all-cause mortality with its wider confidence intervals is a more accurate measure of the full disease burden due to influenza.

For persons over the age of 65 years, the estimated A(H1N1)pdm09-attributed burden was considerably less than for seasonal influenza (Figure 4a, b), however, once admitted to hospital due in part to an influenza infection, the fatality rate for this age group was similar for seasonal and pandemic influenza (Figure 4c). The lower A(H1N1)pdm09 fatality rate for all ages combined is explained by the unusually high number of admissions among persons under the age of 65 years (Figure 4a, b). The low A(H1N1)pdm09-attributed mortality rates in Canada is consistent with the hypothesis of partial prior immunity for persons over the age of 65 which has been confirmed in previous work[5]. Contrary to initial reports where 73% of all laboratory-confirmed A(H1N1)pdm09 deaths reported to the Agency occurred in persons under the age of 65 years, this proportion dropped to 45% for influenza-attributed respiratory deaths and possible much lower for all-cause mortality. The implication is that for hospitalized seniors the pandemic strain was not milder than for seasonal strains and that their infections were less likely to be diagnosed as influenza than for younger persons. Most of the missing pandemic diagnoses were among older patients with pneumonia.

Though no obvious trend was observed over the study period, a full trend analysis was limited by the significant year-to-year variation in the influenza-attributable mortality rate, together with increased virological testing over the study period, and significant coding differences of the underlying cause of death introduced with the conversion to ICD-10.

For internal consistency, we compared the annual estimates of the number of deaths attributable to influenza from different Serfling and Poisson regressions models. The Serfling estimates were dependant on the number of weeks per year that were excluded due to influenza activity, and for most exclusion rules, this method produced lower annual estimates than the Poisson models.

Concern has been expressed that as Serfling models attribute all excess deaths to influenza, that this approach would inherently over-estimated the burden attributable to influenza. It appears that, on the contrary, the fitted cyclical baseline, with only a few data points in the winter months as a guide, tended to overestimate the number of non-influenza deaths in the winter months, and hence underestimate the winter excess due to influenza. Including the proxy variable for influenza activity along with annual multipliers for independent estimates of the annual excess was sufficient to stabilize the annual estimates.

Additional parameters that allowed the baseline to adapt more closely to the weekly data had little effect on the average annual estimates for influenza mortality. For example, deaths in 1st week in January were elevated by an estimated 163 deaths (95% CI 88-240). Removing this parameter from the regression model resulted in these additional deaths being absorbed into the baseline estimates for other weeks. The same was observed for the monthly indicator variables and the RSV proxy variable. Even using a week-of-year indicator variable (53 parameters) produced similar results. On the other hand, removing all parameters related to seasonality resulted in a two-fold increase in the estimated number of influenza-attributed deaths (not shown).

Some earlier models for estimating the burden of influenza mortality used the percentage of tests positive for influenza as the proxy variable for influenza activity and the same multiplier for each season [30]. Including only one multiplier for influenza activity forces the annual mortality estimates to be proportional to the annualized proxy variable and produced annual estimates that were poorly correlated with the estimates for the full model and were also about 10% lower (Table 3).

Our sensitivity analysis was limited in the breadth of comparisons included. Other options for proxy variables are emerging [31] and have not been evaluated in this study. While we included a proxy variable for RSV activity, many other respiratory viruses are now under national surveillance. In addition, our sensitivity analysis was limited to assessing the performance of different models for all-cause mortality only. As the annual estimates of influenza-attributed admissions for children and adults were poorly correlated, further assessment, particularly of models using a single influenza multiplier for more than one season is warranted for other time-series. The assumption that testing was consistent over each season prior to the pandemic seems reasonable based on a previous study of the empirical epidemic curves derived from this data [29].

Some of the annual influenza disease burden estimates (or the lower 95% confidence interval) in the tables or figures are negative. Negative estimates will occur when the true number of events (deaths or admissions) due to influenza is less than the natural variation in the total number of events (all-cause mortality or hospital admission) during periods of influenza activity. For the Serfling estimates, we summed all positive and negative weekly ‘excesses’ over the defined influenza period in order not to introduce biases by ignoring negative estimates. Technically, though plausible in a few rare instances, it is unlikely that an influenza infection ‘saved’ lives, and hence any negative ‘excess’, is most likely due to the random variation of the total number of deaths. Hence, to avoid biasing the annual total, these natural or random dips below baseline must be included to balance out the nature swings above baseline.

Though Poisson regression, or equivalently, negative binomial regression models with annual multipliers to adjust for potential year-to-year differences in the relationship between the proxy variable for the level of influenza activity and the resulting disease burden are emerging as the preferred model, various methods have been used internationally to estimate the A(H1N1)pdm09 mortality burden. A recent review article [32] summarizes many of the international studies to date. As noted in our study, a higher disease burden for pandemic versus seasonal influenza among persons under 65 year of age was a common experience in most countries [32]. Published international estimates of the A(H1N1)pdm09-attributed mortality rate for 2009 have varied. Some of the variation is likely real with higher rates of 11 and 10 per 100 000 population for Mexico (using all-cause mortality) [33] and China (using respiratory and cardiovascular deaths) [32] respectively. Choice of methodology can influence the estimates with one study estimating an influenza-attributable mortality rate of 0.8 per 100,000 for the United States [34] and another by Charu and colleagues at 4.7 (95%CI 2.0 – 7.5) [35]. The lower estimate was produced using a Serfling model with monthly data for pneumonia and influenza deaths, while the latter study used a methodology similar to ours. The estimated mortality rates from the Charu study are similar to ours at 2.6 (95%CI 1.5 – 3.8) compared to 1.7 (95%CI 1.0 – 2.3) for respiratory causes, and in both cases the estimate for circulatory causes was not statistically significant. Though the Charu estimate for cardio-respiratory causes was twice our all-cause estimate, this difference was not statistically significant.

For future estimates of influenza disease burden, increases in virological testing of hospitalized patients along with the ICD-10 coding to identify laboratory-confirmed cases will offer significant improvements in the measurement of influenza activity specific to the region and age group. With a better influenza proxy variable, the expectation is for a slight increase in the estimates of disease burden attributed to influenza. It is therefore important that estimates based on new models forms or even a new parameterization of the regression model be compared head-to-head with a Poisson regression model that includes at least seasonality, secular trend and a proxy variable for influenza or influenza A with annual multipliers and a dispersion parameter or equivalently the use of the negative binomial distribution.

In summary, differences in the ecological estimates of the disease burden attributable to influenza were small in comparison to the variation in disease burden from one season to another. Poisson regression models that included at least seasonality, a secular trend and a proxy variable for influenza or influenza A with annual multipliers and a dispersion parameter to correct for overdispersion produced reasonably consistent estimates of the annual mortality burden attributable to influenza and these estimates were highly correlated with annual estimates for the morbidity burden for adults. The annual morbidity burden for children (under the age of 20 years) was found to be a poor predictor of the corresponding adult burden. Influenza continues to be a significant contributor to mortality.

DR. THOMAS WARREN, SWORN

CROSS-EXAMINATION BY MR. GUTTMAN:

1. Q. Good afternoon, Dr. Warren.

A. Good afternoon.

2. Q. You swore an affidavit on May 25th, 2021 in this matter?

A. Yes.

3. Q. And do you have it before you?

A. Yeah, I have it on another screen right beside me.

4. Q. Okay. And do you have access to some of the exhibits, footnotes that you cited?

A. The references, yes.

5. Q. Okay. You have no changes or corrections to that affidavit?

A. No.

6. Q. So I want to start just by talking about your experience. You work at Halton Healthcare?

A. Yes.

7. Q. And you are an infectious disease consultant; is that right?

A. Yes, I do both infectious diseases and medical microbiology.

8. Q. Right. Okay. And how do you split

your time between those two?

A. It would probably be 90 percent infectious diseases. I do about -- I do -- I'm responsible for 10 weeks of medical microbiology.

9. Q. So that's probably about 20 percent then.

A. Yeah, but in those days that I'm on service for that I would so some other things as well, so I would say it's about 10 percent.

10. Q. Does medical microbiology involve seeing patients?

A. No, medical microbiology is a Royal College speciality for the laboratory, the microbiology laboratory for diagnosing infectious diseases, so I have two -- two Royal College certifications. The infectious diseases is clinical, and that's 90 percent of my time, so that's taking care of infectious diseases patients and medical microbiology is laboratory.

11. Q. And when it comes to your infectious disease practice is that mostly out of the hospital?

A. Yeah. My patient load, and again, probably about 80 percent is inpatients and then 20 percent outpatients.

12. Q. And you see all sorts of infectious diseases, right?

A. Yes. I -- I do all types of infectious diseases, inpatient, outpatient, anything caused by viruses, bacteria, fungus and parasites, so I do acute care in a hospital, including COVID-19, but then chronic care of Hepatitis C, HIV, things like that.

13. Q. So, what percentage of the patients you see outside of the clinic would be COVID patients, sorry, outside of the hospital would be COVID patients?

A. I -- I don't know if I really see any outside of the hospital. I'm on call a third of the time, so about 17 weeks a year, and that's when I would be primarily seeing COVID patients, would be when they're admitted to hospital.

14. Q. When you're in hospital you're seeing all sorts of patients, including --

A. Yes.

15. Q. -- COVID?

A. Yeah.

16. Q. And outside of hospital you're not seeing any COVID patients?

A. No, I have certainly, but it's you

know -- most of that is taken care of by primary care and things like that.

17. Q. Okay. And I see from your CV that you're currently completing a masters in epidemiology?

A. Yes, at the London School of Hygiene and Tropical Medicine in England.

18. Q. Okay. And so you haven't completed that masters yet?

A. No. I'm in the -- my fourth year. Expected completion should be next year.

19. Q. And you don't have a PhD in Epidemiology?

A. I do not.

20. Q. And you're not licensed as a public health doctor?

A. I am not.

21. Q. And you do not have any degrees in public health?

A. No.

22. Q. Now, I was looking at your publications. Your most recent publication is in peer-reviewed publication as of 2015; is that right?

A. Yes, that sounds right.

23. Q. And you don't appear to have any -- well, there's three listed. You don't appear to have

any peer-reviewed publications on respiratory disease; is that right?

A. That's correct.

24. Q. They're in medical microbiology?

A. Yes.

25. Q. Okay. And you don't have any publications on COVID obviously.

A. No.

26. Q. All right. So to start with some introductory questions, you agree that the science around COVID-19 is complex and uncertain?

A. Yes. It's ever evolving, yeah.

27. Q. You just answered my second question, that it's always evolving, because it's only been around for approximately two years; is that right?

A. That's correct.

28. Q. Now, I know that you practice infectious disease and not public health, but you understand that public health practitioners often don't have the luxury of waiting for the science to solidify before recommending action?

A. Okay. Sure.

29. Q. They have to act with the information they have available to them, right?

A. Yes.

30. Q. Okay. And so they would often have to act before there would be a peer review study for instance?

A. Yeah. You know COVID is a -- a new virus, but it's in a family of viruses that we've known about for a long time, and it's in a broader category of respiratory viruses, so certainly inductive implications can be made from experience with similar types of infections in the past.

31. Q. So can you explain to me, having accomplished three of them, what's involved in completing a peer-reviewed study, getting one published?

A. So the one study I did was in Cystic Fibrosis patients and diagnosis of fungal infections on those patients --

32. Q. Sorry, not to interrupt you. I just meant the process. I don't mean the content.

A. So the process, yeah, it depends on if it's a -- a benchry (ph) search which primarily is what I did versus clinical research with patients. So a benchry research involves investigations in the laboratory with usually patient samples in the medical context versus clinical trials can be divided into

retrospective studies which are cohort studies and case control studies versus prospective studies which are intervention randomized control trials which you know take a very long time.

Once the actual experiments and studies are complete then they're written up, submitted for peer review. The -- the papers are reviewed. Often suggestions are made. Those are done and then submitted again and accepted.

33. Q. Okay. And what is a preprint?

A. So a preprint is a publicly available version of the -- of a paper of a study prior to acceptance or -- yeah, prior to peer review. So the study has been completed, the paper has been written, and it's often in the process of peer review, although not all the time, but it's uploaded to a publicly available repository so that there can be public feedback as well as peer review, so that's one aspect of it.

The other aspect of a preprint is so that if there is very important information it can be disseminated before final publication, because the peer review process and the publication process, in the past at least, prior to a couple of years ago, could sometimes be quite long, even in the -- even

measured in years, but certainly months.

34. Q. Right. Okay. Thank you. Okay. And you agree that viruses like COVID evolve over time?

A. Yes. We know that COVID and similar viruses do mutate and evolve over time.

35. Q. And they can become more contagious over time?

A. Yes, they can change. They can become more contagious, less contagious, more virion, less virion.

36. Q. Right. And that's happened in Ontario first with -- in respect of COVID-19, first with Alpha, then with Delta and now with Omicron?

A. Yes, each of those Greek letter named strains are different -- have associated different mutations which affect both their infectivity and you know seriousness of infection.

37. Q. Right. Some of them are more serious than original COVID.

A. Yeah.

38. Q. And I know Omicron's coming on, but right now Delta is still the dominant variant in Ontario?

A. That's correct.

39. Q. And you're aware that cases are currently increasing in most Public Health Units due to the spread of the Delta variant and now Omicron?

A. Correct. Yes. Usually there's an increase in the winter.

40. Q. Right. Okay. All right. I want to take you to paragraph 15 of your affidavit. And here you talk about age being an important risk factor for COVID.

A. Um-hmm.

41. Q. Now, COVID is obviously very lethal for older people, but you agree that young people can still --

A. Yes, any age can be infected.

42. Q. And some young people can still get very sick from COVID.

A. Yes. Any age can potentially get very sick or die, but the risk of serious infection or death is substantially lower in very young compared to the very old.

43. Q. Right. And that's your position in the affidavit. I'm just trying to establish that people -- the effect on young people. Young people can spread the disease to other young people, right?

A. Correct.

44. Q. And they can spread it to seniors.

A. Yeah, there is evidence though that young people actually probably spread less than adults, this infection, but they can transmit it to both young people and adults.

45. Q. And especially if they're living with family members they can -- they can transmit to adults.

A. Yeah. Again, there are studies that show that household transmission from the young to the old is -- is less important than transmission from adults to adults, but, yes, young can transmit to -- to adults.

46. Q. And you agree before some of these young people die they get very sick, right?

A. Yeah, of course. If -- if a young person dies of COVID then they would have severe symptomatic illness beforehand.

47. Q. Right. And when they're very sick they take up a hospital bed.

A. Yes.

48. Q. Okay. In the next paragraph you compare the death rate of people under 60 with motor vehicle fatalities. And I appreciate you are saying the numbers are the same, but you're not looking here

at you know hospitalizations for instance caused by motor vehicles, right?

A. No. I'm looking in this paragraph specifically at fatalities.

49. Q. Right. And we know that motor vehicle accidents have not caused shortages in the ICUs in past years, right?

A. I don't know. I assume not, but I don't know that information.

50. Q. Well, you work in a hospital. You would have heard if there were -- if ICU units were overflowing with motor vehicle accident injuries, wouldn't you?

A. Yeah. I've never experienced that.

51. Q. In your general knowledge it hasn't caused the type of upheaval we saw because of COVID, right, in terms of hospitalization?

A. Correct.

52. Q. And we know from the hospitalizations caused a delay of elective surgeries, right, in Ontario?

A. Yeah. Well, some elective surgeries were cancelled in the first wave pre-emptively, but in the second and third waves because of hospital capacity, that's correct.

53. Q. Right. And some diagnostic procedures were delayed as well because of COVID.

A. That's correct.

54. Q. All right. The next section is on asymptomatic transmission.

A. Um-hmm.

55. Q. And I wanted to take you to an article that you cite, it's called, "An Outbreak of COVID-19 on an Aircraft Carrier." It's not cited in this section. It's cited earlier. It's by Kasper. If you want I can screen it, share the screen, but if you have access to it it's probably easier.

A. Yeah, just let me look it up for a minute. Okay.

56. Q. So this is an article published in the New England Journal of Medicine where Kasper's the lead article, author.

A. Yes.

57. Q. And it's about an outbreak of COVID-19 on an aircraft carrier?

A. That's correct.

58. Q. And just give me one second. Now, you called -- at paragraph 10 of your affidavit you called a population of this study as "relatively healthy." This was the crew of a naval vessel, right,

that was studied?

A. Yeah, it was an aircraft carrier.

59. Q. And you can see under "results" in the third paragraph on page 1 in the abstract that they were "predominantly young," the --

A. Yes.

60. Q. -- staff, and they were:

"In general good health, meeting U.S. Navy standards for sea duty."

A. Correct.

61. Q. So when we say "relatively healthy," this is as about as good as it gets, right?

A. Yes.

62. Q. A better word might have been "very healthy" rather than "relatively."

A. Okay. Sure, very healthy.

63. Q. Right. Okay. Now, in the second sentence under "results," it says:

"Over the course of the outbreak, 1271 crew members (26.6 percent of the crew) tested positive for -- (SARS-CoV-2) -- and more than 1000 infections were identified within 5 weeks after the first laboratory-confirmed infection."

Do you see that?

A. Um-hmm.

64. Q. And then under "conclusions" in the abstract it says:

"SARS-CoV-2 spread quickly among the crew of the U.S.S. Theodore Roosevelt."

Do you see that?

A. Um-hmm.

65. Q. "Transmission was facilitated by close-quarters conditions and by asymptomatic and presymptomatic infected crew members."

See that?

A. Um-hmm.

66. Q. "Nearly half of those who tested positive for the virus never had symptoms."

Do you see that?

A. Yes. Sure.

67. Q. Okay. No problem. Just if you could say, "yes," or, "no," Dr. Warren, for the record that would be great?

A. Yeah.

68. Q. Okay. So if you can turn to page 2424, which is if you could turn to the paragraph in

the lower left-hand corner?

A. Um-hmm.

69. Q. It's says:

"Not surprisingly crew members working in the engine room and other confined areas of the ship faced the higher risk of being infected than their shipmates on deck."

Do you see that?

A. Yes.

70. Q. And that's not surprising because when people are in crowded and closed places COVID transmits more easily.

A. Yes.

71. Q. And then the last sentence of that paragraph, which is the right-hand column says:

"These observations suggest that non-symptomatic or mildly symptomatic crew members played an important role in the rapid spread of the outbreak, much as young adults with asymptomatic infection appear to continue to spread in civilian populations."

Do you see that?

A. Yes.

72. Q. So this article is recognizing that young adults with asymptomatic infection contribute to the spread in civilian population?

A. Well, this study has to be kept in context, right. Like this is a study of a very peculiar environment, and so any extrapolation from this study would have to extrapolate to similar environments.

So you could maybe extrapolate this to a university dorm where you have a lot of healthy young people in relatively close quarters, but the geographic context, i.e., a lot of people in a very small space for a very prolonged period of time is really not reflective of the general broader society, and so you know over-generalization of the results of this study to the broader population is -- I'm not sure is -- is really not justified.

This study has very important conclusions, but these mildly and non-symptomatic persons and crew were you know in very -- in close space for a prolonged period of time with -- with other persons and so in that context, yes, the conclusions can be extrapolated, but it would have to be in those, or something very similar contexts.

73. Q. So fair enough, but all I'm saying

is the first part of that sentence recognizes that:

"Non-symptomatic or mildly symptomatic members played an important role in the rapid spread of the outbreak."

You see that, right?

A. Um-hmm.

74. Q. You might have a different view, but the authors then extrapolated and say:

"Young adults with asymptomatic infection appear to contribute to spread in civilian population."

Right?

A. That's what the authors say.

75. Q. Right.

A. That's correct.

76. Q. Okay. And to be fair, they list under "limitations," on page 2 that their observations apply to a military population may not be fully generalized with the civilians, which I think is the point you just made.

A. Correct.

77. Q. Now, in order to put this study to use I guess you could say:

"The navy initiated several

procedures to create and sustain COVID-19-free environments on its ships."

Do you see that on page 24/25, lower left-hand corner?

A. Yes.

78. Q. Continuing over to the right-hand corner it says what some of those policies are. It says:

"Since these policies, along with preventative measures of mask use, social distancing to the extent possible, smaller group cohorting, strict hand hygiene and regular cleaning of common spaces were put in place. The navy has deployed multiple steps without sustaining another serious outbreak."

Do you see that?

A. Yes.

79. Q. Okay.

A. Yeah, that study -- the study was published quite early in the pandemic and so those policies would have been put in place at the end of the first wave, and there would have been a natural reduction of cases and outbreaks as the summer approached in 2020.

80. Q. Right. My understanding is mask use and social distancing, to the extent possible, is still in place; is that your understanding?

A. In the US military, I'm -- I don't don't know. I would -- I would expect so on -- on ships, but I -- I -- I can't say specifically about the US military.

81. Q. Thank you. Now, the next item I'd like to take you to is the British editorial that's referred to at paragraph 17, the editorial from a British Medial Journal.

A. Reference 46?

82. Q. Yes.

A. Okay.

83. Q. Now, editorials are not peer-reviewed, are they?

A. Not usually, no.

84. Q. Can you describe other differences between an editorial and a regular academic paper?

A. An editorial is usually commissioned about an important topic or another research paper within the -- that particular journal issue. And the editorial is usually an attempt to, by a leader within that field to synthesize information. So if there's new information that has been coming out

to put it in context of the knowledge to date on that particular topic.

85. Q. Right. Okay. And the topic of this editorial is, "Asymptomatic Transmission of COVID-19, What we know and what we don't," right?

A. Yes.

86. Q. And that reflects what we talked about earlier which is uncertainty with these new novel coronaviruses. We know some things, but we don't know other things.

A. That's true.

87. Q. Okay. In the third paragraph, the last sentence, it says:

"Around 49 percent of people initially defined as asymptomatic go on to develop symptoms".

Do you see that?

A. Yes.

88. Q. And my understanding is that's pre-symptomatic, so that population is called "pre-symptomatic."

A. Yes.

89. Q. And this article I guess if you will, look at the paragraph that goes from the left-hand column to the right-hand column, says:

"Viral culture studies suggest that people with SARS-CoV-2 can become infectious."

I'll say COVID:

"can become infectious one to two days before the onset of symptoms and continue to be infectious up to seven days thereafter."

And then it says:

"Symptomatic and presymptomatic transmission have a greater role in the spread of."

COVID, "than truly asymptomatic transmission." See that?

A. Yes.

90. Q. Okay. So do you agree that pre-symptomatic transmission has a greater role than truly asymptomatic transmission, right?

A. Yeah, likely. It is very difficult to do studies on pre-symptomatic transmission though because of the fact that it's hard to define the pre-symptomatic period. So in other papers that I cited, you know it -- it's very difficult -- it's much easier to define what the risk of symptomatic versus asymptomatic transmission is.

And any, I think conclusions about pre-symptomatic are preliminary with regards to its transmission, but in all likelihood it's closer in its risk of transmission to symptomatic than asymptomatic, but the evidence is not definitive.

91. Q. And that's what these authors recognize.

A. Correct.

92. Q. And when someone presents initially with COVID, if they're asymptomatic you don't know whether they're truly asymptomatic or pre-symptomatic until the disease runs its course.

A. That's right.

93. Q. And that's why it's hard to study in part which is what you just said.

A. Yes.

94. Q. Okay. Now, the last sentence of the next paragraph says that:

"Asymptomatic and presymptomatic people may have more contacts than symptomatic people (who are isolating), underlining the importance of hand washing and social distancing measures for everyone."

Do you see that?

A. Yes.

95. Q. And that makes intuitive sense that if you're asymptomatic or pre-symptomatic and you don't have COVID you would have more contacts?

A. Yeah, that makes sense.

96. Q. I want to take you to a document that is not in your materials. Let me see if I can screenshare. Okay. Can you see that?

A. Yeah.

97. Q. So this is Synthesis from Public Health Ontario, dated August 2nd, 2021.

A. Um-hmm.

98. Q. And it talks about the period of communicability, what we know so far.

A. Um-hmm.

99. Q. Do you see that?

A. Yes.

100. Q. And under "Key Findings" it says:

"Epidemiology studies found transmission occurred in the 3-5 days before symptom-onset."

Do you see that?

A. Yes.

101. Q. "And epidemiology, virus culture and modelling studies found

transmission occurred in the 8-10."

Do you see that?

A. Yes.

102. Q. Okay. You don't have any reason to dispute that transmission occurs three to five days before symptom-onset, do you?

A. It can occur. Most transmission occurred -- you know other -- well, studies -- so that can -- that's the period of possible transmission, is between three to five days before, up and to including eight to ten days after, but the most -- it -- it follows a bell curve pattern, a normal distribution, like anything else.

And so the mast majority of transmission occurs from about one, one and a half days prior to symptom-onset until about three to five days after symptom-onset. So while it can occur in that time period the vast majority occurs in -- in a much narrower time frame.

103. Q. Right. So fair enough, the risk of transmission is highest just before and after the time of symptom-onset?

A. Yes.

104. Q. But it can occur three to five days before as we see in this study.

A. It can, but at five days before the likelihood of transmission in that case would be very very low and approaching zero, and same with 10 days after. Again, it follows the normal distribution bell curve and would be very low and those extreme extreme days.

105. Q. Right. Okay. All right.

MR. GUTTMAN: Can I have this marked as an exhibit, Mr. Kittredge?

MR. KITTREDGE: No objections.

MR. GUTTMAN: Okay. Madam Reporter, Exhibit 1.

EXHIBIT NO. 1: Synthesis from Public Health Ontario, dated August 2nd, 2021.

BY MR. GUTTMAN:

106. Q. Thank you. Okay. The next paragraph talks about a study in Wuhan, which I think was done by Cao, paragraph 18 -- sorry, we're back to your affidavit at paragraph 18.

A. Let me just look that up. Yes.

107. Q. Now, you'll agree with me that stringent control measures were imposed in Wuhan between January 23rd and April 8th, 2020?

A. Yes.

108. Q. And this article describes the

results of COVID testing that occurred between May 14th and June 1st, 2020?

A. Yeah. Let me just bring that up again so I can --

109. Q. Sure. It's reference 51.

A. Okay. Yes, it was done between May 14th and June 1st, 2020.

110. Q. And there were no new symptomatic cases and 300 asymptomatic cases were detected.

A. Yes.

111. Q. And the authors conclude that:

"COVID-19 prevalence was five low five to eight weeks after the end of the lockdown."

Do you see the last sentence there?

A. Yes.

112. Q. And then on page 2 the authors note first again the strict lockdown measures. And then they say:

"The pandemic was generally under control following those lockdown measures."

Do you see that?

A. Page 2, which --

113. Q. Second sentence in the first

paragraph.

A. Yes, I see that sentence.

114. Q. Right. And on page 3, in the second sentence on the first -- on the paragraph that goes from the left-hand column to the right-hand column it says:

"With the centralized isolation and treatment of all COVID-19 cases during the lockdown period in Wuhan the risk of residents being infected in the community has been greatly reduced."

Do you see that?

A. Yes.

115. Q. Okay.

A. The purpose of this study was not necessarily to look at the effectiveness of lockdown, but it was meant to assess the risk of transmission of asymptomatic persons.

116. Q. Right. I agree with, but they do recognize the effectiveness of the lockdown.

A. They assert the effectiveness of the lockdown, yes.

117. Q. Right. Okay. And they say -- continuing into the right-hand column they say, nonetheless:

"It's too early to be complacent because, of the existence of asymptomatic positive cases and high level of susceptibility of residents in Wuhan."

Do you see that?

A. I do see that.

118. Q. And then it says:

"Public health measures for the prevention and control of COVID-19 epidemic, including wearing masks, keeping safe social distancing in Wuhan should be sustained."

Do you see that?

A. I do see that.

119. Q. "Vulnerable populations with weakened immunity or co-morbidities, or both, should continue to be appropriately shielded."

Do you see that?

A. I do see that.

120. Q. And then again it says:

"Findings from this study show that COVID-19 was well controlled in Wuhan at the time of the screening programme."

A. Yes, I see that.

121. Q. Now, in terms of asymptomatic transmission, if you go back to page 2 the sentence right above "discussion," it states that:

"Figure 3 shows that districts with a high detection rate of asymptomatic positive persons generally had a high prevalence of confirmed COVID-19 cases."

Do you see that?

A. I see that sentence.

122. Q. Okay. And then Figure 3, we can flip to it, it's on page 5. I'm not going to take you to it, but that's the figure they're referring to.

A. Yes. Yeah, it makes sense, the more cases you have the more likely you're going to have asymptomatic patients there. It's obvious, yeah.

123. Q. Thank you.

A. And approximately a third of some studies show closer to 40, 45 percent of all cases are asymptomatic so wherever you're measuring high level of cases you're going to measure proportionately high levels of asymptomatic people.

124. Q. I'm going to take you to another article you cite in that paragraph, which is the Cao article, or sorry, that's the one we just looked at.

The Chang article.

A. Let me just get --

125. Q. Cite 52.

A. Fifty-two?

126. Q. Yeah, reference 52.

A. Yeah.

MR. GUTTMAN: Mr. Kittredge, I don't know if these studies are already in the record or not, if not I'm going to make them exhibits.

MR. KITTREDGE: You know what I'm not 100 percent sure myself. I've inherited the file, so I'm not -- I mean we have -- we have a book of sources here, but I'm not sure where it's been placed.

MR. GUTTMAN: Okay. So why don't I just -- out of an abundance of caution why don't I --

MR. KITTREDGE: Sure.

MR. GUTTMAN: -- make these exhibits? So we already did one --

MR. KITTREDGE: Assuming they're there let's rely on the copy that's there, but out of an abundance of caution for sure.

MR. GUTTMAN: Okay. All right. So --

MR. KITTREDGE: If you like, do you have the book of sources?

MR. GUTTMAN: I do not handy, no.

MR. KITTREDGE: I'll email that to you right now. Why don't we just mark the whole book as an exhibit?

MR. GUTTMAN: I like to defer to Mr. Hunter on that question, because --

MR. KITTREDGE: Oh, okay.

MR. GUTTMAN: -- if Mr. Hunter is on.

MR. HUNTER: I am. I think at this point why don't we just do it exhibit by exhibit rather than --

MR. GUTTMAN: Sure.

MR. HUNTER: -- you know trying to go through them all and figure out what is and isn't relevant.

MR. KITTREDGE: It's a pretty huge book of sources, so I have no preference, but just thought it might be easier. Okay.

MR. GUTTMAN: Thank you, Mr. Hunter.

MR. KITTREDGE: Yeah, go ahead.

MR. GUTTMAN: Okay. So, Madam Reporter, I'd like to make Exhibit 2, the New England Journal of Medicine article by the author, Matthew Kasper, entitled, "An Outbreak of COVID-19 on an Aircraft Carrier. Kasper, K-A-S-P-E-R. And it's called an, "Outbreak of COVID-19 on an Aircraft

Carrier."

EXHIBIT NO. 2: New England Journal of Medicine article by Matthew Kasper, entitled, "An Outbreak of COVID-19 on an Aircraft Carrier."

And Exhibit 3 would be an editorial from the British Medical Journal by Allyson Pollock, A-L-L-Y-S-O-N, Pollock, P-O-L-L-O-C-K, and James Lancaster, spelt as it sounds, entitled, "Asymptomatic Transmission of COVID-19." If we could make that Exhibit 3?

EXHIBIT NO. 3: Editorial from the British Medical Journal by Allyson Pollock and James Lancaster, entitled, "Asymptomatic Transmission of COVID-19."

And then Exhibit 4 will be Post-lockdown SARS-CoV-2 nucleic acid screening in nearly ten million residents of Wuhan, China, by lead author, Cao, C-A-O, and that's from Nature.

EXHIBIT NO. 4: Post-lockdown SARs-CoV-2 nucleic acid screening in nearly ten million residents of Wuhan, China, lead author, Cao, from Nature.

And I think that's where we've gotten to so far. Okay.

BY MR. GUTTMAN:

127. Q. So do you have the Chang article, Dr. Warren?

A. I do.

128. Q. So this study was published from May 1st, 2020 and corrected on September 8th, 2020, do you see that at the bottom of the page?

A. Yes.

129. Q. So it was published before variants of concern were identified?

A. Yes.

130. Q. And specifically, before the Delta variant emerged?

A. Yes.

131. Q. Okay. And this study looked at 100 COVID cases in Taiwan?

A. Yes.

132. Q. And in the conclusion on page 1 it recognized that the:

"In this study, high transmissibility of COVID-19 before and immediately after symptom onset suggests that finding and isolating symptomatic patients alone may not suffice to contain the epidemic, and more

generalized measures may be required, such as social distancing."

Do you see that?

A. It says that, yes.

133. Q. And at page 2, which is the next page, 1157 --

A. Okay.

134. Q. -- in the paragraph above "methods" it says:

"With proactive containment efforts and comprehensive contact tracing, the number of COVID-19 cases remained low."

In Taiwan:

"as compared with other countries that had widespread outbreaks."

Do you see that?

A. Yes, it says that.

135. Q. Okay. You're not disputing that numbers in Taiwan are low, are you?

A. No, I'm not disputing that.

136. Q. And like every article we have to look at the limitations, so if you could look at the limitations at 1162? So the first limitation was:

"Did not completely examine contacts before the symptom onset of the

index cases. Therefore, we might have underestimated the importance of early transmission."

Do you see that?

A. Yes.

137. Q. And they say:

"Thus, the actual contribution of early transmission to new infections could be greater than our estimates suggests."

Do you see that?

A. Yes, I see that.

138. Q. And then the next sentence is:

"Our findings agree with the recommendation from the WHO to use 4 days before symptom onset as the starting date for contact tracing."

Right?

A. Yes.

139. Q. And that corresponds --

A. The -- sorry, go ahead.

140. Q. I was going to say that corresponds to the possibility of infection three to five days before symptoms-onset which we discussed earlier.

A. Yes. Yeah, the reason I quoted

that study was that they found no transmission among the asymptomatic cases.

141. Q. Okay. Just on that point, on page 1159, first full paragraph, left-hand column.

A. Eleven-fifty-nine, let me just find that.

142. Q. Sure. It says, "Among the 27" -- are you there?

A. And which paragraph? I'm on the page --

143. Q. The first full paragraph on the left-hand column.

A. Okay.

144. Q. "Among the 2761 close contacts, 22 secondary cases of COVID-19 infection." Were detected:

"(including 4 asymptomatic infections)."

A. Yes, I see that.

145. Q. Okay. And then the last sentence:

"The 735 contacts whose initial exposure occurred before symptom onset of the index case were also at risk, with a secondary clinical attack rate of 1.0."

It's the second last sentence in that paragraph.

A. Yes, I see that sentence.

146. Q. And then it says:

"A subgroup of 299 contacts with exclusive presymptomatic exposures were also at risk."

Do you see that?

A. Yes, I see that.

MR. GUTTMAN: All right. If we could have this marked as the next exhibit, Madam Reporter? Sure. Contract Tracing Assessment of COVID-19 Transmission Dynamics in Taiwan and Risk at Different Exposure Periods Before and After Symptom Onset. The lead officer is Cheng, C-H-E-N-G. Okay. Thank you.

EXHIBIT NO. 5: Article entitled, "Contract Tracing Assessment of COVID-19 Transmission in Taiwan and Risk at Different Exposure Periods Before and After Symptom Onset." Lead officer, Cheng.

BY MR. GUTTMAN:

147. Q. So I want to talk about masks now,

so I could take you to paragraph 29 of your affidavit.

A. Yeah.

148. Q. So in the first sentence you refer to the, "World Health Organization Interim Guidance on mask use in the context of COVID-19"?

A. Yes.

149. Q. Okay. Can we call that up? It's reference 63.

A. Yeah, I'm there.

150. Q. Okay. So this is:

"An update of the guidance published on 5 June 2020."

Do you see that in the first sentence?

A. Yes.

151. Q. And it:

"includes new scientific evidence relevant to the use of masks for reducing the spread of."

COVID; do you see that?

A. Yes.

152. Q. Okay. And under "key points," it says:

"(WHO) advises the use of masks as part of a comprehensive package of

prevention and control measures to limit the spread of."

COVID, "the virus."

Sorry:

"SARS-CoV-2, the virus that causes COVID-19."

Do you see that?

A. It says that.

153. Q. Right. So it says it, but the key points in this article, sorry, in this guidance is that they're recommending the use of masks to control the spread of the virus, right?

A. Yes, but they acknowledge later in what I quoted that:

"There's only limited and inconsistent scientific evidence to support the effectiveness of masking of healthy people in the community."

So while they are advising it they're acknowledging that it's not based on good scientific evidence.

154. Q. So we'll get to that sentence that you put in your affidavit, but you acknowledge that their key point is to advise the use of masks?

A. They say that, yes.

155. Q. Okay, but not only do they say it, but they believe it, because they've written it.

A. Correct.

156. Q. Now, you didn't refer in your affidavit to this key point. You only refer to the sentence that you just read to me, right?

A. That's correct.

157. Q. Okay. If we can continue along this key point, it says:

"A mask alone, even when it is used correctly, is insufficient to provide adequate protection or source control. Other infection prevention and control (IPC) measures include hand hygiene, physical distancing of at least 1 metre, avoidance of touching one's face, respiratory etiquette, adequate ventilation in indoor settings, testing, contact tracing, quarantine and isolation."

Do you see that?

A. Yes, I see that.

158. Q. And they say:

"Together these measures are critical to prevent human-to-human

transmission of SARS-CoV-2."

A. Yes, it says that.

159. Q. Right. And masks can be used in two ways, right? They can either protect the person wearing the mask, right?

A. There is theoretical benefit to both the mask wearer and to others, correct, but --

160. Q. That's all I'm talking about now, the theoretical benefit.

A. Sure. Yes, there's theoretical benefit.

161. Q. To the wearer and also to other people. The second way is as a source control, right?

A. Yes, theoretically.

162. Q. Yeah. Okay. So I want to turn to the right-hand column where it says, "Mask use in community settings."

A. Um-hmm.

163. Q. And it says, the second bullet:

"In areas of known or suspected community or cluster."

Of:

"transmission: WHO advises that the general public should wear a non-medical mask in indoor - or outdoor

settings where physical distancing of at least 1 metre cannot be maintained."

Do you see that?

A. I see that.

164. Q. And:

"If indoors, unless ventilation has been be assessed to be adequate1, WHO advises that the general public should wear a non-medical mask, regardless of whether physical distancing - can be maintained."

Do you see that?

A. I see that.

165. Q. Okay. And then on the bottom of the next page it talks about the:

"Methodology for developing the guidance."

A. Hang on. I'll just get there.

166. Q. At the bottom of the left-hand column.

A. Um-hmm.

167. Q. And it says:

"Guidance and recommendations included in this document are based on published WHO guidelines."

You see that, right under:

"Methodology for developing the guidance."

A. Sorry, is this page 3 of the document?

168. Q. No, page 2, sorry.

A. Okay.

169. Q. Last paragraph.

A. Yes.

170. Q. "Guidance and recommendations included in this document are based on published WHO guidelines."

Do you see that?

A. Yes.

171. Q. "In particular the IPC WHO guidelines."

A. Yes.

172. Q. And:

"and control of epidemic- and pandemic-prone acute respiratory infections in health care."

Do you see that?

A. Yes.

173. Q. And also:

"Ongoing evaluations of all

available scientific evidence by the WHO ad hoc COVID-19."

IPC "Development Group."

A. Yes.

174. Q. And it then lists the experts or makes a reference to the experts who are on that group, and it says the, "See acknowledgment section." And if you turn to page -- if you go to the end of the footnotes, that's where the "Acknowledgment" section is?

A. Um-hmm.

175. Q. And there's a list there, first of:

"The WHO Health Emergencies Programme (WHE) Ad-hoc COVID-19 IPC Guidance Development Group."

Do you see that?

A. Um-hmm.

176. Q. And it goes over the page.

A. Yeah.

177. Q. And these are a bunch of academics at different hospitals around the world; is that right?

A. Yes.

178. Q. You'll see three-quarters of the way down there's a member of Public Health Agency of

Canada, Marina Salvadori.

A. Okay. Yes.

179. Q. In alphabetical order.

A. Yeah.

180. Q. Do you know her?

A. I know who she is, yes.

181. Q. Okay. Who is she?

A. She's a pediatric infectious diseases physician. Was working in London, now works for the Public Health Agency of Canada.

182. Q. Right. So back to page where we were, page 2. WHO explains -- this is the sentence going from the left-hand column to the right-hand column:

"During emergencies WHO publishes interim guidance, the development of which follows a transparent and robust process of evaluation of the available evidence on benefits and harms."

Do you see that?

A. Sorry, page 2, and then what --

183. Q. Yeah, going from the left-hand column to the right-hand column, bottom of the left.

A. Okay. Yeah.

184. Q. Should I read the sentence again?

A. No. I see it now. Yes.

185. Q. Okay:

"This evidence is evaluated through expedited systematic reviews and expert consensus building through weekly GDG consultations, facilitated by a methodologist and, when necessary, followed up by surveys."

A. Yes.

186. Q. And then it says, last sentence:

"Draft guidance documents are reviewed by an external review panel of experts prior to publication."

Right?

A. Says that, yes.

187. Q. And the purpose of the guidance is explained in the next paragraph. It:

"Provides guidance for decision makers, public health and IPC professionals, health care managers and health workers in health care settings - for the public and for manufactures of -- masks."

Do you see that?

A. Yes.

188. Q. Okay. So under "Background" the guidance writes, or it's stated in the guidance:

"The use of masks is part of a comprehensive package of prevention and control measures that can limit the spread of certain respiratory viral diseases, including COVID-19."

Do you see that?

A. Yes.

189. Q. And then it explains what we talked about before:

"Masks can be used for protection of healthy persons (worn to protect oneself when in contact with an infected individual) or for source control (worn by an infected individual to prevent onward transmission) or both."

A. It says that.

190. Q. Right. And then if we skip over to page 3 there's a portion that's on "Scientific evidence," and it says --

A. Yes.

191. Q. -- midway down the left-hand column:

"Knowledge about transmission of

the SARS-CoV-2 virus is evolving continuously as new evidence accumulates."

Do you see that?

A. Yes, I see that.

192. Q. And the next paragraph:

"According to available evidence, SARS-CoV-2 mainly spreads between people when an infected person is in close contact with another person."

A. It says that.

193. Q. You don't disagree with that, right?

A. I don't.

194. Q. "Transmissibility of the virus depends on the amount of viable virus being shed and expelled by a person, the type of contact they have with others, the setting and what IPC measures are in place."

Says that, right?

A. It does say that.

195. Q. And you agree with that?

A. Yes.

196. Q. "The virus can spread from an

infected person's mouth or nose in small liquid particles when the person coughs, sneezes, sings, breathes heavily or talks."

See that?

A. I see that.

197. Q. And you agree with that?

A. Yeah. The evidence for singing and breathing or you know talking is limited, but certainly respiratory particles when coughing or sneezing I would agree with.

198. Q. Okay. So do you dispute that more viral load is shed when someone talks loudly or sings?

A. The evidence for that is much less conclusive than for coughing or sneezing.

199. Q. I appreciate what you're saying about the evidence, but doesn't it make intuitive sense that when you're singing or talking loudly more virus would be shed?

A. Possible. Hasn't been quantitated in rigorous studies at this point.

200. Q. And we discussed earlier that rigorous studies would take perhaps years to develop, right?

A. Some, yes, but we've seen with the

vaccine studies they can be done potentially very quickly, in a matter of weeks or a couple of months.

201. Q. Right. And those vaccine studies, that was a huge innovation how quickly they were done, right?

A. Yes. Those type of studies like they've done for vaccines just haven't been done for masks. That's usually the threshold for concluding that something is effective as if a large randomized trial. That's why for all the vaccine trials they needed larger analyzed trials, because that's the threshold for concluding that something's effective.

202. Q. Right, but vaccine studies don't involve knowingly making people take their masks off, right?

A. No, but there are randomized trials in masking as well that have

not showing that it's been effective in the general population.

203. Q. Okay.

A. And in fact, it's not --

204. Q. We'll come to what the WHO says about the evidence, but that's not -- their guidance is to where masks, right?

A. Their guidance is to wear masks,

but as I quote in my study they acknowledge it's not based on good evidence.

205. Q. So the next paragraph talks about "fomite," we can skip that. And then the next paragraph's about "aerosol transmission." And then the first full paragraph on the right-hand column says that:

> "Aerosol transmission can occur in specific settings and circumstances, particularly in indoor, crowded and inadequately ventilated spaces, where infected persons spend long periods of time with others."

Do you see that? It's in the first full paragraph on the right-hand column, first sentence.

A. First full paragraph on the right-hand column.

206. Q. Page 3.

A. Okay. Yes.

207. Q. And:

> "Studies have suggested these can include restaurants, choir practices, fitness classes, nightclubs, offices and places of worship."

Do you see that?

A. Yes, I see that.

208. Q. Okay. And then it says, I think we've already discussed this, but -- for the sake of time I'm not going to go through all the signs, but "Pre-symptomatic transmission? It says:

"Pre-symptomatic transmission - from people who are infected and shedding virus but have not yet developed symptoms - can occur."

I think you agreed with that earlier.

A. Yes.

209. Q. And the next paragraph is "Asymptomatic transmission." We know that your position is that it occurs less frequently, but it can occur, right?

A. It can occur, yes. It's much less frequent than with symptomatic transmission.

210. Q. So if we go to page 8, we find that sentence that you've quoted in your affidavit:

"There is only limited and inconsistent scientific evidence to support the effectiveness of masking of healthy people in the community to prevent infection with respiratory

viruses, including SARS-CoV-2."

Right?

A. Yes.

211. Q. Now, this publication was put out in December 1st, 2020. Are you aware of any developments since then?

A. There has been one large, randomized trial in Bangladesh. It was a cluster randomized trial. It's interesting that it's been slow to be published. And I'm not even aware of a preprint yet of -- of the study. It showed a negligible benefit of masking, so it showed a few things.

Number one, it showed that non-medical masks, which are recommended in this WHO guidance have no effect. So if you go up into the guidance, and on page 2, on the left-hand side it says, "Homemade fabric masks" and in other places in page 1 it says the:

"WHO advises that the general public should wear a non-medical mask."

And so the large randomized trial of over 300,000 people, a cluster randomized trial in Bangladesh showed that non-medical masks have no effect on infection.

And this large, randomized trial, it's available on the investigator's website, many of the investigators were from Yale, some from Stamford, it did not look at hospitalization or death. It merely looked at test confirmed symptoms. And the relative risk reduction was nine percent, and the absolute risk reduction was about .7 percent. And that's in all mask wearers, if you include both non-medical masks and masks.

When they separate it out into non-medical masks and medical masks only the medical masks had any effect, but the absolute risk reduction was .7 percent. And if we take the inverse of that we can get the number needed to treat, which was about 1,400.

And so the study went on for a couple of months, and so you would need about 1,400 people to wear a mask for a couple of months to prevent one test-based infection, which is very very low. That's a very low number needed to treat -- number needed treats and lots of studies would be considered high if it's between 50 and 100. And it did not look at much more important outcomes such as hospitalization or death, so that would the main evidence-base since this was published.

212. Q. So it didn't look at hospitalization or death.

A. That's correct.

213. Q. It looked at cloth masks.

A. It looked at both cloth and medical masks.

214. Q. Are you saying that medical masks aren't helpful in a healthcare setting?

A. No, I'm not saying that at all.

215. Q. You agree that medical masks are helpful in a medical care setting.

A. Yeah, in certain scenarios, in the care of particular patients, yes, for sure.

216. Q. What kind of patients?

A. Yeah, it would include respiratory patients such as patients with COVID-19.

217. Q. Right. So why are they useful -- why do you agree that medical masks are useful in the hospital care setting for treating patients with COVID?

A. There has -- there is evidence in the healthcare setting in similar respiratory infections, such as influenza and other respiratory infections, there is an evidence base for that.

218. Q. Right. Okay, but if I'm exposed to

a COVID or a bunch of COVID people, people with the virus, and I'm in a setting other than a healthcare, would the mask not protect me at that point?

A. Not necessarily. We don't know that. That has to be proven through, again, randomized trials. And there have been two randomized trials in the context of masking the general public for COVID and neither of them -- one showed no benefit, which was the Danish study I referenced, and then the other study, as I said which has been completed but not yet peer-reviewed showed a very very small benefit and only in medical masks versus -- but did not show any benefit of non-medical masks.

219. Q. Okay. So when was this published, the new one you're referring to in the --

A. As I said it hasn't been published in a peer-reviewed --

220. Q. Sorry, I meant is published in the investigatory website?

A. It would have been at the beginning of the summer, which is unusual why it's not, at least in a pre-print form, or even peer-reviewed, because a lot of the -- the vaccine trials went from you know published on investigator websites to -- to peer-review within a couple of months.

This has been close to six months now since it's been available publicly, but not peer-reviewed or published.

221. Q. All right. So they go through the studies, and I understand that you know a randomized control study would be the best, but we have -- they have what they had. And under "Guidance" they say:

"The WHO COVID-19 IPC GDG considered all available evidence on the use of masks by the general public including effectiveness, level of certainty and other potential benefits and harms, with respect to transmission scenarios, indoor versus outdoor settings, physical distancing and ventilation."

And then they say:

"Despite the limited evidence of protective efficacy of mask wearing in community settings, in addition to all other recommended preventive measures, the GDG advised mask wearing in the following settings."

And we went through them, but the first one is:

"In areas with known or suspected community or cluster transmission -- WHO advises mask use by the public in the following situations."

And we already looked through those, right?

A. Yes, we already went through that.

222. Q. So that's the conclusion that WHO came to.

A. Yeah. And I think it's important to you know acknowledge the -- you know the qualified recommendation that they made.

223. Q. Right, but in your --

A. Where they say:

"Despite the limited evidence of protective efficacy of mask wearing in community settings."

224. Q. Right.

A. So -- but they're making that recommendation not based on scientific evidence, but you know with the assumption that masks would be protected in the healthy population community settings, but not based on evidence.

225. Q. Well, I mean I don't think we have to argue about what they say, but we're still in the

WHO guidance.

A. Um-hmm.

226. Q. And they say, "Despite the limited evidence" they made the -- they advised the guidance that they did, right?

A. Yes.

227. Q. All right. The next document I want to take you to is not in your references. I'll see if I can find it.

MR. GUTTMAN: We can make the WHO document an exhibit, Madam Reporter. Yes, please? Thank you. Okay.

EXHIBIT NO. 6: WHO document titled, "Mask use in the context of COVID-19."

BY MR. GUTTMAN:

228. Q. This is a science brief from the Centre for Disease Control and Prevention. You're familiar with the CDC, right?

A. Yes, I am.

229. Q. Okay. This was updated on December 6th, 2021.

A. It says that.

230. Q. And it says data was added. It's the last update:

"These studies address the

association of mask wearing with new infections, including infections related to SARS-CoV-2 variants of concern. All of these studies demonstrated a benefit."

Do you see that?

A. I do not see that.

231. Q. Sorry, it's the first bullet under, "Summary of Recent Changes."

A. I don't -- like I don't --

232. Q. Oh, sorry, sorry. I thought you had it, sorry. I've got to show it to you. My mistake. Okay. There you go. Do you see that?

A. Yes. You know it really depends on what type of studies they're referencing, because there's a clear gradient in the quality of studies. A lot of the studies of mask wearing, as I indicate in my extra report are of very poor quality and are not randomized control trials or meta-analysis.

233. Q. So let's look at the background:

"SARS-CoV-2 infection is transmitted predominantly by inhalation of respiratory droplets generated when people cough, sneeze, sing, talk, or breathe."

Do you see that?

A. I do see that.

234. Q. Okay. And do you agree with that?

A. I agree, but there's a definite -- there -- there are differences between each of those. Certainly people coughing has a much greater risk of transmission than people who are simply breathing. And so each of those has different levels of infectivity.

235. Q. Fair enough. Next sentence:

"CDC recommends community use of masks to prevent transmission of SARS-CoV-2."

Do you see that?

A. I do see that.

236. Q. So their guidance is consistent with the WHO guidance, right?

A. Yeah, the CDC recommends that, but there are many jurisdictions in the US where that's not either recommended or mandated.

237. Q. Fair enough, but here we see the CDC recommending it.

A. They do.

238. Q. Then they make the observation that:

"Masks are primarily intended to reduce the emission of virus-laden droplets by the wearer ("source control")."

Do you see that?

A. I do see that.

239. Q. "Which is especially relevant for asymptomatic or presymptomatic infected wearers who feel well and may be unaware of their infectiousness to others."

Do you see that?

A. I do see that.

240. Q. They're focusing here on source control.

A. Yes.

241. Q. Although in the next sentence they say it:

"Also help reduce inhalation of these droplets by the wearer."

Do you see that?

A. I do see that.

242. Q. Okay. And then it says:

"The community benefit of masking for SARS-CoV-2 control is due to the

combination of these two effects."

Do you see that?

A. I do see that.

243. Q. And:

"Individual prevention benefit increases with increasing numbers of people using masks consistently and correctly."

A. Yeah. And based on that trial that I mentioned you just -- you need very very large numbers of people for a very very long period of time to prevent very small numbers of infection, so the evidence shows that the actual benefit is miniscule.

244. Q. So under the first bullet on page 2, "Human Studies of Masking and SARS-CoV-2 Transmission" --

A. Are you going to go there in your document?

245. Q. Oh, sorry. Good point. Thank you. It talks about:

"A large, well-designed cluster-randomized trial in Bangladesh in late 2020."

Is this what you were talking about?

A. That's correct.

246. Q. Okay. And so what the CDC reports is that -- first of all, it has a sentence about "mask use." Where it's encouraged it's obviously adopted more. And then it says:

"In villages receiving mask interventions, symptomatic seroprevalence of SARS-CoV-2 was reduced by approximately 9 percent relative to comparison villages."

Do you see that, the second sentence?

A. Yeah, that's -- so that's a relative risk reduction.

247. Q. And then it says:

"In villages randomized to receive surgical masks, symptomatic seroprevalence of SARS-CoV-2 was significantly lower."

Do you see that, 11.1 percent overall"?

A. Yeah. Again, so that statement is in there because non-medical masks had no effect, so when they -- that nine percent -- if you separated it out that nine percent is all masks. And if you separate that out into medical and non-medical the non-medical has no significant overall reduction whereas the medical mask has a relative risk reduction

of 11.1 percent.

248. Q. Okay. And then it says, their conclusion is:

"The results of this study show that even modest increases in community use of masks can effectively reduce symptomatic SARS-CoV-2 infections."

A. That's their conclusion, but as I said if you look at the absolute risk reduction, which is 0.7 percent of all mask wearers, and then take the inverse of that which is a standard way of calculating the number needed to treat is 1,400.

And so to prevent one -- to prevent one infection you need about 1,400 people to wear masks for a couple of months as long as the study went on for, so very low rates. And that you know the benefit of this -- of this study shows and this paragraph shows as well is only in medical masks.

249. Q. Okay. So would you agree with me that CDC concludes that:

"The results of this study show that even modest increases in community use of masks can effectively reduce symptomatic SARS-CoV-2 infections."

A. That's what the CDC states, yes.

250. Q. And I take it from what you told me you don't agree that that's what the study stands for? You disagree with the CDC?

A. Well, the real benefit of randomized control trials is that we actually quantitate things. So the large randomized control trials in vaccines quantitates the effect of the vaccine on death and the -- you know quantitates the effect on infection and hospitalization.

And so in this randomized control trial they're looking at the relative risk reduction of nine percent in all mask wearers. As I said there are other ways of looking at it. And one of the most consistent or standard ways of looking at a large, randomized control trial is looking at the number of -- the number needed to treat, which I have referenced a few times.

And so my interpretation of that study would then say you need large amounts of people to wear masks for a relatively long time to prevent what may be a very relatively unimportant outcome which is just symptomatic SARS-CoV-2 infection. So large randomized trials for the vaccine looked at things like hospitalization and death, this study did not.

Those are much more important outcomes

than simply SARS-CoV-2 infection, which is you know very very common.

251. Q. I guess I'm just asking you if you agree that the study stands for:

"Even modest increases in community use of masks can effectively reduce symptomatic SARS-CoV-2 infections."

Do you agree or disagree with that?

A. "Can effectively reduce symptomatic SARS-CoV-2 infections."

By a very small amount, yes.

252. Q. So you don't really agree because you're inserting the words, "By a very small amount."

A. Yes, so I -- I would not agree with that conclusion, no.

253. Q. So your view is in opposition to the CDC's view?

A. Yeah, I would interpret the findings of that study differently than they do. And I think that's the reason it hasn't been published in the last six months.

254. Q. We see here that the Bangladesh study has had no effect on the CDC's guidance, right? They're still recommending mask use in the community.

A. Correct.

255. Q. In fact, they're citing it as another reason to -- more support for their position, right?

A. Yes.

256. Q. Okay. And below the bullets, at the first -- last full paragraph they says:

"At least ten studies have confirmed the benefit of universal masking in community level analyses."

Do you see that?

A. Sorry, is it --

257. Q. Oh, sorry, I haven't -- sorry, sorry. Here we go. Do you see my cursor? It's just this first sentence here below the bullet.

A. Yeah, it says that. And these are probably referencing our, what are called "ecological studies" or "correlation studies," which is the lowest quality of evidence. So just comparing rates of mask use and infection in US states, you can't control for so many variables.

You know studies like that break a rule called the, "ecological fallacy," which is that you shouldn't be measuring something at a population level that you can measure at a patient level, which is mask use. And so there's lots of studies like this, but

they would never be conclusively -- you would never be able to get a vaccine approved based on a study like this, you know just vaccinating -- seeing vaccine rates in one state and comparing infections, and then comparing that to another state.

So these type of studies are -- are there and they're done, but as it says in the WHO guidance, which I had referenced as well, they specifically talk about the significant limitations of ecological studies. And I quoted that in my report.

258. Q. Okay, but you acknowledge that vaccines are very different than masks?

A. But they can be studied the same way because randomized trials for masks have been done, just like randomized trials for vaccines have been done.

259. Q. Well, let's move to your randomized control trial. The only one that I'm aware of is the Flyngard (ph) study that you rely on in your paper.

A. Yes, other than this Bangladesh study as well, yeah.

260. Q. Right.

A. So in SARS-CoV-2 there have been -- I reference it as well in my expert report that there have been a number of randomized control trials in

similar infections such as influenza and masking the general public. And --

261. Q. Right.

A. -- as I -- as I reference meta-analysis of those randomized control trials do not show any significant benefit in masking the general public to prevent similar respiratory tract infections.

262. Q. Right. Okay. So --

A. Do you want me to bring that randomized trial up? Is that what you're --

263. Q. I'm just trying to be efficient in time. Are you aware that the CDC had criticized the Flyngard randomized control trial?

A. I'm sure lots of people have criticized the trial.

264. Q. Okay. So just reading from the top here of the full paragraph there, it says:

"Two studies have been improperly characterized by some sources as showing that surgical or cloth masks offer no benefit. A community-based randomized control trial in Denmark during 2020 assessed whether the use of surgical masks reduced the SARS-CoV-2 infection

rate among wearers (personal protection) by more than 50 percent. 58 Findings were inconclusive, most likely because the actual reduction in infections was lower. The study was too small (i.e., enrolled about 0.1 percent of the population) to assess whether masks could decrease transmission from wearers to others (source control).”

A. It says that.

265. Q. See that?

A. Yes, yeah.

266. Q. And if we go to the study, which is study 64, reference 64 --

MR. GUTTMAN: Well, could we make this document an exhibit, Madam Reporter?

MR. KITTREDGE: Can you please send a copy of that over to me?

MR. GUTTMAN: Yes, sure.

COURT REPORTER: That would be Exhibit 6 I think.

MR. GUTTMAN: I haven’t been keeping track. I thought maybe we were on --

COURT REPORTER: Yeah, it is six, or no, wait. One second. I’m just going to look back

and check. It's Exhibit 7, sorry.

MR. GUTTMAN: Okay.

COURT REPORTER: And it's the CDC Guidelines?

MR. GUTTMAN: Yeah. CDC Science Brief: Community Use of Masks to Control The Spread of SARS-CoV-2.

EXHIBIT NO. 7: CDC Science Brief: Community Use of Masks to Control the Spread of SARS-CoV-2.

COURT REPORTER: Thank you.

MR. GUTTMAN: I'm just going to take a moment, Mr. Kittredge, and send you the --

MR. KITTREDGE: Great. I appreciate it.

MR. GUTTMAN: Can you remind me of your email? It's not copying now.

MR. KITTREDGE: Oh, Rkittredge@jccf.ca, for the record.

MR. GUTTMAN: Yeah. Let's go off the record for a second.

---RECESS TAKEN

---UPON RESUMING

BY MR. GUTTMAN:

267. Q. So this is the trial that you were

talking about and that the CDC refers to, right, the Danish trial?

A. Yes.

268. Q. And its objective was to:

"To assess whether recommending surgical mask use outside the home reduces wearers' risk for SARS-CoV-2 infection in a setting where masks were uncommon and not among recommended public health measures."

Do you see that?

A. Yes.

269. Q. Okay. And under "Results," it says, last sentence:

"Although the difference observed was not statistically significant, the 95 percent CIs are compatible with a 46 percent reduction to a 23 percent increase in infection."

A. Yes, it says that.

270. Q. So that means that the masks either reduced infection by 46 percent or increased it by 23 or somewhere along the line in the middle is what happened?

A. Well, it's the 95 percent

confidence interval, so it suggests that a true effect is probably found -- they're 95 percent certain that the true effect of masking wearing is somewhere between a 46 percent reduction to a 23 percent increase in infection.

271. Q. Right. We don't have more information along where in that spectrum it falls. We just have a 95 percent confidence interval.

A. Yeah. That's a standard way of reporting a result of a randomized control trial.

272. Q. Right, but the CDC criticized it as having an inconclusive finding I think because of the range; do you agree?

A. Well, they criticize it because it was inconclusive, but the finding was that there was not a statistical benefit of masking. Any paper can be criticized if it finds a negative result.

They speculate that there simply wasn't enough participants. And we've seen that with the Bangladesh study that you need very very very large numbers of participants to actually find the benefit, and so the Bangladesh study and this study actually go well together because masking only has a very small, limited benefit if it's done at very large levels for long periods of time.

273. Q. So on page 5 under "Discussion" --
A. Um-hmm.
274. Q. -- last full sentence in the left-hand column --
A. Um-hmm.
275. Q. It's says:
"The findings, however, should not be used to conclude that a recommendation for everyone to wear masks in the community would not be effective in reducing SARS-CoV-2 infections, because the trial did not test the role of masks in source control of SARS-CoV-2 infection."
Do you see that?
A. Yes.
276. Q. So this study did not test the role of masks in source control which we know is one of the two main ways that masks function.
A. That's right, but the Bangladesh study did.
277. Q. Right, but we're just talking about this study now.
A. Correct.
278. Q. And they're saying we shouldn't

conclude, based on this study:

"That a recommendation for everyone to wear masks in the community would not be effective."

That's what this sentence says.

A. Yeah. And I think using the same logic we shouldn't conclude that masks are effective because we don't have strong evidence either way. The best evidence that we have is from randomized control trials. And these are two that we discussed.

279. Q. And at paragraph 31 you don't point out this qualification that the authors used?

A. Paragraph 31, let me just go there. That's right.

280. Q. Okay. And then at page 7, second last sentence, the authors highlight this fact. They've already stated it, but then they says:

"Although masks may also have served as source control in SARS-CoV-2-infected participants, the study was not."

A. Sorry, where are we? Sorry.

281. Q. The second full paragraph.

A. Second full paragraph.

282. Q. Yeah.

A. Okay.

283. Q. That last sentence:

"Although masks may also have served as source control in SARS-CoV-2-infected participants, the study was not designed to determine the effectiveness of source control."

Do you see that?

A. Yes.

284. Q. And then it says:

"The most important limitation is that the findings are inconclusive, with CIs compatible with a 46 percent decrease to a 23 percent increase in infection."

Do you see that?

A. I do see that.

285. Q. Okay. And then down in the last full paragraph, in the middle it says:

"Yet, the findings were inconclusive and cannot definitively exclude a 46 percent reduction to a 23 percent increase in infection of mask wearers in such a setting."

Do you see that?

A. Yes, it says that.

286. Q. And then it says again:

"It is important to emphasize that this trial did not address the effects of masks as source control or as protection in settings where social distancing and other public health measures are not in effect."

A. Yes, it says that.

287. Q. Okay. You mentioned influenza, but you'd agree with me that COVID has a higher hospitalization and death rate than influenza?

A. Well, it depends on what you mean by "influenza," because influenza, like COVID, has different strains, so every year, or every few years there's a new predominant strain you know. In influenza we called it "strains." In COVID we call it "variants," and so --

288. Q. Fair enough. Fair enough. I'm talking about --

A. Some of them are very severe, some influenza --

289. Q. Right.

A. -- like 100 years ago.

290. Q. Right. I'm talking about

non-pandemic influenza, what we've seen in the last 20 years for instance.

A. Yeah, I -- I would agree with that.

291. Q. We've had about 30,000 deaths in Canada from COVID?

A. Yes.

292. Q. And are you aware of how many deaths there were in the last full influenza season, 2018/2019?

A. I don't have it offhand, but on average it's about -- I think about 3,000 deaths. It really varies year to year I think, but on average it's about 3,000 deaths a year.

293. Q. So if I told you it was 225 in the last full influenza season you'd be surprised?

A. What season was that?

294. Q. 2018/2019.

A. Okay. Yeah, I would find that surprising, yeah. The challenge with influenza is that would probably just be limited to tests proven, but many -- because we don't do nearly the testing and follow up with influenza as we've done with COVID-19 the estimated rates are certainly much higher than that.

295. Q. I just want to show you a document.

Do you recognize FluWatch from PHAC?

A. Yes.

296. Q. Okay. I just want to show you. This was an exhibit in another cross-examination, so I don't think we need to make it an exhibit, but on page 8 it says that there were:

"A total of 613 ICU admissions and 224 deaths were reported this."

Flu "season;" do you see that?

A. Yes, I see that, but that would only be limited to ICU admissions, so that's how many deaths were in the ICU. So the actual number of deaths of influenza would be considerably greater.

You're -- you're -- you're limiting the number of deaths to ICU, but the number of actual deaths to influenza would be many many more than that, because most deaths of influenza did not get into the ICU.

297. Q. Well, we can distinguish between reported deaths, but there's nothing in here that limits the number of deaths to ICU admissions here.

A. I don't have that full document, but it appears as though, from what I can see, that's what that's limited to, is telling -- saying at 613 ICU admissions and 24 deaths -- 224 deaths.

298. Q. Well, we may have to come back to this document because certainly in the other -- in the other cross-examination it was recognized that there were 224 deaths. It does say "and" there. It doesn't say "of;" do you see that?

A. Um-hmm. Again, I don't have the whole document, so before kind of concluding that I would want to read the entire document myself.

299. Q. Okay.

MR. GUTTMAN: Maybe we should take a quick break now. I can send you the documents in case --

MR. KITTREDGE: Sure.

MR. GUTTMAN: -- I have more questions on it.

MR. KITTREDGE: Sure. I'll send it to your lawyer who can -- the lawyer for the JCCF who can -- actually, you already have it, Mr. Kittredge. Can you just send it to Dr. Warren?

MR. KITTREDGE: I don't actually have it myself on me. Hadam Kerr (ph) had that, that document. I'm sure it's in the file somewhere, but I don't have it --

MR. GUTTMAN: Okay. I'll send --

MR. KITTREDGE: -- right in front of

me.

MR. GUTTMAN: I'll send it to you.

MR. KITTREDGE: Okay. Great.

MR. GUTTMAN: So maybe we could take a break to 3:10. Can we go off the record?

MR. KITTREDGE: Sure.

---RECESS TAKEN

---UPON RESUMING

MR. GUTTMAN: So if we could make that FluWatch document an exhibit, Madam Reporter?

COURT REPORTER: Yeah, so that would be Exhibit 8, flu document. Could you give me the author again?

MR. GUTTMAN: It's FluWatch.

COURT REPORTER: FluWatch. Okay.

MR. GUTTMAN: -- 2018, 2019 Influenza season. The author is PHAC.

COURT REPORTER: Okay. Thank you so much. It's been noted as Exhibit 8.

EXHIBIT NO. 8: FluWatch 2018, 2019 Influenza season, author PHAC.

BY MR. GUTTMAN:

300. Q. Okay. Dr. Warren, I want to talk about risk factors for contracting COVID-19.

A. Can we just go back to this

document now that I've had a chance to look at it so I can answer your questions?

301. Q. Well, our position is that it's 224.

A. Yeah, so those 224 deaths, if you look in the document it says those are reported from sentinel sites and surveillance. So FluWatch is a compilation of surveillance data, so there are different sites that act as sentinel surveillance and keyed information into FluWatch.

And so the actual number of deaths per year for influenza is much higher than that. And so I've sent Mr. Kittredge an email to a link to an official Canadian website that I've asked him to forward to you, and on that official website, from Canadian website -- do you have access to that?

302. Q. I do not.

A. Okay. Mr. Kittredge, could you send that?

MR. KITTREDGE: I did send it. I didn't look at it. Dan, do you have that?

MR. GUTTMAN: Hold on a sec.

MR. KITTREDGE: It's titled --

MR. GUTTMAN: Yes, I have it.

MR. KITTREDGE: So just for the record

I just forwarded that alone. I received it from Dr. Warren and just forwarded it to you.

MR. GUTTMAN: Okay.

THE WITNESS: This is a website from the Government of Canada. It's Influenza for Health Professionals. And if you scroll down it says, "Epidemiology of influenza in Canada." It says:

"Each year in Canada, it is estimated that influenza causes approximately: - 12,200 hospitalizations."

And "3,500 deaths." So the -- and then right underneath that it says, "Surveillance, FluWatch surveillance," and it explains how that works. And so the number of confirmed deaths from sites that act as surveillance centres is the number you mentioned, but many -- it's known from many studies and -- that many of the deaths, probably most, the vast majority influenza deaths that occur in Canada do not occur at these sentinel sites.

And so the estimated number of influenza deaths per year in Canada, and it ranges based on the severity of the flu season, is 3,500 deaths.

303. Q. Okay. And that's a tenth of what

is -- of the COVID deaths.

A. In the first year, well, I wouldn't say a tenth. In the first year we had, I think it was closer to -- I can look it up. I have it in my -- my report.

304. Q. Well, anyway, you haven't disagreed with me that hospitalization and death rates are higher per COVID, right?

A. They are higher, that's correct.

305. Q. Okay. Thank you.

MR. KITTREDGE: Can you mark that as an exhibit? It's a bit of an unconventional route.

MR. GUTTMAN: I'll let you do that in re-exam.

MR. KITTREDGE: Great. So I take it you have no issue with me opening that link?

MR. GUTTMAN: Well, at this point I don't think so.

MR. KITTREDGE: Okay. Great.

BY MR. GUTTMAN:

306. Q. So moving along, talking about risk factors for contracting COVID-19, would you agree with me, Dr. Warren, that the prevalence of COVID-19 in the community affects the risk of contracting COVID-19?

A. Yes.

307. Q. And that the level of vaccination in the community affects that risk?

A. It's one of the factors, yes.

308. Q. Right. And you have a higher risk of contracting COVID-19 indoors than outdoors?

A. Yes, much higher.

309. Q. And the more people present in a venue at one time the higher the likelihood that there will be someone there who has and can transmit COVID-19?

A. Yeah, that's dependent on a number of factors when you say indoor, size of facility, ventilation. You know it's going to be different at a mall if you have a mall versus you know a small business where people are in an enclosed space.

310. Q. And one of the factors is how closely people are crowded together, right, in the venue?

A. Yes.

311. Q. And sitting next to someone for a prolonged period of time is riskier than just passing by somebody?

A. The time spent with a person would influence the risk of transmission, yes, that's why studies have shown that most transmissions -- some

studies, and I think I quoted in my report, that 80 percent of transmission occurs in households because people are spending very long periods of time in households.

And other studies have shown that casual contact, so that's any kind of casual contact outside of the patient's -- of the person's home, with someone that's not a family member, the risk of transmission is approximately one percent. So about one percent of cases are from those casual transmissions, whereas up to 80 percent in some studies of transmission is within households because they're spending long periods of time close together.

MR. GUTTMAN: Okay. I'm not seeing any indications from my team, so I think those are my questions. And Mr. Kittredge will have a few questions for you.

MR. KITTREDGE: Yeah. Can we take 20 minutes?

MR. GUTTMAN: Sure.

MR. KITTREDGE: Okay. Great. So let's say twenty to four we'll be back.

MR. GUTTMAN: Okay.

MR. KITTREDGE: Okay. Perfect. I'll see you then.

---RECESS TAKEN

---UPON RESUMING

CROSS-EXAMINATION BY MR. HUNTER:

312. Q. Good afternoon, Dr. Warren. I'm John Hunter, another counsel for Ontario. Just wanted to ask you one follow up question from the discussion you had with Mr. Guttman about the number of deaths attributed to influenza.

And you were talking about a Government of Ontario -- sorry, Government of Canada website, correct?

A. Yes.

313. Q. And are you aware of the source of the data that's reported on that website?

A. No, I'm just referring to the website. Do you have it in front of you?

314. Q. Yes.

A. Yeah.

315. Q. So there's just the statement that is, "Epidemiology of influenza in Canada." That's the portion you're referring to?

A. Yeah.

316. Q. Would you agree with me if I suggest that that data was taken from -- it's a NACI document that was sited later down in the paper

called, "Canadian Immunization Guide Chapter on Influenza and Statement on Seasonal Influenza Vaccine for 2021-2022"?

A. I don't know that that's what they referenced. Those type of numbers are very familiar to me. Again, I -- I don't have that literature in front of me, but that's the kind of the -- the numbers I'm used to, so I'm certain they have a good evidence base for that. The NACI documents may or may not. I don't know where they got that number from.

MR. HUNTER: All right. Thank you. Those are my questions then.

MR. KITTREDGE: Okay. I guess to begin with -- oh, I'm sorry, I have to start Zoom. Could I mark that document without showing it to him myself? I can mark it based on what he was shown before, right, otherwise I have to start a new Zoom session on my desktop.

MR. HUNTER: Are we talking about the website?

MR. KITTREDGE: Yeah, the website that he referenced, and you referenced and Guttman referenced.

MR. HUNTER: I'm fine with that.

MR. KITTREDGE: All right. Can we

please mark that website as Government of Canada flu information as an exhibit?

MR. GUTTMAN: Well, no objection. We actually just pdfed it so we'll --

MR. KITTREDGE: Okay. Great. I'll take that.

EXHIBIT NO. 9: Government of Canada flu information.

MR. KITTREDGE: Perfect. All right. Thank you very much.

RE-EXAMINATION BY MR. KITTREDGE:

317. Q. Now, Dr. Warren, you were asked about studies related to mask wearing, and you talked about qualities like randomization and meta-analysis, and you mentioned that there are high qualities studies and low quality studies. Can you tell us a little bit more about what makes a study high quality and what makes a study low quality?

A. Sure. So that's you know part of epidemiological training, and has issues to do with the reliability of the data and issues with bias and confounding and size of studies.

So studies that look at say ecological studies, so ecological studies are say just comparing one country to another, but they are -- there's all

sorts of bias in confounding that can occur there. So while we would look at say one variable, masks, there may be another variable that's much more important that is actually having the effect, and so that would be confounding.

Bias would be things like the reliability of measurement of a particular type of infection, say COVID. So if one country has high mask use, but also does not measure COVID rates that would be bias because it's a -- it's -- it has more to do with the measurement than the actual mask use. And so -- and then -- so that's one type.

Other things are case control studies or cohort studies, and they're similar in that they're not controlled and so you're looking just at two groups and seeing what happens over time, but there's the -- because there's not randomization they're also liable to a fair amount of both bias and confounding.

And so the highest quality evidence, which is widely recognized in epidemiology is randomized control trials and meta-analysis of randomized control trials. So some of the studies that are relied upon for masking are meta-analysis of case control studies or cohort studies. And some of them are very poor with very small numbers.

And so whenever you bring a whole bunch of bad studies together the combination of those bad studies is going to be bad no matter what. And I just mean bad in statistical evidence and statistical power.

And so the Chu study which I referenced and critiqued in the paper, or just really quoted a critique from -- specifically from the Cochrane review, the Chu study is widely sited, but all it is is a meta-analysis of very very small and poor studies which were case control and cohorts studies.

And so, yeah, I can you know bring that up, but some of the studies were in as low numbers of people as like less than 10 in each group whereas you know the randomized trial for the Pfizer vaccine, the original one, I think had 20,000 people in each side, 20,000 randomized vaccine, 20,000 randomized placebo.

You compare that to a meta-analysis of very small studies with maybe 10 people on each side, that was not randomized, not controlled. Putting all of that data together, it doesn't actually give you any firm conclusions at all.

And so the quality of the evidence allows one to make a stronger conclusion or not. And so I give you an example of -- use a vaccine example

many many times, because in order for a vaccine to be approved it has to have a large randomized control trial.

So the Pfizer vaccine, Moderna, Astra Zeneca, they all had very large randomized controlled trials. And randomized controlled trials for masks can be done. There were two. There was -- there's one ongoing in Africa as well, I think Guinea-Bissau or a west African country. And you know these types of trials can be done and they should be done, because then they actually quantitate how effective the intervention is or is not.

318. Q. All right. You mentioned that there's better scientific evidence to support the effectiveness of masking in healthcare settings. Could you tell us a little bit about that?

A. Sure. Again, I don't have all of that data here in front of me, but that has been studied over many years. And it -- it -- it does depend on the indication. So there are some settings where handwashing even or -- or masks have been studied, but haven't been found to be effective, things like MRSA colonization.

And so in some centres, some places, some places in Europe or the United States, they won't

do physical interventions like gowning or masking for some diseases that we would say do here in Canada because those studies are done. Whereas for other indications, say influenza, the evidence is there.

And so those randomized trials have been done. So randomized trials have been done and shown to -- that whatever it is, gowning, masking, not effective for some things, I give MRSA as an example, and there's conflicting -- there's some studies for, some studies against, but -- and then there are indications such as respiratory infections. And -- and -- and you know that's a high-risk setting.

So a setting of a nurse or a doctor in hospital, in a small hospital room, with someone known to be infected with that, or has syndromic symptoms consistent with, like we use the term "ILI" or "influenza-like illness," we often don't you know necessarily make the laboratory confirmed diagnosis all the time, but so when you look at a situation like that that is clearly very different than two healthy people interacting you know in a small store buying milk. And so the evidence in one doesn't necessarily translate into the other.

319. Q. And following up on that, are there any differences between healthcare settings in the

community at large that you think may affect the effectiveness of masks and infectious disease transmissibility in general?

A. Yeah, I think there is a lot of differences. I think in the healthcare setting the patients are known to be unwell, and so if you have a respiratory ward most hospitals have patients kind of grouped.

You have a neurology ward and a respiratory ward, things like that. So in a respiratory ward you have a high burden of illness in a very small area, which is very different than in the community. In the community just statistically you're going to not interact in nearly the same way with sick people as you would in hospital.

And I think an important thing -- there are many other things, but an important thing is the -- the type of potential mask or how it's used. Like as I said the Bangladesh study showed that non-medical mask, cloth masks, did have no effect.

And think about taking on and -- putting on and taking off masks, like healthcare workers are trained to do that because there's a particular way to don and doff PPE. And if it's not done appropriately you actually increase your risk.

Good examples of that is the Eboli outbreak in west Africa where some -- in some studies the highest risk of transmission for healthcare workers was at the time of donning and doffing their PPE, because if it's not done appropriately that's where you're going to get the risk.

And so in the community setting you have people using masks all sorts of ways that shouldn't be done. Like they're constantly pulling it up and down you know to -- to have a drink or whatever, they're touching the mask, putting -- in the healthcare setting that's totally against all the rules of hand hygiene and donning and doffing PPE.

So when you don PPE you used alcohol-based sanitizer or you wash your hands, then you put it on, and then you go in -- any time you you know have to touch your mask or something to adjust it you would do hand hygiene.

Same with doffing it, you come out, you do hand hygiene, then you take your mask off, then you do hand hygiene again. So all of these things in general are not done in the community.

320. Q. All right. And you were asked about the risk of infection in outdoor settings, and you said the risk was much lower than in indoor

settings. Can you tell me a bit more about the risk of infection in an outdoor setting?

A. Yeah, sure. So as I said in my report that the risk of transmission in other important respiratory infections, such as influenza and TB, they're not considered to be transmitted. And so in the absence of specific evidence to COVID-19 it's reasonable to extrapolate from similar very serious infections.

And while the, you know, number of deaths of influenza per year is less than COVID, historically over the decades and centuries it's certainly one of the most important respiratory diseases in history, as is TB. Neither of those illnesses are considered to have any significant transmission outdoors.

So that's what the base line should be. And then we need to say, okay, well, let's try to find some specific evidence about outdoor transmission in influenza. And as I quoted the rates are much much lower. And so I quote that one large study from China where they looked at over 7,000 cases, and there was really only one outdoor transmission involving two people.

And these -- I reference a few studies

from China because they're very helpful, because the Chinese are very good at being able to -- to track down every single case for every single contact. And so just based on that one, you know you're looking at a -- a risk that's 1,000 times less.

I -- I probably wouldn't say that definitely, but in the other references I cited I think we're looking at a risk of outdoor transmission, that's by at least 100 times less than indoor transmission.

321. Q. All right. And similarly, you were asked about the risk of asymptomatic transmission. And you mentioned that asymptomatic cases are far less infectious than symptomatic cases. Can you tell us a little more about that?

A. Yeah, so it can be hard to -- to measure, but in the studies I referenced it seems as thought the rate of transmission from asymptomatic cases is approximately 10 to 25 times less than in symptomatic cases.

And -- and in other places in my report I also talk about how the -- the viral load or, not the viral load, but the CT from swabs of persons with detectable COVID, but asymptomatic is much less, and so that's a correlate of the viral load. And so it's

thought that persons that are asymptomatic have lower concentrations of the virus within a respiratory tract.

322. Q. And just for the sake of keeping the information in the same section of the transcript, can you briefly explain what "CT" refers to?

A. Cycle threshold. And so that's with PCR. So as I indicated in my report PCR testing is one of the standard ways of testing for COVID-19 or SARS-CoV-2. And the cycle threshold is, as I indicated in reports, it's an amplification of the RNA, or into DNA, and it's the amplification number. So the lower it is the higher the amount of virus is in this group, and that was the test was taken from.

323. Q. Okay. Great. Towards the end of your discussion with Mr. Guttman regarding the aircraft carrier study, I believe that might have been Exhibit 1, but you mentioned that there is a natural reduction in COVID cases in the summer, and then at another point in your cross-examination you mentioned that an increase in cases in the winter, or in December is to be expected. Can you tell us a bit more about that?

A. Yeah, so all respiratory viruses follow seasonal patterns, certainly influenza. And as

I indicated in my report the other four coronaviruses together are one of the most important causes of the common cold, follow a seasonal pattern. And in that paper that I reference in the study it's clear that the peak every year is in January, at least in the United States. The study was out of the US.

And so all-important respiratory viruses, influenza, peri-influenza, human metapneumovirus, RSV and the seasonal coronaviruses all follow a seasonal pattern. And so it would be expected, and I showed in my report that COVID-19 does also follow a seasonal pattern.

And so certainly the highest peaks within Canada have been within the coldest months in the -- in you know almost two years that we've been seeing this virus in Canada. And that, as I explained in my expert report can be shown from many other jurisdictions around the world.

So in general it's not the only factor, but it's a very important factor. The colder it is and the less humid the -- which often go together, the -- you know there -- there's increased rates.

324. Q. Right. Would you expect to see cases rise and fall with the same seasonal sort of pattern if no measures were implemented to control

COVID? Obviously, the numbers may be different, but would you expect the seasonal pattern to stay the same?

A. Yeah, absolutely. So we have that every year with influenza with 10 other respiratory viruses, so there's a -- there's a season, there's a time, there's a -- usually a peak. They often don't overlap, so historically prior to COVID we would see something like RSV maybe in the fall, then influenza, and then after -- after influenza we would see peaks of other respiratory viruses, like peri-influenza and human metapneumo.

And so, yeah, they -- they all have a seasonal pattern. And they all have a peak. They rise and then they naturally come down.

325. Q. And I'd like to take you to the mask use in the context of COVID-19 interim guidance from the World Health Organization, which I believe was Exhibit 6 if I'm not -- yes, I think it's Exhibit 6. Are you able to pull that up?

A. Yeah, just give me a minute.

326. Q. Sure. We're just looking at the first page.

A. Right.

MR. GUTTMAN: Do you remember what

reference that was on my reference?

MR. KITTREDGE: I hate to scroll up and check because I'm kind of -- I'll lose my page entirely. It's at --

THE WITNESS: Yeah, I'll find it.

BY MR. KITTREDGE:

327. Q. Do you have the book of sources?

A. Yeah. I think it's --

328. Q. It's on page 12 of 18 of that.

MR. GUTTMAN: It's reference 63.

THE WITNESS: Yeah.

MR. KITTREDGE: Thank you.

THE WITNESS: Yeah. I'm bringing it up now. Okay. I've got it up.

BY MR. GUTTMAN:

329. Q. All right. On the first page, the very last section that's called, "Mask Use in Community Settings." There are two points, two bullet points there, one which has two sub-bullet points. Can you read the second point with its sub-bullet points to me, please?

A. Sure:

"In areas of known or suspected community or cluster SARS-CoV-2 transmission: WHO advises that the

general public should wear a non-medical mask in indoor (e.g. shops, shared workplaces, schools - see Table 2 for details) or outdoor settings where physical distancing of at least 1 metre cannot be maintained."

Point two:

"If indoors, unless ventilation has been be assessed to be adequate1, WHO advises that the general public should wear a non-medical mask, regardless of whether physical distancing of at least 1 metre can be maintained."

330. Q. What was the guidance in Canada for physical distancing?

A. Well, the guidance in Canada is based on a two-metre physical distancing, which is different than the WHO here.

331. Q. All right. And you were asked about your professional experience. I wonder if you could tell us a little bit about your experience with COVID during the last two years?

A. Sure. So I practice clinical infectious diseases, so that means I'm seeing patients every single day that I'm not on vacation, and have

been in full-time practice for 10 years. As I said I primarily have an inpatient practice.

I'm on call for 17 weeks a year, so that's a third of the year. And then when I'm not on call maintain an outpatient practice as well as do some administrative work like medical microbiology, infection control.

So in the past two years or so, just under two years that COVID's been around, again, I've been on call a third of the time and have taken care of all kinds of COVID patients in the ICU, on the ward, and then much less kind of outpatient -- outpatient work.

Yeah, in our particular hospital we've had -- you know we've had the opportunity to help other hospitals and taking overflow cases from them, so I've seen the whole spectrum of -- of COVID cases from the very mild to the very severe.

332. Q. All right.

MR. KITTREDGE: I have no further questions, so thanks so much for your time.

THE WITNESS: Thank you.

MR. KITTREDGE: And I guess we're ready to go off the record, unless there's any objection to that?

MR. HUNTER: No.

MR. KITTREDGE: No.

---Whereupon the concluded adjourned at 4:03p.m.

TRANSCRIBER'S CERTIFICATE

I, Sandi Baxter, Transcriber, certify:

That the foregoing proceedings were recorded on audio digital recording;

That the contents of the recordings were thereafter transcribed by me;

That the foregoing is a true and correct transcript to the best of my skill and ability of the audio digital recording so taken.

Dated this 29th day of December, 2021.

COVID-19 Overview of the Period of Communicability – What We Know So Far

Introduction

Public Health Ontario (PHO) is actively monitoring, reviewing and assessing relevant information related to Coronavirus Disease 2019 (COVID-19). "What We Know So Far" documents provide a rapid review of the evidence related to a specific aspect or emerging issue related to COVID-19.

Updates to Latest Version

This document replaces the previous version *COVID-19 – What We Know So Far About…The Period of Communicability* (March 30, 2020) and presents results of an updated rapid review. This updated rapid review draws primarily on systematic reviews and meta-analyses, and primary research where applicable, updating evidence on the period of communicability.

See PHO's rapid review *Factors Affecting COVID-19 Period of Communicability – What We Know So Far* for the latest evidence on how host factors (e.g., age, immune system compromise, disease severity) can alter the period of communicability.[1]

Key Findings

- The specific period of communicability estimates varied among the reviewed studies and study types. Epidemiology studies found transmission occurred in the 3–5 days before symptom-onset and epidemiology, virus culture and modelling studies found transmission occurred in the 8–10 days post symptom-onset in index cases.
- While specific period of communicability estimates varied among the reviewed studies, there was concurrence that the risk of communicability peaked shortly before and after the time of symptom-onset in index cases.

Background

The period of communicability is when a patient is shedding virus at a sufficient quantity and viability to infect another person. Currently, the infectious dose for humans is not known. In a ferret model, inoculations of 5×10^4 to 5×10^6 plaque-forming units (PFUs) caused mild clinical disease with viral shedding in the upper respiratory tract (URT) of all animals (12/12), while a dose of 5×10^2 PFUs reduced shedding to 1/6 animals.[2] Infectivity is also dependent upon exposure time and route of transmission. Based on experiments in mice and modelling studies, the infectious dose was about 6.4×10^4 to 9.8×10^5 virus copies and the risk of a single virus copy to infect after one-hour exposure through aerosol route

was 10^{-6} to 10^{-4} and through close contact was $10^{-1.3}$. The infectious dose is an important metric that requires further research, especially when attempting to define the period of communicability using viral isolation and viral loads as measures.

For this rapid review, we infer the period of communicability of COVID-19 from studies investigating:

- Live virus culture
- Epidemiology and contact tracing
- Modelling
- Viral RNA shedding

Live virus refers to the detection of a cytopathic effect (CPE) in cell cultures or the isolation of live virus from cell cultures inoculated with clinical samples from patients with COVID-19. In general, the presence of live virus in a sample from a patient with COVID-19 is an indication that the patient is infectious; however, this does not always equate to infectiousness, as infectiousness is dose-dependent. Epidemiological studies with contact tracing are another good indicator of the period of communicability, especially for the presymptomatic transmission period, if accurate tracing of presymptomatic patients and their close contacts was conducted. Modelling studies, using information from the other types of evidence, provide additional insights into the period of communicability. Specifically, modelling studies are important for estimating the period of presymptomatic transmission and the period when transmission risk is highest. Viral RNA shedding provides additional evidence for the period of communicability and refers to the detection of various targeted RNA sequences in patient samples through reverse transcription polymerase chain reaction (RT-PCR). A positive RT-PCR may or may not represent the presence of live or infectious virus, as the RNA detected potentially only represents the presence of fragmented or residual viral particles.

This review synthesizes the current literature investigating the period of communicability of COVID-19, while considering the sub-intervals of the period of communicability: 1) presymptomatic transmission period, 2) period of highest risk of transmission, and 3) timing of when infectiousness ends.

Methods

In considering feasibility, scope, and a need for responsiveness, we chose a rapid review as an appropriate approach to determining the period of communicability of COVID-19. A rapid review is a knowledge synthesis where certain steps of the systematic review process are truncated in order to be timely (e.g., quality assessment).[4]

On December 2, 2020, PHO Library Services conducted a literature search in MEDLINE, National Institutes of Health (NIH) COVID-19 Portfolio (pre-prints), Embase and Scopus on December 3, 2020 (Appendix A; search strategies available upon request). We searched PubMed and Google Scholar on December 31, 2020 for additional articles of interest.

English-language peer-reviewed and non-peer-reviewed records that described the period of communicability of COVID-19 were included. We restricted the search to articles published after January 1, 2020. This rapid review concentrated on evidence from systematic reviews and meta-analyses, supplemented by primary literature where appropriate and necessary. We reviewed citations from included articles to identify additional research.

Prior to posting, PHO subject-matter experts review all "What We Know So Far" documents.

As the COVID-19 pandemic continues to evolve and the scientific evidence rapidly expands, the information provided in these documents is only current as of the date of the literature searches.

The potential impact of COVID-19 variants of concern on the period of communicability is out-of-scope for this rapid review.

Findings

We screened 371 reviews and 930 primary research articles for this rapid review (Appendix A). After screening the literature for relevant articles, we included 14 systematic reviews (with or without meta-analyses), 2 rapid reviews, and 29 primary research articles. 24.4% (11/45) of studies were non-peer reviewed pre-print articles.

We organized evidence by type (systematic review, then primary research if applicable), then by sample size (number of studies or patients). Evidence pertaining to the URT was selected as a primary focus of this review, as the URT is the most likely source of infectious Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2). If authors did not report the total number of patients in a systematic review, only the total number of studies was included.

Live SARS-CoV-2 Shedding (Viral Culture)

Live virus was detected from 13 days before symptom-onset (BSO) to 32 days post symptom-onset (PSO). Authors did not routinely report average periods for live virus detection or isolation, rather they reported ranges or time-specific probabilities of detection. Nonetheless, the probability of detecting live virus was highest in the 8 to 10 days PSO, with few studies examining communicability BSO (Figure 1).

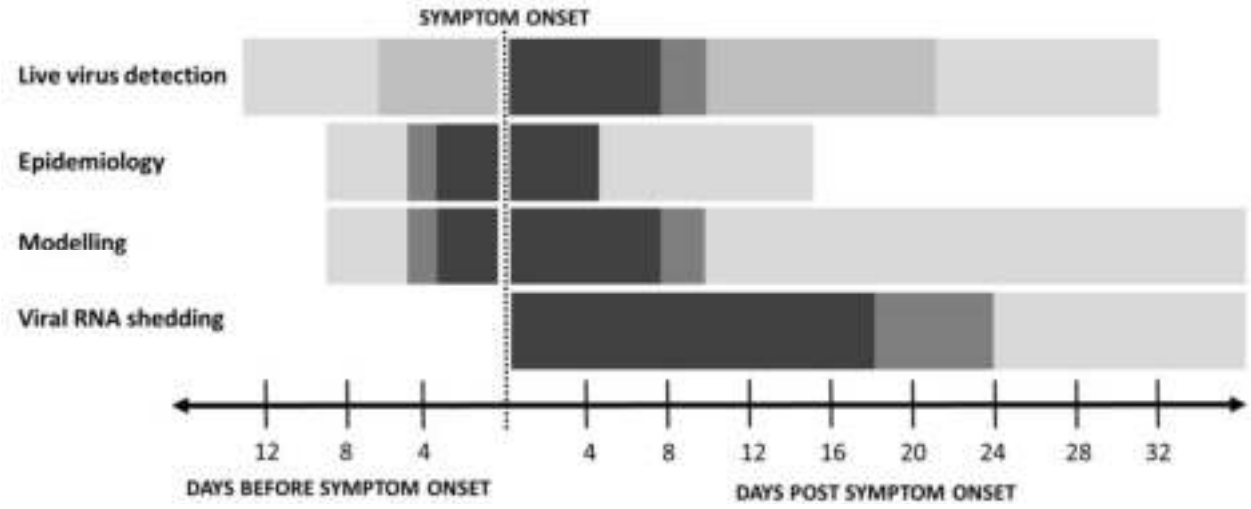
SYSTEMATIC AND RAPID REVIEWS

We examined five systematic reviews that reported on the detection of live SARS-CoV-2 from respiratory samples collected before (n=2 studies) and after (n=5 studies) symptom-onset (2 studies examined both periods). The detection of live virus was reported from 6 days BSO to 32 days PSO, with most studies reporting transmission within 10 days PSO.

- In a rapid review of 25 studies, the Public Health Agency of Canada (PHAC) reported that live SARS-CoV-2 was detected from respiratory samples collected from patients 1–6 days BSO and up to 8–10 days PSO.[5]
- In a systematic review, Walsh et al. adapted data from Singanayagam et al. to estimate viral culture positivity from respiratory samples (n=121 samples).[6,7] At 7 days PSO, the estimated culture positivity was 40.1% (95% confidence interval [CI]: 22.8–60.4), positivity decreased to 6.0% (95% CI: 0.9–31.2) at 10 days PSO and 0.03% (95% CI: 0.0–9.4) at 14 days PSO. Among the 13 studies included in the review, five reported the last day of positive culture occurred within 10 days PSO, another five studies reported that 3% of patients had positive cultures later than 10 days PSO.
- In a systematic review of 13 studies and 1,314 patients, Park et al. (pre-print) reported that the median duration of live virus shedding in respiratory samples was 9 days PSO (interquartile range [IQR]: 10), the mean ± standard deviation (SD) duration was 11.8 ± 8.47 days PSO (range: 2–32 days).[8]

- In a systematic review of 8 studies and 359 patients, Cevik et al. reported that no live virus was detectable in URT samples collected later than 9 days PSO.[9] The authors also noted that viral loads in URT samples peaked during the first week of illness.
- In a systematic review and meta-analysis of 4 studies and 304 patients, Fontana et al. reported that successful virus isolation from respiratory samples ranged from 6 days BSO to 20 days PSO.[10]

Figure 1. Summary of the period of communicability of COVID-19, for each type of study. The relative proportion of studies reporting a finding increases as the shading darkens (higher relative concordance among studies = black; lower relative concordance among studies = light grey).



PRIMARY RESEARCH

In 11 primary research articles, the detection of live SARS-CoV-2 from respiratory samples ranged from 13 days BSO to 32 days PSO. The majority of live virus detections were from respiratory samples collected within 10 days PSO (Figure 1).

- Singanayagam et al. examined 246 URT samples (RT-PCR positive) from 176 patients (mild to moderate disease in the United Kingdom) and found the median duration of live virus shedding was 4 days PSO (IQR: 1–8; range: -13 to 12).[7] The culture positivity rate was significantly higher during week 1 than week 2 (74% vs 20%; p=0.002).
- In a study of 195 patients in Australia, Basile et al. reported that the mean period from symptom-onset to positive viral culture was 4.5 days (range: 0–18).[11] Cultures were more likely to be positive from samples collected within the first week PSO, compared to the second week (80% vs. 45%; p=0·002), and between the second and third week (45% vs. 4%; p<0·001).
- In a study of 155 patients (174 nasopharyngeal [NP] swabs and 9 sputum samples) in Marseille, France, La Scola et al. did not detect live virus in respiratory samples collected after 8 days PSO, although viral RNA shedding occurred up to 20 days PSO.[12]
- In a study of 129 patients with severe disease in The Netherlands, van Kampen et al. reported that less than 5% of respiratory samples had viable virus when collected at 15.2 days PSO (95%

CI: 13.4–17.2) or more.[13] The median time of infectious virus shedding was 8 days PSO (IQR: 5–11; range: 0–20).

- In South Korea, researchers studied 285 patients that were repeat-positive by RT-PCR after being discharged from isolation after 14 days.[14] The average time from symptom-onset to re-positive test was 44.9 days (range: 8–82). No live virus was detected on respiratory samples from 108 patients; however, it is unclear when samples were collected for these patients.
- In a study of 105 patients in Spain, Folgueira et al. (pre-print) reported that the proportion of respiratory samples with positive cultures decreased as time from symptom-onset increased.[15] In hospitalized patients with severe disease (n=56 samples), 56.0% (14/25) of samples collected within 7 days PSO produced a positive viral culture, followed by 60.0% (9/15) of samples collected 8–14 days PSO, 60.0% (6/10) from 15–21 days PSO, and 33.3% (2/6) past 21 days (latest was 32 days PSO).
- Bullard et al., in a Manitoba study of 90 samples, reported that the probability of successful viral culture in NP swabs peaked at 80% at 3 days PSO (no growth occurred >8 days PSO).[16]
- In a Singapore study of 74 patients (152 samples), Young et al. reported that all NP swabs failed to grow in culture after 14 days PSO. In culture-positive NP samples, 57.1% (12/21) of positive samples were collected at 7 days PSO or less; 42.9% (9/21) were collected more than 7 days PSO (latest was 14 days PSO; 20/21 of positive samples were collected ≤10 days PSO).[17] Virus isolation decreased as PSO time increased (OR: 0.81; 95% CI: 0.70–0.92; p<0.0001).
- Perera et al. (pre-print), in a study of 35 patients (32 with mild disease; 68 samples) in Hong Kong, found that live SARS-CoV-2 were rarely detectable beyond 8 days PSO.[18] From 1–2 days PSO, 53% (8/15) of samples were successfully cultured, followed by 35% (8/23) at 3–8 days PSO, and 0% (0/30) at 9–30 days PSO.
- Sohn et al., in a study of 48 patients in South Korea with no symptoms or with mild disease in the late phase of disease, reported that no samples produced CPE in cell cultures when collected 20 days PSO or more.[19]
- In a skilled nursing facility in Washington, United States (US), Arons et al. reported that in 17 of 24 presymptomatic patients, live virus was detected from 6 days BSO to 9 days PSO.[20]

Epidemiological Studies

The period of communicability from epidemiological studies ranged approximately from 9 days BSO to 15 days PSO, with most transmission occurring approximately 3–5 days BSO to 5 days PSO (Figure 1).

It is important to note that definitions for asymptomatic, presymptomatic and symptomatic patients varied among studies. In addition, studies varied in their definitions of index cases (e.g., symptomatic or asymptomatic, or both included) and not all studies tested asymptomatic contacts of index patients.

SYSTEMATIC REVIEWS

No systematic reviews or meta-analyses examined the period of communicability of COVID-19 using epidemiological studies. However, five systematic reviews and meta-analyses reported that secondary attack rates were lower among contacts of presymptomatic patients, compared to symptomatic patients. These studies demonstrated that the risk of transmission from presymptomatic and asymptomatic index cases was relatively lower, compared to transmission from symptomatic cases, and that most transmission occurred after symptom-onset in index cases.

- In a systematic review of 19 studies, Madewell et al. reported that the household secondary attack rate in contacts of symptomatic cases (20%; 95% CI: 14.0–25.7) was significantly higher than that for asymptomatic cases (0.7%; 95% CI: 0.0–3.8) (p<0.001).[21] The authors noted that primary studies varied with respect to how they defined index cases and household contacts. In addition, the authors could not rule out transmission from outside households (which could lead to overestimation of secondary attack rates).
- In a systematic review and meta-analysis of five studies, Byambasuren et al. reported that the secondary attack rate was 42% lower among contacts of asymptomatic cases compared to symptomatic cases (pooled relative risk [RR]: 0.58; 95% CI: 0.34–0.99; p=0.047; fixed-effects model).[22] The authors defined exposure as contact with a confirmed case or potential contact with another pre-symptomatic person.
- In a living systematic review and meta-analysis of five empirical and modelling studies, Buitrago-Garcia et al. reported that the secondary attack rate was potentially lower in contacts of asymptomatic cases than symptomatic cases (pooled RR: 0.35; 95% CI: 0.10–1.27).[23] Similarly, the secondary attack rate was possibly lower for contacts of presymptomatic cases versus symptomatic cases (pooled RR: 0.63; 95% CI: 0.18–2.26).
- In a systematic review of three studies, Koh et al. reported that household secondary attack rates in contacts of symptomatic index cases (20.0%; 95% CI: 11.4–28.6) was higher than the secondary attack rates in contacts of asymptomatic index cases (4.7%; 95% CI: 1.1–8.3) (RR: 3.2; 95% CI: 1.5–7.1).[24] The authors noted that clinical definitions and follow-up periods varied among studies.
- Qiu et al. (pre-print) in a systematic review reported that the secondary attack rate in contacts of asymptomatic patients ranged from 0.0–2.8% (n=9 studies), which was lower than the secondary attack rates from presymptomatic patients that ranged from 0.7–31.8% (n=10 studies).[25]

PRIMARY STUDIES

We reviewed 11 epidemiological and contact tracing studies (primary studies) which were in general agreement with findings from viral culture studies. The period of communicability ranged from 9 days BSO to 5 days PSO, with most transmission occurring 3–5 days BSO to 5 days PSO.

- In a contact tracing study of 100 index cases and 2,761 close contacts in Taiwan, Cheng et al. reported that the secondary attack rate was 1.0% (95% CI: 0.6–1.6; n=1,818) when contacts were exposed to index cases within 5 days PSO.[26] When contacts were exposed to index cases after 5 days PSO, the secondary attack rate was 0.0% (95% CI: 0.0–0.4; n=852).
- In a study of 72 infector-infectee pairs in South Korea, Chun et al. estimated that the mean transmission-onset was 1.3 days PSO (95% CI: 0.38–2.55) and the median transmission-onset was 0.68 days PSO (95% CI: -0.09 to 1.73).[27] Transmission-onset peaked at 0.72 days BSO.
- In a study of 47 clusters (53 index patients and 100 secondary cases) in Beijing, China, Zhang et al. reported that 15 secondary cases were exposed to index patients up to 5 days BSO (n=2 clusters).[28]
- In an epidemiological study of 93 cases in Singapore and 135 cases in Tianjin, China, Tindale et al. estimated that infections occurred an average of 2.0 days BSO in Singapore and 3.7 days BSO in Tianjin.[29]
- In a contact tracing study of 15 cases in Wuxi, China, Gao et al. reported that transmission occurred from 2–9 days BSO.[30]

- Gong et al. studied three clusters (14 cases) in Shanghai, China, where 5 secondary cases were infected by index cases from 1–7 days BSO to 1 day PSO.[31]
- In a study of 243 cases in Singapore, Wei et al. determined that in 4 of 7 clusters, transmission occurred 1–3 days BSO, while timing of infection in the remaining 3 clusters could not be determined.[32]
- Xia et al. (pre-print) reviewed 74 secondary cases from Hubei Province, China. The majority of the secondary cases (73.0%) were infected BSO of first-generation cases, while 18.9% and 8.1% were infected on the same day of symptom-onset or PSO (latest was 15 days PSO), respectively. 66.2% of the secondary cases were infected within 3 days BSO, with 6.8% prior to 3 days BSO (earliest was 5 days BSO).[33]
- In a cluster (9 cases) investigation in Shanghai, China, Kong et al. reported that transmission occurred in secondary cases 3–4 days BSO in index cases; seven cases occurred due to exposures on the day of onset to 2 days PSO.[34] The secondary cases had additional contacts that could have contributed to transmission, but the authors attest risk was low since they were asymptomatic during a 14-day quarantine period (no positive RT-PCR tests).
- In a family cluster in Zhoushan, China, Li et al. reported that 4 of 5 familial contacts were possibly infected after exposure to the presymptomatic index case 4–7 days BSO.[35]
- In a study of a cluster of 8 cases in Hefei, China, Huang et al. reported that 6 of 7 secondary cases were likely exposed 1 day BSO in the index case, one case was exposed either 3 days BSO or 1 day PSO.[36]

Modelling Studies

Modelling studies were in agreement with other lines of evidence for the period of communicability of COVID-19. Specifically, modelling studies identified that the risk of transmission is highest just before and after the time of symptom-onset in index cases, with most transmission occurring approximately 3–5 days BSO to 8–10 days PSO (Figure 1).

SYSTEMATIC AND RAPID REVIEWS

One systematic review and meta-analysis and a rapid review modelled the period of communicability.

- Benefield et al. (pre-print), in a systematic review and meta-analysis of 32 studies and 715 patients, reported that the individual-level viral dynamics of SARS-CoV-2 show a clear pattern of a peak in viral load at or before the appearance of symptoms and a steady log-fold decline over the next 21 days.[37] The pooled median duration of viral RNA shedding (49 studies and 917 patients) in respiratory samples was 4.8 days PSO (95% CI: 4.4–5.1), with a 5th percentile of 0.5 days (95% CI: 0.46–0.58) and a 95th percentile of 43.7 days (95% CI: 38.6–48.9). The authors attest that RNA positivity represents presence of live and infectious virus, rejecting existing evidence that RNA-positivity does not always represent live virus; therefore, caution must be used when interpreting the authors' conclusions.
- In a rapid scoping review of 13 studies and through modelling, Byrne et al. reported the central tendency of the preclinical infectious period to range from about 0.5–4.0 days BSO with one study as an outlier at 8.2 days.[38]

PRIMARY STUDIES

Seven modelling studies examined the period of communicability. In most modelling studies, the risk of communicability peaked at symptom-onset in index cases.

- He et al. reported that infectiousness peaked at symptom-onset or day zero (95% CI: -0.9 to 0.9), decreasing rapidly by 7 days PSO.[39] The authors further estimated that the proportion of presymptomatic transmission was 44% (95% CI: 30–57). He et al. estimated that the proportion of transmission earlier than 7 days BSO was less than 0.1%, 1% at 5 days BSO or earlier, and 9% at 3 days BSO or earlier. The authors suggested that contact tracing should enquire about close contacts up to 2–3 days BSO. Slifka and Gao have raised concerns with the methodology and interpretation of findings in He et al.[40] Slifka and Gao contend that modelling studies tend to over-emphasize transmission at or before symptom-onset, due in part to smaller sample sizes during this period.
- After correcting coding in the He et al. model, Ashcroft et al. estimated that the proportion of presymptomatic infections traced at 1 day BSO in the index patient was 33% (95% CI: 19–51); at 2 days BSO was 61% (95% CI: 40–83); at 3 days BSO was 80% (95% CI: 57–96); at 4 days BSO was 91% (95% CI: 71–99); and at 5 days BSO was 97% (95% CI: 82–100).[41] The re-analysis and correction found a similar presymptomatic proportion of 45.6% (95% CI: 23.8–75.8) as He et al. The fraction of presymptomatic transmission was 3% at 5 days BSO or earlier and 20% at 3 days BSO or earlier. The authors suggest that contact tracing should enquire about close contacts beyond 3 days BSO, but do not define a specific end range.
- In a study of 1,178 patients and 15,648 contacts in China, Hu et al. (pre-print) modelled the period of communicability.[42] The greatest probability of transmission from index cases occurred 1.8 days BSO, with 95% of transmission occurring 8.8 days BSO to 9.5 days PSO.
- Prakash (pre-print), using published data on 1,251 patients, reported that infectiousness peaked prior to symptom-onset based on RT-PCR and live virus culture; however, the central tendency for this presymptomatic period was not reported but was approximately less than 2 days BSO (see Figure 3 in paper).[43] The proportion of presymptomatic transmission was 68.4% (95% CI: 67.0–69.7)
- Casey et al. (pre-print), in a modelling study that used published data, reported that the mean transmission time was from 2.9 days BSO (95% CI: 3.2–2.6) to 1.2 days PSO (95% CI: 0.9–1.6).[44] Using unweighted pooled estimates, the transmission peaked at 0.60 days BSO (95% CI: -3.01 to 1.81). The proportion of presymptomatic transmission from pooled estimates was 56.4% (34.9–78.0).
- Zhao developed a likelihood framework to estimate the presymptomatic transmission period from the serial interval observations from individual transmission events.[45] The estimated mean presymptomatic transmission period was 2.2 days BSO (95% CI: 1.3–4.7).
- Using mathematical modelling, with data on incubation periods and serial intervals, Zhang (pre-print) estimated that average presymptomatic transmission occurred 3.8 days BSO (SD: 6.1).[46]

SARS-CoV-2 RNA Shedding (RT-PCR Testing)

For this review, we avoided using cycle threshold (CT) values from RT-PCR testing to infer infectiousness, since individual studies use variable reaction conditions and target genes when correlating CT values in RT-PCR tests to respective live virus detection.[47,48] Therefore, comparisons among studies is not feasible.

Overall, studies investigating SARS-CoV-2 RNA detection were in agreement with studies detecting live virus or epidemiological studies. The detection of viral RNA decreased over time since symptom-onset, with most studies showing RNA detection up to 24 days PSO; however, there is no way to convert RNA shedding to infectiousness (Figure 1).

SYSTEMATIC REVIEWS

In seven systematic reviews and meta-analyses, the mean period of viral RNA shedding in respiratory samples was 17.0–28.7 days PSO (11.1–11.4 days in children). In two systematic reviews and meta-analyses, the median duration was 14.0–24.0 days PSO.

- In a systematic review of 133 studies, Park et al. reported that the median duration of viral RNA shedding in respiratory samples was 24.0 days PSO (IQR: 19), the mean ± SD duration was 28.7 days ± 15.8 days PSO (range: 5–95).[8]
- Walsh et al., in a review of 50 studies, reported that the viral load in URT samples was highest around the time of symptom-onset to a few days after, remained high for approximately 7 days PSO, and became undetectable within 14 days PSO.[49] Using 88 studies, the median duration of viral RNA shedding in URT samples was 14.5 days PSO (range: 1–53.5).
- In a systematic review and meta-analysis of 43 studies and 3,229 patients, Cevik et al. reported that the pooled mean duration of viral RNA shedding in URT samples was 17.0 days PSO (95% CI: 15.5–18.6) using a random-effects model.[9] URT viral RNA shedding was highest 0–5 days PSO, then decreases.
- In a systematic review and meta-analysis of 37 studies, Morone et al. reported that the median duration of viral RNA shedding from respiratory samples was 14 days PSO (IQR: 12).[50]
- In a systematic review and meta-analysis of 28 studies, Fontana et al. reported that the median duration of viral RNA shedding was 18.4 days PSO (95% CI: 15.5–21.3; range: 1–83).[10]
- Two systematic reviews focused on children (≤18 years).
    - In a systematic review of 17 studies of children, Xu et al. reported that the mean duration of viral RNA shedding in respiratory samples was 11.1 ± 5.8 days PSO.[51]
    - In a systematic review of 13 studies of children, Li et al. reported a pooled mean duration of viral RNA shedding was 11.4 days PSO (95% CI: 10.1–12.8).[52]

Limitations

We should acknowledge that a relatively large proportion (24%) of the research articles in this rapid review were non-peer-reviewed, pre-print articles. In addition, most of the systematic reviews we included used the same pre-print articles in meta-analyses. Considering the rapid emergence of the COVID-19 pandemic, the volume of pre-print research is expected given the need for rapid dissemination of data.

We did not check systematic reviews for overlap among reviews in the studies that they included. Further, we did not check if our included primary studies were included in the systematic reviews. Thus, there is some duplication of findings. Not all studies performed serial testing for the explicit purpose of determining the period of communicability; thus, some studies could underestimate the average duration of communicability.

In the case of epidemiological studies focusing on contact tracing, the evidence is still emerging and based mostly on small clusters. In contact tracing studies, it was not always possible to monitor all

contacts identified from the presymptomatic period of the index cases, likely leading to an underestimation of secondary attack rates attributed to exposure during this presymptomatic period. We must note that definitions for asymptomatic, presymptomatic and symptomatic patients varied among studies. In addition, studies varied in their definitions of index cases (e.g., symptomatic or asymptomatic, or both included) and not all studies tested asymptomatic contacts of index patients. The definitions of asymptomatic patients varied in studies, which could have led to overestimates and underestimates of secondary attack rates. In addition, there is likely time-dependent recall bias in determining close contacts, especially when looking further backward from date of symptom-onset. Furthermore, the definition of a contact varies among studies, leading to variability in estimates. In studies of asymptomatic index patients, it is unclear in some instances when potential exposure occurred; therefore, the date of first positive RT-PCR was day zero, potentially leading to shorter estimates of the period of viral RNA shedding. Clinical or surveillance definitions of asymptomatic, presymptomatic, and symptomatic patients are variable across studies, potentially affecting estimates of the period of communicability. Since sequencing of virus from index cases and secondary cases were not compared, it is possible that different strains were involved with infectee-infector pairs, thus not representing true transmission pairs.

There was a high degree of heterogeneity among studies used in meta-analyses, mostly due to varying methodologies and small sample sizes. Different studies also observed cell cultures for various periods of time (4 days to over 7 days) and used different cell lines, both factors that could affect the probability of detecting of live virus. The reaction conditions and specific gene targets used in RT-PCR assays varied among studies, making it difficult to compare studies and when performing meta-analyses.

Even when live virus is detected from patients, it is still not known if these patients are truly infective.[53] Factors to consider when determining infectiousness include viral loads, infectious dose, transmission route, and length of exposure. Given these limitations and the uncertainty associated with the period of presymptomatic infectiousness and prolonged shedding of live virus, a definitive period of communicability is difficult to state.

Period of Presymptomatic Transmission: Implications for Practice

Currently, Ontario recommends that the contact tracing period begins 48 hours prior to symptom-onset in the corresponding case or when the case had a positive sample collected (if asymptomatic at sample collection time).[54] This is aligned with other public health agencies in Canada and internationally.[55,56]

Under any scenario, extending the period >48 hours to trace close contacts may potentially identify and isolate additional exposed contacts, thereby, preventing further transmission. However, to our knowledge, there are no empirical studies testing the effectiveness of extending or shortening the presymptomatic period for contact tracing on reducing spread from exposed contacts. Given the relatively few primary studies of infector-infectee pairs assessing pre-symptomatic spread >2 days before symptom-onset, and their limitations to confidently identify the source case (vs the index case), there is insufficient evidence to extend the current pre-symptomatic period of communicability.

- In settings that are considered high-risk for transmission or where there are vulnerable populations (e.g., long-term care, congregate living, hospitals), an extension of the presymptomatic period of communicability to >48 hours could be considered to increase identification of exposed contacts. However, additional public health resources would be required to identify and trace potential contacts.

- In households, workplaces, and school environments where there has been ongoing exposure to a case, extending the presymptomatic period of communicability would likely not increase the effectiveness of contact tracing.

Conclusions

There are differences in the findings across included studies due to different designs and sample size; however, there were primary epidemiological studies identified that indicated individuals can be infectious up to 3–5 days prior to symptom-onset and epidemiological, live virus and modelling studies that indicated the period of communicability is approximately 8–10 days after symptom-onset, with infectiousness highest just before or after the time of symptom-onset.

PHO will continue to monitor the scientific evidence on the period of communicability of COVID-19, updating this document as necessary and making recommendations should a change in practice to contact tracing will be needed.

An Outbreak of Covid-19 on an Aircraft Carrier

Matthew R. Kasper, Ph.D., Jesse R. Geibe, M.D., Christine L. Sears, M.D., Asha J. Riegodedios, M.S.P.H., Tina Luse, M.P.H., Annette M. Von Thun, M.D., Michael B. Gillingham, M.D.

ABSTRACT

BACKGROUND

An outbreak of coronavirus disease 2019 (Covid-19) occurred on the U.S.S. *Theodore Roosevelt*, a nuclear-powered aircraft carrier with a crew of 4779 personnel.

METHODS

We obtained clinical and demographic data for all crew members, including results of testing by real-time reverse-transcriptase polymerase chain reaction (rRT-PCR). All crew members were followed up for a minimum of 10 weeks, regardless of test results or the absence of symptoms.

RESULTS

The crew was predominantly young (mean age, 27 years) and was in general good health, meeting U.S. Navy standards for sea duty. Over the course of the outbreak, 1271 crew members (26.6% of the crew) tested positive for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection by rRT-PCR testing, and more than 1000 infections were identified within 5 weeks after the first laboratory-confirmed infection. An additional 60 crew members had suspected Covid-19 (i.e., illness that met Council of State and Territorial Epidemiologists clinical criteria for Covid-19 without a positive test result). Among the crew members with laboratory-confirmed infection, 76.9% (978 of 1271) had no symptoms at the time that they tested positive and 55.0% had symptoms develop at any time during the clinical course. Among the 1331 crew members with suspected or confirmed Covid-19, 23 (1.7%) were hospitalized, 4 (0.3%) received intensive care, and 1 died. Crew members who worked in confined spaces appeared more likely to become infected.

CONCLUSIONS

SARS-CoV-2 spread quickly among the crew of the U.S.S. *Theodore Roosevelt*. Transmission was facilitated by close-quarters conditions and by asymptomatic and presymptomatic infected crew members. Nearly half of those who tested positive for the virus never had symptoms.

From the U.S. Navy Bureau of Medicine and Surgery, Falls Church (M.R.K., B.L.G.), and the Navy and Marine Corps Public Health Center, Portsmouth (J.R.G., A.J.R., T.L., A.M.V.T., G.D., R.J.H.) — both in Virginia; U.S. Navy Seventh Fleet, Yokosuka, Japan (C.L.S.); U.S. Pacific Fleet, Pearl Harbor, Hawaii (M.B.M.); the U.S. Naval Hospital Guam, Apra Harbor (N.O., D.H., R.F.); and the Uniformed Services University of the Health Sciences, Bethesda (T.H.B.), and the Naval Medical Research Center, Silver Spring (A.W.A.) — both in Maryland. The U.S.S. *THEODORE ROOSEVELT* was conducting operations in the western Pacific Ocean when an outbreak of infection with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) occurred on board. On identification of the outbreak, the ship was diverted to U.S. Naval Base Guam. The base hospital, a 42-bed inpatient facility, provides medical care for U.S. military beneficiaries and others in the region. Although the initial response was handled by the medical staffs of the ship and Naval Hospital Guam, it was quickly augmented by a joint medical task force.

This report provides key findings from the U.S. Navy response and epidemiologic investigation of the outbreak. Over the course of the response, every member of the crew of the U.S.S. *Theodore Roosevelt* was evaluated, tested, placed in isolation or quarantine, and monitored on a daily basis to ensure their well-being. Our findings offer insights into the epidemiology and outcomes of SARS-CoV-2 infection in healthy, fit, military-aged adults who are housed in close quarters.

METHODS

INITIAL RESPONSE TO THE OUTBREAK AND FOLLOW-UP

The ship had been at sea for 13 days when three crew members presented to the medical department with symptoms suggestive of coronavirus disease 2019 (Covid-19). All three underwent testing by real-time reverse-transcriptase polymerase chain reaction (rRT-PCR) and were found to be positive for SARS-CoV-2. Over the next 24 hours, additional symptomatic crew members and approximately 400 close contacts were identified by contact tracing. Four days after the first positive test result was reported, the ship reached Naval Base Guam. Crew members with confirmed cases of Covid-19 were placed in isolation on Naval Base Guam or in the base hospital. Persons with one or more negative Covid-19 tests and no symptoms were quarantined in hotels off base or on Naval Base Guam. In addition, essential personnel who were uninfected stayed aboard the ship in port.

All members of the crew underwent screening for signs and symptoms of Covid-19 and testing by rRT-PCR. Those who tested positive for SARS-CoV-2 were placed in isolation and received twice-daily symptom, temperature, and pulse oximetry checks. Those who tested negative were placed in quarantine. Ultimately, 4079 SARS-CoV-2–negative crew members who did not have symptoms were quarantined in 11 hotels in Guam. All were placed in single-occupancy rooms.

A surveillance model was implemented that relied on in-person health screenings. These screenings were supplemented by self-reporting with the use of a symptom checker developed by Defense Digital Service. Health screenings and symptom-checker data were collated and analyzed each morning by 9 a.m. and again in the evening by 9 p.m. Crew members who had progressive symptoms or were deemed to have conditions potentially placing them at higher risk for poorer outcomes were followed up with additional screening. Any crew members who were determined by on-site medical providers to need closer observation or treatment were transported to Naval Hospital Guam for care. In addition to Covid-19–related health surveillance, crew members received primary care, pharmacy, and psychiatric services to ensure a complete scope of medical coverage.

On completion of prespecified periods of isolation or quarantine, all personnel were required to undergo repeat rRT-PCR testing. To be eligible for exit testing, a crew member had to remain in isolation or quarantine for a minimum of 14 days. Those in isolation were also required to be symptom-free for 3 days before exit testing. Any crew member in quarantine in whom symptoms developed was tested and moved to isolation for at least 14 additional days. All crew members were followed up for a minimum of 10 weeks, regardless of their Covid-19 status.

LABORATORY TESTING

Nasopharyngeal swab specimens were obtained from all members of the crew with the use of viral transport medium swab kits. The presence of SARS-CoV-2 infection was determined by rRT-PCR testing with the Thermo Fisher ABI 7500 or the Bio-Rad CFX96 Touch Real-Time PCR Detection System. Samples were processed with either the Qiagen QIAamp Viral RNA Mini Kit or the Roche MagNA Pure 96 instrument for automated nucleic acid extraction, and testing was performed with the Seegene Allplex 2019-nCOV assay test kit or the Centers for Disease Control

and Prevention (CDC) emergency-use-authorization assay.[1] These assays included the detection of two targets in the nucleocapsid gene, N1 and N2. Surveillance testing for influenza-like illness was conducted with the Biofire Respiratory 2 Panel.

COLLECTION OF OUTBREAK DATA

The Navy and Marine Corps Public Health Center was tasked with providing public health support for the outbreak investigation and conducting data analysis in alignment with its core public health mission. Data were collected as part of a coordinated public health outbreak investigation conducted by the Navy to bring the outbreak under control, ensure the well-being of the crew, assess the spread and effects of SARS-CoV-2, and implement measures to return the crew to work safely. Under Navy public health support criteria, the intent of the outbreak investigation was to mitigate spread, inform decision making, gather information for use in other outbreaks, and decrease the effect on the health of the crew. This project was deemed to be nonresearch with respect to the use of human subject information and was exempt from review by the institutional review board as an emergency public health outbreak investigation.

A roster of Electronic Data Interchange Personal Identifiers for the shipboard population was matched to Defense Manpower Data Center personnel rosters from February 2020 to identify demographic information for each crew member and to confirm personal identifiers. Civilian personnel and anyone with an Electronic Data Interchange Personal Identifier that did not match with Defense Manpower Data Center were excluded from analysis. The Defense Enrollment Eligibility Reporting System was used to identify race and ethnic group for all crew members. Ages of crew members at time of the outbreak were calculated from the date of birth to March 3, 2020.

Medical surveillance data collected by the ship medical department, Naval Hospital Guam, and the joint medical task force were collated with the roster to create a data set that included dates of symptom onset, daily clinical signs and symptoms, and test results. Data from the Defense Digital Service MySymptoms symptom-tracker application were also collated into the final data set. For the purpose of this analysis, fever is defined as subjective fever reported by the crew member or a measured temperature of 100.0°F or higher. All other symptoms were reported by the crew members. Data on health-related factors were obtained from a number of existing clinical Military Health System data sources, including the Armed Forces Health Longitudinal Technology Application and Military Health System Genesis.

A confirmed case of Covid-19 was defined as one in which a nasopharyngeal swab specimen was positive for SARS-CoV-2 by rRT-PCR. A suspected case of Covid-19 was defined as one that met Council of State and Territorial Epidemiologists clinical criteria for Covid-19 without a positive test result. Confirmed cases were further classified as symptomatic (with symptom onset before the first positive laboratory test), presymptomatic (with the first positive laboratory test before subsequent symptom onset), and asymptomatic (positive laboratory test but clinical criteria never met). Patients with confirmed or suspected infection were classified as having been hospitalized for Covid-19 if the admission diagnosis suggested a Covid-19–related illness.

STATISTICAL ANALYSIS

Data collation and analysis were performed with the use of SAS software, version 9.4 (SAS Institute). Baseline characteristics among crew members who were infected and those who were not infected were compared and univariate odds ratios with 95% confidence intervals were calculated with OpenEpi (www.openepi.com). For denominators of less than 20, odds ratios were not calculated. All reported odds ratios are not adjusted for multiple comparisons.

RESULTS

TIMELINE OF THE OUTBREAK

Between March 23 and May 18, 2020, a total of 1271 crew members (26.6% of the crew) tested positive for SARS-CoV-2. An additional 60 crew members had suspected Covid-19 (Fig. 1). Of the 1331 crew members with confirmed or suspected Covid-19, 572 (43.0%) remained asymptomatic throughout the outbreak, 293 (22.0%) were symptomatic at the time that they tested positive, and an additional 406 (30.5%) were presymptomatic at the time that they tested positive. In all, 978 (76.9%) of the 1271 crew members with labora-

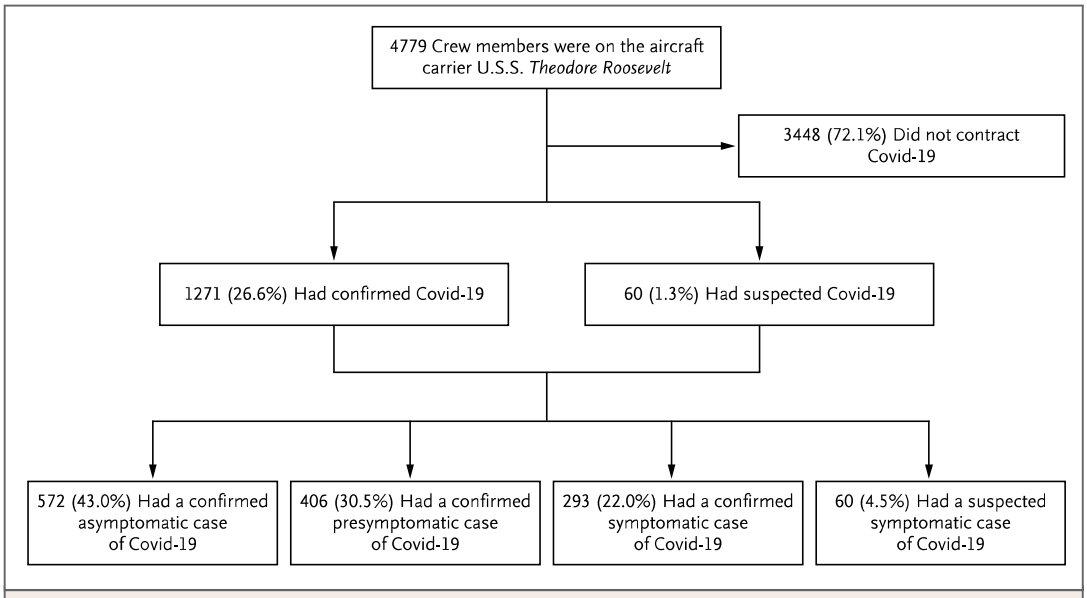

Figure 1. Distribution of Personnel According to Case Status.

A confirmed case of coronavirus disease 2019 (Covid-19) was defined as one in which a nasopharyngeal swab specimen was positive for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) by real-time reverse-transcriptase polymerase chain reaction. A suspected case was defined as one that met Council of State and Territorial Epidemiologists clinical criteria for Covid-19 without a positive test result. Confirmed cases were further classified as symptomatic (with symptom onset before the first positive laboratory test), presymptomatic (with the first positive laboratory test before subsequent symptom onset), and asymptomatic (positive laboratory test but clinical criteria never met).

tory-confirmed Covid-19 did not have symptoms at the time that they tested positive, and 699 (55.0%) had symptoms develop at any time during the clinical course.

Testing for influenza-like illnesses had been conducted on a limited number of specimens before and after the start of the outbreak. Testing of specimens obtained from 5 crew members during the week before the outbreak identified 3 crew members who were positive for human rhinovirus or enterovirus, 1 who was positive for respiratory syncytial virus (RSV), and 1 with no pathogens detected. After the outbreak was identified on March 23, specimens from 16 crew members were tested: 10 crew members had no pathogens detected, 3 were positive for human rhinovirus or enterovirus, 2 were positive for coronavirus OC43 (not SARS-CoV-2), and 1 was positive for both human rhinovirus or enterovirus and RSV.

The outbreak epidemic curve is shown in Figure 2. In retrospect, crew members with symptomatic confirmed or suspected Covid-19 had symptoms as early as March 11, 2020, and continued to receive diagnoses up to the end of the analysis period. Epidemic curves according to sex and crew type show parallel infection rates for men and women. Although the ship docked in Guam on March 27, 2020, the outbreak continued for at least an additional 6 weeks.

CHARACTERISTICS OF THE CREW MEMBERS

The crew was predominantly young (mean age, 27 years) and male (78.3%) and was racially and ethnically diverse. At the time of deployment, all crew members were in general good health and met the U.S. Navy standards for sea duty. Ultimately, Covid-19 cases were evenly distributed across sexes, races and ethnic groups, and crew types (Table 1). Enlisted personnel (90% of the shipboard population) appeared more likely than officers to have confirmed or suspected Covid-19.

Data were analyzed to identify higher-risk work spaces. Those working in tighter spaces (e.g., reactor, engineering, supply, and weapons

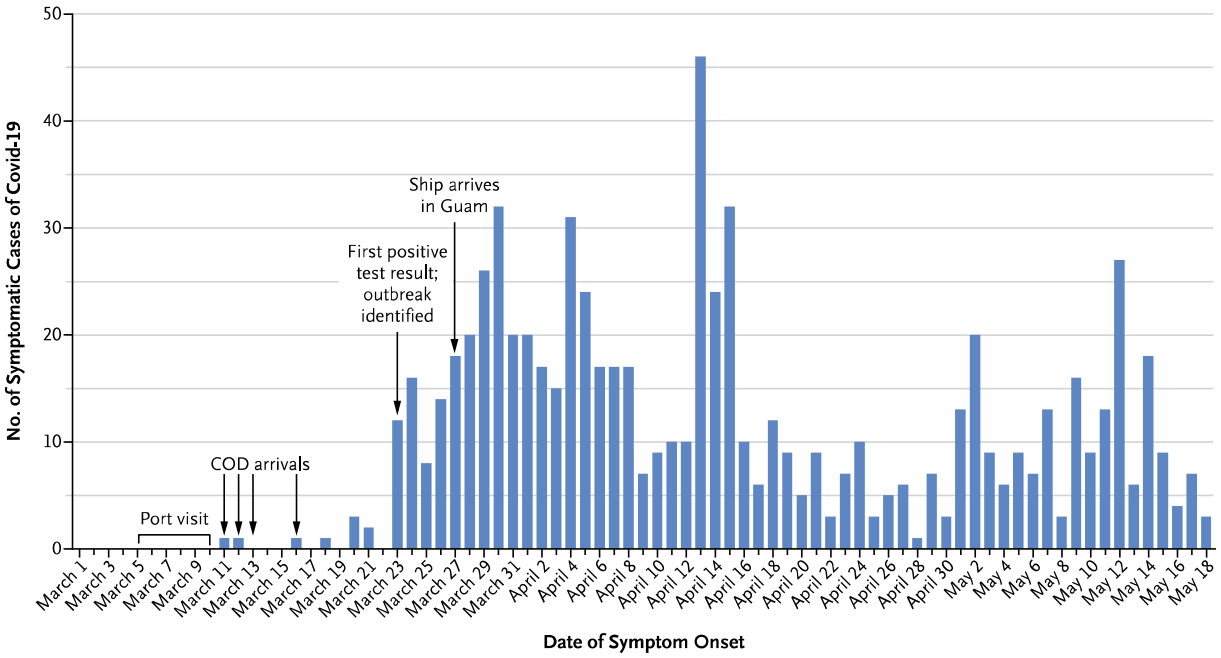

Figure 2. Numbers of Symptomatic Confirmed or Suspected Covid-19 Cases over Time.
Personnel, supplies, and mail are delivered to an aircraft carrier during carrier onboard delivery (COD).

departments) appeared more likely to have confirmed or suspected Covid-19 than those working in a combination of open-air and confined conditions (e.g., air and deck crew). Members of the medical department, who wore personal protective equipment when evaluating crew members, had a somewhat lower attack rate (16.7% [8 cases among 48 personnel) than the overall crew, despite being at highest risk as a result of exposure to patients with Covid-19 in a small space.

SYMPTOMS AND CARE

Among the crew members who had symptomatic Covid-19 (confirmed or suspected), headache was the most common symptom reported at any point during illness (occurring in 68.0%), followed by cough (59.5%), nasal or sinus congestion (43.8%), and altered sense of taste or smell (42.3%) (Fig. 3). The predominant symptoms reported at the onset of illness were cough (32.8%), headache (31.0%), and altered sense of taste or smell (24.1%). Shortness of breath at any point during illness was reported by 20.3% of the crew members with symptomatic cases, and 7.0% noted shortness of breath as an initial presenting symptom. In addition, 26.2% of the crew members with symptomatic Covid-19 reported chest pain or chest pressure at some point during their illness. Fever was reported as an initial presenting symptom by 5.3% of the crew members with symptomatic Covid-19, and fever at any point during illness was reported by 13.2%. Measured temperature readings showed that 2.8% of the crew members who had Covid-19 had a recorded temperature of 100.0°F or above, as compared with 0.3% of the crew members who did not have Covid-19. Among the crew members with Covid-19 for whom pulse oximetry data were available, approximately 0.5% had readings below 95% while breathing ambient air, with 0.08% below 94% and none below 90%.

Of the 1271 crew members who tested positive for SARS-CoV-2 plus the 60 who had suspected Covid-19, 23 (1.7%) received hospital care, for a mean of 16 days after symptom onset. Four crew members (0.3% of those with suspected or laboratory-confirmed Covid-19) were admitted to the intensive care unit, 1 of whom died from Covid-19–related cardiovascular complications. Before hospitalization, crew mem-

* Percentages may not total 100 because of rounding. Covid-19 denotes coronavirus disease 2019.
† The Defense Enrollment Eligibility Reporting System was used to identify race and ethnic group for all crew members.
‡ Augmented crew reside on the ship only at certain times when a ship is under way and provide specialized capability such as air squadrons, submarine groups, destroyer squadrons, and helicopter maritime strike squadrons.
§ Crew members in the departments of reactor, engineering, supply, weapons and in the combat support division tend to work in more confined spaces than those in the air and deck departments. Crew members in the air and deck departments tend to work in a combination of open-air and confined conditions. Medical personnel work in confined spaces but wear personal protective equipment when caring for crew members.
¶ Underweight was defined as a body-mass index (BMI, the weight in kilograms divided by the square of the height in meters) of less than 18.5; normal or healthy weight, 18.5 to 24.9; overweight, 25.0 to 29.9; and obese, 30 or higher.
‖ Conditions were identified from October 1, 2017, through March 1, 2020, with the use of the following data sources: Theater Medical Data Store, Comprehensive Ambulatory/Professional Encounter Record, Standard Inpatient Data Record, Armed Forces Health Longitudinal Technology Application Clinical Data Repository, Military Health System (MHS) GENESIS, TRICARE Encounter Data, and Periodic Health Assessment.

bers with Covid-19 who became hospitalized were more likely to report cough (68%), body aches (58%), and fever (32%) than those who did not. One third of hospitalized patients reported fever before their hospitalization, as compared with 12% of nonhospitalized crew members with Covid-19. During the outbreak, as a precautionary measure, admission criteria were revised to permit hospitalization of crew members with less severe symptoms.

DISCUSSION

The epidemiology of SARS-CoV-2 infection in young, healthy populations has not been studied extensively.[2] The outbreak of Covid-19 on the U.S.S. *Theodore Roosevelt* provided an unusual opportunity to assess an outbreak in a predominantly young, healthy, working-age population. Approximately 69% of crew members were younger than 30 years of age, and no crew member was older than 65 years. All were up to date with their immunizations. Over the course of the outbreak and the subsequent response by the U.S. Navy, every crew member underwent evaluation, testing, and follow-up. This level of controlled evaluation and documentation is difficult to achieve in civilian populations.

On ships at sea, respiratory viruses such as influenza and enteric pathogens such as norovirus can spread quickly.[3,4] In the early weeks of the pandemic, several outbreaks of Covid-19 occurred on cruise ships, most notably on the *Diamond Princess*.[5,6] The medical department of a ship can be overwhelmed quickly by a major outbreak of disease, as is similarly seen with health care fa-

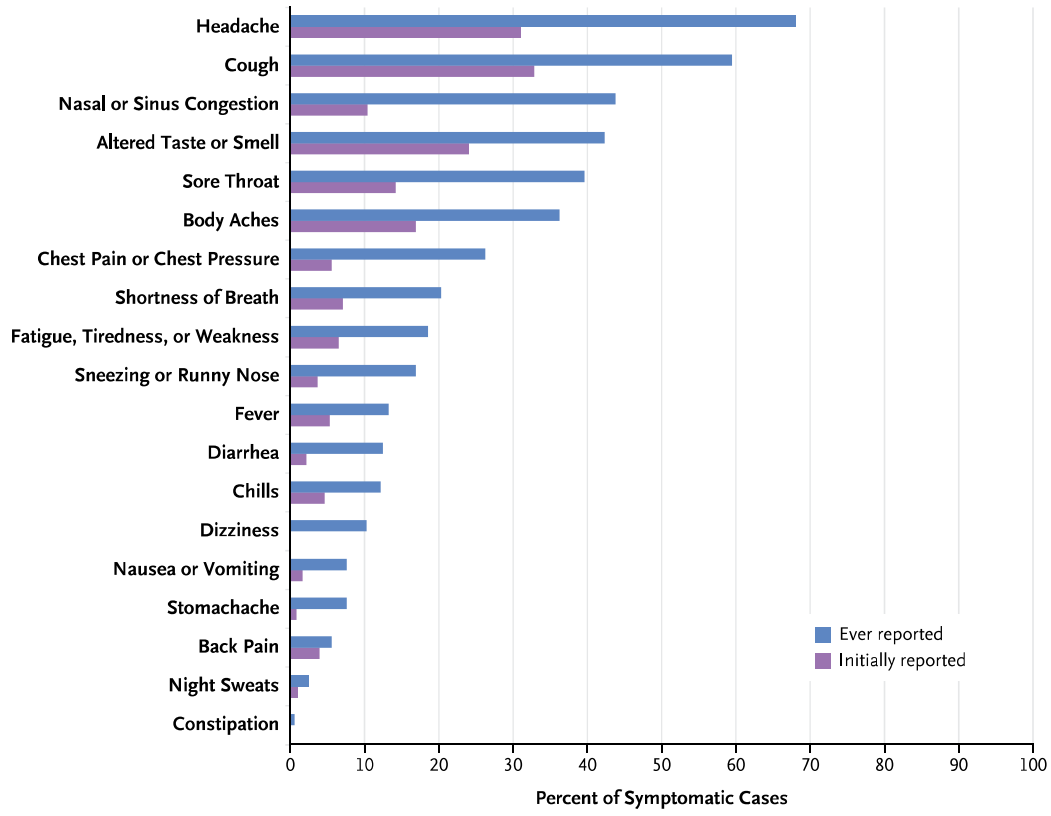

Figure 3. Distribution of Symptomatic Confirmed or Suspected Covid-19 Cases According to Symptoms.

cilities in civilian communities.[7] The shipboard environment on naval vessels is generally more confined. Typically, enlisted crew members sleep in open bays packed with dozens of tightly spaced bunks, work in densely populated areas, and congregate in gathering points such as the gyms and galleys (Figs. S1 and S2 in the Supplementary Appendix, available with the full text of this article at NEJM.org). These conditions probably facilitated the transmission of SARS-CoV-2, as evidenced by the higher likelihood of Covid-19 among enlisted crew members than among officers (Table 1).

Not surprisingly, crew members working in the engine room and other confined areas of the ship faced a higher risk of being infected than their shipmates on deck. A study conducted by the Navy and Marine Corps Public Health Center and the CDC, involving 384 volunteer U.S.S. *Theodore Roosevelt* crew members, showed similar results: those working in confined spaces had higher odds of contracting Covid-19.[8] A majority of infected crew members did not note symptoms at the time that Covid-19 was diagnosed by rRT-PCR testing. In addition, crew members with unusual or atypical symptoms may not have considered themselves to be infected with SARS-CoV-2.[9] These observations suggest that nonsymptomatic or mildly symptomatic crew members played an important role in the rapid spread of the outbreak, much as young adults with asymptomatic infection appear to contribute to spread in civilian populations.[10,11]

Although cases of serious illness occur in younger persons, they are less frequent and typically less severe than those in older persons.[9,11] In the case of the U.S.S. *Theodore Roosevelt*, few crew members were hospitalized. Certain coexisting conditions, such as hypertension, obesity, and diabetes, are associated with higher mortality.[12-14] In our findings, we noted a number of coexisting conditions among hospitalized crew members,

including uncomplicated, mild, and medically managed asthma, lung disease (e.g., bronchitis), hypertension, and liver disease–related conditions.

Although we were able to confirm the outcomes in all infected crew members, data collection was limited by the quality of records, particularly those generated in the early days of the outbreak. Future studies involving longitudinal cohorts may provide greater insight into the epidemiology of SARS-CoV-2 infection in young adults. Our observations within a military population may not be fully generalizable to civilians. The CDC case definition for Covid-19, along with clinical criteria, changed over time (e.g., the outbreak began in March 2020, and the CDC-published case definition for Covid-19 changed in April 2020). Multiplex testing by polymerase chain reaction identified other causes of influenza-like illness on board the ship. Any effect that the case definition or other respiratory pathogens may have had on classifying a case of Covid-19 is limited, because the majority of cases were confirmed by rRT-PCR testing. Finally, the crew of the U.S.S. *Theodore Roosevelt*, like all members of the U.S. military forces, have equal access to health care. This is not true for all civilians in the United States.

Since this outbreak occurred, the U.S. Navy has incorporated lessons learned to enhance the safety and readiness of its crews. To minimize the risk of deploying with asymptomatic carriers of SARS-CoV-2 on board, the Navy has initiated several procedures to create and sustain Covid-19–free environments on its ships. Before deployment, all members of a ship's crew are placed in "restriction of movement" and insulated from community exposure for 14 days. To identify asymptomatic or presymptomatic carriers, the Navy added rRT-PCR testing at the end of the "restriction of movement" period. Navy ships have sharply reduced shore leaves at foreign ports to prevent crew members from bringing the virus on board. Since these policies (along with preventive measures of mask use, social distancing to the extent possible, small-group cohorting, strict hand hygiene, and regular cleaning of common spaces) were put in place, the Navy has deployed multiple ships without sustaining another serious outbreak. The concept of creating virus-free "bubbles" is a strategy the Navy has used and has been mirrored by the National Basketball Association and Major League Soccer to enable competition while minimizing the risk of player exposure. It is unlikely that this strategy is practical for all employers, much less the general population; however, creating bubbles or cohorts for select populations may be achievable.

Organizations seeking to safeguard their employees, customers, patients, or students may benefit from assuming that Covid-19 will be introduced into their populations and rigorously enforcing measures to minimize viral transmission by all, since persons may be unaware that they are infected.

Asymptomatic transmission of covid-19

What we know, and what we don't

Allyson M Pollock, [1] James Lancaster[2]

The UK's £100bn "Operation Moonshot" to roll out mass testing for covid-19 to cities and universities around the country raises two key questions. How infectious are people who test positive but have no symptoms? And, what is their contribution to transmission of live virus?

Unusually in disease management, a positive test result is the sole criterion for a covid-19 case. Normally, a test is a support for clinical diagnosis, not a substitute. This lack of clinical oversight means we know very little about the proportions of people with positive results who are truly asymptomatic throughout the course of their infection and the proportions who are paucisymptomatic (subclinical), presymptomatic (go on to develop symptoms later), or post-infection (with viral RNA fragments still detectable from an earlier infection).

Earlier estimates that 80% of infections are asymptomatic were too high and have since been revised down to between 17% and 20% of people with infections.[1 2] Studies estimating this proportion are limited by heterogeneity in case definitions, incomplete symptom assessment, and inadequate retrospective and prospective follow-up of symptoms, however.[3] Around 49% of people initially defined as asymptomatic go on to develop symptoms.[4 5]

It's also unclear to what extent people with no symptoms transmit SARS-CoV-2. The only test for live virus is viral culture. PCR and lateral flow tests do not distinguish live virus. No test of infection or infectiousness is currently available for routine use.[6-8] As things stand, a person who tests positive with any kind of test may or may not have an active infection with live virus, and may or may not be infectious.[9]

The relations between viral load, viral shedding, infection, infectiousness, and duration of infectiousness are not well understood. In a recent systematic review, no study was able to culture live virus from symptomatic participants after the ninth day of illness, despite persistently high viral loads in quantitative PCR diagnostic tests. However, cycle threshold (Ct) values from PCR tests are not direct measures of viral load and are subject to error.[10]

While viral load seems to be similar in people with and without symptoms, the presence of RNA does not necessarily represent transmissible live virus. The duration of viral RNA shedding (interval between first and last positive PCR result for any sample) is shorter in people who remain asymptomatic, so they are probably less infectious than people who develop symptoms.[11]

Viral culture studies suggest that people with SARS-CoV-2 can become infectious one to two days before the onset of symptoms and continue to be infectious up to seven days thereafter; viable virus is relatively short lived.[7] Symptomatic and presymptomatic transmission have a greater role in the spread of SARS-CoV-2 than truly asymptomatic transmission.[1 2 12 13]

The transmission rates to contacts within a specific group (secondary attack rate) may be 3-25 times lower for people who are asymptomatic than for those with symptoms.[1 12 14 15] A city-wide prevalence study of almost 10 million people in Wuhan found no evidence of asymptomatic transmission.[16] Coughing, which is a prominent symptom of covid-19, may result in far more viral particles being shed than talking and breathing, so people with symptomatic infections are more contagious, irrespective of close contact.[17] On the other hand, asymptomatic and presymptomatic people may have more contacts than symptomatic people (who are isolating), underlining the importance of hand washing and social distancing measures for everyone.

Missed opportunity

By failing to integrate testing into clinical care, we have missed an important opportunity to better understand the role of asymptomatic infection in transmission. Given the variation in prevalence and testing strategies by region, the proportions of people with positive and negative test results should be published alongside the purpose of the testing strategy and the population tested (screening healthy populations in schools, universities, and health and social care, or testing people with symptoms). Government regulations on recording the age, ethnicity, sex, and place of residence of people with positive results must also be followed.[18]

Searching for people who are asymptomatic yet infectious is like searching for needles that appear and reappear transiently in haystacks, particularly when rates are falling.[19] Mass testing risks the harmful diversion of scarce resources. A further concern is the use of inadequately evaluated tests as screening tools in healthy populations.[20]

The UK's testing strategy needs to be reset in line with the Scientific Advisory Group for Emergencies' recommendation that "Prioritising rapid testing of symptomatic people is likely to have a greater impact on identifying positive cases and reducing transmission than frequent testing of asymptomatic people in an outbreak area."[21]

Testing should be reintegrated into clinical care with clinical and public health oversight and case definitions based on clinical diagnosis. Carefully designed prospective studies of cases and contacts are needed to estimate transmission rates by people

with and without symptoms. These should include careful investigations of outbreaks—for example, testing all contacts of people with a clear history of exposure, especially in high risk environments such as nursing homes, prisons, and other institutional settings.

Coronavirus infection surveys by the Office for National Statistics[22] and the REACT survey[23] could be expanded to include clinical follow-up of participants combined with tests of viral load and viral cultures. The absence of strong evidence that asymptomatic people are a driver of transmission is another good reason for pausing the roll out of mass testing in schools, universities, and communities.

Post-lockdown SARS-CoV-2 nucleic acid screening in nearly ten million residents of Wuhan, China

Shiyi Cao[1,11], Yong Gan[1,11], Chao Wang[1,11], Max Bachmann[2], Shanbo Wei[3], Jie Gong[4], Yuchai Huang[1], Tiantian Wang[1], Liqing Li[5], Kai Lu[6], Heng Jiang[7,8], Yanhong Gong[1], Hongbin Xu[1], Xin Shen[1], Qingfeng Tian[9], Chuanzhu Lv[10]✉, Fujian Song[2]✉, Xiaoxv Yin[1]✉ & Zuxun Lu[1]✉

Stringent COVID-19 control measures were imposed in Wuhan between January 23 and April 8, 2020. Estimates of the prevalence of infection following the release of restrictions could inform post-lockdown pandemic management. Here, we describe a city-wide SARS-CoV-2 nucleic acid screening programme between May 14 and June 1, 2020 in Wuhan. All city residents aged six years or older were eligible and 9,899,828 (92.9%) participated. No new symptomatic cases and 300 asymptomatic cases (detection rate 0.303/10,000, 95% CI 0.270–0.339/10,000) were identified. There were no positive tests amongst 1,174 close contacts of asymptomatic cases. 107 of 34,424 previously recovered COVID-19 patients tested positive again (re-positive rate 0.31%, 95% CI 0.423–0.574%). The prevalence of SARS-CoV-2 infection in Wuhan was therefore very low five to eight weeks after the end of lockdown.

The Coronavirus Disease 2019 (COVID-19) was first reported in December 2019, and was classified as a pandemic by the World Health Organization on March 11, 2020[1]. Following strict lockdown measures, the COVID-19 epidemic was generally under control in China, and the whole country has progressed into a post-lockdown phase. In this phase, countries face new problems and challenges, including how to accurately assess the post-lockdown risk of the COVID-19 epidemic, how to avoid new waves of COVID-19 outbreaks, and how to facilitate the resumption of economy and normal social life. As the city most severely affected by COVID-19 in China, Wuhan had been under lockdown measures from January 23 until April 8, 2020. During the first 2 months after city's reopening, there were only a few sporadic COVID-19 cases in Wuhan (six newly confirmed cases from April 8 to May 10, 2020[2]). However, there was still concern about the risk of COVID-19 in Wuhan, which seriously affected the resumption of industrial production and social services, and hampered the normal lives of residents. In order to ascertain the current status of the COVID-19 epidemic, the city government of Wuhan carried out a comprehensive citywide nucleic acid screening of SARS-CoV-2 infection from May 14, 2020 to June 1, 2020.

The citywide screening of SARS-CoV-2 infection in Wuhan is a mass screening programme in post-lockdown settings, and provided invaluable experiences or lessons with international relevance as more countries and cities around the world entering the post-lockdown phase. In this study, we report the organisation process, detailed technical methods used, and results of this citywide nucleic acid screening.

Results

There were 10,652,513 eligible people aged ≥6 years in Wuhan (94.1% of the total population). The nucleic acid screening was completed in 19 days (from May 14, 2020 to Jun 1, 2020), and tested a total of 9,899,828 persons from the 10,652,513 eligible people (participation rate, 92.9%). Of the 9899,828 participants, 9,865,404 had no previous diagnosis of COVID-19, and 34,424 were recovered COVID-19 patients.

The screening of the 9,865,404 participants without a history of COVID-19 found no newly confirmed COVID-19 cases, and identified 300 asymptomatic positive cases with a detection rate of 0.303 (95% CI 0.270–0.339)/10,000. The median age-stratified Ct-values of the asymptomatic cases were shown in Supplementary Table 1. Of the 300 asymptomatic positive cases, two cases came from one family and another two were from another family. There were no previously confirmed COVID-19 patients in these two families. A total of 1174 close contacts of the asymptomatic positive cases were traced, and they all tested negative for the COVID-19. There were 34,424 previously recovered COVID-19 cases who participated in the screening. Of the 34,424 participants with a history of COVID-19, 107 tested positive again, giving a repositive rate of 0.310% (95% CI 0.423–0.574%).

Virus cultures were negative for all asymptomatic positive and repositive cases, indicating no "viable virus" in positive cases detected in this study.

All asymptomatic positive cases, repositive cases and their close contacts were isolated for at least 2 weeks until the results of nucleic acid testing were negative. None of detected positive cases or their close contacts became symptomatic or newly confirmed with COVID-19 during the isolation period. In this screening programme, single and mixed testing was performed, respectively, for 76.7% and 23.3% of the collected samples. The asymptomatic positive rates were 0.321 (95% CI 0.282–0.364)/10,000 and 0.243 (95% CI 0.183–0.315)/10,000, respectively.

The 300 asymptomatic positive persons aged from 10 to 89 years, included 132 males (0.256/10,000) and 168 females (0.355/10,000). The asymptomatic positive rate was the lowest in children or adolescents aged 17 and below (0.124/10,000), and the highest among the elderly aged 60 years and above (0.442/10,000) (Table 1). The asymptomatic positive rate in females (0.355/10,000) was higher than that in males (0.256/10,000).

The asymptomatic positive cases were mainly domestic and unemployed residents (24.3%), retired older adults (21.3%), and public service workers (11.7%) (Fig. 1).

The asymptomatic positive rate in urban districts was on average 0.456/10,000, ranging from 0.317/10,000 in Hongshan to 0.807/10,000 in Wuchang district. A lower rate of asymptomatic positive cases was found in suburban districts (0.132/10,000), ranging from 0.047/10,000 in Xinzhou to 0.237/10,000 in Jiangan district (Fig. 2).

Among the 7280 residential communities in Wuhan, asymptomatic positive cases were identified in 265 (3.6%) communities (only one case detected in 246 communities), while no asymptomatic positive cases were found in other 96.4% communities.

Testing of antibody against SARS-CoV-2 virus was positive IgG (+) in 190 of the 300 asymptomatic cases, indicating that 63.3% (95% CI 57.6–68.8%) of asymptomatic positive cases were actually infected. The proportion of asymptomatic positive cases with both IgM (−) and IgG (−) was 36.7% (95% CI: 31.2–42.4%; $n = 110$), indicating the possibility of infection window or false positive results of the nucleic acid testing (Table 2).

Higher detection rates of asymptomatic infected persons were in Wuchang, Qingshan and Qiaokou districts, and the prevalence of previously confirmed COVID-19 cases were 68.243/10,000, 53.767/10,000, and 100.047/10,000, respectively, in the three districts. Figure 3 shows that districts with a high detection rate of asymptomatic positive persons generally had a high prevalence of confirmed COVID-19 cases ($r_s = 0.729$, $P = 0.002$).

Discussion

The citywide nucleic acid screening of SARS-CoV-2 infection in Wuhan recruited nearly 10 million people, and found no newly confirmed cases with COVID-19. The detection rate of asymptomatic positive cases was very low, and there was no evidence of transmission from asymptomatic positive persons to traced close contacts. There were no asymptomatic positive cases in 96.4% of the residential communities.

Previous studies have shown that asymptomatic individuals infected with SARS-CoV-2 virus were infectious[3], and might subsequently become symptomatic[4]. Compared with symptomatic patients, asymptomatic infected persons generally have low quantity of viral loads and a short duration of viral shedding, which decrease the transmission risk of SARS-CoV-2[5]. In the present study, virus culture was carried out on samples from asymptomatic positive cases, and found no viable SARS-CoV-2 virus. All close contacts of the asymptomatic positive cases tested negative, indicating that the asymptomatic positive cases detected in this study were unlikely to be infectious.

There was a low repositive rate in recovered COVID-19 patients in Wuhan. Results of virus culturing and contract tracing found no evidence that repositive cases in recovered COVID-19 patients were infectious, which is consistent with evidence from other sources. A study in Korea found no confirmed COVID-19 cases by monitoring 790 contacts of 285 repositive cases[6]. The official surveillance of recovered COVID-19 patients in China also revealed no evidence on the infectiousness of repositive cases[7]. Considering the strong force of infection of COVID-19[8–10], it is expected that the number of confirmed cases is associated with the risk of being infected in communities. We

Table 1 Characteristics of asymptomatic positive individuals.

	Total (%)	Asymptomatic positive persons (%)	Detection rate per 10,000 (95% CI)	*P* value
Total	9,899,828 (100.0)	300 (100.0)	0.303 (0.270–0.339)

East Lake Scenic Area of Wuhan	85,884 (0.9)	0 (0.0)	0.000 (0.000–0.430)	

χ^2 test was used to assess the association between the detection rate of asymptomatic cases increased and sex and age. Urban districts of Wuhan includes Wuchang, Qingshan, Qiaokou, Hanyang, Jiangan, Jianghan, and Hongshan; Suburban districts of Wuhan includes Hannan, Caidian, Dongxihu, Xinzhou, Jiangxia, Huangpi, East Lake High-tech Development Area, and East Lake Scenic Area of Wuhan.

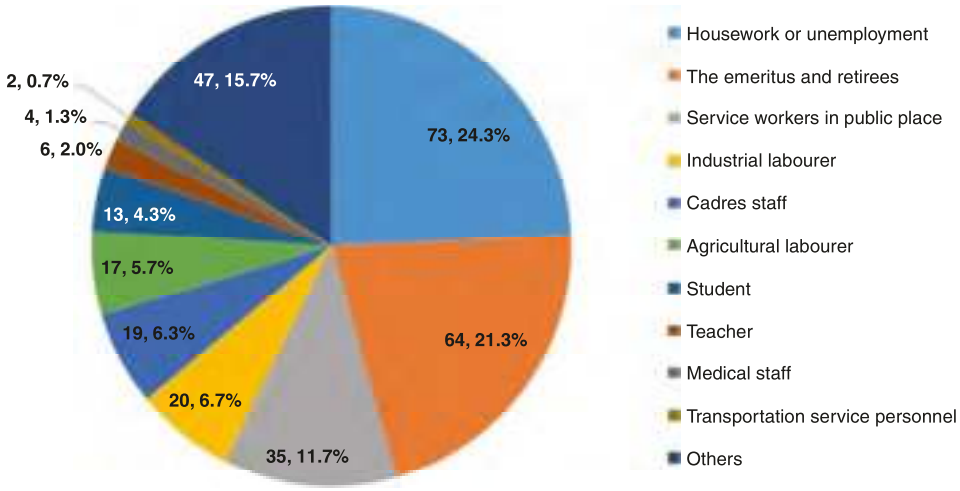

Fig. 1 The occupation distribution of asymptomatic positive cases (%). Note: Others included the self-employed, military personnel, and so on. (Source data are provided as s Source Data file.).

found that asymptomatic positive rates in different districts of Wuhan were correlated with the prevalence of previously confirmed cases. This is in line with the temporal and spatial evolution (especially the long-tailed characteristic) of infectious diseases[11].

Existing laboratory virus culture and genetic studies[9,10] showed that the virulence of SARS-CoV-2 virus may be weakening over time, and the newly infected persons were more likely to be asymptomatic and with a lower viral load than earlier infected cases. With the centralized isolation and treatment of all COVID-19 cases during the lockdown period in Wuhan, the risk of residents being infected in the community has been greatly reduced. When susceptible residents are exposed to a low dose of virus, they may tend to be asymptomatic as a result of their own immunity. Serological antibody testing in the current study found that at least 63% of asymptomatic positive cases were actually infected with SARS-CoV-2 virus. Nonetheless, it is too early to be complacent, because of the existence of asymptomatic positive cases and high level of susceptibility in residents in Wuhan. Public health measures for the prevention and control of COVID-19 epidemic, including wearing masks, keeping safe social distancing in Wuhan should be sustained. Especially, vulnerable populations with weakened immunity or co-morbidities, or both, should continue to be appropriately shielded.

Findings from this study show that COVID-19 was well controlled in Wuhan at the time of the screening programme. After two months since the screening programme (by August 9, 2020), there were no newly confirmed COVID-19 cases in Wuhan.

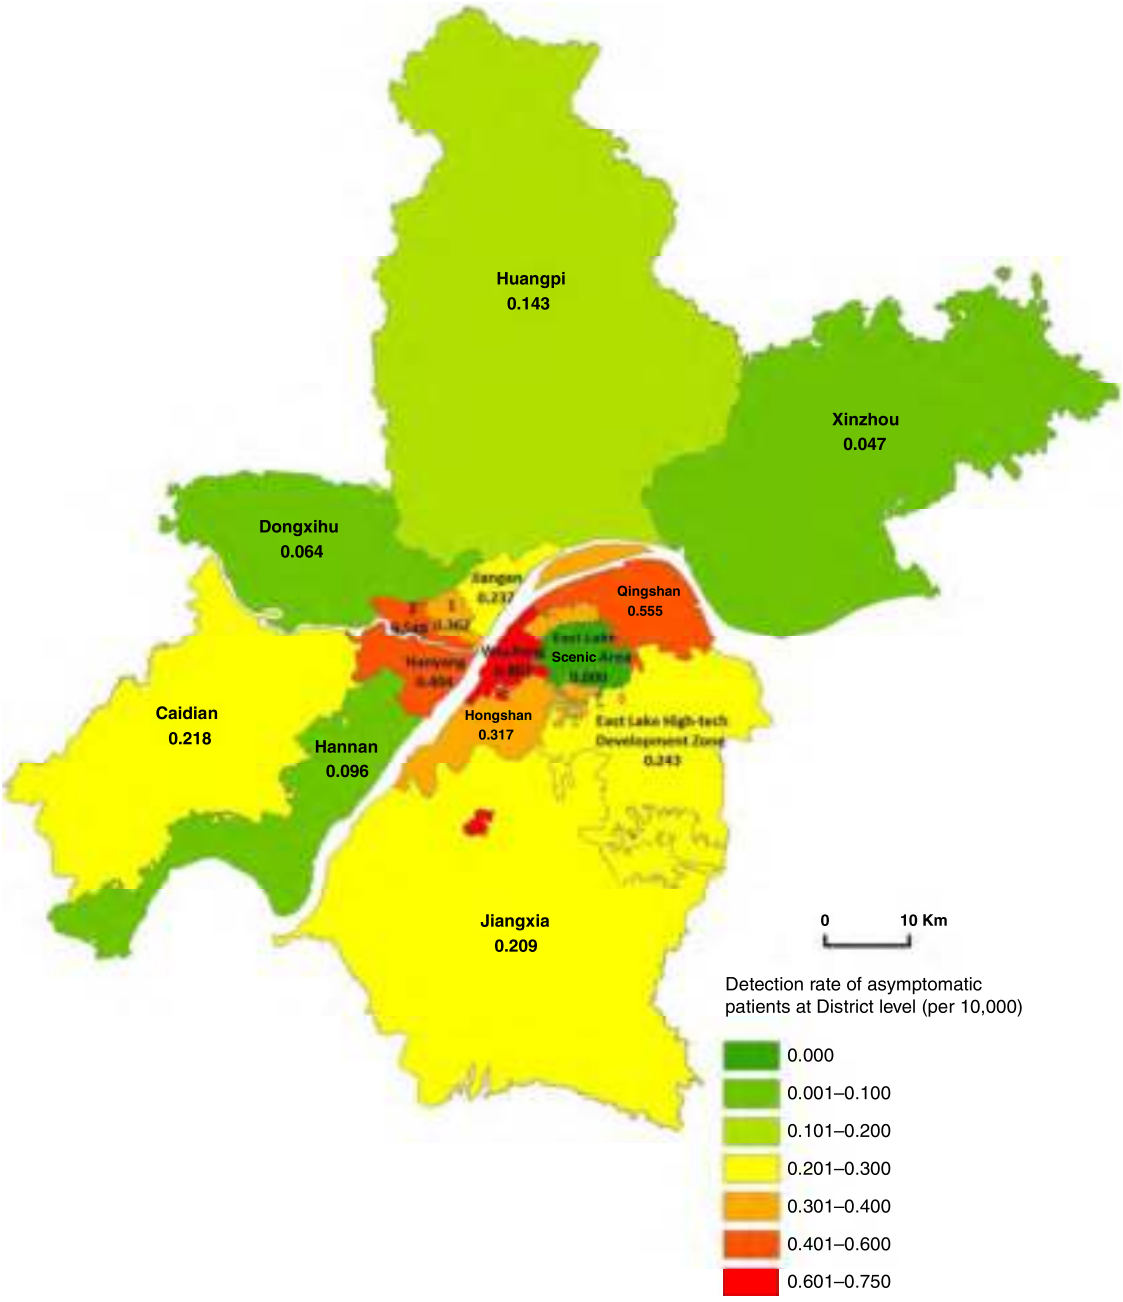

Fig. 2 The geographic distribution of the detection rate of asymptomatic positive cases. Note: 1 represents Jianghan district; 2 represents Qiaokou district. (Source data are provided as s Source Data file.).

Table 2 Results of the detection of antibody in 300 asymptomatic positive persons.

IgM Results	IgG	Asymptomatic positive persons	% (95% CI)
−	+	161	53.7 (47.8–59.4)
−	−	110	36.7 (31.2–42.4)
+	+	29	9.7 (6.6–13.6)
+	−	0	0.0 (0.0–1.2)

"−" indicates negative; "+" indicates positive.

Further testing of SARS-CoV-2 in samples collected from market environment settings in Wuhan were conducted, and found no positive results after checking a total of 52,312 samples from 1795 market setting during June 13 to July 2, 2020[12].

This study has several limitations that need to be discussed. First, this was a cross-sectional screening programme, and we are unable to assess the changes over time in asymptomatic positive and reoperative results. Second, although a positive result of nucleic acid testing reveals the existence of the viral RNAs, some false negative results were likely to have occurred, in particular due to the relatively low level of virus loads in asymptomatic infected individuals, inadequate collection of samples, and limited accuracy of the testing technology[13]. Although the screening programme provided no direct evidence on the sensitivity and specificity of the testing method used, a meta-analysis reported a

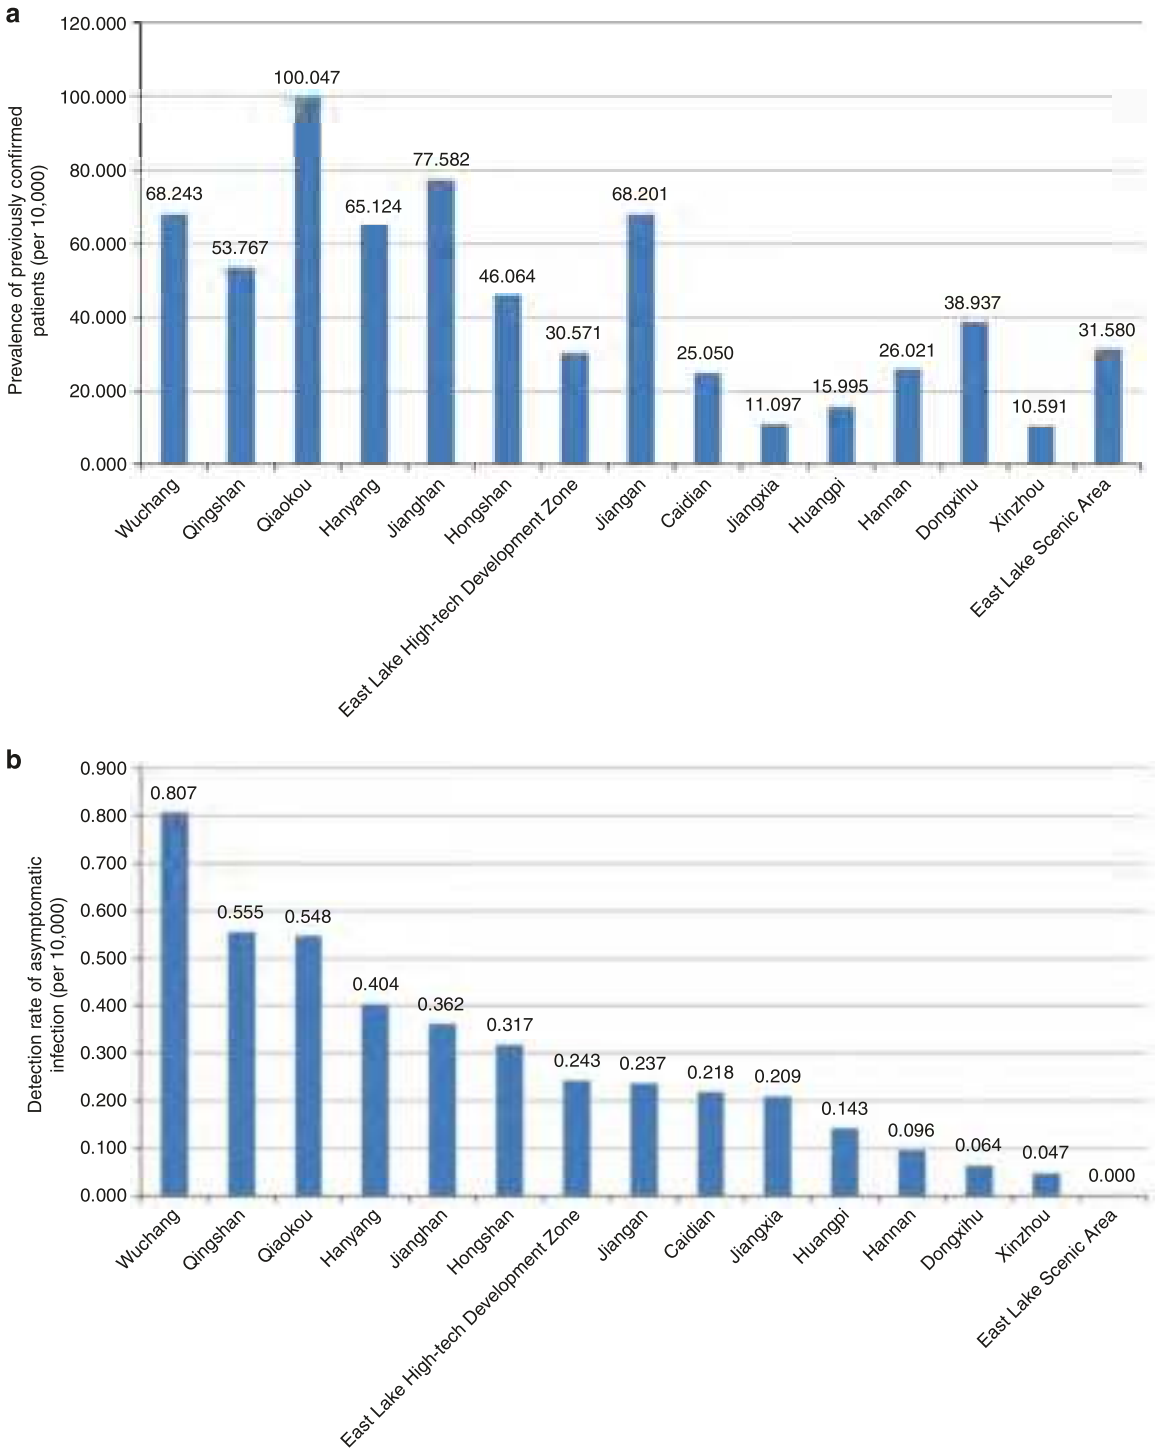

Fig. 3 The prevalence of previously confirmed patients and the detection rate of asymptomatic positive cases of COVID-19 in each district in Wuhan. **a** The prevalence of previously confirmed patients of COVID-19 in each district in Wuhan. **b** The detection rate of asymptomatic positive cases of COVID-19 in each district in Wuhan. (Source data are provided as s Source Data file.).

pooled sensitivity of 73% (95% CI 68–78%) for nasopharayngeal and throat swab testing of COVID-19[14]. Testing kits used in the screening programme were publicly purchased by the government and these kits have been widely used in China and other countries. Multiple measures were taken to possibly minimise false negative results in the screening programme. For example, standard training was provided to health works for sample collection to ensure the sample quality. The experiment procedures, including specimen collection, extraction, PCR, were according to official guidelines (Supplementary Note 1). For the real-time RT-PCR assay, two target genes were simultaneously tested. Even so, false negative results remained possible, particularly in any mass screening programmes. However, even if test sensitivity was as low as 50%, then the actual prevalence would be twice as high as reported in this study, but would still be very low. Around 7.1% of eligible residents did not participate in the citywide nucleic acid screening and the screening programme did not collect detailed data on reasons for nonparticipation, which is a limitation of this

study. Although there were no official statistics, a large number of migrant workers and university students left Wuhan before the lockdown, joining their families in other cities or provinces for traditional Chinese New Year. Therefore, it is likely that most nonparticipants were not in Wuhan at the time of the screening. The main objective of the screening programme was to assess the risk of COVID-19 epidemic in residents who were actually living in the post-lockdown Wuhan. Therefore, the estimated positive rates are unlikely to be materially influenced by nonparticipation of residents who were not in Wuhan or some residents who did not participate in the screening for other reasons. Moreover, people who left Wuhan were the target population for monitoring in other provinces and cities and were required to take nucleic acid testing. Although there was no official statistics showing the positive rate of nucleic acid testing in this population, there was no report that shown a higher positive rate of nucleic acid testing than our findings.

In summary, the detection rate of asymptomatic positive cases in the post-lockdown Wuhan was very low (0.303/10,000), and there was no evidence that the identified asymptomatic positive cases were infectious. These findings enabled decision makers to adjust prevention and control strategies in the post-lockdown period. Further studies are required to fully evaluate the impacts and cost-effectiveness of the citywide screening of SARS-CoV-2 infections on population's health, health behaviours, economy, and society.

Methods

Study population and ethical approvals. Wuhan has about 11 million residents in total, with seven urban and eight suburban districts. Residents are living in 7280 residential communities (or residential enclosures, "xiao-qu" in Chinese), and each residential community could be physically isolated from other communities for preventing transmission of COVID-19.

The screening programme recruited residents (including recovered COVID-19 patients) currently living in Wuhan who were aged ≥6 years (5,162,960 males, 52.2%). All participants provided written or verbal informed consent after reading a statement that explained the purpose of the testing. For participants who aged 6–17 years old, consent was obtained from their parents or guardians. The study protocol for an evaluation of the programme based on anonymized screening data was approved by the Ethics Committee of the Tongji Medical College Institutional Review Board, Huazhong University of Science and Technology, Wuhan, China (No. IROG0003571).

Organizational guarantee and community mobilization. A citywide nucleic acid screening group was formed, with specialized task teams contributing to comprehensive coordination, technical guidance, quality control, participation invitation, information management, communication, and supervision of the screening. The city government invested 900 million yuan (RMB) in the testing programme. From 14 May to 1 June 2020, in the peak time, up to 2907 sample collection sites were functioning at the same time in Wuhan. Each sample collection site had an assigned sample collection group, including several health professionals (staffed according to the number of communities' residents), 2–4 community managers, 1–2 police officers, and 1–2 inspectors. The sampling sites were set up based on the number and accessibility of local residents. Local community workers were responsible for a safe and orderly sampling process to minimise the waiting time. In addition, mobile sampling teams were formed by primary health care professionals and volunteers to conduct door-to-door sampling for residents who had physical difficulties or were unable to walk.

About 50,000 health professionals (mainly doctors and nurses from community health centers) and more than 280,000 person-times of community workers and volunteers contributed to sample collection, transport of equipment and samples collected, arrangement of participation process, and maintaining order of sampling sites. Public information communication and participant invitation were implemented through mass media, mobile messages, WeChat groups, and residential community broadcasts, so as to increase residents' awareness and the participation.

Acquisition, preservation, and transport of samples. All sampling personnel received standard training for the collection of oropharyngeal swab samples. To minimise the risk of cross-infection, the sampling process strictly followed a disinfection process and environmental ventilation were ensured. The collected samples were stored in a virus preservation solution or immersed in isotonic saline, tissue culture solution, or phosphate buffer (Supplementary note 1). Then, all samples were sent to testing institutions within 4 h using delivery boxes for biological samples refrigerated with dry ice to guarantee the stability of nucleic acid samples.

Technical methods for laboratory testing of collected samples. A total of 63 nucleic acid testing laboratories, 1451 laboratory workers and 701 testing equipment were involved in the nucleic acid testing. Received samples were stored at 4 °C and tested within 24 h of collection. Any samples that could not be tested within 24 h were stored at −70 °C or below (Supplementary note 1). In addition to "single testing" (i.e., separate testing of a single sample), "mixed testing" was also performed for 23% of the collected samples to increase efficiency, in which five samples were mixed in equal amounts, and tested in the same test tube. If a mixed testing was positive for COVID-19, all individual samples were separately retested within 24 h[15].

Details regarding technical methods for sequencing and virus culture were provided in Supplementary note 1. Real-time reverse transcriptase-polymerase chain reaction (RT-PCR) assay method was used for the nucleic acid testing. We simultaneously amplified and tested the two target genes: open reading frame 1ab (ORF1ab) and nucleocapsid protein (N) (Supplementary Note 1). A cycle threshold value (Ct-value) less than 37 was defined as a positive result, and no Ct-value or a Ct-value of 40 or more was defined as a negative result. For Ct-values ranging from 37 to 40, the sample was retested. If the retest result remained less than 40 and the amplification curve had obvious peak, the sample was classified as positive; otherwise, it was reported as being negative. These diagnostic criteria were based on China's official recommendations[16].

For asymptomatic positive cases, virus culture was carried out in biosafety level-3 laboratories. The colloidal gold antibody test was also performed for asymptomatic positive cases (Supplementary note 1). All testing results were double entered into a specifically designed database, and managed by the Big Data and Investigation Group of the COVID-19 Prevention and Control Centre in Wuhan, which was established to collect and manage data relevant to the COVID-19 epidemic.

Participant data collection and management. Before sample collection, residents electronically (using a specifically designed smartphone application) self-uploaded their personal information, including ID number, name, sex, age, and place of residence. Then, the electronic machine system generated a unique personal barcode and stuck it on the sample tube to ensure the match between the sample and the participant. Then trained staff interviewed each individual regarding the history of COVID-19 and previous nucleic acid testing. There was a database of confirmed COVID-19 cases in Wuhan, which can be used to validate the self-reported previous COVID-19 infection. All information was entered into a central database. The testing results were continually uploaded to the central database by testing institutions. Contact tracing investigations were conducted on participants who tested positive for SARS-CoV-2, to track and manage their close contacts. The pre-existing unique identification code for each resident was used as the programme's identification number, to ensure information accuracy during the whole process of screening, from sampling, nucleic acid testing, result reporting, the isolation of detected positive cases, and tracing of close contacts of positive cases. All screening information was kept strictly confidential and was not allowed to be disclosed or used for other purposes other than clinical and public health management. Personal information of asymptomatic positive cases was only disclosed to designated medical institutions and community health centres for the purpose of medical isolation and identification of close contacts. Researcher was blind to the study hypothesis during data collection.

Biological security guarantee. Nucleic acid testing was performed in biosafety level-2 (BSL-2) laboratories, and virus culture was conducted in biosafety level-3 laboratories. Sampling and testing personnel adopted the personal protective measures according to the standard of biosafety level-3 laboratories. Participating laboratories implemented control measures to guarantee biological safety in accordance with relevant regulations[17].

Result query and feedback. Two to three days after sample collection, participants could inquire about their test results using WeChat or Alipay application by their unique ID numbers. The results included text descriptions of nucleic acid testing and coloured health codes. A green coloured health code refers to a negative result, and a red coloured health code indicates a positive result.

Definition and management of identified confirmed cases and close contacts. In this study, all confirmed COVID-19 cases were diagnosed by designated medical institutions according to National Guidelines for the Prevention and Control of COVID-19 (Supplementary Note 2). Asymptomatic positive cases referred to individuals who had a positive result during screening, and they had neither a history of COVID-19 diagnosis, nor any clinical symptoms at the time of the nucleic acid testing. Close contacts were individuals who closely contacted with an asymptomatic positive person since 2 days before the nucleic acid sampling[16]. Repositive cases refer to individuals who recovered from previously confirmed COVID-19 disease and had a positive testing again in the screening programme. All repositive cases, asymptomatic positive persons, and their close contacts were

isolated for at least 2 weeks in designated hotels managed by primary health care professionals, and they were released from isolation only if two consecutive nucleic acid tests were negative.

Statistical analysis. Detection rate of asymptomatic positive or repositive cases was calculated by dividing the number of individuals with a positive result of nucleic acid testing by the number of participants tested. Because of extremely low detection rates, we calculated 95% confidence intervals of estimated proportions using Pearson–Klopper exact method, implemented through R package "binom" version 1.1-1[18]. SPSS version 22.0 was used for other statistical analyses. We analyzed the distribution of asymptomatic positive cases and assessed the Spearman correlation between the asymptomatic positive rate and the prevalence of previously confirmed COVID-19 cases in different districts of Wuhan. Differences in asymptomatic positive rates by sex and age groups were assessed using the χ^2 test. ArcGIS 10.0 was used to draw a geographic distribution map of asymptomatic positive cases. A value of $P < 0.05$ (two-tailed) was considered statistically significant.

Reporting summary. Further information on research design is available in the Nature Research Reporting Summary linked to this article.

Data availability

Detailed data directly used to generate each figure or table of this study are available within the article, Supplementary Information and source data are provided with this paper.

Acknowledgements

We would like to thank all institutions and all citizens in Wuhan for their support for citywide nucleic acid screening work. We also would like to thank the Wuhan city government for this citywide nucleic acid testing, sampling and management, and thank the big data and investigation group of COVID-19 prevention and control institution in Wuhan (the data and investigation group of Wuhan Municipal Health Commission) for their efforts in the data collection. In addition, we would like to thank the National Social Science Foundation of China (Grant No. 18ZDA085) for supporting the fund.

Author contributions

S.Y.C., C.W., X.X.Y., and Z.X.L. conceived the study. C.W., Y.C.H., T.T.W., K.L., H.B.X., and X.S. participated in the acquisition of data. S.B.W. and J.G. were responsible for the on-site specimen collection, laboratory testing quality evaluation, and control. Y.C.H., T.T.W., and L.Q.L. analyzed the data. H.J., Y.H.G., and F.J.S. gave advice on methodology. Q.F.T. and C.Z.L. investigated the responses to the citywide nucleic acid testing among residents lived in outside of Wuhan city. S.Y.C., Y.G., C.W., and X.X.Y. drafted the manuscript, Y.G., M.B., and F.J.S. revised the manuscript, and M.B., C.Z.L., and F.J.S. critically commented and edited the manuscript. All authors read and approved the final manuscript. Z.X.L. is the guarantor of this study.

Contact Tracing Assessment of COVID-19 Transmission Dynamics in Taiwan and Risk at Different Exposure Periods Before and After Symptom Onset

Hao-Yuan Cheng, MD, MSc; Shu-Wan Jian, DVM, MPH; Ding-Ping Liu, PhD; Ta-Chou Ng, BSc; Wan-Ting Huang, MD; Hsien-Ho Lin, MD, ScD; for the Taiwan COVID-19 Outbreak Investigation Team

IMPORTANCE The dynamics of coronavirus disease 2019 (COVID-19) transmissibility are yet to be fully understood. Better understanding of the transmission dynamics is important for the development and evaluation of effective control policies.

OBJECTIVE To delineate the transmission dynamics of COVID-19 and evaluate the transmission risk at different exposure window periods before and after symptom onset.

DESIGN, SETTING, AND PARTICIPANTS This prospective case-ascertained study in Taiwan included laboratory-confirmed cases of COVID-19 and their contacts. The study period was from January 15 to March 18, 2020. All close contacts were quarantined at home for 14 days after their last exposure to the index case. During the quarantine period, any relevant symptoms (fever, cough, or other respiratory symptoms) of contacts triggered a COVID-19 test. The final follow-up date was April 2, 2020.

MAIN OUTCOMES AND MEASURES Secondary clinical attack rate (considering symptomatic cases only) for different exposure time windows of the index cases and for different exposure settings (such as household, family, and health care).

RESULTS We enrolled 100 confirmed patients, with a median age of 44 years (range, 11-88 years), including 44 men and 56 women. Among their 2761 close contacts, there were 22 paired index-secondary cases. The overall secondary clinical attack rate was 0.7% (95% CI, 0.4%-1.0%). The attack rate was higher among the 1818 contacts whose exposure to index cases started within 5 days of symptom onset (1.0% [95% CI, 0.6%-1.6%]) compared with those who were exposed later (0 cases from 852 contacts; 95% CI, 0%-0.4%). The 299 contacts with exclusive presymptomatic exposures were also at risk (attack rate, 0.7% [95% CI, 0.2%-2.4%]). The attack rate was higher among household (4.6% [95% CI, 2.3%-9.3%]) and nonhousehold (5.3% [95% CI, 2.1%-12.8%]) family contacts than that in health care or other settings. The attack rates were higher among those aged 40 to 59 years (1.1% [95% CI, 0.6%-2.1%]) and those aged 60 years and older (0.9% [95% CI, 0.3%-2.6%]).

CONCLUSIONS AND RELEVANCE In this study, high transmissibility of COVID-19 before and immediately after symptom onset suggests that finding and isolating symptomatic patients alone may not suffice to contain the epidemic, and more generalized measures may be required, such as social distancing.

The coronavirus disease 2019 (COVID-19) outbreak that originated in Wuhan, China, spread to more than 100 countries within 2 months of when the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) was identified in January 2020.[1,2] Following the Wuhan lockdown and other extreme social-distancing measures conducted by the Chinese government, several countries with widespread outbreaks implemented similar measures, including shutting down entire cities or communities, banning international or domestic travel, conducting border control with symptom screening, and implementing isolation and quarantine.

The unknown epidemiologic characteristics and transmission dynamics of a novel pathogen, such as SARS-CoV-2, complicate the development and evaluation of effective control policies.[3] The serial interval of COVID-19, defined as the interval between the symptom onset of the index case and that of the secondary case, was found to be short (4-5 days) and was similar to the estimated incubation period.[4] The short serial interval of COVID-19 and results from viral shedding studies suggested that most transmission occurred near or even before the time of symptom onset.[4-6] On the other hand, prolonged viral shedding raised concerns about prolonged infectiousness of patients and the need for extended isolation. A few preliminary contact-tracing studies showed that the highest-risk exposure setting of COVID-19 transmission was the household.[7-9] Nevertheless, it is not known when and how long a patient with COVID-19 should be isolated or whether close contacts should be quarantined. Additional information is needed about the transmission risk at different time points before and after symptom onset and with different types of exposures, such as through the household or a health care facility.

In Taiwan, the first COVID-19 case was confirmed on January 21, 2020.[10] With proactive containment efforts and comprehensive contact tracing, the number of COVID-19 cases remained low, as compared with other countries that had widespread outbreaks.[11,12] Using the contact tracing data in Taiwan, we aimed to delineate the transmission dynamics of COVID-19, evaluate the infection risk at different exposure windows, and estimate the infectious period.

Key Points

Question What is the transmissibility of coronavirus disease 2019 (COVID-19) to close contacts?

Findings In this case-ascertained study of 100 cases of confirmed COVID-19 and 2761 close contacts, the overall secondary clinical attack rate was 0.7%. The attack rate was higher among contacts whose exposure to the index case started within 5 days of symptom onset than those who were exposed later.

Meaning High transmissibility of COVID-19 before and immediately after symptom onset suggests that finding and isolating symptomatic patients alone may not suffice to interrupt transmission, and that more generalized measures might be required, such as social distancing.

Methods

Study Population

On January 15, 2020, in response to the outbreak in Wuhan, the Taiwan Centers for Disease Control (Taiwan CDC) made COVID-19 a notifiable disease. We conducted a prospective case-ascertained study that enrolled all the initial 100 confirmed cases in Taiwan between January 15 and March 18, 2020, and their close contacts. All contacts were followed up until 14 days after the last exposure to the index case. The last follow-up date was April 2, 2020.

The study followed the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) reporting guideline.[13] Information was collected according to the pronouncement of the Central Epidemic Command Center and in accordance with Article 17 of the Communicable Disease Control Act.[14] As part of the public health response functions of the Central Epidemic Command Center for surveillance purposes, institutional review board approval of this study and informed consent were waived. Prior to analysis, the data were deidentified.

Ascertainment of Cases

A confirmed case met the criteria of notification for COVID-19 in Taiwan and tested positive by real-time reverse transcriptase–polymerase chain reaction (RT-PCR) test.[15] Detailed information, including demographic and clinical data, was reported to the National Notifiable Disease Surveillance System.[16] The investigation team determined the clinical severity of the confirmed patients following the World Health Organization (WHO) interim guidance.[17]

Contact Tracing for COVID-19

When a patient was laboratory-confirmed to have SARS-CoV-2 infection, a thorough epidemiological investigation, including contact tracing, was implemented by the outbreak investigation team of the Taiwan CDC and local health authorities. The period of investigation started at the date at symptom onset (and could be extended to up to 4 days before symptom onset when epidemiologically indicated) and ended at the date at COVID-19 confirmation. For asymptomatic confirmed cases, the period of investigation was based on the date at confirmation (instead of date at onset) and was determined according to epidemiological investigation. The definition of a close contact was a person who did not wear appropriate personal protection equipment (PPE) while having face-to-face contact with a confirmed case for more than 15 minutes during the investigation period. A contact was listed as a household contact if he or she lived in the same household with the index case. Those listed as family contacts were family members not living in the same household.

For health care settings, medical staff, hospital workers, and other patients in the same setting were included; close contact was defined by contacting an index case within 2 m without appropriate PPE and without a minimal requirement of exposure time. Whether the PPE was regarded as “appropriate” depended on the exposure setting and the procedures performed. For example, for physicians who performed aerosol-generating procedures, such as intubation, an N95 respirator

[b] Defined as the elapsed time between the date at symptom onset of the index case and the first date at exposure. For example, people from the group "<0 days" had their first contact with the index case before the case had any symptoms.

was required. For such procedures, a surgical mask would not be appropriate PPE. Accordingly, the medical staff would be listed as a close contact.

All close contacts were quarantined at home for 14 days after their last exposure to the index case. During the quarantine period, any relevant symptoms (fever, cough, or other respiratory symptoms) of close contacts would trigger RT-PCR testing for COVID-19. For high-risk populations, including household and hospital contacts, RT-PCR was performed regardless of symptoms. Essentially, these high-risk contacts were tested once when they were listed as a close contact. If the initial COVID-19 test result was negative, further testing would only be performed if a close contact developed symptoms during quarantine. The Taiwan CDC used an electronic tracing system (Infectious Disease Contact Tracing Platform and Management System) to follow and record the daily health status of those quarantined contacts.[18] The information collected included age, sex, the index case, date at exposure, and the exposure setting.

Data Processing and Analysis

Paired data of index case and close contacts were extracted from the contact tracing database and outbreak investigation reports. For a family cluster, the index case was determined based on the temporality of symptom onset and review of the epidemiological link. A secondary case was excluded from the paired data if the beginning of exposure was after symptom onset of the secondary case (only applied when the secondary case was symptomatic). For health care contacts, the date at exposure would be the date at admission of the case if the exact date at exposure was not recorded.

Incubation period and serial interval were estimated using the contact tracing data in Taiwan and publicly available data sets globally (eMethods in the Supplement). We used the Bayesian hierarchical model to increase the stability in small-sample estimation. The exposure window period was defined as the period between the first and last day of reported exposure to the index case based on contact investigation. Following the WHO, we defined the secondary clinical attack rate as the ratio of symptomatic confirmed cases among the close contacts.[19] We analyzed the dynamic change of secondary clinical attack rate in relation to symptom onset of the index case (days <0, 0-3, 4-5, 6-7, 8-9, or >9).

The percentage of missing information was small (7.0% for age, 6.1% for sex, and 3.3% for time from onset to exposure; **Table 1**). In the univariable analysis of secondary clinical attack rate by different exposure characteristics (eg, age), close contacts with missing information in that particular exposure attribute were excluded. All statistical tests were 2-sided with an α level of .05. All confidence intervals (CIs) were 95%. R software (R Foundation for Statistical Computing) and RStan (Stan Development Team) were used for data management and analysis.

Results

As of March 18, 2020, there were 100 patients with laboratory-confirmed COVID-19 in Taiwan, including 10 clusters of patients and 9 asymptomatic patients. The median age of the 100 patients was 44 years old (range, 11-88 years); 44 were men and 56 were women. Of the 2761 close contacts that were identi-

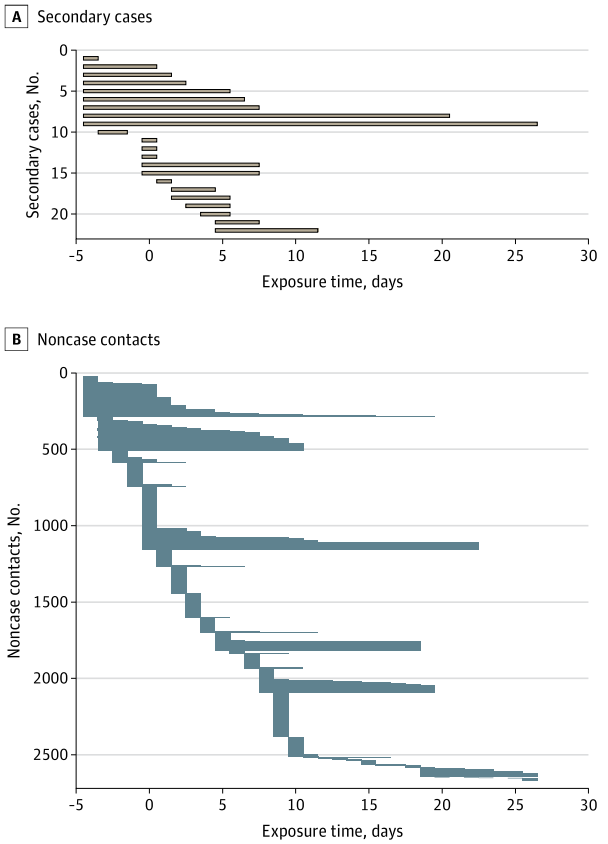
Downloaded From: https://jamanetwork.com/ on 06/16/2021

fied, 5.5% were household contacts, 2.8% were nonhousehold family contacts, and 25.3% were health care contacts (Table 1). Through contact tracing, 23 secondary cases were found. One of the 23 cases was excluded from subsequent transmission-pair analysis because the documented day at exposure occurred after symptom onset of the secondary case. None of the 9 asymptomatic case patients transmitted a secondary case. Using the data on the 22 paired cases, we estimated that the median incubation period was 4.1 days (95% credible interval [CrI], 0.4-15.8), and the median serial interval was 4.1 days (95% CrI, 0.1-27.8) (eTables 1-5 and eFigures 1-5 in the Supplement).

Among the 2761 close contacts, 22 secondary cases of COVID-19 infection (including 4 asymptomatic infections) were detected, with an infection risk of 0.8% (95% CI, 0.5%-1.2%). The secondary clinical attack rate was 18 of 2761, or 0.7% (95% CI, 0.4%-1.0%). **Figure 1** shows the exposure window of all contacts. All of the 22 secondary cases had their first exposure before the sixth day of the index case's symptom onset. By comparison, only 68% of noncase contacts had their first exposure before day 6 (Table 1). The secondary clinical attack rate was higher among those whose initial exposure to the index case was within 5 days of symptom onset than those who were exposed after day 6 (zero transmission of 852 contacts [95% CI, 0%-0.4%]) (**Table 2** and **Figure 2**A). The 735 contacts whose initial exposure occurred before symptom onset of the index case were also at risk, with a secondary clinical attack rate of 1.0% (95% CI, 0.5%-2.0%). A subgroup of 299 contacts with exclusive presymptomatic exposures were also at risk (secondary clinical attack rate, 0.7% [95% CI, 0.2%-2.4%]).

The secondary clinical attack rate was 4.6% (95% CI, 2.3%-9.3%) among 151 household contacts and 5.3% (95% CI, 2.1%-12.8%) in 76 nonhousehold family contacts (Table 2). The high attack rate from early exposure remained when the analysis was restricted to household and nonhousehold family contacts (**Table 3** and Figure 2B). The attack rates were higher among those aged 40 to 59 years (1.1% [95% CI, 0.6%-2.1%]) and those aged 60 years and older (0.9% [95% CI, 0.3%-2.6%]). The 786 close contacts of the 6 confirmed cases presenting with severe disease were at a higher risk compared with the 1097 close contacts of the 56 cases presenting with mild disease (risk ratio, 3.76 [95% CI, 1.10-12.76] and 3.99 [95% CI, 1.00-15.84] for severe pneumonia and acute respiratory distress syndrome/sepsis, respectively). Among the 91 close contacts of the 9 asymptomatic cases, no secondary transmission was observed. The secondary attack rate among contacts of cases with infection acquired in Taiwan was higher than that among contacts of cases with infection acquired outside of Taiwan (Table 2).

Figure 1. Exposure Window Period Among Secondary Cases and Noncase Contacts



The exposure time was defined as the period from the first day of exposure to the index case to the last day of exposure. Time zero indicates the day of symptom onset of the index case.

Discussion

Our analysis of close contacts to confirmed COVID-19 cases revealed a relatively short infectious period of COVID-19 and a higher transmission risk around the time of symptom onset of the index case, followed by a lower transmission risk at the later stage of disease. The observed decreasing transmission risk over time for COVID-19 was in striking contrast to the transmission pattern of severe acute respiratory syndrome (SARS), in which the transmission risk remained low until after day 5 of symptom onset in the index cases.[20] Our study and the study by Nishiura et al[4] revealed a short serial interval of COVID-19, with a median of 4 to 5 days. In contrast, the mean serial interval of SARS was estimated to be 8.4 days in Singapore.[20] The present contact tracing analysis suggested that the shorter serial interval of COVID-19 was due to the combination of early-stage transmission and a short period of infectiousness.

The observed pattern of the secondary clinical attack rate over time was also consistent with the quantitative data of the SARS-CoV-2 viral shedding in upper respiratory specimens, which has been found in China to be a high viral load around the time of symptom onset, followed by a gradual decrease in viral shedding to a low level after 10 days.[5] The viral load was similar among asymptomatic, minimally symptomatic, and symptomatic patients. Another virological study in patients with COVID-19 in Germany also found no viable isolates of the virus after the first week of symptoms.[21] Our findings agree with the virological data on high transmissibility of COVID-19 in the first week after the onset of symptoms and decreased risk afterwards.[21] We also documented and quantified the

[c] All the reported exposures occurred during the presymptomatic period of the index case.

transmission potential of COVID-19 in a subgroup of contacts whose exposure occurred exclusively during the presymptomatic period of the index case. Our analysis revealed a similar clinical attack rate between the contacts who only had presymptomatic exposure and those who had postsymptomatic exposure.

To summarize the evidence, the decreasing risk for secondary infection over time in our study, the observed short serial interval, and the trend of decreasing viral shedding and viability after symptom onset strongly suggested high transmissibility of the disease near or even before the day of symptom onset. Because the onset of overt clinical symptoms, such as fever, dyspnea, and signs of pneumonia, usually occurred 5 to 7 days after initial symptom onset, the infection might well have been transmitted at or before the time of detection.[22,23] This characteristic makes containment efforts challenging. In a modeling study, Hellewell et al[24] found that the possibility of controlling COVID-19 through isolation and contact tracing decreased with increasing proportion of transmission that occurred before symptom onset. The findings of this modeling study, when viewed in the context of our findings, might help to explain the difficult situation in such areas and countries as China, South Korea, Iran, and Italy. Aggressive social distancing and proactive contact tracing might be necessary to block the transmission chain of COVID-19 and to keep presumptive patients away from susceptible populations with a high risk for severe disease.

The observed short duration of infectiousness with lower risk of transmission 1 week after symptom onset has important implications for redirecting the efforts to control COVID-19. Given the nonspecific and mostly mild symptoms of COVID-19 at presentation, patients are often identified and hospitalized at a later stage of disease when the transmissibility of infection has started to decrease. In this case, hospitalization would not be helpful for isolation and reducing transmission, and should be only for patients whose clinical course is sufficiently severe. When the number of confirmed cases rapidly increases, home care for patients with mild illness may be

[b] Secondary clinical attack rate.

preferred.[25] In Taiwan (where patients with COVID-19 have been routinely hospitalized), the most prolonged duration of hospital isolation for the 100 confirmed cases was more than 2 months. If every patient with mild illness is to be isolated in the hospital or other isolation facilities for such a prolonged period during a large epidemic, the health care system would soon be overwhelmed, and the case-fatality rate may increase, as observed in Wuhan.[26,27] Similarly, better understanding of the potential duration of transmission could help direct containment strategies. For example, contact tracing could focus on the contacts near or even before symptom onset of the index cases when the number of index cases or contacts is too large for all contacts to be traced, given the available resources.

Several patients in our study were initially considered to have pneumonia of unknown etiology and had multiple contacts in the health care setting before being diagnosed. However, the number of health care contacts that led to nosocomial transmission was low. Besides the basic PPE used by medical staffs, this finding might be due to the late admissions of these patients and their lower risk of transmitting COVID-19 by the time of hospitalization. This pattern is compatible with the observations in China and Hong Kong. In China, the number of nosocomial infections might be lower than reported because some health care workers acquired infections in their households rather than in the health care faciltiy.[9] In Hong Kong, most hospitalization was also delayed to at least 5 days after disease onset.[28] In closed settings such as a hospital or a cruise ship,[29,30] fomite transmission might play an important role, amplifying the risk of transmission and making the temporality of transmission less identifiable.[30-32] Better understanding of the dynamic change of transmissibility of COVID-19 over time and how health care workers are most likely to be infected could allow for better targeting of control measures, including the use of appropriate PPE.

In the contact tracing cohort, we observed a relatively low transmission rate of COVID-19. During the study period (January to early March 2020), the major containment measures in Taiwan were travel alerts with restriction to affected countries (principally China), home quarantine for travelers entering Taiwan, and comprehensive contact tracing for confirmed cases.[11] In response to a possible shortage of face masks,

Downloaded From: https://jamanetwork.com/ on 06/16/2021

the government proactively initiated a name-based rationing system for mask purchase and boosted the production of face masks to ensure the availability for both N95 respirators and face masks to both health care professionals and the general public. A general recommendation on social distancing from the government was not in place, but spontaneous behavioral changes that reduced community mobility were observed.[33]

Limitations

Our study has limitations. First, we did not completely examine contacts before the symptom onset of the index cases. Therefore, we might have underestimated the importance of early transmission. Thus, the actual contribution of early transmission to new infections could be greater than our estimates suggests. Our findings agree with the recommendation from the WHO to use 4 days before symptom onset as the starting date for contact tracing.[19] This modification may help to further understand the pattern of early transmission in COVID-19. Second, we could not completely separate out the effect of close household contact and early contact given the strong correlation of the 2. The increased transmissibility in the early stage of COVID-19 may be partially attributed to the effect of household and nonhousehold family contacts rather than increased infectiousness at the early stage. When we stratified by type of exposure, however, the pattern of early transmission remained.

Conclusions

In summary, the findings of this study suggest that most transmission of COVID-19 occurred at the very early stage of the disease or even before the onset of symptoms, and the secondary clinical attack rate among contacts decreased over time as symptoms developed and progressed. The pattern of high transmissibility near and before symptom onset and the likely short infectious period of the virus could inform control strategies for COVID-19, as well as additional studies to fully elucidate the transmission dynamics of the virus.

ARTICLE INFORMATION

Accepted for Publication: April 21, 2020.

Published Online: May 1, 2020. doi:10.1001/jamainternmed.2020.2020

Correction: This article was corrected on September 8, 2020, to fix transposed numbers of men and women study participants in the Abstract and in the Results section; an error in the definition of serial interval in the Introduction; the misspelling of 2 names in the Group Information section; and typographical data errors in the Supplement.

Open Access: This is an open access article distributed under the terms of the CC-BY License. © 2020 Cheng H-Y et al. *JAMA Internal Medicine*.

Author Contributions: Drs Cheng and Lin had full access to all of the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis.
Concept and design: Cheng, Jian, Huang, Lin.
Acquisition, analysis, or interpretation of data: All authors.
Drafting of the manuscript: Cheng, Jian, Ng, Lin.
Critical revision of the manuscript for important intellectual content: Cheng, Jian, Liu, Huang, Lin.
Statistical analysis: Cheng, Jian, Ng, Lin.
Obtained funding: Lin.

Editor's Note

Contact Tracing, Testing, and Control of COVID-19—Learning From Taiwan

Robert Steinbrook, MD

Taiwan is a country of about 24 million people, 81 miles off the coast of mainland China. As of late April 2020, Taiwan had about 330 confirmed cases of coronavirus disease 2019 (COVID-19) and 6 deaths. By comparison, the US had about 1 million confirmed cases of COVID-19, and 60 000 deaths.

In this issue of *JAMA Internal Medicine*, there is a remarkable report from Taiwan on the use of contact tracing and virologic polymerase chain reaction testing to assess the transmission dynamics of COVID-19 in the country's initial 100 confirmed cases.[1] Among 2761 close contacts of the 100 cases, confirmed between January 15 and March 18, 2020, Cheng et al report that there were 22 paired-index secondary cases and an overall secondary clinical attack rate of 0.7% (95% CI, 0.4%-1.0%).[1]

Related article page 1156 and 1262

The study has important messages for the control of COVID-19 throughout the world. First, people with COVID-19 were found to be most infectious to others before and within 5 days of symptom onset. Within 5 days of symptom onset, the attack rate was 1.0% (95% CI, 0.6%-1.5%). With exclusive presymptomatic exposures, the attack rate was 0.7% (95% CI, 0.2%-2.4%), and with exposures 6 days or more after symptom onset, there were 0 cases from 852 contacts (95% CI, 0%-0.4%).[1]

These findings underscore the pressing public health need for accurate and comprehensive contact tracing and testing. Testing only those people who are symptomatic will miss many infections and render contact tracing less effective. The finding that asymptomatic people and those with minimal or fewer symptoms early in infection are those most likely to transmit COVID-19 strongly argues for maintaining social distancing and

Mask use in the context of COVID-19

Interim guidance

1 December 2020

World Health Organization

This document, which is an update of the guidance published on 5 June 2020, includes new scientific evidence relevant to the use of masks for reducing the spread of SARS-CoV-2, the virus that causes COVID-19, and practical considerations. It contains updated evidence and guidance on the following:

- mask management;
- SARS-CoV-2 transmission;
- masking in health facilities in areas with community, cluster and sporadic transmission;
- mask use by the public in areas with community and cluster transmission;
- alternatives to non-medical masks for the public;
- exhalation valves on respirators and non-medical masks;
- mask use during vigorous intensity physical activity;
- essential parameters to be considered when manufacturing non-medical masks (Annex).

Key points

- The World Health Organization (WHO) advises the use of masks as part of a comprehensive package of prevention and control measures to limit the spread of SARS-CoV-2, the virus that causes COVID-19. A mask alone, even when it is used correctly, is insufficient to provide adequate protection or source control. Other infection prevention and control (IPC) measures include hand hygiene, physical distancing of at least 1 metre, avoidance of touching one's face, respiratory etiquette, adequate ventilation in indoor settings, testing, contact tracing, quarantine and isolation. Together these measures are critical to prevent human-to-human transmission of SARS-CoV-2.
- Depending on the type, masks can be used either for protection of healthy persons or to prevent onward transmission (source control).
- WHO continues to advise that anyone suspected or confirmed of having COVID-19 or awaiting viral laboratory test results should wear a medical mask when in the presence of others (this does not apply to those awaiting a test prior to travel).
- For any mask type, appropriate use, storage and cleaning or disposal are essential to ensure that they are as effective as possible and to avoid an increased transmission risk.

Mask use in health care settings

- WHO continues to recommend that health workers (1) providing care to suspected or confirmed COVID-19 patients wear the following types of mask/respirator in addition to other personal protective equipment that are part of standard, droplet and contact precautions:
  - medical mask in the absence of aerosol generating procedures (AGPs)
  - respirator, N95 or FFP2 or FFP3 standards, or equivalent in care settings for COVID-19 patients where AGPs are performed; these may be used by health workers when providing care to COVID-19 patients in other settings if they are widely available and if costs is not an issue.
- In areas of known or suspected community or cluster SARS-CoV-2 transmission WHO advises the following:
  - universal masking for all persons (staff, patients, visitors, service providers and others) within the health facility (including primary, secondary and tertiary care levels; outpatient care; and long-term care facilities)
  - wearing of masks by inpatients when physical distancing of at least 1 metre cannot be maintained or when patients are outside of their care areas.
- In areas of known or suspected sporadic SARS-CoV-2 transmission, health workers working in clinical areas where patients are present should continuously wear a medical mask. This is known as targeted continuous medical masking for health workers in clinical areas;
- Exhalation valves on respirators are discouraged as they bypass the filtration function for exhaled air by the wearer.

Mask use in community settings

- Decision makers should apply a risk-based approach when considering the use of masks for the general public.
- In areas of known or suspected community or cluster SARS-CoV-2 transmission:
  - WHO advises that the general public should wear a non-medical mask in indoor (e.g. shops, shared workplaces, schools - see Table 2 for details) or outdoor settings where physical distancing of at least 1 metre cannot be maintained.
  - If indoors, unless ventilation has been be assessed to be adequate[1], WHO advises that the general public should wear a non-medical mask, regardless of whether physical distancing of at least 1 metre can be maintained.

[1] For adequate ventilation refer to regional or national institutions or heating, refrigerating and air-conditioning societies enacting ventilation requirements. If not available or applicable, a recommended ventilation rate of 10 l/s/person should be met (except healthcare facilities which have specific requirements). For more information consult "Coronavirus (COVID-19) response

  - Individuals/people with higher risk of severe complications from COVID-19 (individuals ≥ 60 years old and those with underlying conditions such as cardiovascular disease or diabetes mellitus, chronic lung disease, cancer, cerebrovascular disease or immunosuppression) should wear medical masks when physical distancing of at least 1 metre cannot be maintained.
- In any transmission scenarios:
  - Caregivers or those sharing living space with people with suspected or confirmed COVID-19, regardless of symptoms, should wear a medical mask when in the same room.

Mask use in children (2)

- Children aged up to five years should not wear masks for source control.
- For children between six and 11 years of age, a risk-based approach should be applied to the decision to use a mask; factors to be considered in the risk-based approach include intensity of SARS-CoV-2 transmission, child's capacity to comply with the appropriate use of masks and availability of appropriate adult supervision, local social and cultural environment, and specific settings such as households with elderly relatives, or schools.
- Mask use in children and adolescents 12 years or older should follow the same principles as for adults.
- Special considerations are required for immunocompromised children or for paediatric patients with cystic fibrosis or certain other diseases (e.g., cancer), as well as for children of any age with developmental disorders, disabilities or other specific health conditions that might interfere with mask wearing.

Manufacturing of non-medical (fabric) masks (Annex)

- Homemade fabric masks of three-layer structure (based on the fabric used) are advised, with each layer providing a function: 1) an innermost layer of a hydrophilic material 2) an outermost layer made of hydrophobic material 3) a middle hydrophobic layer which has been shown to enhance filtration or retain droplets.
- Factory-made fabric masks should meet the minimum thresholds related to three essential parameters: filtration, breathability and fit.
- Exhalation valves are discouraged because they bypass the filtration function of the fabric mask rendering it unserviceable for source control.

Methodology for developing the guidance

Guidance and recommendations included in this document are based on published WHO guidelines (in particular the WHO Guidelines on infection prevention and control of epidemic- and pandemic-prone acute respiratory infections in health care) (2) and ongoing evaluations of all available scientific evidence by the WHO ad hoc COVID-19 Infection Prevention and Control Guidance Development Group (COVID-19 IPC GDG) (see acknowledgement section for list of GDG members). During emergencies WHO publishes interim guidance, the development of which follows a transparent and robust process of evaluation of the available evidence on benefits and harms. This evidence is evaluated through expedited systematic reviews and expert consensus-building through weekly GDG consultations, facilitated by a methodologist and, when necessary, followed up by surveys. This process also considers, as much as possible, potential resource implications, values and preferences, feasibility, equity, and ethics. Draft guidance documents are reviewed by an external review panel of experts prior to publication.

Purpose of the guidance

This document provides guidance for decision makers, public health and IPC professionals, health care managers and health workers in health care settings (including long-term care and residential), for the public and for manufactures of non-medical masks (Annex). It will be revised as new evidence emerges.

WHO has also developed comprehensive guidance on IPC strategies for health care settings (3), long-term care facilities (LTCF) (4), and home care (5).

Background

The use of masks is part of a comprehensive package of prevention and control measures that can limit the spread of certain respiratory viral diseases, including COVID-19. Masks can be used for protection of healthy persons (worn to protect oneself when in contact with an infected individual) or for source control (worn by an infected individual to prevent onward transmission) or both.

However, the use of a mask alone, even when correctly used (see below), is insufficient to provide an adequate level of protection for an uninfected individual or prevent onward transmission from an infected individual (source control). Hand hygiene, physical distancing of at least 1 metre, respiratory etiquette, adequate ventilation in indoor settings, testing, contact tracing, quarantine, isolation and other infection prevention and control (IPC) measures are critical to prevent human-to-human transmission of SARS-CoV-2, whether or not masks are used (6).

Mask management

For any type of mask, appropriate use, storage and cleaning, or disposal are essential to ensure that they are as effective as possible and to avoid any increased risk of transmission. Adherence to correct mask management practices varies, reinforcing the need for appropriate messaging (7).

WHO provides the following guidance on the correct use of masks:

- Perform hand hygiene before putting on the mask.
- Inspect the mask for tears or holes, and do not use a damaged mask.
- Place the mask carefully, ensuring it covers the mouth and nose, adjust to the nose bridge and tie it securely to minimize any gaps between the face and the mask. If using ear loops, ensure these do not cross over as this widens the gap between the face and the mask.

resources from ASHRAE and others''
https://www.ashrae.org/technical-resources/resources

- Avoid touching the mask while wearing it. If the mask is accidently touched, perform hand hygiene.
- Remove the mask using the appropriate technique. Do not touch the front of the mask, but rather untie it from behind.
- Replace the mask as soon as it becomes damp with a new clean, dry mask.
- Either discard the mask or place it in a clean plastic resealable bag where it is kept until it can be washed and cleaned. Do not store the mask around the arm or wrist or pull it down to rest around the chin or neck.
- Perform hand hygiene immediately afterward discarding a mask.
- Do not re-use single-use mask.
- Discard single-use masks after each use and properly dispose of them immediately upon removal.
- Do not remove the mask to speak.
- Do not share your mask with others.
- Wash fabric masks in soap or detergent and preferably hot water (at least 60° Centigrade/140° Fahrenheit) at least once a day. If it is not possible to wash the masks in hot water, then wash the mask in soap/detergent and room temperature water, followed by boiling the mask for 1 minute.

Scientific evidence

Transmission of the SARS-CoV-2 virus

Knowledge about transmission of the SARS-CoV-2 virus is evolving continuously as new evidence accumulates. COVID-19 is primarily a respiratory disease, and the clinical spectrum can range from no symptoms to severe acute respiratory illness, sepsis with organ dysfunction and death.

According to available evidence, SARS-CoV-2 mainly spreads between people when an infected person is in close contact with another person. Transmissibility of the virus depends on the amount of viable virus being shed and expelled by a person, the type of contact they have with others, the setting and what IPC measures are in place. The virus can spread from an infected person's mouth or nose in small liquid particles when the person coughs, sneezes, sings, breathes heavily or talks. These liquid particles are different sizes, ranging from larger 'respiratory droplets' to smaller 'aerosols.' Close-range contact (typically within 1 metre) can result in inhalation of, or inoculation with, the virus through the mouth, nose or eyes (8-13).

There is limited evidence of transmission through fomites (objects or materials that may be contaminated with viable virus, such as utensils and furniture or in health care settings a stethoscope or thermometer) in the immediate environment around the infected person (14-17). Nonetheless, fomite transmission is considered a possible mode of transmission for SARS-CoV-2, given consistent finding of environmental contamination in the vicinity of people infected with SARS-CoV-2 and the fact that other coronaviruses and respiratory viruses can be transmitted this way (12).

Aerosol transmission can occur in specific situations in which procedures that generate aerosols are performed. The scientific community has been actively researching whether the SARS-CoV-2 virus might also spread through aerosol transmission in the absence of aerosol generating procedures (AGPs) (18, 19). Some studies that performed air sampling in clinical settings where AGPs were not performed found virus RNA, but others did not. The presence of viral RNA is not the same as replication- and infection-competent (viable) virus that could be transmissible and capable of sufficient inoculum to initiate invasive infection. A limited number of studies have isolated viable SARS-CoV-2 from air samples in the vicinity of COVID-19 patients (20, 21).

Outside of medical facilities, in addition to droplet and fomite transmission, aerosol transmission can occur in specific settings and circumstances, particularly in indoor, crowded and inadequately ventilated spaces, where infected persons spend long periods of time with others. Studies have suggested these can include restaurants, choir practices, fitness classes, nightclubs, offices and places of worship (12).

High quality research is required to address the knowledge gaps related to modes of transmission, infectious dose and settings in which transmission can be amplified. Currently, studies are underway to better understand the conditions in which aerosol transmission or superspreading events may occur.

Current evidence suggests that people infected with SARS-CoV-2 can transmit the virus whether they have symptoms or not. However, data from viral shedding studies suggest that infected individuals have highest viral loads just before or around the time they develop symptoms and during the first 5-7 days of illness (12). Among symptomatic patients, the duration of infectious virus shedding has been estimated at 8 days from the onset of symptoms (22-24) for patients with mild disease, and longer for severely ill patients (12). The period of infectiousness is shorter than the duration of detectable RNA shedding, which can last many weeks (17).

The incubation period for COVID-19, which is the time between exposure to the virus and symptom onset, is on average 5-6 days, but can be as long as 14 days (25, 26).

Pre-symptomatic transmission – from people who are infected and shedding virus but have not yet developed symptoms – can occur. Available data suggest that some people who have been exposed to the virus can test positive for SARS-CoV-2 via polymerase chain reaction (PCR) testing 1-3 days before they develop symptoms (27). People who develop symptoms appear to have high viral loads on or just prior to the day of symptom onset, relative to later on in their infection (28).

Asymptomatic transmission – transmission from people infected with SARS-CoV-2 who never develop symptoms – can occur. One systematic review of 79 studies found that 20% (17–25%) of people remained asymptomatic throughout the course of infection. (28). Another systematic review, which included 13 studies considered to be at low risk of bias, estimated that 17% of cases remain asymptomatic (14%–20%) (30). Viable virus has been isolated from specimens of pre-symptomatic and asymptomatic individuals, suggesting that people who do not have symptoms may be able to transmit the virus to others. (25, 29-37)

Studies suggest that asymptomatically infected individuals are less likely to transmit the virus than those who develop symptoms (29). A systematic review concluded that individuals who are asymptomatic are responsible for transmitting fewer infections than symptomatic and pre-symptomatic cases (38). One meta-analysis estimated that there is a 42% lower relative risk of asymptomatic transmission compared to symptomatic transmission (30).

Guidance on mask use in health care settings

Masks for use in health care settings

Medical masks are defined as surgical or procedure masks that are flat or pleated. They are affixed to the head with straps that go around the ears or head or both. Their performance characteristics are tested according to a set of standardized test methods (ASTM F2100, EN 14683, or equivalent) that aim to balance high filtration, adequate breathability and optionally, fluid penetration resistance (39, 40).

Filtering facepiece respirators (FFR), or respirators, offer a balance of filtration and breathability. However, whereas medical masks filter 3 micrometre droplets, respirators must filter more challenging 0.075 micrometre solid particles. European FFRs, according to standard EN 149, at FFP2 performance there is filtration of at least 94% solid NaCl particles and oil droplets. US N95 FFRs, according to NIOSH 42 CFR Part 84, filter at least 95% NaCl particles. Certified FFRs must also ensure unhindered breathing with maximum resistance during inhalation and exhalation. Another important difference between FFRs and other masks is the way filtration is tested. Medical mask filtration tests are performed on a cross-section of the masks, whereas FFRs are tested for filtration across the entire surface. Therefore, the layers of the filtration material and the FFR shape, which ensure the outer edges of the FFR seal around wearer's face, result in guaranteed filtration as claimed. Medical masks, by contrast, have an open shape and potentially leaking structure. Other FFR performance requirements include being within specified parameters for maximum CO_2 build up, total inward leakage and tensile strength of straps (41, 42).

A. Guidance on the use of medical masks and respirators to provide care to suspected or confirmed COVID-19 cases

Evidence on the use of mask in health care settings

Systematic reviews have reported that the use of N95/P2 respirators compared with the use of medical masks (see mask definitions, above) is not associated with statistically significant differences for the outcomes of health workers acquiring clinical respiratory illness, influenza-like illness (risk ratio 0.83, 95%CI 0.63-1.08) or laboratory-confirmed influenza (risk ratio 1.02, 95%CI 0.73-1.43); harms were poorly reported and limited to discomfort associated with lower compliance (43, 44). In many settings, preserving the supply of N95 respirators for high-risk, aerosol-generating procedures is an important consideration (45).

A systematic review of observational studies on the betacoronaviruses that cause severe acute respiratory syndrome (SARS), Middle East respiratory syndrome (MERS) and COVID-19 found that the use of face protection (including respirators and medical masks) is associated with reduced risk of infection among health workers. These studies suggested that N95 or similar respirators might be associated with greater reduction in risk than medical or 12–16-layer cotton masks. However, these studies had important limitations (recall bias, limited information about the situations when respirators were used and limited ability to measure exposures), and very few studies included in the review evaluated the transmission risk of COVID-19 (46). Most of the studies were conducted in settings in which AGPs were performed or other high-risk settings (e.g., intensive care units or where there was exposure to infected patients and health workers were not wearing adequate PPE).

WHO continues to evaluate the evidence on the effectiveness of the use of different masks and their potential harms, risks and disadvantages, as well as their combination with hand hygiene, physical distancing of at least 1 metre and other IPC measures.

Guidance

WHO's guidance on the type of respiratory protection to be worn by health workers providing care to COVID-19 patients is based on 1) WHO recommendations on IPC for epidemic- and pandemic-prone acute respiratory infections in health care (47); 2) updated systematic reviews of randomized controlled trials on the effectiveness of medical masks compared to that of respirators for reducing the risk of clinical respiratory illness, influenza-like illness (ILI) and laboratory-confirmed influenza or viral infections. WHO guidance in this area is aligned with guidelines of other professional organizations, including the European Society of Intensive Care Medicine and the Society of Critical Care Medicine, and the Infectious Diseases Society of America (48, 49).

The WHO COVID-19 IPC GDG considered all available evidence on the modes of transmission of SARS-CoV-2 and on the effectiveness of medical mask versus respirator use to protect health workers from infection and the potential for harms such as skin conditions or breathing difficulties.

Other considerations included availability of medical masks versus respirators, cost and procurement implications and equity of access by health workers across different settings.

The majority (71%) of the GDG members confirmed their support for previous recommendations issued by WHO on 5 June 2020:

1. In the absence of aerosol generating procedures (AGPs)[2], WHO recommends that health workers providing care to patients with suspected or confirmed COVID-19 should wear a medical mask (in addition to other PPE that are part of droplet and contact precautions).
2. In care settings for COVID-19 patients where AGPs are performed, WHO recommends that health workers should wear a respirator (N95 or FFP2 or FFP3 standard, or equivalent) in addition to other PPE that are part of airborne and contact precautions.

In general, health workers have strong preferences about having the highest perceived protection possible to prevent COVID-19 infection and therefore may place high value on the potential benefits of respirators in settings without AGPs. WHO recommends respirators primarily for settings where AGPs are performed; however, if health workers prefer them and they are sufficiently available and cost is not an issue, they could also be used during care for COVID-19 patients in other settings. For additional guidance on PPE, including PPE

[2] The WHO list of AGPs includes tracheal intubation, non-invasive ventilation, tracheotomy, cardiopulmonary resuscitation, manual ventilation before intubation, bronchoscopy, sputum induction using nebulized hypertonic saline, and dentistry and autopsy procedures.

beyond mask use by health workers, see WHO IPC guidance during health care when COVID-19 infection is suspected (3) and also WHO guidance on the rational use of PPE (45).

Exhalation valves on respirators are discouraged as they bypass the filtration function for exhaled air.

B. Guidance on the use of mask by health workers, caregivers and others based on transmission scenario

Definitions

Universal masking in health facilities is defined as the requirement for all persons (staff, patients, visitors, service providers and others) to wear a mask at all times except for when eating or drinking.

Targeted continuous medical mask use is defined as the practice of wearing a medical mask by all health workers and caregivers working in clinical areas during all routine activities throughout the entire shift.

Health workers are all people primarily engaged in actions with the primary intent of enhancing health. Examples are: nursing and midwifery professionals, doctors, cleaners, other staff who work in health facilities, social workers, and community health workers.

Evidence on universal masking in health care settings

In areas where there is community transmission or large-scale outbreaks of COVID-19, universal masking has been adopted in many hospitals to reduce the potential of transmission by health workers to patients, to other staff and anyone else entering the facility (50).

Two studies found that implementation of a universal masking policy in hospital systems was associated with decreased risk of healthcare-acquired SARS-CoV-2 infection. However, these studies had serious limitations: both were before-after studies describing a single example of a phenomenon before and after an event of interest, with no concurrent control group, and other infection control measures were not controlled for (51, 52). In addition, observed decreases in health worker infections occurred too quickly to be attributable to the universal masking policy.

Guidance

Although more research on universal masking in heath settings is needed, it is the expert opinion of the majority (79%) of WHO COVID-19 IPC GDG members that universal masking is advisable in geographic settings where there is known or suspected community or cluster transmission of the SARS-CoV-2 virus.

1. In areas of known or suspected community or cluster SARS-CoV-2 transmission, universal masking should be advised in all health facilities (see Table 1).

- All health workers, including community health workers and caregivers, should wear a medical mask at all times, for any activity (care of COVID-19 or non-COVID-19 patients) and in any common area (e.g., cafeteria, staff rooms).
- Other staff, visitors, outpatients and service providers should also wear a mask (medical or non-medical) at all times
- Inpatients are not required to wear a mask (medical or non-medical) unless physical distancing of at least 1 metre cannot be maintained (e.g., when being examined or visited at the bedside) or when outside of their care area (e.g., when being transported).
- Masks should be changed when they become soiled, wet or damaged or if the health worker/caregiver removes the mask (e.g., for eating or drinking or caring for a patient who requires droplet/contact precautions for reasons other than COVID-19).

2. In the context of known or suspected sporadic SARS-CoV-2 virus transmission, WHO provides the following guidance:

- Health workers, including community health workers and caregivers who work in clinical areas, should continuously wear a medical mask during routine activities throughout the entire shift, apart from when eating and drinking and changing their medical masks after caring for a patient who requires droplet/contact precautions for other reasons. In all cases, medical masks must be changed when wet, soiled, or damaged; used medical masks should be properly disposed of at the end of the shift; and new clean ones should be used for the next shift or when medical masks are changed.
- It is particularly important to adopt the continuous use of masks in potentially high transmission risk settings including triage, family physician/general practitioner offices; outpatient departments; emergency rooms; COVID-19 designated units; haematology, oncology and transplant units; and long-term health and residential facilities.
- Staff who do not work in clinical areas (e.g., administrative staff) do not need to wear a medical mask during routine activities if they have no exposure to patients.

Whether using masks for universal masking within health facilities or targeted continuous medical mask use throughout the entire shift, health workers should ensure the following:

- Medical mask use should be combined with other measures including frequent hand hygiene and physical distancing among health workers in shared and crowded places such as cafeterias, break rooms, and dressing rooms.
- The medical mask should be changed when wet, soiled, or damaged.
- The medical mask should not be touched to adjust it or if displaced from the face for any reason. If this happens, the mask should be safely removed and replaced, and hand hygiene performed.
- The medical mask (as well as other personal protective equipment) should be discarded and changed after caring for any patient who requires contact/droplet precautions for other pathogens, followed by hand hygiene.
- Under no circumstances should medical masks be shared between health workers or between others wearing them. Masks should be appropriately disposed of whenever removed and not reused.

- A particulate respirator at least as protective as a United States of America (US) National Institute for Occupational Safety and Health-certified N95, N99, US Food and Drug Administration surgical N95, European Union standard FFP2 or FFP3, or equivalent, should be worn in settings for COVID-19 patients where AGPs are performed (see WHO recommendations below). In these settings, this includes continuous use by health workers throughout the entire shift, when this policy is implemented.

Note: Decision makers may consider the transmission intensity in the catchment area of the health facility or community setting and the feasibility of implementing a universal masking policy compared to a policy based on assessed or presumed exposure risk. Decisions need to take into account procurement, sustainability and costs of the policy. When planning masks for all health workers, long-term availability of adequate medical masks (and when applicable, respirators) for all workers should be ensured, in particular for those providing care for patients with confirmed or suspected COVID-19. Proper use and adequate waste management should be ensured.

The potential harms and risks of mask and respirator use in the health facility setting include:

- contamination of the mask due to its manipulation by contaminated hands (53, 54);
- potential self-contamination that can occur if medical masks are not changed when wet, soiled or damaged; or by frequent touching/adjusting when worn for prolonged periods (55);
- possible development of facial skin lesions, irritant dermatitis or worsening acne, when used frequently for long hours (56-58);
- discomfort, facial temperature changes and headaches from mask wearing (44, 59, 60);
- false sense of security leading potentially to reduced adherence to well recognized preventive measures such as physical distancing and hand hygiene; and risk-taking behaviours (61-64);
- difficulty wearing a mask in hot and humid environments
- possible risk of stock depletion due to widespread use in the context of universal masking and targeted continuous mask use and consequent scarcity or unavailability for health workers caring for COVID 19 patients and during health care interactions with non-COVID-19 patients where medical masks or respirators might be required.

Alternatives to medical masks in health care settings

The WHO's disease commodity package (DCP) for COVID-19 recommends medical masks for health workers to be type II or higher (65). Type II medical masks provide a physical barrier to fluids and particulate materials and have bacterial filtration efficiency of ≥98% compared to Type I mask, which has bacterial filtration efficiency of ≥95% and lower fluid resistance (66) In case of stock outs of type II or higher medical masks, health workers should use a type I medical mask as an alternative. Other alternatives such as face shields or fabric masks should be carefully evaluated.

Face shields are designed to provide protection from splashes of biological fluid (particularly respiratory secretions), chemical agents and debris (67, 68) into the eyes. In the context of protection from SARS-CoV-2 transmission through respiratory droplets, face shields are used by health workers as personal protective equipment (PPE) for eye protection in combination with a medical mask or a respirator (69, 70) While a face shield may confer partial protection of the facial area against respiratory droplets, these and smaller droplets may come into contact with mucous membranes or with the eyes from the open gaps between the visor and the face (71,67).

Fabric masks are not regulated as protective masks or part of the PPE directive. They vary in quality and are not subject to mandatory testing or common standards and as such are not considered an appropriate alternative to medical masks for protection of health workers. One study that evaluated the use of cloth masks in a health care facility found that health care workers using 2 ply cotton cloth masks (a type of fabric mask) were at increased risk of influenza-like illness compared with those who wore medical masks (72).

In the context of severe medical mask shortage, face shields alone or in combination with fabric mask may be considered as a last resort (73). Ensure proper design of face shields to cover the sides of the face and below the chin.

As for other PPE items, if production of fabric masks for use in health care settings is proposed locally in situations of shortage or stock out, a local authority should assess the product according to specific minimum performance standards and required technical specifications (see Annex).

Additional considerations for community care settings

Like other health workers, community health workers should apply standard precautions for all patients at all times, with particular emphasis regarding hand and respiratory hygiene, surface and environmental cleaning and disinfection and the appropriate use of PPE. When a patient is suspected or confirmed of having COVID-19, community health workers should always apply contact and droplet precautions. These include the use of a medical mask, gown, gloves and eye protection (74).

IPC measures that are needed will depend on the local COVID-19 transmission dynamics and the type of contact required by the health care activity (see Table 1). The community health workforce should ensure that patients and workforce members apply precautionary measures such as respiratory hygiene and physical distancing of at least 1 metre (3.3 feet). They also may support set-up and maintenance of hand hygiene stations and community education (74). In the context of known or suspected community or cluster transmission, community health workers should wear a medical mask when providing essential routine services (see Table 1).

Table 1. Mask use in health care settings depending on transmission scenario, target population, setting, activity and type*

Transmission scenario	Target population (who)	Setting (where)	Activity (what)	Mask type (which one) *
Known or suspected community or cluster transmission of SARS-CoV-2	Health workers and caregivers	Health facility (including primary, secondary, tertiary care levels, outpatient care, and long-term care facilities)	For any activity in patient-care areas (COVID-19 or non-COVID-19 patients) or in any common areas (e.g., cafeteria, staff rooms)	Medical mask (or respirator if aerosol generating procedures performed)
	Other staff, patients, visitors, service suppliers		For any activity or in any common area	Medical or fabric mask
	Inpatients	In single or multiple-bed rooms	When physical distance of at least 1 metre cannot be maintained	
	Health workers and caregivers	Home visit (for example, for antenatal or postnatal care, or for a chronic condition)	When in direct contact with a patient or when a distance of at least 1 metre cannot be maintained.	Medical mask
		Community	Community outreach programmes/essential routine services	
Known or suspected sporadic transmission of SARS-CoV-2 cases	Health workers and caregivers	Health facility (including primary, secondary, tertiary care levels, outpatient care, and long-term care facilities)	In patient care area- irrespective of whether patients have suspected/confirmed COVID-19	Medical mask
	Other staff, patients, visitors, service suppliers and all others		No routine activities in patient areas	Medical mask not required. Medical mask should be worn if in contact or within 1 metre of patients, or according to local risk assessment
	Health workers and caregivers	Home visit (for example, for antenatal or postnatal care, or for a chronic condition)	When in direct contact or when a distance of at least 1metre cannot be maintained.	Medical mask
		Community	Community outreach programs (e.g., bed net distribution)	
No documented SARS-CoV-2 transmission	Health workers and caregivers	Health facility (including primary, secondary, tertiary care levels, outpatient care, and long-term care facilities)	Providing any patient care	Medical mask use according to standard and transmission-based precautions
		Community	Community outreach programs	
Any transmission scenario	Health workers	Health care facility (including primary, secondary, tertiary care levels, outpatient care, and long-term care facilities), in settings where aerosol generating procedures (AGP) are performed	Performing an AGP on a suspected or confirmed COVID-19 patient or providing care in a setting where AGPs are in place for COVID-19 patients	Respirator (N95 or N99 or FFP2 or FFP3)

**This table refers only to the use of medical masks and respirators. The use of medical masks and respirators may need to be combined with other personal protective equipment and other measures as appropriate, and always with hand hygiene.*

Guidance on mask use in community settings

Evidence on the protective effect of mask use in community settings

At present there is only limited and inconsistent scientific evidence to support the effectiveness of masking of healthy people in the community to prevent infection with respiratory viruses, including SARS-CoV-2 (75). A large randomized community-based trial in which 4862 healthy participants were divided into a group wearing medical/surgical masks and a control group found no difference in infection with SARS-CoV-2 (76). A recent systematic review found nine trials (of which eight were cluster-randomized controlled trials in which clusters of people, versus individuals, were randomized) comparing medical/surgical masks versus no masks to prevent the spread of viral respiratory illness. Two trials were with healthcare workers and seven in the community. The review concluded that wearing a mask may make little or no difference to the prevention of influenza-like illness (ILI) (RR 0.99, 95%CI 0.82 to 1.18) or laboratory confirmed illness (LCI) (RR 0.91, 95%CI 0.66-1.26) (44); the certainty of the evidence was low for ILI, moderate for LCI.

By contrast, a small retrospective cohort study from Beijing found that mask use by entire families before the first family member developed COVID-19 symptoms was 79% effective in reducing transmission (OR 0.21, 0.06-0.79) (77). A case-control study from Thailand found that wearing a medical or non-medical mask all the time during contact with a COVID-19 patient was associated with a 77% lower risk of infection (aOR 0.23; 95% CI 0.09–0.60) (78). Several small observational studies with epidemiological data have reported an association between mask use by an infected person and prevention of onward transmission of SARS-CoV-2 infection in public settings. (8, 79-81).

A number of studies, some peer reviewed (82-86) but most published as pre-prints (87-104), reported a decline in the COVID-19 cases associated with face mask usage by the public, using country- or region-level data. One study reported an association between community mask wearing policy adoption and increased movement (less time at home, increased visits to commercial locations) (105). These studies differed in setting, data sources and statistical methods and have important limitations to consider (106), notably the lack of information about actual exposure risk among individuals, adherence to mask wearing and the enforcement of other preventive measures (107, 108).

Studies of influenza, influenza-like illness and human coronaviruses (not including COVID-19) provide evidence that the use of a medical mask can prevent the spread of infectious droplets from a symptomatic infected person to someone else and potential contamination of the environment by these droplets (75). There is limited evidence that wearing a medical mask may be beneficial for preventing transmission between healthy individuals sharing households with a sick person or among attendees of mass gatherings (44, 109-114).

A meta-analysis of observational studies on infections due to betacoronaviruses, with the intrinsic biases of observational data, showed that the use of either disposable medical masks or reusable 12–16-layer cotton masks was associated with protection of healthy individuals within households and among contacts of cases (46). This could be considered to be indirect evidence for the use of masks (medical or other) by healthy individuals in the wider community; however, these studies suggest that such individuals would need to be in close proximity to an infected person in a household or at a mass gathering where physical distancing cannot be achieved to become infected with the virus. Results from cluster randomized controlled trials on the use of masks among young adults living in university residences in the United States of America indicate that face masks may reduce the rate of influenza-like illness but showed no impact on risk of laboratory-confirmed influenza (115, 116).

Guidance

The WHO COVID-19 IPC GDG considered all available evidence on the use of masks by the general public including effectiveness, level of certainty and other potential benefits and harms, with respect to transmission scenarios, indoor versus outdoor settings, physical distancing and ventilation. Despite the limited evidence of protective efficacy of mask wearing in community settings, in addition to all other recommended preventive measures, the GDG advised mask wearing in the following settings:

1. In areas with known or suspected community or cluster transmission of SARS-CoV-2, WHO advises mask use by the public in the following situations (see Table 2):

   Indoor settings:

   - in public indoor settings where ventilation is known to be poor regardless of physical distancing: limited or no opening of windows and doors for natural ventilation; ventilation system is not properly functioning or maintained; or cannot be assessed;
   - in public indoor settings that have adequate[3] ventilation if physical distancing of at least 1 metre cannot be maintained;
   - in household indoor settings: when there is a visitor who is not a household member and ventilation is known to be poor, with limited opening of windows and doors for natural ventilation, or the ventilation system cannot be assessed or is not properly functioning, regardless of whether physical distancing of at least 1 metre can be maintained;
   - in household indoor settings that have adequate ventilation if physical distancing of at least 1 metre cannot be maintained.

[3] For adequate ventilation refer to regional or national institutions or heating, refrigerating and air-conditioning societies enacting ventilation requirements. If not available or applicable, a recommended ventilation rate of 10 l/s/person should be met (except healthcare facilities which have specific requirements). For more information consult "Coronavirus (COVID-19) response resources from ASHRAE and others''
https://www.ashrae.org/technical-resources/resources

Table 2. Mask use in community settings depending on transmission scenario, setting, target population, purpose and type*

Transmission scenario	Situations/settings (where)	Target Population (who)	Purpose of mask use (why)	Mask type (which one)
Known or suspected community or cluster transmission of SARS-CoV-2	Indoor settings, where ventilation is known to be poor or cannot be assessed or the ventilation system is not properly maintained, regardless of whether physical distancing of at least 1 meter can be maintained	General population in public* settings such as shops, shared workplaces, schools, churches, restaurants, gyms, etc. or in enclosed settings such as public transportation. For households, in indoor settings, when there is a visitor who is not a member of the household	Potential benefit for source control	Fabric mask
	Indoor settings that have adequate [4] ventilation if physical distancing of at least 1 metre cannot be maintained			
	Outdoor settings where physical distancing cannot be maintained	General population in settings such as crowded open-air markets, lining up outside a building, during demonstrations, etc.		
	Settings where physical distancing cannot be maintained, and the individual is at increased risk of infection and/or negative outcomes	Individuals/people with higher risk of severe complications from COVID-19: • People aged ≥60 years • People with underlying comorbidities, such as cardiovascular disease or diabetes mellitus, chronic lung disease, cancer, cerebrovascular disease, immunosuppression, obesity, asthma	Protection	Medical mask
Known or suspected sporadic transmission, or no documented SARS-CoV-2 transmission	Risk-based approach	General population	Potential benefit for source control and/or protection	Depends on purpose (see details in the guidance content)
Any transmission scenario	Any setting in the community	Anyone suspected or confirmed of having COVID-19, regardless of whether they have symptoms or not, or anyone awaiting viral test results, when in the presence of others	Source control	Medical mask

**Public indoor setting includes any indoor setting outside of the household*

[4] For adequate ventilation refer to regional or national institutions or heating, refrigerating and air-conditioning societies enacting ventilation requirements. If not available or applicable, a recommended ventilation rate of 10l/s/person should be met (except healthcare facilities which have specific requirements).). For more information consult "Coronavirus (COVID-19) response resources from ASHRAE and others'' https://www.ashrae.org/technical-resources/resources

In outdoor settings:

- where physical distancing of at least 1 metre cannot be maintained;
- individuals/people with higher risk of severe complications from COVID-19 (individuals ≥ 60 years old and those with underlying conditions such as cardiovascular disease or diabetes mellitus, chronic lung disease, cancer, cerebrovascular disease or immunosuppression) should wear medical masks in any setting where physical distance cannot be maintained.

2. In areas with known or suspected sporadic transmission or no documented transmission, as in all transmission scenarios, WHO continues to advise that decision makers should apply a risk-based approach focusing on the following criteria when considering the use of masks for the public:

- **Purpose of mask use**. Is the intention source control (preventing an infected person from transmitting the virus to others) or protection (preventing a healthy wearer from the infection)?
- **Risk of exposure to SARS-CoV-2**. Based on the epidemiology and intensity of transmission in the population, is there transmission and limited or no capacity to implement other containment measures such as contact tracing, ability to carry out testing and isolate and care for suspected and confirmed cases? Is there risk to individuals working in close contact with the public (e.g., social workers, personal support workers, teachers, cashiers)?
- **Vulnerability of the mask wearer/population**. Is the mask wearer at risk of severe complications from COVID-19? Medical masks should be used by older people (≥ 60 years old), immunocompromised patients and people with comorbidities, such as cardiovascular disease or diabetes mellitus, chronic lung disease, cancer and cerebrovascular disease (117).
- **Setting in which the population lives**. Is there high population density (such as in refugee camps, camp-like settings, and among people living in cramped conditions) and settings where individuals are unable to keep a physical distance of at least 1 metre (for example, on public transportation)?
- **Feasibility**. Are masks available at an affordable cost? Do people have access to clean water to wash fabric masks, and can the targeted population tolerate possible adverse effects of wearing a mask?
- **Type of mask**. Does the use of medical masks in the community divert this critical resource from the health workers and others who need them the most? In settings where medical masks are in short supply, **stocks should be prioritized for health workers and at-risk individuals.**

The decision of governments and local jurisdictions whether to recommend or make mandatory the use of masks should be based on the above assessment as well as the local context, culture, availability of masks and resources required.

3. In any transmission scenario:

- Persons with any symptoms suggestive of COVID-19 should wear a medical mask and (5) additionally:
  - self-isolate and seek medical advice as soon as they start to feel unwell with potential symptoms of COVID-19, even if symptoms are mild);
  - follow instructions on how to put on, take off, and dispose of medical masks and perform hand hygiene (118);
  - follow all additional measures, in particular respiratory hygiene, frequent hand hygiene and maintaining physical distance of at least 1 metre from other persons (46). If a medical mask is not available for individuals with suspected or confirmed COVID-19, a fabric mask meeting the specifications in the Annex of this document should be worn by patients as a source control measure, pending access to a medical mask. The use of a non-medical mask can minimize the projection of respiratory droplets from the user (119, 120).
  - Asymptomatic persons who test positive for SARS-CoV-2, should wear a medical mask when with others for a period of 10 days after testing positive.

Potential benefits/harms

The potential advantages of mask use by healthy people in the general public include:

- reduced spread of respiratory droplets containing infectious viral particles, including from infected persons before they develop symptoms (121);
- reduced potential for stigmatization and greater of acceptance of mask wearing, whether to prevent infecting others or by people caring for COVID-19 patients in non-clinical settings (122);
- making people feel they can play a role in contributing to stopping spread of the virus;
- encouraging concurrent transmission prevention behaviours such as hand hygiene and not touching the eyes, nose and mouth (123-125);
- preventing transmission of other respiratory illnesses like tuberculosis and influenza and reducing the burden of those diseases during the pandemic (126).

The potential disadvantages of mask use by healthy people in the general public include:

- headache and/or breathing difficulties, depending on type of mask used (55);
- development of facial skin lesions, irritant dermatitis or worsening acne, when used frequently for long hours (58, 59, 127);
- difficulty with communicating clearly, especially for persons who are deaf or have poor hearing or use lip reading (128, 129);
- discomfort (44, 55, 59)
- a false sense of security leading to potentially lower adherence to other critical preventive measures such as physical distancing and hand hygiene (105);
- poor compliance with mask wearing, in particular by young children (111, 130-132);
- waste management issues; improper mask disposal leading to increased litter in public places and environmental hazards (133);
- disadvantages for or difficulty wearing masks, especially for children, developmentally challenged persons, those with mental illness, persons with cognitive impairment, those with asthma or chronic respiratory or breathing problems, those who have had facial trauma or recent oral maxillofacial surgery and those living in hot and humid environments (55, 130).

Considerations for implementation

When implementing mask policies for the public, decision-makers should:

- clearly communicate the purpose of wearing a mask, including when, where, how and what type of mask should be worn; explain what wearing a mask may achieve and what it will not achieve; and communicate clearly that this is one part of a package of measures along with hand hygiene, physical distancing, respiratory etiquette, adequate ventilation in indoor settings and other measures that are all necessary and all reinforce each other;
- inform/train people on when and how to use masks appropriately and safely (see mask management and maintenance sections);
- consider the feasibility of use, supply/access issues (cleaning, storage), waste management, sustainability, social and psychological acceptance (of both wearing and not wearing different types of masks in different contexts);
- continue gathering scientific data and evidence on the effectiveness of mask use (including different types of masks) in non-health care settings;
- evaluate the impact (positive, neutral or negative) of using masks in the general population (including behavioural and social sciences) through good quality research.

Mask use during physical activity

Evidence

There are limited studies on the benefits and harms of wearing medical masks, respirators and non-medical masks while exercising. Several studies have demonstrated statistically significant deleterious effects on various cardiopulmonary physiologic parameters during mild to moderate exercise in healthy subjects and in those with underlying respiratory diseases (134-140). The most significant impacts have been consistently associated with the use of respirators and in persons with underlying obstructive airway pulmonary diseases such as asthma and chronic obstructive pulmonary disease (COPD), especially when the condition is moderate to severe (136). Facial microclimate changes with increased temperature, humidity and perceptions of dyspnoea were also reported in some studies on the use of masks during exercise (134, 141). A recent review found negligeable evidence of negative effects of mask use during exercise but noted concern for individuals with severe cardiopulmonary disease (142).

Guidance

WHO advises that people should not wear masks during vigorous intensity physical activity (143) because masks may reduce the ability to breathe comfortably. The most important preventive measure is to maintain physical distancing of at least 1 meter and ensure good ventilation when exercising.

If the activity takes place indoors, adequate ventilation should be ensured at all times through natural ventilation or a properly functioning or maintained ventilation system (144). Particular attention should be paid to cleaning and disinfection of the environment, especially high-touch surfaces. If all the above measures cannot be ensured, consider temporary closure of public indoor exercise facilities (e.g., gyms).

Face shields for the general public

At present, face shields are considered to provide a level of eye protection only and should not be considered as an equivalent to masks with respect to respiratory droplet protection and/or source control. Current laboratory testing standards only assess face shields for their ability to provide eye protection from chemical splashes (145).

In the context of non-availability or difficulties wearing a non-medical mask (in persons with cognitive, respiratory or hearing impairments, for example), face shields may be considered as an alternative, noting that they are inferior to masks with respect to droplet transmission and prevention. If face shields are to be used, ensure proper design to cover the sides of the face and below the chin.

Medical masks for the care of COVID-19 patients at home

WHO provides guidance on how to care for patients with confirmed and suspected COVID-19 at home when care in a health facility or other residential setting is not possible (5).

- Persons with suspected COVID-19 or mild COVID-19 symptoms should wear a medical mask as much as possible, especially when there is no alternative to being in the same room with other people. The mask should be changed at least once daily. Persons who cannot tolerate a medical mask should rigorously apply respiratory hygiene (i.e., cover mouth and nose with a disposable paper tissue when coughing or sneezing and dispose of it immediately after use or use a bent elbow procedure and then perform hand hygiene).
- Caregivers of or those sharing living space with people with suspected COVID-19 or with mild COVID-19 symptoms should wear a medical mask when in the same room as the affected person.

Annex: Updated guidance on non-medical (fabric) masks

Background

A non-medical mask, also called fabric mask, community mask or face covering, is neither a medical device nor personal protective equipment. Non-medical masks are aimed at the general population, primarily for protecting others from exhaled virus-containing droplets emitted by the mask wearer. They are not regulated by local health authorities or occupational health associations, nor is it required for manufacturers to comply with guidelines established by standards organizations. Non-medical masks may be homemade or manufactured. The essential performance parameters include good breathability, filtration of droplets originating from the wearer, and a snug fit covering the nose and mouth. Exhalation valves on masks are discouraged as they bypass the filtration function of the mask.

Non-medical masks are made from a variety of woven and non-woven fabrics, such as woven cotton, cotton/synthetic blends, polyesters and breathable spunbond polypropylene, for example. They may be made of different combinations of fabrics, layering sequences and available in diverse shapes. Currently, more is known about common household fabrics and combinations to make non-medical masks with target filtration efficiency and breathability (119, 146-150). Few of these fabrics and combinations have been systematically evaluated and there is no single design, choice of material, layering or shape among available non-medical masks that are considered optimal. While studies have focussed on single fabrics and combinations, few have looked at the shape and universal fit to the wearer. The unlimited combination of available fabrics and materials results in variable filtration and breathability.

In the context of the global shortage of medical masks and PPE, encouraging the public to create their own fabric masks may promote individual enterprise and community integration. Moreover, the production of non-medical masks may offer a source of income for those able to manufacture masks within their communities. Fabric masks can also be a form of cultural expression, encouraging public acceptance of protection measures in general. The safe re-use of fabric masks will also reduce costs and waste and contribute to sustainability (151-156).

This Annex is destined intended for two types of readers: homemade mask makers and factory-made masks manufacturers. Decision makers and managers (national/sub-national level) advising on a type of non-medical mask are also the focus of this guidance and should take into consideration the following features of non-medical masks: breathability, filtration efficiency (FE), or filtration, number and combination of fabric layers material used, shape, coating and maintenance.

Evidence on the effectiveness of non-medical (fabric) masks

A number of reviews have been identified on the effectiveness of non-medical masks (151-156). One systematic review (155) identified 12 studies and evaluated study quality. Ten were laboratory studies (157-166), and two reports were from a single randomized trial (72, 167). The majority of studies were conducted before COVID-19 emerged or used laboratory generated particles to assess filtration efficacy. Overall, the reviews concluded that cloth face masks have limited efficacy in combating viral infection transmission.

Homemade non-medical masks

Homemade non-medical masks made of household fabrics (e.g., cotton, cotton blends and polyesters) should ideally have a three-layer structure, with each layer providing a function (see Figure 1) (168). It should include:

1. an innermost layer (that will be in contact with the face) of a hydrophilic material (e.g., cotton or cotton blends of terry cloth towel, quilting cotton and flannel) that is non-irritating against the skin and can contain droplets (148)
2. a middle hydrophobic layer of synthetic breathable non-woven material (spunbond polypropylene, polyester and polyaramid), which may enhance filtration, prevent permeation of droplets or retain droplets (148, 150)
3. an outermost layer made of hydrophobic material (e.g. spunbond polypropylene, polyester or their blends), which may limit external contamination from penetrating through the layers to the wearer's nose and mouth and maintains and prevents water accumulation from blocking the pores of the fabric (148).

Although a minimum of three layers is recommended for non-medical masks for the most common fabric used, single, double or other layer combinations of advanced materials may be used if they meet performance requirements. It is important to note that with more tightly woven materials, breathability may be reduced as the number of layers increases. A quick check may be performed by attempting to breathe, through the mouth, through the multiple layers.

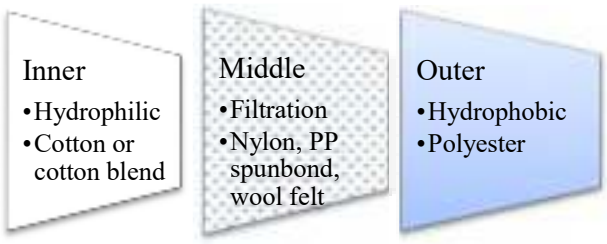

Figure 1. Non-medical mask construction using breathable fabrics such as cotton, cotton blends, polyesters, nylon and polypropylene spunbond that are breathable may impart adequate filtration performance when layered. Single- or double-layer combinations of advanced materials may be used if they meet performance requirements (72).

Assumptions regarding homemade masks are that individual makers only have access to common household fabrics and do not have access to test equipment to confirm target performance (filtration and breathability). Figure 1 illustrates a multi-layer mask construction with examples of fabric options. Very porous materials, such as gauze, even with multiple layers, may provide very low filtration efficiency (147). Higher thread count fabrics offer improved filtration performance (169). Coffee filters, vacuum bags and materials not meant for clothing should be avoided as they may contain injurious content when breathed in. Microporous films such as Gore-Tex are not recommended (170).

Factory-made non-medical masks: general considerations for manufacturers

The non-medical mask, including all components and packaging, must be non-hazardous, non-toxic and child-friendly (no exposed sharp edges, protruding hardware or rough materials). Factory-made non-medical masks must be made using a process that is certified to a quality management system (e.g., ISO 9001). Social accountability standards (e.g., SAI SA8000) for multiple aspects of fair labour practices, health and safety of the work force and adherence to UNICEF's Children's Rights and Business Principles are strongly encouraged.

Standards organizations' performance criteria

Manufacturers producing masks with consistent standardized performance can adhere to published, freely available guidance from several organizations including those from: the French Standardization Association (AFNOR Group), The European Committee for Standardization (CEN), Swiss National COVID-19 Task Force, the American Association of Textile Chemists and Colorists (AATCC), the South Korean Ministry of Food and Drug Safety (MFDS), the Italian Standardization Body (UNI) and the Government of Bangladesh.

Essential parameters

The essential parameters presented in this section are the synthesis of the abovementioned regional and national guidance. They include filtration, breathability and fit. Good performance is achieved when the three essential parameters are optimized at the preferred threshold (Figure 2).

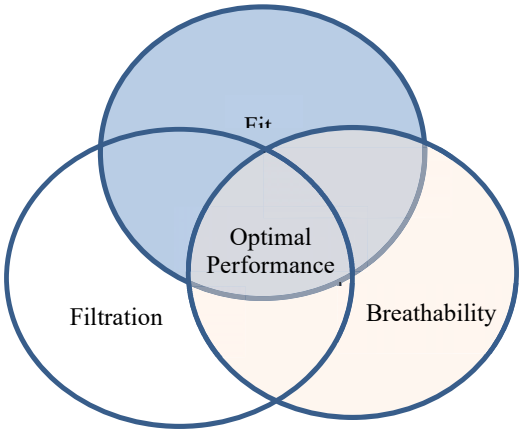

Figure 2. Illustration of the three essential parameters of filtration, breathability and fit.

The summary of the three essential parameters can be found in Table 1 and the additional performance considerations in Table 2. The minimum threshold is the minimum acceptable parameter, while the preferred threshold is the optimum.

Filtration and breathability

Filtration depends on the filtration efficiency (in %), the type of challenge particle (oils, solids, droplets containing bacteria) and the particle size (see Table 1). Depending on the fabrics used, filtration and breathability can complement or work against one another. The selection of material for droplet filtration (barrier) is as important as breathability. Filtration is dependent on the tightness of the weave, fibre or thread diameter. Non-woven materials used for disposable masks are manufactured using processes to create polymer fibres that are thinner than natural fibres such as cotton and that are held together by partial melting.

Breathability is the difference in pressure across the mask and is typically reported in millibars (mbar) or Pascals (Pa) or, normalized to the cm^2 in $mbar/cm^2$ or Pa/cm^2. Acceptable breathability of a medical mask should be below 49 Pa/cm^2. For non-medical masks, an acceptable pressure difference, over the whole mask, should be below 60 Pa/cm^2, with lower values indicating better breathability.

Non-medical fabric masks consisting of two layers of polypropylene spunbond and two layers of cotton have been shown to meet the minimum requirements for droplet filtration and breathability of the CEN CWA 17553 guidance. It is preferable not to select elastic material to make masks as the mask material may be stretched over the face, resulting in increased pore size and lower filtration through multiple usage. Additionally, elastic fabrics are sensitive to washing at high temperatures thus may degrade over time.

Coating the fabric with compounds like wax may increase the barrier and render the mask fluid resistant; however, such coatings may inadvertently completely block the pores and make the mask difficult to breathe through. In addition to decreased breathability unfiltered air may more likely escape the sides of the mask on exhalation. Coating is therefore not recommended.

Valves that let unfiltered air escape the mask are discouraged and are an inappropriate feature for masks used for the purpose of preventing transmission.

Table 1. Essential parameters (minimum and preferred thresholds) for manufactured non-medical mask

Essential Parameters	Minimum threshold	Preferred threshold
1. Filtration*		
1.1. filtration efficiency	70% @ 3 micron	> 70%, without compromising breathability
1.2. Challenge particle	Solid: sodium chloride (NaCl), Talcum powder, Holi powder, dolomite, Polystyrene Latex spheres Liquid: DEHS Di-Ethyl-Hexyl-Sebacat, paraffin oil	Based on availability
1.3. Particle size	Choose either sizes: 3 µm, 1 µm, or smaller	Range of particle sizes
2. Breathability		
2.1. Breathing resistance**	≤60 Pa/cm^2	Adult: ≤ 40 Pa/cm^2 Paediatric: ≤ 20 Pa/cm^2
2.2 Exhalation valves	Not recommended	N/A
3. Fit		
3.1. Coverage	Full coverage of nose and mouth, consistent, snug perimeter fit at the nose bridge, cheeks, chin and lateral sides of the face; adequate surface area to minimize breathing resistance and minimize side leakage	Same as current requirements
3.2 Face seal	Not currently required	Seal as good as FFR (respirator): Fit factor of 100 for N95 Maximum Total Inward Leakage of 25% (FFP1 requirement)
3.2. Sizing	Adult and child	Should cover from the bridge of the nose to below the chin and cheeks on either side of the mouth Sizing for adults and children (3-5, 6-9, 10-12, >12)
3.3Strap strength		> 44.5 N

* Smaller particle may result in lower filtration.
** High resistance can cause bypass of the mask. Unfiltered air will leak out the sides or around the nose if that is the easier path.

Fit: shape and sizing

Fit is the third essential parameter, and takes into consideration coverage, seal, sizing, and strap strength. Fit of masks currently is not defined by any standard except for the anthropometric considerations of facial dimensions (ISO/TS 16976-2) or simplified to height mask (South Korean standard for KF-AD). It is important to ensure that the mask can be held in place comfortably with as little adjustment of the elastic bands or ties as possible.

Mask shapes typically include flat-fold or duckbill and are designed to fit closely over the nose, cheeks and chin of the wearer. Snug fitting designs are suggested as they limit leaks of unfiltered air escaping from the mask (148). Ideally the mask should not have contact with the lips, unless hydrophobic fabrics are used in at least one layer of the mask (148). Leaks where unfiltered air moves in and out of the mask may be attributed to the size and shape of the mask (171).

Additional considerations

Optional parameters to consider in addition to the essential performance parameters include if reusable, biodegradability for disposal masks, antimicrobial performance where applicable and chemical safety (see Table 2).

Non-medical masks intended to be reusable should include instructions for washing and must be washed a minimum of five cycles, implying initial performance is maintained after each wash cycle.

Advanced fabrics may be biodegradable or compostable at the end of service life, according to a recognized standard process (e.g., UNI EN 13432, UNI EN 14995 and UNI / PdR 79).

Manufacturers sometimes claim their NM masks have antimicrobial performance. Antimicrobial performance may be due to coatings or additives to the fabric fibres. Treated fabrics must not come into direct contact with mucous membranes; the innermost fabric should not be treated with antimicrobial additives, only the outermost layer. In addition, antimicrobial fabric standards (e.g., ISO 18184, ISO 20743, AATCC TM100, AATCC 100) are generally slow acting. The inhibition on microbial growth may take full effect after 2- or 24-hour contact time depending on the standard. The standards have generally been used for athletic apparel and substantiate claims of odour control performance. These standards are not appropriate for non-medical cloth masks and may provide a false sense of protection from infectious agents. If claims are maid, manufacturers should specify which standard supports antimicrobial performance, the challenge organism and the contact time.

Volatile additives are discouraged as these may pose a health risk when inhaled repeatedly during wear. Certification according to organizations including OEKO-TEX (Europe) or SEK (Japan), and additives complying with REACH (Europe) or the Environmental Protection Agency (EPA, United States of America) indicate that textile additives are safe and added at safe levels.

Table 2. Additional parameters for manufactured non-medical masks

Additional parameters	Minimum thresholds
If reusable, number of wash cycles	5 cycles
Disposal	Reusable If biodegradable (CFC-BIO), according to UNI EN 13432, UNI EN 14995
Antimicrobial (bacteria, virus, fungus) performance	ISO 18184 (virus) ISO 20743 (bacteria) ISO 13629 (fungus) AATCC TM100 (bacteria)
Chemical safety	Comply with REACH regulation, including inhalation safety

Science Brief: Community Use of Masks to Control the Spread of SARS-CoV-2

Updated Dec. 6, 2021

Summary of Recent Changes

Last updated December 6, 2021

- Data were added from studies published since the last update. These studies address the association of mask wearing with new infections, including infections related to SARS-CoV-2 variants of concern. All of these studies demonstrated a benefit.
- A section was added on mask wearing among children.

Background

SARS-CoV-2 infection is transmitted predominantly by inhalation of respiratory droplets generated when people cough, sneeze, sing, talk, or breathe. CDC recommends community use of masks to prevent transmission of SARS-CoV-2. Masks are primarily intended to reduce the emission of virus-laden droplets by the wearer ("source control"), which is especially relevant for asymptomatic or presymptomatic infected wearers who feel well and may be unaware of their infectiousness to others (estimated to account for more than 50% of SARS-CoV-2 transmissions).[1, 2] Masks also help reduce inhalation of these droplets by the wearer ("filtration for wearer protection"). The community benefit of masking for SARS-CoV-2 control is due to the combination of these two effects (source control and filtration for wearer protection); individual prevention benefit increases with increasing numbers of people using masks consistently and correctly.

Source Control to Block Exhaled Virus

Multi-layer cloth masks block release of exhaled respiratory particles into the environment,[3-6] along with any microorganisms associated with these particles.[7, 8] Cloth masks not only effectively block most large droplets (i.e., 20-30 microns and larger),[9] but they can also block the exhalation of fine droplets and particles (also often referred to as aerosols) smaller than 10 microns[3, 5] which increase in number with the volume of speech[10-12] and specific types of phonation.[13] Multi-layer cloth masks can both block 50-70% of these fine droplets and particles[3, 14] and limit the forward spread of those that are not captured.[5, 6, 15, 16] Upwards of 80% blockage has been achieved in human experiments,[4] with cloth masks in some studies performing on par with surgical masks as barriers for source control.[3, 9, 14, 17] In one study, conducted prior to widespread circulation of the Delta variant, masks worked equally well for blocking aerosolized particles containing both "wild-type" virus and the Alpha variant (a more infectious variant).[17]

Filtration for Wearer Protection

Studies demonstrate that cloth mask materials can also reduce wearers' exposure to infectious droplets through filtration, including filtration of fine droplets and particles less than 10 microns. The relative filtration effectiveness of various masks has varied widely across studies, in large part due to variation in experimental design and particle sizes analyzed. Multiple layers of cloth with higher thread counts have demonstrated superior performance compared to single layers of cloth with lower thread counts, in some cases filtering nearly 50% of fine particles less than 1 micron.[14, 18-30] Some materials (e.g., polypropylene) may enhance filtering effectiveness by generating triboelectric charge (a form of static electricity) that enhances capture of charged particles[20] while others (e.g., silk) may help repel moist droplets[31] and reduce fabric wetting and thus maintain breathability and comfort. In addition to the number of layers and choice of materials, other techniques can improve wearer protection by improving fit and thereby filtration capacity. Examples include but are not limited to mask fitters, knotting-and-tucking the ear loops of medical procedures masks, using a cloth mask placed over a medical procedure mask, and nylon hosiery sleeves.[32-36]

Human Studies of Masking and SARS-CoV-2 Transmission

- A large, well-designed cluster-randomized trial in Bangladesh in late 2020 found that surgical or cloth mask distribution, role-modeling, and active mask promotion tripled mask use to 42.3% in intervention villages compared to 13.3% in comparison villages. In villages receiving mask interventions, symptomatic seroprevalence of SARS-CoV-2 was reduced by approximately 9% relative to comparison villages. In villages randomized to receive surgical masks, symptomatic seroprevalence of SARS-CoV-2 was significantly lower (relative reduction 11.1% overall). The results of this study show that even modest increases in community use of masks can effectively reduce symptomatic SARS-CoV-2 infections (COVID-19).[37]
- A study of an outbreak aboard the USS Theodore Roosevelt, an environment notable for congregate living quarters and close working environments, found that use of face coverings on-board was associated with a 70% reduced risk of infection.[38]
- In a study of 124 Beijing households with ≥ 1 laboratory-confirmed case of SARS-CoV-2 infection, mask use by the index patient and family contacts before the index patient developed symptoms reduced secondary transmission within the households by 79%.[39]
- A study examining SARS-CoV-2 secondary attack rates among eight public K-12 school districts in Massachusetts (70 schools with >33,000 enrolled students) during the 2020–21 school year found an unadjusted secondary attack rate of 11.7% for unmasked versus 1.7% for masked interactions.[40]
- A retrospective case-control study from Thailand documented that, among more than 1,000 persons interviewed as part of contact tracing investigations, those who reported having always worn a mask during high-risk exposures experienced a greater than 70% reduced risk of acquiring infection compared with persons who did not wear masks under these circumstances.[41]
- During July 15–August 31, 2021, when Delta was the predominant strain circulating in the U.S., about one in five K–12 public non-charter schools open for in-person learning in Maricopa and Pima Counties, Arizona, experienced a school-associated outbreak. Outbreaks were three and a half times more likely (adjusted odds ratio 3.5, 95% confidence interval 1.8-6.6) in schools without mask mandates.[42]
- In a nationwide analysis of data collected during July 1-September 4, 2021, U.S. counties without school mask requirements experienced larger increases in pediatric COVID-19 case rates (18.53 per 100,000 per day more cases) after the start of school compared with counties with school mask requirements.[43]
- An investigation of a high-exposure event in the U.S., in which 2 symptomatically ill hair stylists interacted for an average of 15 minutes with each of 139 clients during an 8-day period, found that none of the 67 clients who subsequently consented to an interview and testing developed infection. The stylists and all clients universally wore masks in the salon as required by local ordinance and company policy at the time.[44]
- Investigations involving infected passengers aboard flights longer than 10 hours strongly suggest that masking prevented in-flight transmissions, as demonstrated by the absence of infection developing in other passengers and crew in the 14 days following exposure.[45, 46]

At least ten studies have confirmed the benefit of universal masking in community level analyses: in a unified hospital system,[47] a German city,[48] two U.S. states,[49, 50] a panel of 15 U.S. states and Washington, D.C.,[51, 52] as well as both Canada[53] and the U.S.[54-56] nationally. Each analysis demonstrated that, following directives from organizational and political leadership for universal masking, new infections fell significantly. Two of these studies[51, 52] and an additional analysis of data from 200 countries that included the U.S.[56] also demonstrated reductions in mortality. Another 10-site study showed reductions in hospitalization growth rates following mask mandate implementation.[54] A separate series of cross-sectional surveys in the U.S.

suggested that a 10% increase in self-reported mask wearing tripled the likelihood of stopping community transmission.[57] An economic analysis using U.S. data found that, given these effects, increasing universal masking by 15% could prevent the need for lockdowns and reduce associated losses of up to $1 trillion or about 5% of gross domestic product.[52]

Two studies have been improperly characterized by some sources as showing that surgical or cloth masks offer no benefit.[58,59] A community-based randomized control trial in Denmark during 2020 assessed whether the use of surgical masks reduced the SARS-CoV-2 infection rate among wearers (personal protection) by more than 50%.[58] Findings were inconclusive,[58] most likely because the actual reduction in infections was lower. The study was too small (i.e., enrolled about 0.1% of the population) to assess whether masks could decrease transmission from wearers to others (source control). A second study of 14 hospitals in Vietnam during 2015 found that cloth masks were inferior to surgical masks for protection against clinical upper respiratory illness or laboratory-confirmed viral infection.[59] The study had a number of limitations including the lack of a true control (no mask) group for comparison, limited source control as hospitalized patients and staff were not masked, unblinded study arm assignments potentially biasing self-reporting of illness, and the washing and re-use of cloth masks by users introducing the risk of infection from self-washing. A follow up study in 2020 found that healthcare workers whose cloth masks were laundered by the hospital were protected equally as well as those that wore medical masks.[60]

Potential Adverse Health Effects of Mask Wearing

Adults

Research supports that under most circumstances, mask wearing has no significant adverse health effects for wearers. Studies of healthy hospital workers, older adults, and adults with chronic obstructive pulmonary disease (COPD) reported no to minimal changes in oxygen or carbon dioxide levels while wearing a cloth or surgical mask either during rest or moderate physical activity.[61-65] The safety of mask use during low to moderate levels of exercise has been confirmed in studies of healthy adults and adolescents.[64, 66-70] Some,[71-74] but not all,[67] studies have found that during intense exercise, especially when approaching the aerobic threshold, wearing a mask can increase dyspnea (difficulty breathing), perceived exertion, and claustrophobia, and produce modest negative effects on measured cardiopulmonary parameters. In some people, face masks worn for longer durations might be associated with skin reactions such as acne, itching, dry skin and worsening of existing dermatoses.[75-77] Wearing a surgical mask and N95 respirator may have a higher risk of skin reactions compared with a cloth mask.[76-78]

Children

A study of 60 elementary school children reported no adverse cardiovascular (e.g., heart rate) or pulmonary (e.g., peripheral oxygen saturation) effects among children while wearing a cloth face covering in a classroom for 30 consecutive minutes of instructional time.[79] A separate study observed no oxygen desaturation or respiratory distress after 60 minutes of monitoring among children less than 2 years of age when masked during normal play.[80] A randomized trial among 40 children aged 3–10 years old scheduled for elective surgery, found that protective surgical face masks could be used safely in the postoperative period.[81] In a prospective school-based cohort study of children aged 10–17 years who wore masks for 6–7 hours during the school day, some children self-reported general (4–7%) or situation-specific (2–4%) side-effects such as skin irritation, headache, or difficulty breathing during physical education.[82]

The potential impact of masks on language and emotional development has been examined in several studies.[83-89] Some research suggests children and adults, and especially toddlers (aged 3–5 years) can have difficulty inferring emotion from facial features presented on photographs of persons with their lower facial features covered by a mask.[83] However, a study of 7- to 13-year-old children determined the decrement in emotional inference observed when the lower half of a photographed face was covered with a mask was equivalent to that associated with covering the eyes with sunglasses, leading the authors to conclude that in combination with other contextual cues, masks are unlikely to produce serious impairments of children's social interactions.[84] A study of 2-year-old children concluded that they were able to recognize familiar words presented without a mask and when hearing words through opaque masks.[85] Among children with autism spectrum disorders (ASD), interventions including positive reinforcement and coaching caregivers to teach mask wearing have improved participants'

Conclusions

Experimental and epidemiologic data support community masking to reduce the spread of SARS-CoV-2, including alpha and delta variants, among adults and children. The prevention benefit of masking is derived from the combination of source control and wearer protection. The relationship between source control and wearer protection is likely complementary and possibly synergistic, so that individual benefit increases with increasing community mask use. Mask use has been found to be safe and is not associated with clinically significant impacts on respiration or gas exchange under most circumstances, except for intense exercise. The limited available data indicate no clear evidence that masking impairs emotional or language development in children. Further research is needed to assess masks, particularly to identify the combinations of materials that maximize both their blocking and filtering effectiveness, as well as fit, comfort, durability, and consumer appeal.

Table: Summary of studies that have assessed the effect of mask wearing on COVID-19 infection risks

	Type of investigation	Location	Study months	Population studied	Intervention	Outcome
Abaluck[37]	Cluster-randomized trial	Bangladesh	Nov 2020–April 2021	342,183 adults in 572 villages	Mask promotion strategies	In villages receiving mask interventions, symptomatic seroprevalence of SARS-CoV-2 was reduced by approximately 9% (adjusted prevalence ratio 0.91, 95% CI 0.82-1.00) relative to comparison villages
Payne[38]	Cohort study	USS Theodore Roosevelt, Guam (USA)	March 2020	382 U.S. Navy service members	Mask wearing (self-report)	Masking reduced risk of infection by 70% (unadjusted OR 0.30, 95% CI = 0.17–0.52)
Wang Y[39]	Cohort study	Households in Beijing (China)	February–March 2020	124 households of diagnosed cases comprising 335 people	Mask wearing by index cases or ≥1 household member prior to index case's diagnosis (self-report)	Masking reduced risk of secondary infection by 79% (adjusted OR 0.21, 95% CI = 0.06–0.79)
Hendrix[44]	Cohort study	Hair salon in Springfield, MO (USA)	May 2020	2 symptomatically infected stylists and 139 patrons	Universal masking in salon (by local ordinance and company policy)	No COVID-19 infections among 67 patrons who were tested in follow-up

	Type of investigation	Location	Study months	Population studied	Intervention	Outcome
Doung-Ngern[41]	Case-control study	Bangkok (Thailand)	April–May 2020	839 close contacts of 211 index cases	Mask wearing by contact at time of high-risk exposure to case (self-report)	Always having used a mask reduced infection by 77% (adjusted OR 0.23, 95% CI = 0.096–0.60)
Gallaway[49]	Population-based intervention	Arizona (USA)	January–August 2020	State population	Mandatory mask wearing in public	Temporal association between institution of masking policy and subsequent decline in new diagnoses
Rader[57]	Serial cross-sectional surveys	USA	June–July 2020	374,021 persons who completed web-based surveys	Self-reported mask wearing in grocery stores and in the homes of family or friends	10% increase in mask wearing tripled the likelihood of stopping community transmission (adjusted OR 3.53, 95% CI = 2.03-6.43)
Wang X[47]	Population-based intervention with trend analysis	Boston, MA (USA)	March–April 2020	9,850 healthcare workers (HCW)	Universal masking of HCW and patients, Mass General Brigham health care system	Estimated daily decline in new diagnoses among HCW of 0.49%
Mitze[48]	Population-based intervention with trend analysis	Jena (Thuringia), Germany	April 2020	City population aged ≥15 years	Mandatory mask wearing in public spaces (e.g., public transport, shops)	Estimated daily decline in new diagnoses of 1.28 percentage points
Van Dyke[50]	Population-based intervention with trend analysis	Kansas (USA)	June–August 2020	State population	Mandatory mask wearing in public spaces	Estimated case rate per 100,000 decreased by 0.08 in counties with mask mandates but increased by 0.11 in those without

	Type of investigation	Location	Study months	Population studied	Intervention	Outcome
Lyu and Wehby[51]	Population-based intervention with trend analysis	15 U.S. states and Washington, DC	March–May 2020	State population	Mandatory mask wearing in public	Estimated overall initial daily decline in new diagnoses of 0.9%, grew to 2.0% at 21 days following mandates
Joo[54]	Population-based intervention with trend analysis	USA	March–October 2020	State populations	Mandatory mask wearing in public	Estimated decline in weekly hospitalization rates by 5.6 percentage points for adults aged 18–64 years after mandate implementation, compared with growth rates during the 4 weeks preceding implementation of the mandate
Guy[56]	Population-based intervention with trend analysis	2,313 counties, USA	March–December 2020	County population	Mandatory mask wearing in public	Estimated overall initial daily decline in new diagnoses of 0.5%, grew to 1.8% at 81–100 days following mandates; estimated overall initial daily decline in deaths of 0.7%, grew to 1.9% at 81-100 days following mask mandate implementation

	Type of investigation	Location	Study months	Population studied	Intervention	Outcome
Jehn[42]	Population-based intervention with trend analysis	Arizona (USA)	July–August 2021	1,020 K–12 schools	School mask policies	Odds of a school-associated COVID-19 outbreak in schools without a mask requirement were 3.5 times higher than those in schools with an early mask requirement (OR = 3.5; 95% CI = 1.8–6.9)
Budzyn[43]	Population-based intervention with trend analysis	USA	July–September 2021	520 counties	School mask requirements	Increases in pediatric COVID-19 case rates during the start of the 2021–22 school year were smaller in U.S. counties with school mask requirements than in those without school mask requirements
Karaivanov[53]	Counterfactual modeling using national data	Canada	March–August 2020	County population	Mandatory mask wearing indoors	Estimated weekly 22% decline in new diagnoses following mask mandates

	Type of investigation	Location	Study months	Population studied	Intervention	Outcome
Chernozhukov[55]	Counterfactual modeling using national data	USA	March–May 2020	State population	Mandatory mask wearing for employees in public businesses	Nationally mandating face masks for employees early in the pandemic could have reduced weekly growth rate of cases and deaths by more than 10 percentage points in late April and 34% (95% CI: 19–47%) fewer deaths nationally by end of May
Leffler[90]	Population-based intervention with trend analysis	169 countries	January–May 2020	County population	Mask wearing by tradition, mandate, or recommendation	Duration of mask wearing by the public was negatively associated with per-capita mortality from COVID-19

FluWatch

Public Health Agency of Canada | Agence de la santé publique du Canada

2018-19 Influenza Season (Aug 26, 2018 to Aug 24, 2019)

Overall Summary

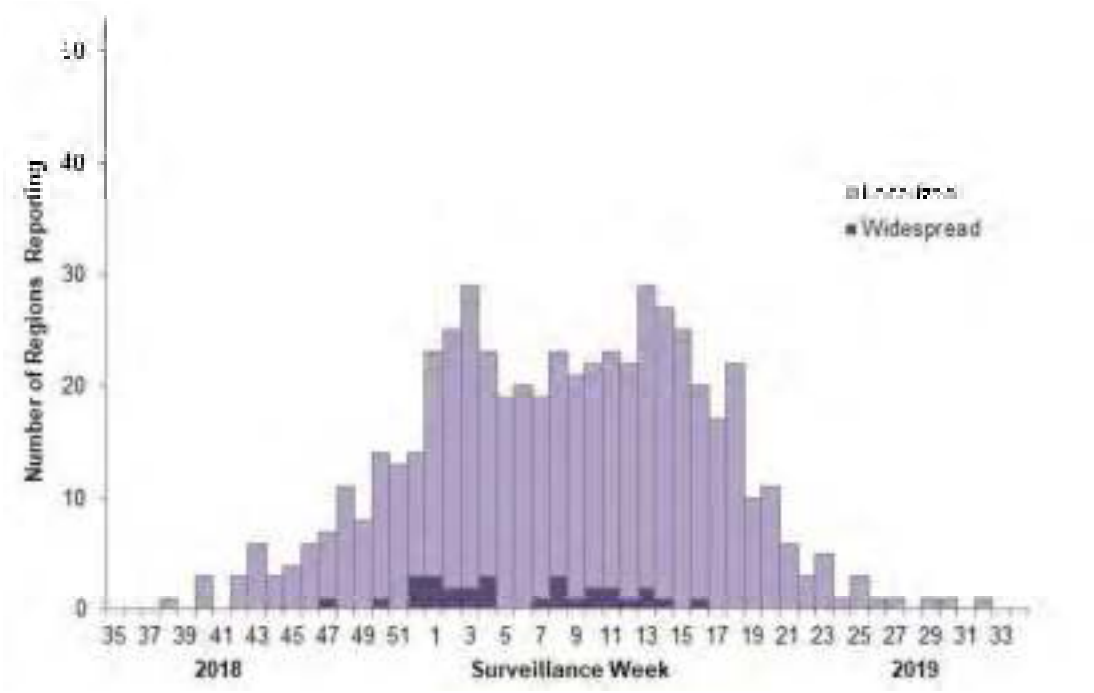
- During the influenza season, the FluWatch report is based on weekly data. This report is a summary of all of the data received for the 2018-19 influenza season and a comparison of these data to the previous five seasons.
- The 2018-19 influenza season in Canada was longer than the previous five seasons and was characterized by two waves of influenza A activity and very little influenza B circulation. The national season started in week 43 (October 21-27, 2018), peaked in week 52 (December 23-29, 2018) and ended in week 21 (May 19-25, 2019).
- A(H1N1) was predominant in the earlier part of the season (October to February) followed by a smaller wave of A(H3N2) circulation (March to April). Overall, A(H1N1) was the predominant strain nationally this season.
- Two waves of activity were observed in the number of reported outbreaks. The predominant subtype for typed outbreaks was A(H1N1) in the early part of the season (October to January), and A(H3N2) in the latter part of the season (Feburary onward).
- The annual seasonal hospitalization rate was above average compared to the previous five seasons. Adults 65 years of age and older had the highest overall hospitalization rate; however, the highest cumulative hospitalization rate shifted during the season from children 0-4 years of age (November to March) to adults 65 years of age and older (March onward), likely due to the second wave of A(H3N2).
- Overall, influenza vaccine coverage in the 2018-19 season (42%) was significantly higher than in the previous two seasons. Coverage was estimated at 34% for adults aged 18 to 64 years and 70% among seniors.
- Vaccine effectiveness studies in both the outpatient setting and adult inpatient setting observed good protection against A(H1N1) and little to no protection against A(H3N2) viruses relative to what is expected for influenza vaccine effectiveness.

Influenza/Influenza-like Illness (ILI) Activity (geographic spread)

Data on the geographic spread of influenza and influenza-like illness (ILI) are provided by all provinces and territories. All provinces and territories reported activity level data for each week of the 2018-19 influenza season.

- The number of surveillance regions reporting localized and widespread influenza activity peaked in week three and again in week 13 (Figure 1).
- Maps of the level of influenza activity reported by surveillance regions each week over the course of the season can be viewed here.

Figure 1 – Number of regions reporting widespread and localized influenza activity, Canada, weeks 2018-35 to 2019-34



Laboratory-Confirmed Influenza Detections

Data on laboratory-confirmed influenza detections are provided by 32 provincial, regional and some hospital laboratories. On average 99.6% of labs reported each week. During the 2018-19 season a total of 48,818 influenza detections were reported. Based on the seasonal thresholds for start and end of season (i.e. when the percentage of tests positive for influenza crossed 5%), the national influenza season started in week 43, peaked in week 52 and ended in week 21 (Figure 2).

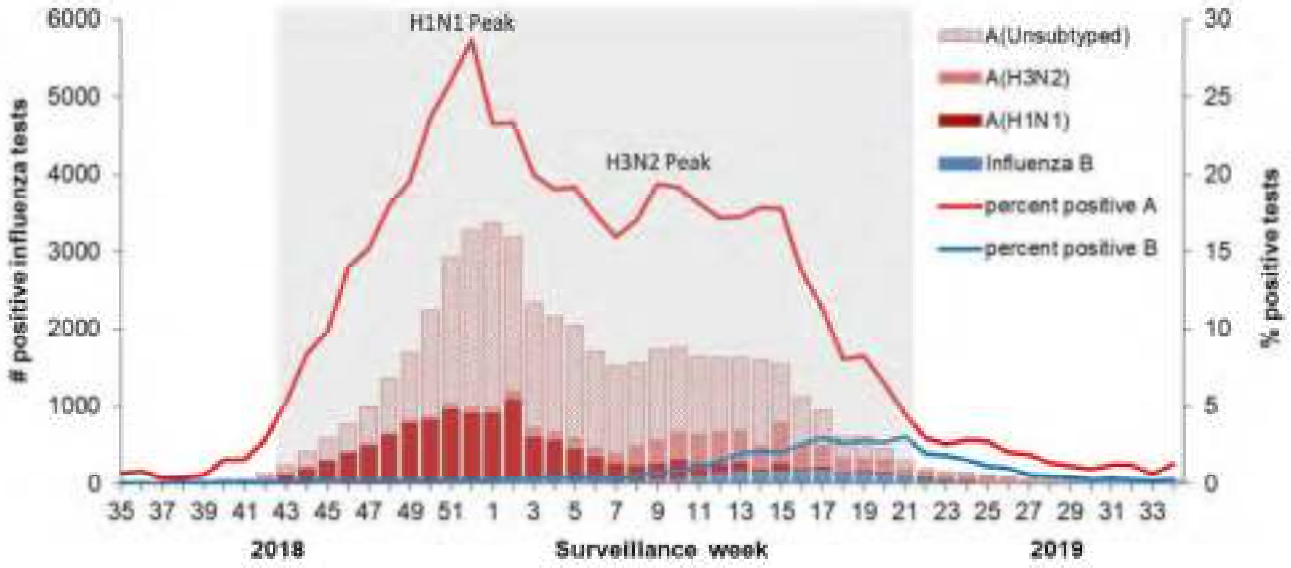
- Nearly all (95%) of influenza detections this season were influenza A. A(H1N1) was the predominant influenza strain and was the driver of the peak in percent positive detections in week 52. Among the 16,602 influenza A viruses that were subtyped this season, 69% were A(H1N1).
- The proportion of subtyped influenza A detections that were A(H3N2) began to increased markedly in mid-January (week three) and A(H3N2) became the predominant strain by week eight. This second more moderate wave of influenza A detections peaked in week nine and persisted near peak levels through to week 15.
- In the early part of the season (the A(H1N1) wave), influenza A activity was within the expected range; however, due to circulation of A(H3N2) in the latter part of the season, the overall proportion of detections of influenza A was higher compared to previous seasons.
- Compared to the last five seasons, the 2018-19 season started five weeks earlier than average; the number of weeks from the start of the season to the peak (10 weeks) was slightly longer than the average (nine weeks); and the length of the season (31 weeks) was six weeks longer than average (25 weeks).
- Canada observed the lowest cumulative total influenza B detections (5%) since the 2009 pandemic. Influenza B activity began to increase in week nine and peaked in week 17 but remained below previous seasonal values for the entire season.
- The distribution of influenza detections by type and subtype in provinces and territories was similar to the national distribution. The proportion of detections of influenza B was between zero and 5%. Among jurisdictions from which influenza A subtype information was provided, the proportion of A(H1N1) ranged from 62 to 100% of subtyped influenza A detections (Figure 3).

Detailed information on age and influenza type/subtype was received for 39,192 of laboratory-confirmed influenza cases. Among influenza A detections where subtype was identified (13,718), subtype distribution varied by age-group (Figure 4). A(H1N1) was the predominant subtype in all age groups except those 65 years of age and older, among

whom A(H3N2) was the predominant subtype (66%). Children less than five years of age had the highest proportion of A(H1N1) among subtyped influenza A detections (86%).

For more detailed weekly and cumulative influenza data, see the text descriptions for Figures 2 and 3 or the Respiratory Virus Detections in Canada Report.

Figure 2 – Number of positive influenza tests and percentage of positive tests, by type, subtype and report week, Canada, weeks 2018-35 to 2019-34



The shaded area indicates weeks where the positivity rate was at least 5% and a minimum of 15 positive tests were observed, signalling the period of seasonal influenza activity.

Data for week 14 excludes subtyping results from one jurisdiction due to batch reporting of subtype information. The results for week 14 should be interpreted with caution.

Figure 3 – Cumulative numbers of positive influenza specimens by type/subtype and province/territory, Canada, weeks 2018-35 to 2019-34

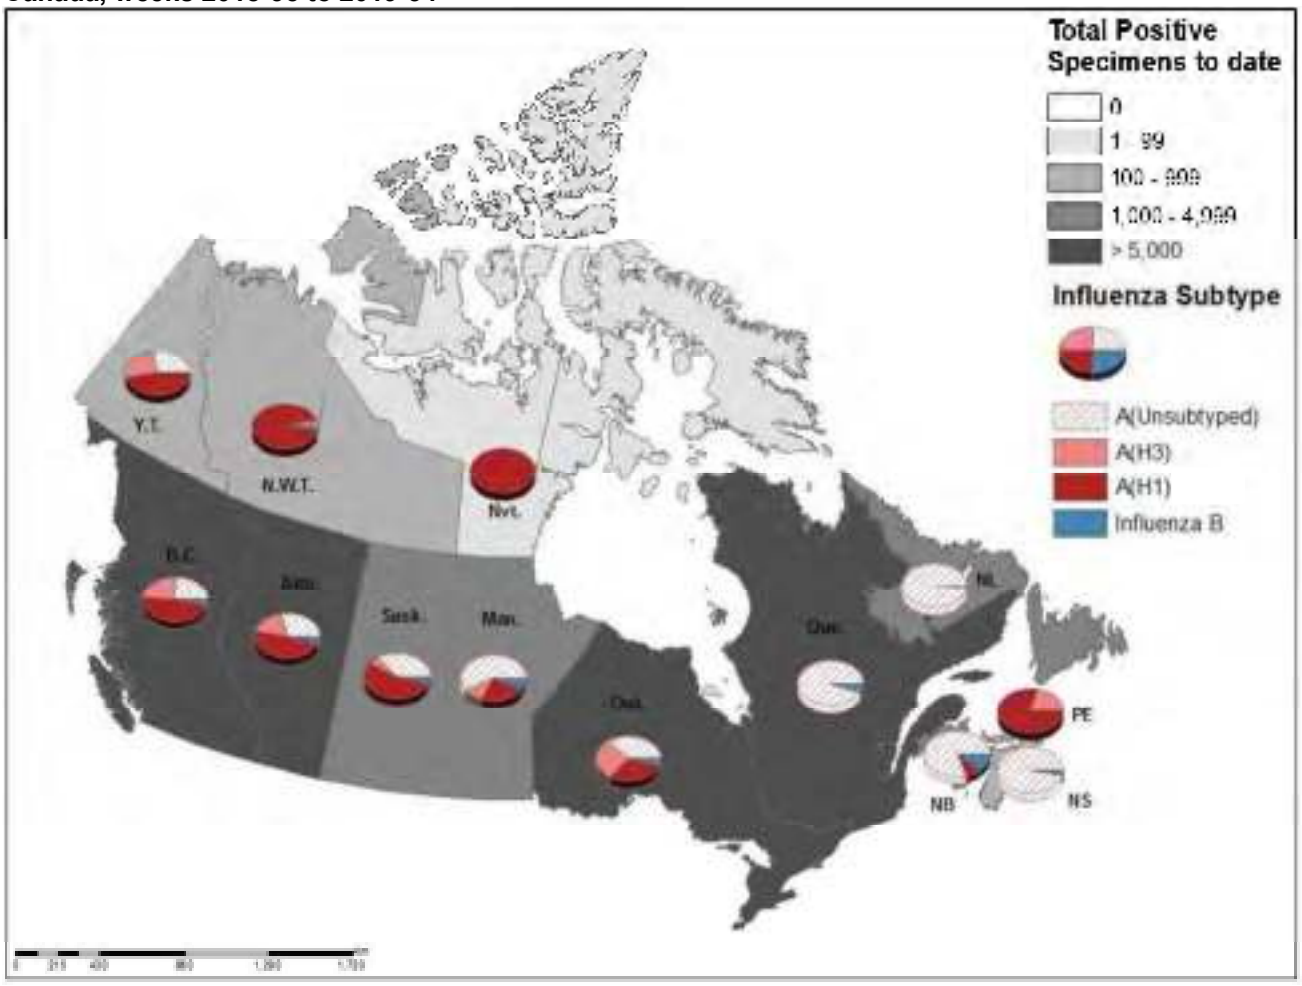


Figure 4 – Proportion of positive influenza A specimens by subtype and age-group reported through case-based laboratory reporting, Canada, weeks 2018-35 to 2019-34

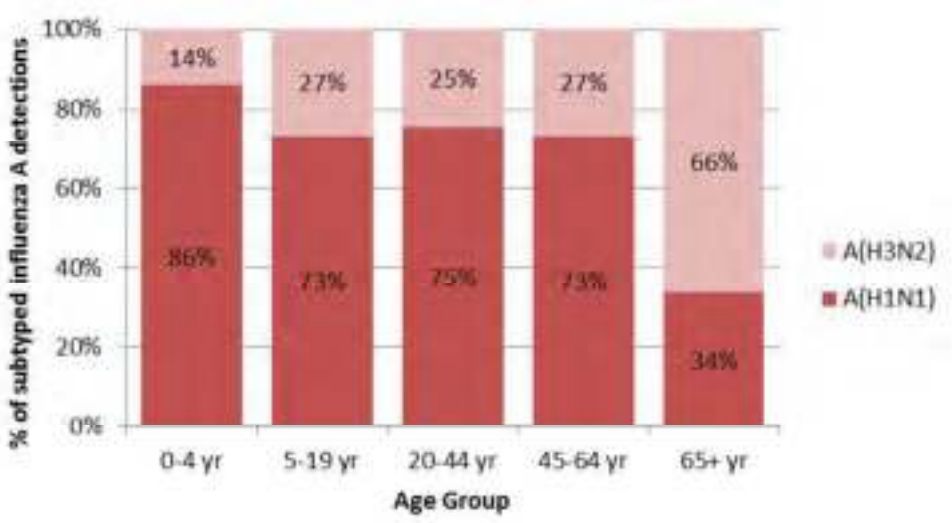


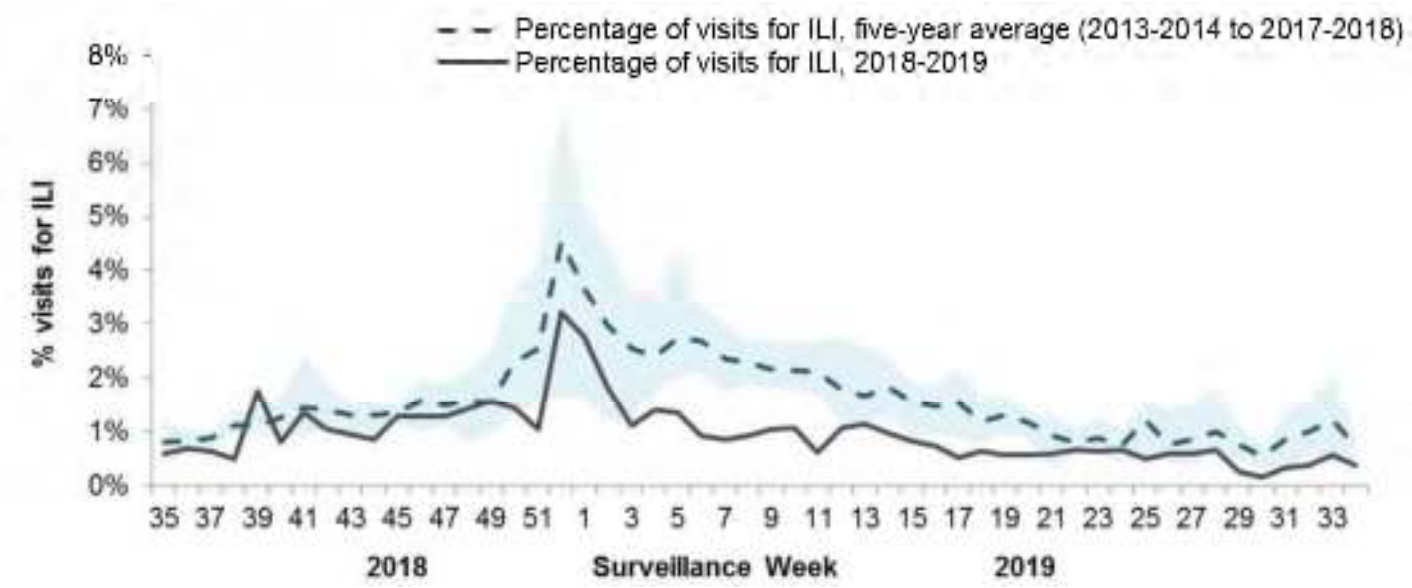
Syndromic / Influenza-like Illness Surveillance

Healthcare Practitioners Sentinel Syndromic Surveillance

On average, during the 2018-19 season, 106 healthcare practitioners across the country participated in influenza-like illness (ILI) surveillance for the FluWatch program. Each week these sentinel healthcare practioners report the proportion of patients in their practice who had ILI.

- Overall, ILI activity was below the five-year average for the majority of weeks this influenza season (range: 0.1% to 3.2%).
- 1.1% of all patient visits reported by sentinels were due to ILI this season (i.e. week 43 to week 21).
- The percentage of visitis for ILI reported by sentinels peaked in week 52 at 3.2%, consistent with the peak week of laboratory detections (Figure 5).
- For the majority of the season, the highest percentage of visits for ILI was reported among those less than 20 years of age. The lowest percentage of visits for ILI was reported among the 65+ year age group.

Figure 5 – Percentage of visits for ILI reported by sentinels by report week, Canada, weeks 2018-35 to 2019-34



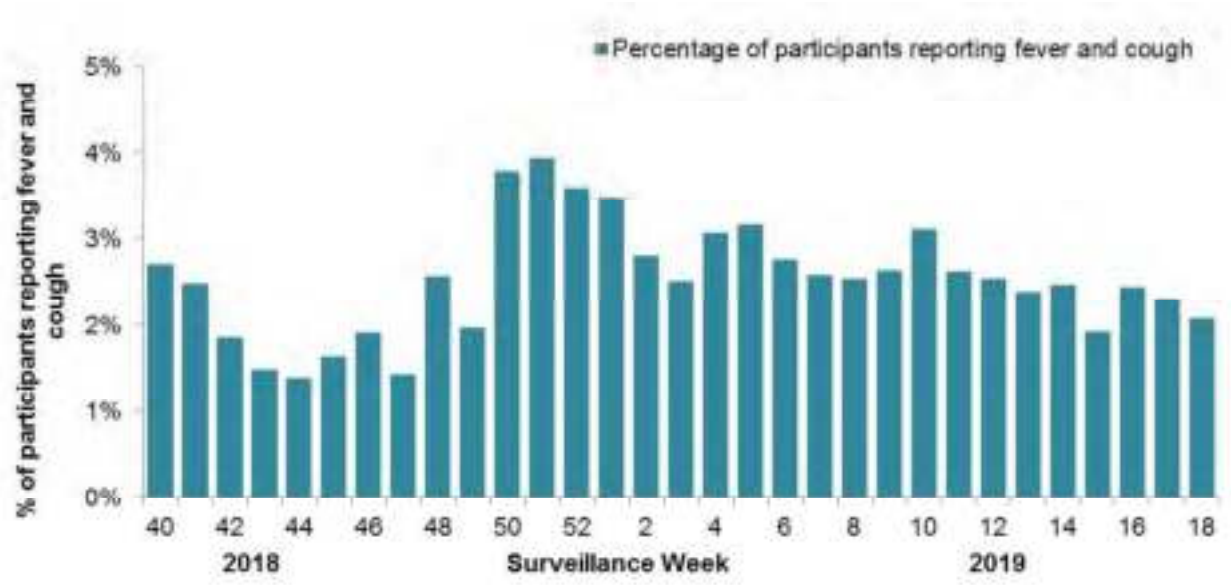
The shaded area represents the maximum and minimum percentage of visits for ILI reported by week from seasons 2013-2014 to 2017-2018

Participatory Syndromic Surveillance

FluWatchers are Canadians who report via a weekly online questionnaire if they have had symptoms of ILI in the preceding week. FluWatchers surveillance for the 2018-19 started in week 40 (October) and ended in week 18 (May). A total of 3,205 participants reported at least once this season, resulting in 64,728 completed questionnaires.

- The majority (75%) of FluWatchers particpants were adults 20-64 years of age. The age distribution of all FluWatchers participants this season was as follows:
  - 4% - 0 to 4 years of age
  - 15% - 5-19 years of age
  - 43% - 20 to 44 years of age
  - 33% - 45 to 64 years of age
  - 5% - 65 years of age and older
- 31% of FluWatchers reported experiencing cough and fever at least once this season.
- The percentage of FluWatchers reporting fever and cough peaked in week 51 with 3.9% of participants reporting cough and fever, consistent with the peak week of laboratory detections (Figure 6).
- A total of 1599 reports of cough and fever were reported by FluWatchers, of which 73% (1175) reported at least 24 hours off work or school, and 19% (306) reported a visit to a health care practitioner.
- A total of 46 tests for influenza and 15 positive tests were reported by FluWatchers.

Figure 6 – Percentage of FluWatchers participants reporting fever and cough, Canada, weeks 2018-40 to 2019-18



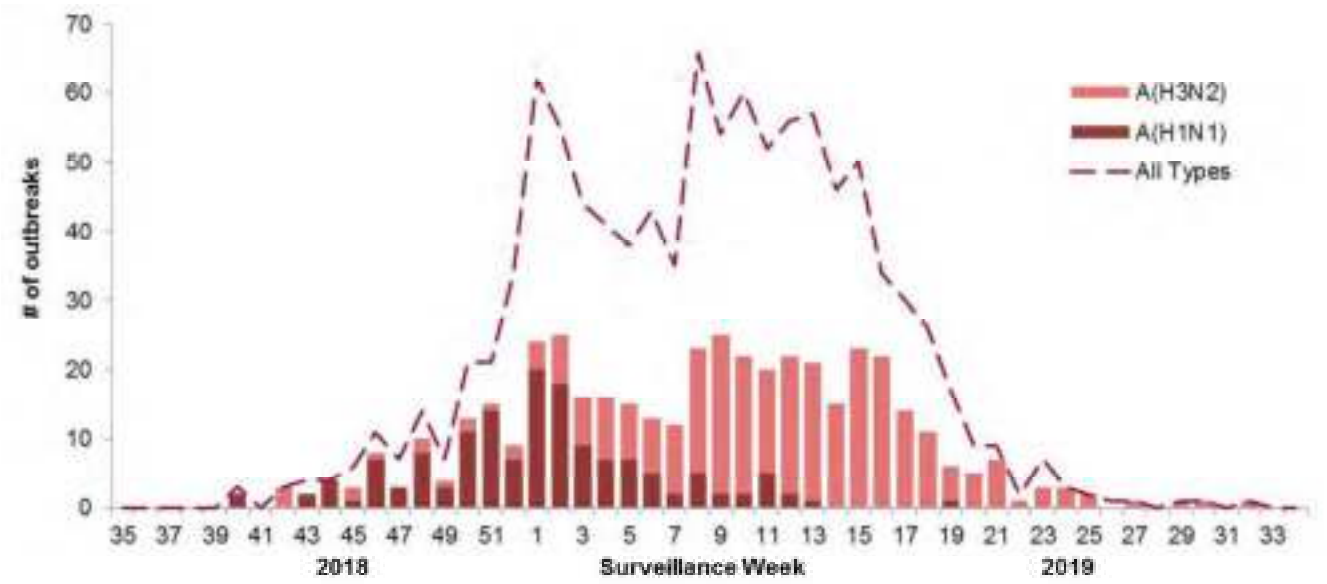
Influenza Outbreak Surveillance

Outbreak activity reports were provided by all provinces and territories each week this season. Not all provinces/territories conduct influenza outbreak surveillance in all the noted facilities. A total of 1038 laboratory-confirmed influenza outbreaks were reported (Figure 7).

- Two waves of activity were observed in the number of reported outbreaks.
- 62% (639) of reported outbreaks were in long-term care facilities (LTCF), 13% (138) were in acute care facilities, 3% (32) in schools and daycares and 22% (229) were in other settings (e.g. retirement homes, correctional facilities, etc.).
- Among the outbreaks for which influenza type (951) and subtype (446) were available, 98% (929) were associated with influenza A and 67% (298) were associated with influenza A(H3N2) respectively.
- Among the 220 outbreaks for which facility type was known and influenza A subtype was available:
    - 67% (173) of LTCF outbreaks were associated with influenza A(H3N2)
    - 65% (30) of acute care facility outbreaks were associated with influenza A(H3N2)
    - 85% (17) of school outbreaks were associatd with influenza A(H1N1).
- The predominant subtype for typed outbreaks was A(H1N1) from weeks 43 to two and A(H3N2) from weeks six to 29; between weeks three to five the number of A(H1N1) and A(H3N2) outbreaks was approximately equal.

In addition, a total of 180 outbreaks of influenza-like illness were reported; 112 occurred in LTCF, 62 in schools, five in acute care facilities, and one in a setting categorized as “other” (e.g. retirement homes, correctional facilities, etc.)

Figure 7 – Number of influenza outbreaks by report week (all types) and number of subtyped influenza A outbreaks by subtype and report week, Canada, weeks 2018-35 to 2019-34



Severe Outcomes Influenza Surveillance

Provincial/Territorial Influenza Hospitalizations and Deaths

Nine provinces and territories report influenza associated hospitalizations and deaths for all ages to FluWatch each week – Alberta, Manitoba, Saskatchewan, Newfoundland, Prince Edward Island, Nova Scotia, New Brunswick, Yukon and the Northwest Territories. The number of reporting provinces/territories varied over the course of the season. On average, seven provinces/territories reported each week.

A total of 3,657 influenza-associated hospitalizations were reported which corresponds to an annual seasonal hospitalization incidence of 45 hospitalizations per 100,000 population in the 2018-19 season (Table 1).

- 96% (3,525) were associated with influenza A.
- Among the 2,149 hospitalized cases for which the influenza subtype was available, the majority were associated with A(H1N1) (68%).
- Similar to the temporal pattern observed in laboratory detections, in the earlier part of the season (October to February) the majority (93%) of hospitalizations for which the influenza subtype was available were A(H1N1). In the latter part of the season (March to April) the majority (87%) of hospitalizations were A(H3N2).
- Overall, adults ≥ 65 years of age had the highest rate of hospitalizations (132 hospitalizations per 100,000 population); however, children 0-4 years of age had the highest cumulative hospitalization rate in the first part of the season from weeks 45 to 10, while adults ≥ 65 years of age had the highest cumulative rates in the second part of the season from weeks 10 to 29 which is likely due to the change in predominant subtype over time.
- This season's hospitalization rate (45 per 100,000 population) was slightly above the average compared to the previous five seasons (40 per 100,000 population), and notably higher than the annual seasonal hospitalization rates of the previous two A(H1N1) predominant seasons (25 and 34 per 100,000 population). The higher observed hospitalization rate relative to previous A(H1N1)-predominant seasons is likely due to the circulation of A(H3N2) in the latter part of the season.

Table 1 – Estimated annual seasonal incidence of influenza hospitalizations (per 100,000 population) by age group reported by participating provinces and territories[1], Canada, 2013/14 to 2018/19 influenza seasons

	Influenza Season (Predominant Influenza A Subtype)					
Age Groups (Years)	2013-14[2] (H1N1)	2014-15 (H3N2)	2015-16 (H1N1)	2016-17 (H3N2)	2017-18 (H3N2)	2018-19 (H1N1)
0-4	51	46	96	42	69	97
5-19	7	16	16	10	17	22
20-44	13	13	16	6	12	14
45-64	29	16	37	22	41	40
65+	41	207	68	143	268	132
Overall	25	45	34	34	64	45

1. Influenza-associated hospitalizations are reported by N.L., P.E.I, N.S., N.B., Man., Alb., Y.T. and N.W.T. Data provided by Sask is not included in these rates as only hospitalizations that require intensive medical care are reported by Sask. The annual seasonal hospitalization rate for a given season is calculated using the population by age-group in participating provinces and territories.
2. During the 2013-14 season N.B. did not report influenza-associated hospitalizations.
3. Highlighted boxes indicate the age group with the highest rate during the season.

A total of 613 ICU admissions and 224 deaths were reported this season.

- 97% (595) of reported ICU admissions and 98% (220) of reported deaths were associated with influenza A.
- Similar to the previous two A(H1N1)-predominant seasons, the highest proportion of ICU admissions was reported among adults 45-64 years of age (39%).
- The highest proportion of deaths was reported among adults ≥ 65 years of age (66%). This was approximately 20% higher than the number reported in the previous two A(H1N1)-predominant seasons and approximately 20% lower than the number reported in the previous three A(H3N2)-predominant seasons, likely as a result of the mixed A(H1N1) and A(H3N2) season.

Pediatric Influenza Hospitalizations and Deaths

Pediatric hospitalization data are provided by the Canadian Immunization Monitoring Program Active (IMPACT). IMPACT actively monitors pediatric influenza hospitalizations from 12 hospital sites in British Columbia, Alberta, Saskatchewan, Manitoba, Ontario, Quebec, Nova Scotia and Newfoundland.

A total of 1,352 pediatric hospitalized cases were reported this season. While the total number of hospitalized cases was above the five-year average (mean: 888; range: 593 to 1350) and the average of the last two A(H1N1)-predominant seasons (mean:1,032; range:714 to 1350), the number of hospitalized cases each week was within the expected range based on the minimum and maximum number of weekly cases observed in the previous five seasons.

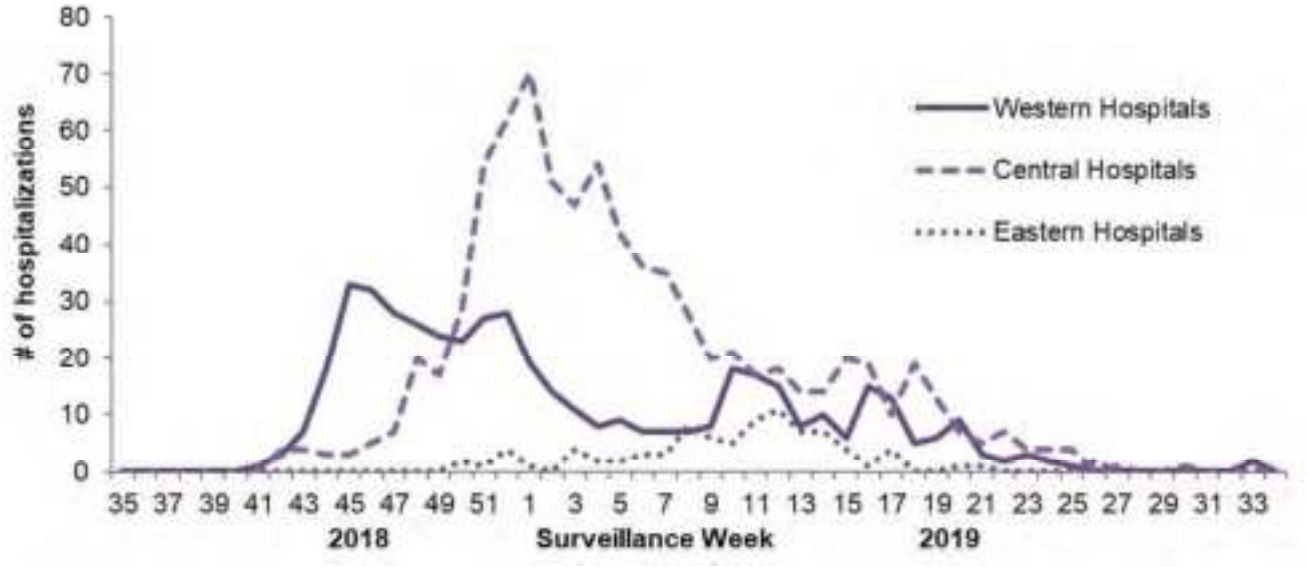
- Nationally, reports began earlier than previous seasons and peaked in week 52 consistent with the peak week of laboratory detections; however peaks varied by region, with an earlier peak in activity in sites in western Canada and a later peak of activity in sites in eastern Canada (Figure 8).
- More subtle peaks in activity can also be observed in western and central sites between weeks nine and 20 and in weeks 17 to 21 in eastern sites which may have resulted from the second wave of A(H3N2) activity and, along with this season's longer duration, may have contributed to the higher than average hospitalization counts.
- 91% (1,227) of pediatric hospitalized cases were associated with influenza A.
- Among the 402 pediatric hospitalized cases for which the influenza subtype was available, 80% (323) were associated with A(H1N1).
- 66% of pediatric hospitalized cases were among children under five years of age (Figure 9). This is consistent with the average proportion of hospitalized cases under five in the past five seasons (65%) and slightly less than the average of the two post-pandemic A(H1N1)-predominant seasons (71%) which were in 2013-14 and 2015-16.

Among the 1,352 pediatric hospitalized cases, a total of 271 (20%) ICU admissions and 10 (0.7%) deaths were reported. The proportion of hospitalized cases resulting in ICU admission was slightly above the average from the past five seasons (17%) and the last two A(H1N1)-predominant seasons (17%). The proportion of hospitalized cases

resulting in death was consistent with the average from the past five seasons (0.6%) and slightly above the average of the last two A(H1N1)-predominant seasons (0.4%).

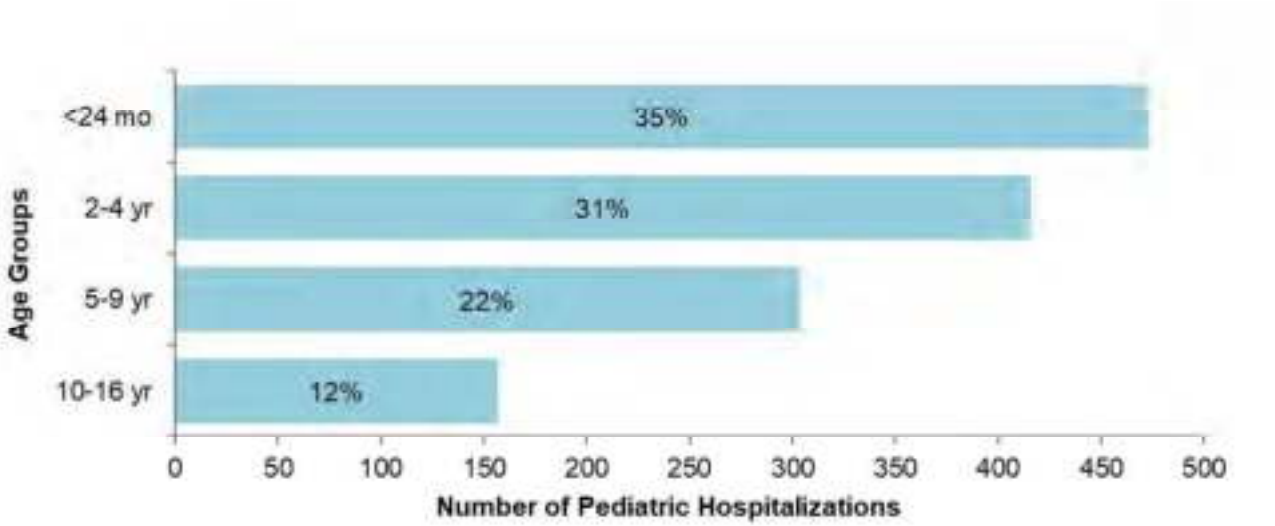
- 59% (161) of ICU admissions were among children under five years of age.
- 92% (248) of ICU admissions were associated with influenza A; 83% of the 111 cases for which the influenza A subtype was available were associated with A(H1N1).
- 80% (8) of deaths occurred in children two to four years of age.
- All deaths were associated with influenza A.

Figure 8 – Number of pediatric (≤16 years of age) hospitalizations reported by the IMPACT network, by region and by week of admission, Canada, weeks 2018-35 to 2019-34



Western hospitals consist of four sites in Vancouver, Calgary, Edmonton and Saskatoon. Central hospitals consist of 6 sites in Winnipeg, Toronto, Ottawa, Montreal and Quebec City. Eastern hospitals consist of 2 sites in Halifax & St. John's.

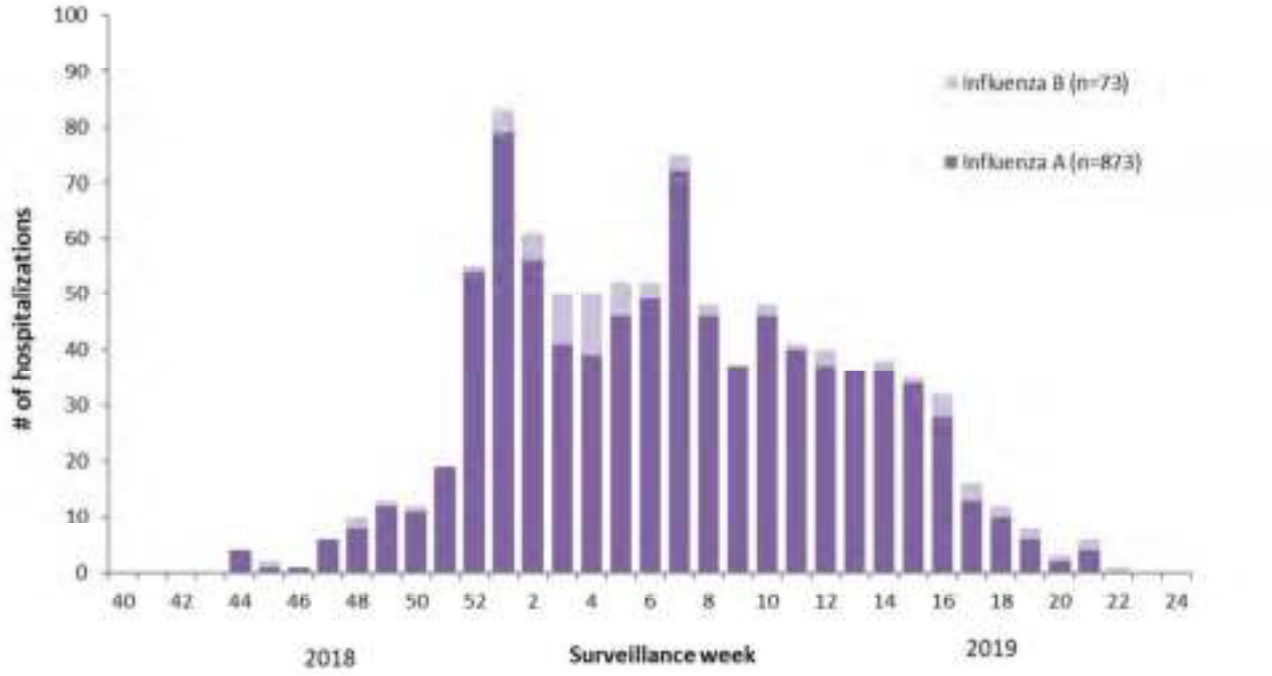
Figure 9 – Number and percentage of pediatric hospitalizations (≤16 years of age) with influenza by age-group reported by the IMPACT network, Canada, weeks 2018-35 to 2019-34



Adult Influenza Hospitalizations and Deaths

Surveillance of laboratory-confirmed influenza-associated adult (≥16 years of age) hospitalizations by the Canadian Immunization Research Network (CIRN) Serious Outcomes Surveillance (SOS) network began on November 1st (week 44) for the 2018-19 season and ended on June 1st (week 22). CIRN-SOS collects influenza hospitalization data from eight hospital sites in Ontario, Quebec, and Nova Scotia.

Figure 10 – Number of adult hospitalizations (≥16 years of age) with influenza reported by CIRN-SOS by surveillance week and influenza type, Canada, weeks 2018-44 to 2019-22



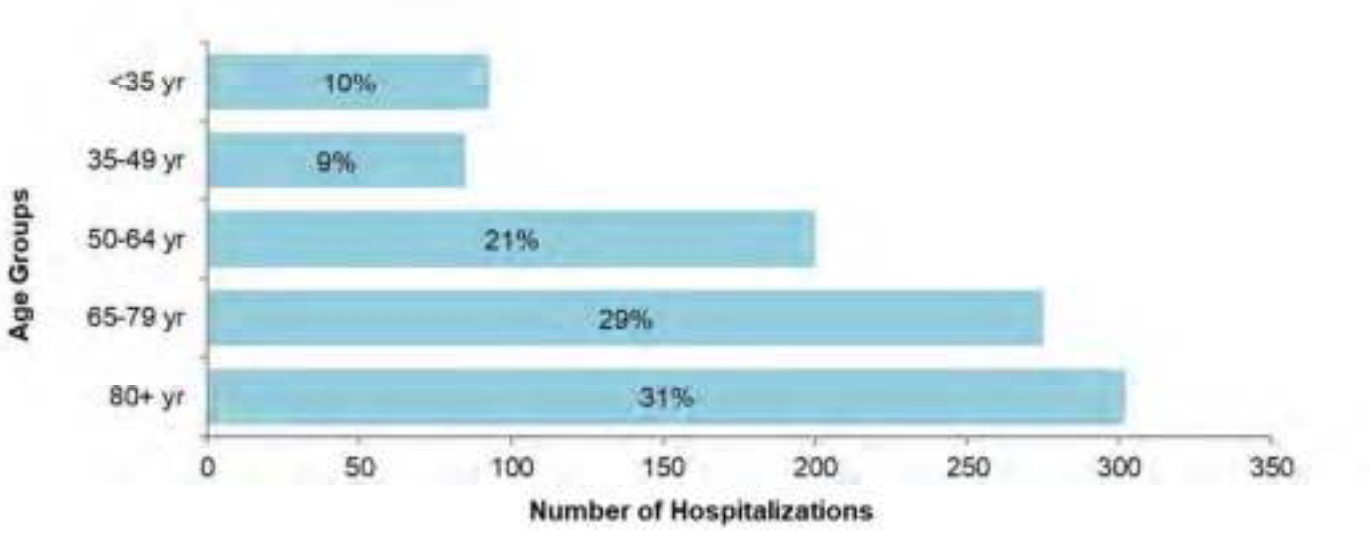
A total of 946 hospitalizations were reported by CIRN-SOS sentinels this season (age ≥16) (Figure 10):

- 92% (873) of hospitalizations were associated with influenza A.
- Among the 838 hospitalized cases for which the influenza subtype was available, 52% (439) were associated with A(H1N1).
- The highest proportion of hospitalized cases (31%) was among adults aged 80 years and over, followed by adults aged 65-79 years (29%) (Figure 11). The mean age of hospitalized cases was 67 years (range: 16 to 100).
- 89% of hospitalized cases reported at least one comorbid condition; vascular disorders were the most common comorbity (70% of all patients reporting a comorbidity) followed by cardiac disorders (43%).

A total of 137 (14%) ICU admissions and 65 (7%) deaths were reported.

- 95% (131) of ICU admissions were associated with influenza A.
- The majority of ICU admissions were among adults under the age of 65 (63%).
- The majority of deaths occurred among adults over the age of 65 (75%) with a mean age of 77 years.

Figure 11 – Number and percentage of adult hospitalizations (≥16 years of age) with influenza by age group reported by CIRN-SOS, Canada, 2018-19, weeks 2018-44 to 2019-22



Influenza Strain Characterizations

During the 2018-19 season, the National Microbiology Laboratory (NML) characterized 2,545 influenza viruses received from Canadian laboratories: 1,656 A(H1N1), 649 A(H3N2), 240 influenza B. Antigenic characterization is established by hemagglutination inhibition (HI) assay using cell-passaged vaccine reference viruses for A(H1N1) and influenza B, and the egg-passaged vaccine reference virus for A(H3N2). Over recent years, circulating strains of A(H3N2) have evolved, and are increasingly difficult to characterize by HI assay. Genetic characterization is established by sequencing the hemagglutinin gene of the influenza viruses to compare their genetic properties.

Influenza A(H3N2)

The influenza A(H3N2) component of the 2018-19 Northern Hemisphere influenza vaccine was an A/Singapore/INFIMH-16-0019/2016-like virus which belongs to the genetic group 3C.2a1.

All of the A(H3N2) viruses (649) were genetically characterized and 42% (378) of A(H3N2) viruses also grew to sufficient hemagglutination titer for antigenic characterization by HI assay (Table 2). Among all influenza A(H3N2) viruses genetically characterized, the most common subclade observed this season was 3C.2a1 (Figure 12). Of the A(H3N2) viruses characterized antigenically by HI assay (Figure 13-A):

- 56% (212) were characterized as A/Singapore/INFIMH-16-0019/2016-like by HI testing using antiserum raised against egg-propagated A/Singapore/INFIMH-16-0019/2016.
- 44% (166) of viruses showed reduced titer with ferret antisera raised against egg-propagated A/Singapore/INFIMH-16-0019/2016
- Among A(H3N2) viruses that showed reduced titer to A/Singapore/INFIMH-16-0019/2016, a greater proportion belonged to the genetic subclade 3C.3a. This is consistent with the genetic differences between subclades 3C.3a and 3C.2a1.

Table 2 – Genetic and antigenic characterization among characterized A(H3N2) viruses, Canada, weeks 2018-35 to 2019-34 (n=648)

Genetic clade	Genetic charaterization only	Antigenic characterization:		Total A(H3N2)
		Similar to A/Singapore/INFIMH-16-0019/2016	Reduced titer to A/Singapore/INFIMH-16-0019/2016	
Clade 3C.2a	20	17	3	40
Subclade 3C.2a1	242	132	16	390
Clade 3C.3a	8	63	147	218
Total	270	212	166	648

Influenza A(H1N1)

The influenza A(H1N1) component of the 2018-19 Northern Hemisphere influenza vaccine was an A/Michigan/45/2015-like virus.

Approximately 97% (1612) of the A(H1N1) viruses characterized were antigenically similar to A/Michigan/45/2015, while only 3% (44) of viruses showed reduced titer with ferret antisera raised against cell culture-propagated A/Michigan/45/2015 (Figure 13-B).

Influenza B

The recommended influenza B components for the 2018-19 Northern Hemisphere influenza vaccine were an B/Colorado/06/2017-like virus (Victoria lineage) and a B/Phuket/3073/2013-like virus (Yamagata lineage). The B/Colorado/06/2017-like virus was included in both the trivalent and quadrivalent vaccines. The B/Phuket/3073/2013-like virus was included in the quadrivalent influenza vaccine.

The majority of B viruses characterized, 70% (168), showed reduced titer with ferret antisera raised against cell culture-propagated B/Colorado/06/2017 (Figure 13-C). Sequence analysis showed that 96% (162) of viruses that showed reduced titer had a three amino acid deletion (162-164) in the hemagglutinin gene. Of the remaining B viruses characterized, 19% (46) were characterized as B/Colorado/06/2017-like (Victoria lineage) and 11% (26) were characterized as B/Phuket/3073/2013-like (Yamagata lineage).

Figure 12 – Distribution of genetic clades among characterized influenza A(H3N2) viruses, Canada, weeks 2018-35 to 2019-34

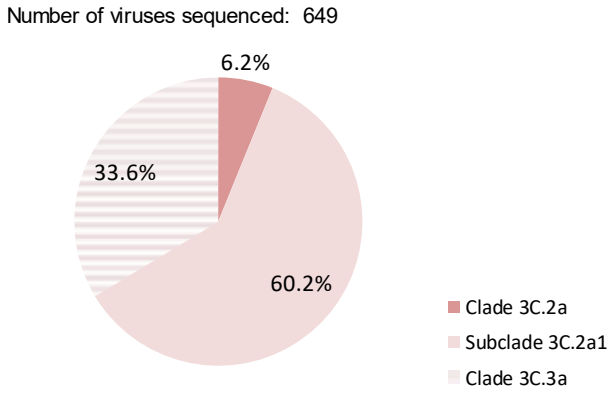


Figure 13 – Distribution of antigenic phenotypes among characterized influenza viruses, Canada, weeks 2018-35 to 2019-34

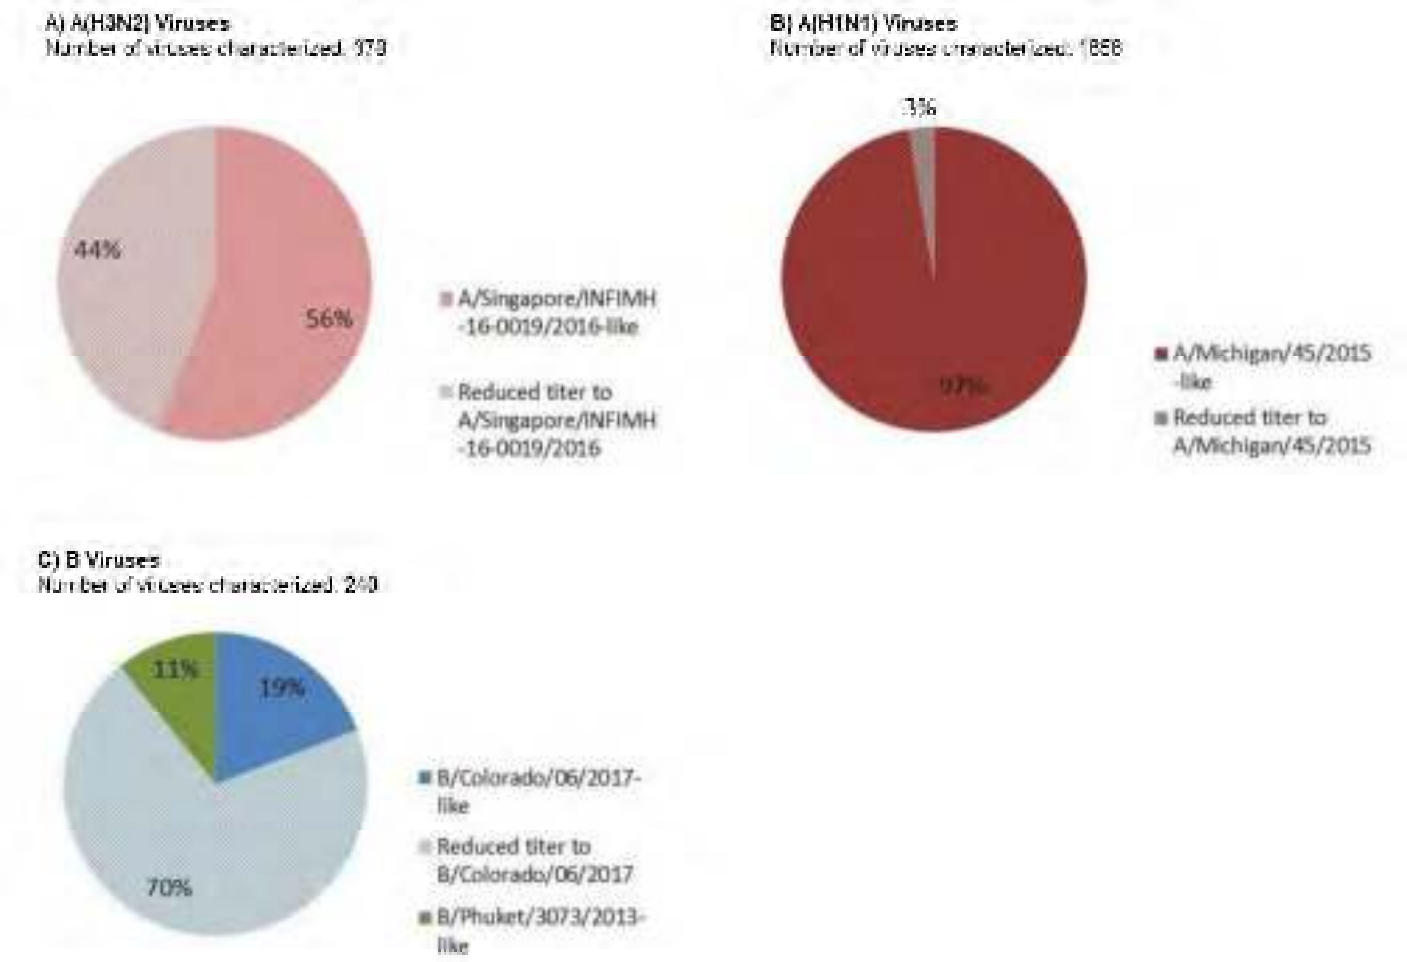

Antiviral Resistance

All influenza viruses characterized at the NML in the 2018-19 season were resistant to amantadine and sensitive to zanamivir. All influenza A(H3N2), all influenza B viruses, and all but four A(H1N1) viruses were sensitive to oseltamivir. The four A(H1N1) viruses resistant to oseltamivir had a H275Y mutation in the viral neuraminidase. The proportion of influenza viruses resistant to oseltamivir in 2018-19 is similar to recent seasons. Since the 2009 pandemic, nearly all circulating strains of influenza have been sensitive to oseltamivir and zanamivir. Widespread resistance to amantadine among influenza A viruses has been observed for more than 10 years.

Table 3 – Proportion of characterized influenza viruses resistant to antivirals by type and subtype, Canada, 2018-35 to 2019-34

Virus type and subtype	Oseltamivir		Zanamivir		Amantadine	
	# tested	# resistant (%)	# tested	# resistant (%)	# tested	# resistant (%)
A (H3N2)	222	0 (0%)	222	0 (0%)	135	135 (100%)
A (H1N1)	1084	4 (0.4%)	1082	0 (0%)	391	391 (100%)
B	142	0 (0%)	142	0 (0%)	NA[1]	NA[1]
TOTAL	1448	4 (0.3%)	1446	0 (0%)	526	526 (100%)

[1]NA: Not Applicable

Vaccine Monitoring

Vaccine monitoring refers to activities related to the monitoring of influenza vaccine coverage and effectiveness.

The quadrivalent vaccines used in the 2018-19 northern hemisphere influenza season contained:

- an A/Michigan/45/2015 (H1N1)pdm09-like virus;
- an A/Singapore/INFIMH-16-0019/2016 (H3N2)-like virus;
- a B/Colorado/06/2017-like virus (B/Victoria/2/87 lineage); and
- a B/Phuket/3073/2013-like virus (B/Yamagata/16/88 lineage).

The B/Colorado/06/2017-like virus was included in both the trivalent and quadrivalent vaccines.

Vaccine Coverage

The Seasonal Influenza Immunization Coverage Survey is an annual telephone survey conducted between January and February that collects information from Canadians on whether they received the annual seasonal influenza vaccine that season. Vaccine coverage is measured as the percentage of people who received the influenza vaccine in a specific influenza season. More detail on the methodology used for the coverage survey can be viewed here.

Overall, influenza vaccination coverage in the 2018-2019 season (42%) was significantly higher than the 2017-2018 season (38%) and the 2016-2017 season (36%). The vaccination rate was lowest among adults 18-64 years of age without any chronic medical condition (31%); however, coverage increased mostly among this subgroup when compared to the previous two seasons. Among high-risk groups, vaccination coverage rates for adults 18-64 years of age with a chronic medical condition (43%) and seniors 65 years of age and older (70%) remained steady over the past three seasons.

Table 4 – Influenza vaccine coverage among adults (≥ 18 years of age) by age group, gender and chronic disease[1], Seasonal Influenza Vaccination Coverage Survey, Canada, September 2018-February 2019

	Male		Female		Combined	
Age group (years)	Total	Vaccine Coverage (%)	Total	Vaccine Coverage (%)	Total	Vaccine Coverage (%)
All adults (≥18)	1568	36.6	2150	46.8	3726	41.8
18-64	1252	28.6	1640	39.9	2898	34.3
without chronic diseases	948	25.8	1171	36.1	2124	30.8
with chronic diseases	304	36.3	465	48.5	770	42.8
≥65	316	69.0	510	70.9	828	69.9

[1]Excluded from stratified analysis: eight people who did not disclose their gender and four people (18-64 years old) who did not disclose whether they had any chronic diseases.

Vaccine Effectiveness

The Canadian Sentinel Practitioner Surveillance Network (SPSN) provides estimates of the effectiveness of the seasonal influenza vaccine in preventing primary care visits for laboratory confirmed influenza among Canadians of all ages but primarily those from 20-64 years of age.

Based on data collected between November 1, 2018 and April 30, 2019, VE against any influenza, foremost driven by A(H1N1) viruses, was 56% (95% CI: 47 to 64%), and for A(H1N1) alone was 67% (95% CI: 58 to 75%) (Table 5). This substantial protection against A(H1N1) was observed in all age groups. Conversely, the SPSN reported little or no vaccine protection against A(H3N2) viruses, with an overall VE against medically-attended outpatient A(H3N2) illness of 17% (95% CI: -13 to 39). Overall, the A(H3N2) VE estimate for 2018-19 was lower than expected generally for

A(H3N2) vaccines (~30%), and similar to that observed by SPSN in the 2017-18 A(H3N2)-dominant season where VE was estimated at 14% (95% CI: -8 to 31).

More information on the SPSN including study methodology and available publications can be viewed here.

The Serious Outcomes Surveillance (SOS) Network of the Canadian Immunization Research Network (CIRN-SOS) provides estimates of the effectiveness of the seasonal influenza vaccine in preventing hospitalization for laboratory-confirmed influenza in adults.

Based on data collected between November 1, 2018 and June 1, 2019 among adult (≥16 years of age) hospitalized cases of influenza, VE against any influenza was 43% (95% CI: 28 to 55%), and for A(H1N1) alone was 68% (95% CI: 52 to 79%). CIRN-SOS also reported little or no vaccine protection against A(H3N2) viruses, with an overall VE against hospitalized cases of influenza A(H3N2) of 19% (95% CI: -35 to 51). The number of influenza B hospitalized cases was too low to calculate an adjusted VE estimate.

More information on the CIRN-SOS Network including study methodology and available publications can be viewed here.

Table 5 – Vaccine effectiveness estimates against primary care visits (SPSN - November 1, 2018, to April 30, 2019) and hospitalizations (CIRN-SOS - November 1, 2018 to June 1, 2019)

	SPSN (Primay Care Visits)†		CIRN-SOS (Adult Hospitalizations)	
	VE(%) (CI)*	N	VE(%) (CI)**	N
All Influenza	56 (47, 64)	3034	43 (28, 55)	1350
Influenza A	55 (46, 63)	2992	58 (43, 69)	1105
Influenza A H1N1	67 (58, 75)	2630	68 (52, 79)	562
Influenza A H3N2	17 (-13, 39)	1993	19 (-35, 51)	409
Influenza B	72 (27, 89)	1703	n/a***	140

† SPSN 2018-19 estimates are published and available here and here
CI: 95% confidence interval
*adjusted for age, province, specimen collection interval and calendar time (natural cubic spline with 3 equally spaced knots)
** VE for All Influenza, Influenza A, Influenza A/H1, and Influenza A/H3 was adjusted for age, pregnancy and current or past smoker.
VE for 16-49 and 50-64 age groups was adjusted for age, body mass index categories, pregnancy and medications prior to admission.
VE for 65-75 and >75 age groups was adjusted for age, Frailty index prior to admission; and current or past smoker.
***Sample size was too small to calculate an adjusted estimate

What health professionals need to know

Influenza is a respiratory illness caused primarily by the influenza A and B viruses.

While most people recover in 7 to 10 days, severe illness can occur. Some groups are at a greater risk of influenza-related complications.

Getting vaccinated against influenza each fall is the best way to help prevent infection.

For the 2021-22 flu season, it is especially important for Canadians to get the flu vaccine to reduce:

- the morbidity and mortality associated with influenza
- any further pressure on the health care system during the COVID-19 pandemic

Access the 2021-2022 seasonal influenza vaccine mobile guide.

For additional advice regarding the administration of seasonal influenza vaccine in the context of the COVID-19 pandemic, refer to

- Guidance on the use of seasonal influenza vaccine in the presence of COVID-19

Get free influenza awareness and educational products

Agent of disease

Influenza A and B are the main influenza viruses that cause seasonal outbreaks in humans.

Influenza A viruses are classified into subtypes based on 2 surface proteins:

1. hemagglutinin (HA)
2. neuraminidase (NA)

Of these, the influenza A viruses that have caused widespread human disease over the decades are:

- 3 subtypes of HA (H1, H2 and H3)
- 2 subtypes of NA (N1 and N2)

Influenza B has evolved into 2 lineages:

1. B/Yamagata
2. B/Victoria

Over time, antigenic variation (antigenic drift) of strains occurs within an influenza A subtype or B lineage. The ever-present possibility of antigenic drift requires seasonal influenza vaccines to be reformulated annually. Antigenic drift may occur in 1 or more influenza virus strains. This is why a new flu vaccine is needed each flu season.

Spectrum of clinical illness

Influenza virus infection causes a wide spectrum of illness. It ranges from asymptomatic to mild and from uncomplicated illness to severe, complicated illness.

Influenza symptoms typically include sudden onset of:

- high fever
- cough
- muscle aches and pains

Other common symptoms include:

- headache
- chills or feeling feverish
- fatigue
- loss of appetite
- sore throat
- runny/stuffy nose

In some people, especially children, nausea, vomiting and diarrhea may occur.

While most people recover in 7 to 10 days, severe illness can develop. Some groups are at increased risk of complications and hospitalization.

Symptoms of the flu can be similar to symptoms of COVID-19. Refer to the section on COVID-19 for health professionals for more information.

Transmission

Influenza is primarily transmitted by droplets and spread through coughing or sneezing. It may also be transmitted through direct or indirect contact with infected respiratory secretions.

The incubation period of influenza is usually 2 days, but can range from 1 to 4 days. Adults may be able to spread influenza to others from 1 day before symptoms start to approximately 5 days after.

Children and people with weakened immune systems may be infectious for longer.

Risk groups for influenza-related complications

The people at high risk of influenza-related complications or hospitalization include:

- people who are pregnant
- children and adults with the following chronic health conditions:
  - cardiac or pulmonary disorders
  - diabetes mellitus and other metabolic diseases
  - cancer and other immune compromising conditions due to underlying disease and/or therapy
  - renal disease
  - anemia or hemoglobinopathy
  - neurological or neurodevelopmental conditions
  - morbid obesity (body mass index of 40 and over)
  - children up to 18 years of age undergoing treatment for long periods with acetylsalicylic acid (ASA)
- residents of nursing homes and other chronic care facilities
- adults 65 years of age and older
- all children younger than 60 months of age
- people who have reduced access to health care, such as vulnerable populations like those experiencing homelessness or those with disabilities
- people who are at an increased risk of illness because of living conditions, such as those:
  - living in shelters who experience overcrowding

- who have limited access to facilities for personal hygiene
- persons with disabilities who might have limited capacity to understand or perform personal hygiene practices

The following statement elaborates on persons at high risk of influenza-related complications:

- National Advisory Committee on Immunization (NACI): Canadian Immunization Guide Chapter on Influenza and Statement on Seasonal Influenza Vaccine for 2021-2022

Additionally, to reduce the risk of severe illness that could potentially arise from co-infection with SARS-CoV-2 and influenza, it is particularly recommended that the following groups also receive the influenza vaccine this season:

- people at high risk of severe COVID-19 related illness
- people capable of transmitting influenza to those at high risk of severe illness related to COVID-19

For additional advice regarding the administration of seasonal influenza vaccine in the context of the COVID-19 pandemic, refer to:

- Guidance on the use of seasonal influenza vaccine in the presence of COVID-19

Prevention and control

Annual influenza vaccination is the most effective way to help prevent influenza and its complications.

NACI is an external advisory body to the Public Health Agency of Canada. NACI makes recommendations on the optimal use of vaccines available for use in Canada.

Every year, NACI issues a statement on seasonal influenza vaccine to inform health care providers on its use based on the most current data available.

Further clinical guidance about vaccination, including vaccine administration advice and additional safety considerations, can be found in the Canadian Immunization Guide.

NACI recommends influenza vaccine for all Canadians aged 6 months and older who do not have a contraindication to the vaccine.

To reduce the morbidity and mortality associated with influenza, immunization programs should focus on people 6 months of age and older who are:

- at high risk of influenza-related complications
- especially capable of transmitting influenza to those at high risk, including:
  - health care and other care providers in facilities and community settings
  - household contacts (adults and children) of individuals at high risk of influenza-related complications, including:
    - infants less than 6 months old
    - members of a household expecting a newborn during influenza season
  - those providing regular child care to children younger than 60 months of age
  - those providing services in closed or relatively closed settings to those at high risk, such as a ship's crew

These immunization programs should also specifically include those who:

- provide essential community services

- are directly involved in culling operations with poultry infected with avian influenza

Trivalent (3 strains) and quadrivalent (4 strains) influenza vaccines are authorized for use in Canada. Not all vaccine products are available in all jurisdictions. Availability of some products may be limited. Therefore, individual provinces and territories must be consulted about the products available in their jurisdictions.

Health care providers should offer influenza vaccine when it becomes available in the fall. Decisions about the precise timing of vaccination programs in a given geographic area are made considering:

- local influenza activity
- programmatic factors

It is preferable to administer vaccines before the onset of flu season. However, vaccination is still effective and may be offered until the end of the season.

For people 12 years of age and older, the administration of other vaccines can be given at the same time as, or before or after, seasonal influenza vaccines, including:

- the live-attenuated influenza vaccine
- COVID-19 vaccines

It is safe to administer a COVID-19 vaccine at the same time as other vaccines, such as the influenza vaccine.

For children 5 to 11 years of age, NACI recommends that a 14-day interval between a COVID-19 vaccine and other vaccines be considered. This is a precautionary measure to help better monitor possible side effects from a

COVID-19 vaccine. Provinces and territories will decide on an interval for this age group as part of their vaccination programs.

To help prevent the spread of influenza and COVID-19, health care providers can:

- receive influenza vaccine themselves to help prevent transmitting influenza to their patients
- discuss the risks and benefits of the influenza vaccine with patients, as well as the risks of not being vaccinated
- use every opportunity to administer the flu vaccine to people at risk, even after influenza activity has been documented in the community
- teach patients about public health measures to reduce and prevent the spread of influenza and COVID-19
- inform patients that symptoms of influenza and COVID-19 are similar and what to do if they start to develop symptoms

For additional advice regarding the administration of seasonal influenza vaccine in the context of the COVID-19 pandemic, refer to:

- Guidance on the use of seasonal influenza vaccine in the presence of COVID-19

Treatment

Most people with influenza will become only mildly ill and do not need medical care or antiviral medication.

Health care providers may wish to consider prescribing antiviral drugs to reduce influenza morbidity and mortality, especially for people in high-risk groups or who are severely ill. Antivirals drugs licensed in Canada for influenza treatment and/or prophylaxis include:

- oseltamivir
- zanamivir
- peramivir

Their use will depend on a number of factors, such as:

- patient risk
- relevant history
- duration and severity of symptoms

For information on the clinical management of influenza, consult the following guidance:

- Association of Medical Microbiology and Infectious Disease Canada (AMMI)
  - Use of antiviral drugs for seasonal influenza: Foundation document for practitioners, update 2019 (PDF)
  - Algorithm for oseltamivir and zanamivir treatment of mild or uncomplicated influenza in adults (PDF)
- Canadian Critical Care Society's guidance on managing patients with severe acute respiratory infection in an intensive care setting (PDF)

Epidemiology of influenza in Canada

Influenza and pneumonia are ranked among the top 10 leading causes of death in Canada.

Each year in Canada, it is estimated that influenza causes approximately:

- 12,200 hospitalizations
- 3,500 deaths

Surveillance

FluWatch surveillance

FluWatch, Canada's national influenza surveillance system, monitors the spread of influenza and influenza-like illnesses (ILI). It provides current information about circulating influenza strains. It also indicates what proportion of those are resistant to antivirals.

For the latest information on influenza activity in Canada, visit FluWatch report.

Primary care physicians, nurse practitioners and registered nurses can become FluWatch sentinel practitioners. Visit FluWatch Sentinel Practitioner ILI Surveillance Program for more information.

You may also encourage your patients to track influenza and COVID-19 by becoming a FluWatcher.

International surveillance

Every year, worldwide seasonal influenza causes an estimated:

- 1 billion infections
- 3 to 5 million cases of severe illness
- 290,000 to 650,000 deaths

For current international activity, visit the World Health Organization's FluNet website.

The following list of undertakings, advisements and refusals is meant as a guide only for the assistance of counsel and no other purpose

INDEX OF UNDERTAKINGS

The questions/requests undertaken are noted by U/T and appear on the following page number: 11.

INDEX OF ADVISEMENTS

The questions/requests taken under advisement are noted by U/A and appear on the following page numbers: 16, 17.

INDEX OF REFUSALS

The questions/requests refused are noted by R/F and appear on the following page number: 34.

INDEX OF EXHIBITS

NUMBER/DESCRIPTION PAGE NO.

1: Photograph of Trinity Bible Chapel Sanctuary, January 24, 2021. 26

--- Upon commencing at 1:02 p.m.

THE REPORTER: Counsel, as you all know, because we are using a virtual connection, everyone is going to have to be more conscious than ever of not speaking over each other. If I cannot hear the end of a question or the beginning of an answer, you are going to have a very poor record. If I have to consistently interrupt because I cannot hear or understand something that is said, you will not have a good examination flow. If there is an objection, I must be able to hear it and know who is objecting. If I do have to interrupt, please be patient and understand my goal is to provide you with a perfect record of these proceedings. Please move your papers and/or legal pads away from your phone so there is no ambient noise.

From time to time we've noticed the audio can be affected, and if so, we may need to stop the proceedings and wait a moment for the audio to improve, either by reconnecting or asking that everyone use the conference call number if you're using computer audio.

Would the witness please identify himself and spell your first and last name?

THE DEPONENT: My name is Jacob Reaume, J-A-C-O-B-R-E-A-U-M-E.

THE REPORTER: Our witness today is Jacob Reaume. If there are any questions about the witness' identity, would counsel please advise on the record now?

Hearing no objection, counsel, are you ready for me to affirm the witness?

MR. HUNTER: Yes.

JACOB REAUME, Affirmed

CROSS-EXAMINATION BY MR. HUNTER:

1 Q. Good afternoon, Pastor Reaume. My name is Josh Hunter and I'll be asking you some questions on behalf of the Attorney General of Ontario. I understand you swore an affidavit on June 4, 2021. Do you have that affidavit with you?

A. I do not have it in front of me, no.

2 Q. Are you able to access it?

A. I certainty can, yes.

3 Q. I'm going to be asking you some questions about it, so if you can pull that up that would be appreciated.

A. Yes, absolutely.

I now have it in front of me.

Q. Thank you. I'm going to start on the first page with paragraph 2. I understand you're the senior pastor of the Respondent, Trinity Bible Chapel in Waterloo?

A. That is correct.

Q. And I understand you have a baccalaureate degree in religious education?

A. That is correct.

Q. And a Master of Divinity?

A. Correct.

Q. Do you have any other university degrees?

A. No, I do not.

Q. Do you have any other professional qualifications?

A. I am an ordained minister. So I was ordained many years ago to be a pastor, and I have completed a program in church planting.

Q. And you're not a lawyer?

A. I am not a lawyer.

Q. You are not a physician?

A. I am not a physician.

Q. And you're not any other kind of regulated health professional?

A. I am not.

Q. You don't have any training in epidemiology?

A. I do not have training in epidemiology.

Q. Or in public health?

A. I do not.

Q. Or in statistics?

A. Nope. No training in statistics outside of what I would have learned in high school.

Q. I'd like to ask you some questions about Trinity Bible Chapel, the facility in Waterloo. And I understand you say at paragraph 4 that it houses over 900 people based on fire code regulations. Is that for the whole building or is that particular rooms?

A. That would be the building in its entirety.

Q. And how many -- I'm not going to go into like offices, but how many large rooms that can hold gatherings are there in that facility?

A. Well, there would be a sanctuary, and then we have a very large gymnasium, and then there is a number of classrooms as well as offices.

Q. And do you know the capacity of

the sanctuary?

A. I don't know it specifically, no.

Q. And about what percentage of the facility would you say the sanctuary takes up?

A. Well, I would say... as far as fire code?

Q. Just square footage. I'm just trying to get a bit of a mental picture of what your facility looks like.

A. In all honesty, I don't know specifically the number offhand.

Q. More than half?

A. I don't have reason to believe it's more than half, no, but again I'm not certain.

Q. I'm not asking for scientific certainty on this point. I'm just trying to get a sense of, you know, is it -- I know you have a school in the building as well. I'm just trying to get a general sense of what the split is between the school facilities and between the church facilities?

A. It's hard to say offhand. I mean certainly we can house a lot of people as I indicated, but I don't know the percentages. I think -- I don't know them. If I had a floor plan

in front of me I would be able to better say, but I don't know them.

Q. Do you have a floor plan of the facility?

A. I would have access to one if I wanted one, but I don't have one readily available, no.

Q. Can we get a copy of it?

MS. BILDY: Counsel, I'm sorry to interrupt. I don't want to interrupt your flow, but I see that Pastor Hildebrandt has come into the room. And I asked him to be on standby, but you probably would rather he not be in here right now. So, Pastor Hildebrandt, if you could just sign out for right now and we'll bring you in when this examination is finished.

Thank you. Sorry to interrupt.

MR. HUNTER: Thank you, Ms. Bildy.

BY MR. HUNTER:

Q. So just before that I was just asking if we could get a copy of the floor plan of the facility.

A. Well, I believe that you have a copy, because it has come up in some of our, I believe, contempt hearings in the past. But if you

don't have that available I'm certain that that can be sent your way.

25 Q. Can we have an undertaking to that effect, Ms. Bildy?

U/T MS. BILDY: Yes. Specifically the floor plan? Or is there something -- we prepared some documents that showed how many people you can space out at one point. Is there something specific?

MR. HUNTER: Both those would be great.

U/T MS. BILDY: Yes. We will endeavour do give you what we have.

MR. HUNTER: Thank you.

BY MR. HUNTER:

26 Q. Pastor Reaume, paragraphs 10 to 12 of your affidavit there's some discussion about various steps the Waterloo Police were or were not taking in regards to protests in June 2020. I just want to understand, are you aware that the Waterloo Police reports to the Waterloo Police Services Board, not the Province of Ontario?

A. I'm not -- I mean that would make sense to me, but I'm not completely certain of all the dynamics there.

27 Q. Fair enough. It's a matter of

law. I guess the other question is, are you aware that the fact that the police exercised their discretion not to take enforcement activity on a particular occasion does not mean the conduct involved was or was not against the law?

A. Would you ask that question again, please?

28 Q. Sure. You understand the police have discretion whether to lay charges in a particular circumstance?

A. I understand that, yes.

29 Q. And so the fact that the police do or do not lay charges doesn't itself say whether or not the conduct at issue was against the law.

A. That makes sense to me.

30 Q. Now, exhibit R of your affidavit there's some photographs you had about I believe it was a counter-protest to a White Lives Matter march. Sorry, it's a newspaper report.

I understand you were not present at the White Lives Matter march, correct?

A. No.

31 Q. Or at the counter-protest?

A. I was not there.

32 Q. So this is just you reading an

article in the newspaper?

A. These are articles from somewhere on the internet perhaps, whatever the news source says.

33 Q. Actually if you could just turn it up for a second, please.

A. Sorry?

34 Q. Could you just turn to exhibit R?

A. Turn to exhibit R? Yes, one moment.

35 Q. I believe it's on page 126 and 127 of the PDF if that's helpful.

A. Okay. 126. It's just loading here. I see that. Wilmont Township anti-racism rally.

36 Q. And the quote I want to take you to is actually on the next page, page 127.

A. Sure. Go ahead.

37 Q. The chair of Waterloo Region is reported as saying, "the timing for any kind of in-person gathering isn't right"; is that correct?

A. I'm sorry. Where does it say that?

38 Q. It's about... after there's related stories and then a line?

A. It says:

"Karen Redman, the chair of the Region of Waterloo, says the timing for any kind of in-person gathering isn't right."

That is what it says.

39 Q. Thank you. And then it goes on to say -- this is at the bottom of the page:

"Waterloo regional police were on site of the rally to monitor and ensure public safety and say that they will work with bylaw on potential charges under the reopening Ontario act."

A. It does say that.

40 Q. Now, at exhibit S of your affidavit you attach some photographs from the St. Jacobs Farmers' Market, correct?

A. That is what they are, yes.

41 Q. You did not take those photographs?

A. I did not take those.

42 Q. Do you know who did?

A. I believe the individual's name is in the affidavit.

43 Q. No. It just says a parishioner of yours, that's why I'm asking.

A. I think somebody was actually named in the affidavit. And so if those pictures...

44 Q. Let's take a look at the affidavit then.

So it's at paragraph 70 on page 14 of the affidavit.

A. Mm-hmm.

45 Q. You just say a series of six photographs taken that day by a member of TBC's congregation.

A. So we're on page did you say 14?

46 Q. Page 14, yes. First paragraph, paragraph 70.

A. So if you go up to paragraph 67 there is mention of photographs, and I guess that would be exhibit Q which were taken by Alan Vandergaag.

47 Q. So that's May 8th, the week before. Are you saying it's the same person taking them on May 15th?

A. I'm not saying that. But I do know that there was an individual named in there.

It is in paragraph 67.

48 Q. Okay. But my question is do you know who took the photographs on May 15th marked as exhibit S?

A. Honestly, it was a while ago and I think I know, and if I were to go back to my notes, but I can't say definitively.

49 Q. Would you be able to go back to your notes and let us know? You can do that later. We don't need to do that right now.

A. Yeah. We can do that at another time perhaps.

50 Q. Can we get an undertaking to inform us who the source of the photographs are in exhibit S?

U/A MS. BILDY: Counsel, I will take that under advisement. I believe that they were -- my recollection is that this was a person who did not want her name to be publicized in any way. So perhaps with some assurances that the name is not going to be disclosed beyond your awareness then I think we can provide that name.

MR. HUNTER: That's fine of course.

THE DEPONENT: I would rather not give an undertaking to give the name of the person

involved. I'm willing to consider it. I think I know who it was, and I would prefer not to undertake to that.

MR. HUNTER: Well, it's your counsel who we've asked and she's taken it under advisement, which is fine for me for now. Obviously we'll follow up if need be, but of course we are entitled to the source of the information.

BY MR. HUNTER:

51 Q. I actually have the same question about exhibit T which is at paragraph 71, who the source of the photographs of Shade's Mills Conservation Authority is, and I'd ask for the same undertaking.

U/A MS. BILDY: Yes, also taken under advisement. I don't think there's an issue with that name, but I will let you know.

MR. HUNTER: Thank you.

BY MR. HUNTER:

52 Q. Next I'm going to ask you a question about exhibit U. This was another newspaper article about a vigil for indigenous children found at former residential schools. You were not at that vigil, correct?

A. I was not there.

53 Q. And I think there's some comments about what Waterloo bylaw were doing. Again, are you aware that, as the name implies, Waterloo bylaw officers work for the Region of Waterloo, not for the province?

A. That would make sense to me, but I'm not completely familiar with the relationship.

54 Q. So at paragraphs 13 to 16 of your affidavit you talk about some of the restrictions and how they were changing in the summer and early fall of 2020. Do you see that?

A. I'm at paragraph 13.

55 Q. Yes. And so would you agree with me that when the Covid situation improved in the summer of 2020 the gathering restrictions were loosened and your congregation was able to legally gather together?

A. Well, there was still limitations I believe on what the gathering limits were. And there might have been limitations as to what could be done inside. So were we completely free by law, or at least by these regulations, I don't believe we were. But certainly the limitations were loosened, if that's what you're asking.

56 Q. What I was asking was -- I mean

you had 30 percent capacity at that time indoors. And you've said your building has a capacity of about 900 people. So you could have at least 300 or so inside your church at one time.

A. That is possible.

57 Q. And then that happened again, you know, there was a second lockdown. But then, again, as the situation started to improve after the second lockdown the restrictions were again lifted. I think this is at paragraph 25. Sorry, no, wrong paragraph.

Paragraph 45. In February of 2021 when Waterloo was placed back into the red zone again you were allowed to hold religious gatherings at 30 percent of each room, correct?

A. So this is paragraph 45?

58 Q. Yes.

A. So my affidavit does say we were limited to 30 percent of room capacity. There you go.

59 Q. And you were able to hold services lawfully at that capacity limit?

A. If that's what the regulation says then that's what my affidavit says.

60 Q. At paragraph 26 of your affidavit

you say that you assume your congregants as adults are capable of making their own health decisions; is that correct?

A. Yes, that's correct.

61 Q. And you believe also that people shouldn't be forced to do something they believe they shouldn't unless the law of God requires them to do it; is that correct?

A. That's correct, yes.

62 Q. And so you believe that people are entitled to make their own health decisions about smoking at the workplace?

A. I think that would be fine.

63 Q. Even though it might have an impact on others sitting at the cubical next door?

A. I think it would be upon the owner of the establishment. All things considered, I believe ethically it should be upon the owner of the establishment to make that decision.

64 Q. And so the government shouldn't be able to regulate whether you can smoke at the office?

A. I believe -- I don't believe that is the government's prerogative, no.

65 Q. And should people be able to make

decisions about if they want to have a few drinks before dinner before driving home?

A. Well, I think when you get into that particular issue you're dealing with impairing, potentially impairing a driver, and now you're dealing -- you're potentially putting someone else at risk on the road. But if you're asking me how I think the government should legislate on that particular issue, is that what you're asking me?

66 Q. I'm asking about your belief that people should be able to make their own health decisions unfettered by the government, and the government -- we just had the example of secondhand smoking, it's not the place for the government to regular that. I think it's fair to say, given this whole application, that it's not the place of the government to regulate gathering limits, at least in places of worship, to protect public health.

I'm just asking about some other examples of areas where people make personal decisions and the government may want to regulate it to protect others. And so I just want your view, does the government have the ability to legislate driving if you make the personal health

decision to have a medicinal brandy before heading on the road?

A. Right. And so I think that issue is a little more complex in that when it comes to regulating how people drive on the highway there's an issue as to whether something should be actually regulated. Okay? So should it be law? Or if there is an accident, who's liable? Okay?

And so it seems to me as I read the scriptures, and you look at how law is implemented in scripture, an example of such a law would be -- it's regulated in the Old Testament that fences were to be placed around holes on private property if there's a hole that's dug. Okay? But what happens is if the fence -- my understanding is if the fence is not erected, you know, someone is not going to be find or go to jail for it. What happens is if somebody falls in the hole and is injured it's the property owner that must pay the victim.

So I guess your question is, is how should -- if you're getting to it, how do I think these regulations should play out. I think certainly if somebody is impaired behind the wheel and they cause an accident then they should be

liable for damages. Which is different from saying specifically that there should be a blood alcohol limit in somebody's body. Is it irresponsible to drink and drive? It most definitely is. Would I have some serious concerns if I found out that members of my congregation were doing that, I most definitely would.

But if the question is pertaining to what degree of government should be regulating things, my point is that in such instances it should fall upon if there is harm then there should be lawsuits and whatnot upon the individual involved. And so this is something I have given thought to.

67 Q. Now, at exhibit E of your affidavit you set out some of the measures your church did take to combat the spread of Covid-19. I just want to ask you a few questions about those measures, what you did do and what you didn't do. Did you require members of different households to distance themselves?

A. Can you please let me know what page you're on? I'm going to go down to that page, okay?

68 Q. Sure. I was talking more

generally, but you do set out some of the measures you took at exhibit E which is at page 48 of the PDF. I'm not sure those are all the measures you took that's why I want to ask you some questions about it.

A. And so which measure are you referring to?

69 Q. So I'm asking you -- I don't see it listed here, but I'm asking if it's something your church did, which is require members of different households to be separated by I think it was the recommended two metres?

A. And you're asking whether I required that?

70 Q. Correct.

A. Right. So what we did for awhile there is we put stickers on the seats, but we certainly would not tell family members not to sit with each other. I don't believe that ever happened.

71 Q. And what about if they weren't family members, or not members of the same household to be more precise?

A. If they were not members of the same household? I don't remember ever telling

someone not to sit beside somebody else. But the labels were on the seats, and there you have it.

72 Q. Did you require congregants to wear masks?

A. We informed people as to what the legislation was, and I never told somebody to put on a mask.

73 Q. Did your congregants generally wear masks?

A. I would say no, the overwhelming majority would not.

74 Q. I'm just going to share my screen for a second.

Can you see the photograph on my screen?

A. I'm just trying to get that up because I've been looking at my affidavit here. Just a second.

I'm aware of that photograph, yes.

75 Q. So my understanding is this is a photograph that was tweeted by Randy Hillier who was attending the service at your church on January 24, 2021; is that correct?

A. My understanding is that Randy Hillier tweeted that, yes.

76 Q. And this is the interior of your sanctuary?

A. It most definitely is.

77 Q. And I think you'd agree with me that -- I mean I don't see anyone wearing a mask, but at least if there's any there's certainly very few; would that be correct?

A. Oh, I don't -- that is absolutely correct. There seems to be very few wearing masks if there are any.

78 Q. Could I have that marked as an exhibit, please?

EXHIBIT NO. 1: Photograph of Trinity Bible Chapel Sanctuary, January 24, 2021.

MR. HUNTER: Any objection, Ms. Bildy?

MS. BILDY: No, I have no objection.

MR. HUNTER: So that will be exhibit 1, photograph of Trinity Bible Chapel sanctuary, January 24, 2021.

BY MR. HUNTER:

79 Q. Did you require rapid testing before congregants came to a service?

A. No.

80 Q. Did you require congregants to

show proof of vaccination before they come to services?

A. No.

81 Q. Did you collect congregants' contact information so public health could contact them if someone present did test positive?

A. There was a season where we had contact information and then there was a season when we didn't.

82 Q. Was there a reason for that change?

A. Well, there's multiple reasons.

83 Q. What were some of those reasons?

A. Well, one of the reasons is we didn't feel comfortable asking people for their contact information when we were constantly under surveillance by media and police.

84 Q. And you'd agree with me that if public health had no way of knowing who was present at a church it would be rather difficult to do contact tracing, wouldn't it?

A. Well, it would be very difficult for them.

85 Q. So they'd have no way of knowing if, you know, different cases were linked to

attendance at the church?

A. Right. They'd have no way of knowing that unless someone were to volunteer the information or I were to volunteer the information.

86 Q. But you wouldn't have had the records to volunteer the information of everyone who was there if you weren't collecting it, would you?

A. Well, I wouldn't have it written, but I quite often have a very good idea of who's at church and who's not.

87 Q. All 300 or so of them?

A. Yeah. Before I preach I kind of scan up and down. I usually have a good idea of who's there or not. Not always. It's not 100 percent, but I'm pretty good at it.

88 Q. So at paragraphs 80 and following of your affidavit, I'm not going to take you to them, but you set out some of the various religious beliefs you and your congregation hold. And I just want to ask you some questions about them. I just want to make sure I understand the scope of what your religious beliefs do and do not permit.

Does your religion prohibit you from wearing masks at a religious service?

A. So that's a really good question. And I want to kind of tackle that from a few different angles, and one is that the scriptures teach us that -- so I did a survey of this in the Bible when we first started doing this and looking through the scriptures, because this is an issue I've never dealt with before.

And as you look through the scriptures there's certain instances where people wear masks or their faces are veiled, and the overwhelming amount of them have to do with shame. So, for example, there's an instance in the Book of Genesis where a woman is a prostitute and she has her face covered, and it seems to be that that's shameful.

There's other instances where there is an encounter with God, and God is repulsed by the people's sins, and so the scriptures will say he hides his face from them. And that's speaking specifically of his face of blessing. And there's other instances where people are hiding from God because of their shame and they don't want to be seen by God. A very obvious instance would be in Genesis 3 when Adam and Eve are hiding because of their sin behind the bush. And so these instances are many in the scriptures, and I've surveyed I

think pretty well every single one of them.

And so to answer your question, is it against my religion to wear a face mask in worship? Well, the scriptures seem to indicate that it is a shameful thing to cover your face, or actually I should rather say that it is an expression of shame; you're trying to hide something.

And furthermore, as you look at it the apostles, and the apostle Paul I believe says, "He longed to see his people face-to-face." So the desire to see somebody face-to-face is a desire that is articulated in scripture.

But on this particular issue the way that we've handled it as a church is we've said that it's a Romans 14 issue. When I talk about Romans 14 what I'm referring to is there are some things that are issues of conscience. So they're not clearly taught one way or another in scripture. You could kind of go one way or you could go the other.

And so what we've told people is if your conscience is afflicted and your conscience is telling you to wear a face covering then you must wear a face covering and to not do that that would be sin. If your conscience is telling you not to

wear a face covering then you can't wear one. That's sin.

And so there are certain issues that are very clear in scripture. This is an issue where you look at the evidence and you kind of weigh it one way or another. I've come to my conclusions, and I'm not shy about sharing them with my congregation. But because we haven't had as much time to think about this we are -- that's where we are. It's an issue of conscience.

Now, is it -- but here's a better question as it pertains to this issue. Is it a matter of doctrine or a matter of Christian conviction that the government has no right to tell us what to wear when we go to worship? That is a matter of Christian conviction, okay? So people have gone to jail for that and they've been punished for that in the past, and that has been the impetus, or at least part of the impetus even behind wars in the past. So that is a very serious issue.

Because the issue of the government telling people what to wear, especially on their faces when they go to their place of worship and to worship God Almighty is not the government's

prerogative. And so if you want to ask me what my view is on that I feel very strongly. Whether an individual is required to wear a face mask and what their conscience is telling them to do that is upon them but it is not upon the state.

89 Q. I'm going to ask you about a number of different topics. So I'm kind of asking you the same question, whether you believe that this is something that is mandated by your religion or not. So the next topic I want to ask you about is requiring social distancing between households when at worship to protect public health.

A. And what would you like to know about that?

90 Q. Is that something that your religion would forbid?

A. My religion forbids, my God forbids me from telling people where they can and cannot stand. That's what cults do. They tell people whose hands they can't shake. And they tell people who they cannot hug and who they can hug. And so I don't want to be a cult leader. I don't want to go outside of what the scriptures teach me. And that's not my prerogative to tell people where they can stand and who they can stand with and who

they can meet with and who they can or cannot eat with.

91 Q. And does your religion prohibit people from getting vaccinated?

A. Again, the vaccination issue is -- again, I go back to the Book of Romans, chapter 14, which again deals with issues of conscience. And in the Book of Romans, chapter 14, the Apostle Paul was dealing with a controversy where some people thought they should eat things and some other people thought they shouldn't eat things.

And the Apostle Paul says, essentially, whatever is not done in faith in sin. And so if an individual -- and this is recorded in our historic confessions. It's recorded in the London Baptist Confession which was written in 1689, and it speaks of matters of conscience. And I would certainly agree to most of what's in that London Baptist Confession. And it speaks to issues of conscience.

And, again, if a person is taking the vaccine in faith then it's not sin. If a person is taking the vaccine, but it's not done in faith then it is sin. And the contrary is true. So medical choices of this nature fall down to an issue of conscience. And for some people, yes, I would say

unequivocally and patently it is sinful for them to take the vaccine and for some people I would say unequivocally and patently it is not sinful to take the vaccine.

And the thing about Christianity and about the Bible is that it doesn't speak to every single issue of life. And on those issues the Christian religion has historically, at least Baptists and Protestants have taught that there are matters of conscience, and what is not done in faith is sin. Or what is not done in faith is sin and what is done in faith is not sin.

92 Q. Have you yourself been vaccinated?

R/F MS. BILDY: Sorry, I'm going to object to that question. That's not something that is before the court, it's not relevant to this examination and it's personal information.

MR. HUNTER: I have your refusal. Thank you.

BY MR. HUNTER:

93 Q. Going back to this idea of conscience. I just want to explore it a bit more so I can understand how your religious beliefs about conscience interplay with this. I assume you'd agree with me that conscience of course has

to be properly formed?

A. Right. A conscience -- the conscience must be informed by the word of God which is scripture.

94 Q. And I was going to say, and for your religious tradition that would be scripture, correct?

A. Scripture is our record of God speaking to us in print.

95 Q. And as you've already discussed, there's matters on which scripture does not provide a definitive answer, correct?

A. Well, there might be, yes. There certainly are.

96 Q. Obviously it was written over thousands of years dealing with the conditions of the people of God at those times. We didn't have all the modern technological -- or some of the issues. So there's going to be matters that people are going to have to either interpret scripture or rely on their conscience to decide how to deal with them in the modern world, correct?

A. Well, when it comes to ethical issues or medical issues the scripture will inform the conscience. Now, the question is: Are we

seeing the world properly? And what is the information that we have? So I believe that on all ethical issues the scripture does inform us. On, you know, what colour of shoelaces I wear I don't think it really informs me on that.

97 Q. And so -- I just want to understand your belief. If it ultimately comes down to one can't go against one's conscience the government doesn't have the ability to make determinations on those matters for people; is that your belief?

A. My belief that if the government is attempting to coerce conscience on an issue that the scripture does not permit them to coerce conscience then it is likely that that government is now tyrannical.

98 Q. And, therefore, in your view should not be followed?

A. Well, it would depend on the individual's conscience, again, right? But if their conscience says do not do this and that conscience is properly informed by scripture then they ought not follow, that is correct.

99 Q. So let's just talk about that in some different scenarios, and maybe scripture will

deal with them or maybe they won't, but I just want to try and understand how we'd apply this concept.

You know, what if one's conscience thinks we shouldn't pay taxes to the government because it's going to use them for unethical things such as maybe going to war or promoting beliefs that you don't agree with. Would that be something you would have the conscientious right not to pay your taxes?

A. Well, this is an interesting question. And certainly the scriptures tell us to pay taxes frankly. And there are parts of scripture where we are told to pay taxes. But there also is other responsibilities and other things that we must pay for also. So, for example, to feed children that God has entrusted to us, or care for our families. And so if it came between paying taxes and feeding children, then I think the children would take first place. But under normal circumstances Christians are required to pay their taxes.

100 Q. And even though the government may use those funds to, you know, perhaps promote social causes that would go against the gospel.

A. Well, I mean the Lord Jesus taught

to render under Caesar that which is Caesar's, and he was talking about taxes, and so those tax dollars were used to crucify him.

101 Q. And I assume, you know, if we're talking about there's a fire code limit on your building, if, you know, you had say 1500 people show up one day for service would you have to comply with those fire code regulations to keep everyone from being trampled in case there was a fire?

A. Well, we would have to ask ourselves what is the most responsible decision in that instance. I mean 1500 people is an extreme example. But what about if our fire code was 900, what about 901? So we would have to weigh the situation and we would have to weigh the need of the people.

Certainly in my mind fire codes are reasonable capacities on limits as far as how many can attend. Certainly a facility like ours I've never found the fire code to be onerous. I've never found it to be a hindrance to our worship. But, mind you, if there were people that were in desperate need of hearing the gospel of Jesus Christ and desiring to do so and sit under the

preached word and worship Christ and receive Christian fellowship we would have to weigh that out.

102 Q. And ultimately it would be your decision following your conscience as leader of the congregation whether to follow that law or not?

A. Right. And so this goes back to I think the previous conversation we had. And, again, as a property owner ultimately I think the call is upon the property owners to do these things.

Now, do we follow building code with all of our construction projects? As far as I know, and I certainly desire that we do because those make good sense. They can be a little onerous at times. Do we have our books audited every year? We most definitely do. Do we try to keep above board with the CRA? We've done everything we can to do that.

But if it comes to fire codes, again, the scriptures teach us that human life is the priority. And so if there is a human being who is in need then I don't think we're going to turn them away in that case. Now, if the human being is going to be put in danger in that instance then

we're going to have to weigh that also.

But it's kind of like asking the question, you know, if you have a soup kitchen and your fire code is 250 people for your soup kitchen, and so 250 starving, emaciated people show up, do you let in the next 10 and they're emaciated too? Well, I think I'd let in the next 10, because that's what goodwill is and that's what kindness and love is.

103 Q. And ultimately that would be your decision whether or not to do, and you don't think the government or perhaps a court should be able to make that decision for you?

A. Well, I think if someone was penalized for doing that it wouldn't be proper, but the person who made the decision has to take that -- you know, they're taking that responsibility upon themselves.

104 Q. And, of course, you've been willing to defy court orders on several occasions in the last couple of months?

A. Well, I've been convicted, I believe, of it two times.

105 Q. And so I know you've said on a couple of different occasions that there's God's

law and man's law, and if there's a conflict between them God's law is what has to be followed, correct?

A. God's law is from all eternity. And so his law is the superior law that is the true standard of righteousness and holiness.

106 Q. And so I think, therefore, you'd be of the view that freedom of religion cannot be limited?

A. Well, I think there's certain questions that have to be answered. And I don't -- are you asking should freedom of religion be limited in an ideal society? Is that what you're asking? In our society I don't think there should be limits on freedom of religion, but I'm talking about an ideal society.

So I guess to answer your question I can answer this another way. If a religion says our religion requires us to offer our children up to Moloch to be killed, which has happened in the Old Testament, you might be aware of that, that should not be considered as a free religion. Right? That's not freedom of religion, because God's law forbids murder, and murdering children is against God's law. And so that should not fall

under unlimited freedom of religion. So there is bounds on that and it is bound by God's law.

107 Q. You'd agree that, you know, the Christian church's freedom should not be limited by the law?

A. Well, I mean it depends what the freedom is. But certainly our worship and the preaching of God's word and our prayers, I mean, I don't know, there might be some exception out there that I'm not aware of, but certainly orthodox Christianity should not be limited.

MR. HUNTER: Can we go off the record for a minute, please?

--- Off-the-record discussion

--- Recess at 1:47 p.m.

--- On resuming at 1:54 p.m.

MR. HUNTER: Thank you, Pastor Reaume. Those are all my questions. Ms. Bildy may have some questions for you.

MS. BILDY: Actually I think we're fine. We don't need a redirect.

MR. HUNTER: Thank you. We can go off the record then.

---Whereupon the proceedings adjourned at 1:55 p.m.

REPORTER'S CERTIFICATE

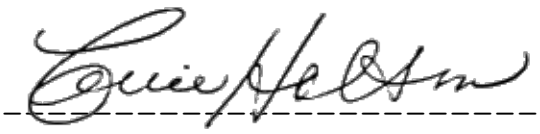
I, CONNIE A. HOLTON, CSR, Certified Shorthand Reporter, certify;

That the foregoing proceedings were taken before me at the time and place therein set forth, at which time the witness was put under oath by me;

That the testimony of the witness and all objections made at the time of the examination were recorded stenographically by me and were thereafter transcribed;

That the foregoing is a true and correct transcript of my shorthand notes so taken.

Dated this 23rd day of December, 2021.



Per: Connie A. Holton, CSR

CROSS-EXAMINATION BY MR. HUNTER..... 6

The following list of undertakings, advisements and refusals is meant as a guide only for the assistance of counsel and no other purpose

INDEX OF UNDERTAKINGS

The questions/requests undertaken are noted by U/T and appear on the following page number: 10.

INDEX OF ADVISEMENTS

The questions/requests taken under advisement are noted by U/A and appear on the following page numbers: (None noted).

INDEX OF REFUSALS

The questions/requests refused are noted by R/F and appear on the following page number: 15.

INDEX OF EXHIBITS

NUMBER/DESCRIPTION PAGE NO.

(NONE MARKED)

--- Upon commencing at 2:00 p.m.

THE REPORTER: Counsel, as you all know, because we are using a virtual connection, everyone is going to have to be more conscious than ever of not speaking over each other. If I cannot hear the end of a question or the beginning of an answer, you are going to have a very poor record. If I have to consistently interrupt because I cannot hear or understand something that is said, you will not have a good examination flow. If there is an objection, I must be able to hear it and know who is objecting. If I do have to interrupt, please be patient and understand my goal is to provide you with a perfect record of these proceedings. Please move your papers and/or legal pads away from your phone so there is no ambient noise.

From time to time we've noticed the audio can be affected, and if so, we may need to stop the proceedings and wait a moment for the audio to improve, either by reconnecting or asking that everyone use the conference call number if you're using computer audio.

Would the witness please identify himself and spell your first and last name?

THE DEPONENT: My first name is Henry. And the last name is Hildebrandt, H-I-L-D-E-B-R-A-N-D-T.

THE REPORTER: Our witness today is Henry Hildebrandt. If there are any questions about the witness' identity, would counsel please advise on the record now?

Hearing no objection, counsel, are you ready for me to affirm the witness?

MR. HUNTER: Yes.

HENRY HILDEBRANDT, Affirmed

CROSS-EXAMINATION BY MR. HUNTER:

1 Q. Good afternoon, Pastor Hildebrandt. My name is Josh Hunter. I'm counsel for the Attorney General of Ontario. I'm going to be asking you some questions about an affidavit you swore on June 4th of 2021. Do you have a copy of that affidavit with you?

A. I do not have it here with me.

2 Q. Are you able to get a copy of the affidavit?

A. I believe I could. I'm sorry, I am not close to -- I didn't realize I would need it here so I don't have it.

3 Q. Ms. Bildy, is there a way we can

facilitate? Obviously I would like the witness to have his affidavit before him before I ask him questions about it.

MS. BILDY: Of course. My apologies for not making that clear. Pastor Hildebrandt, if you have it on your computer, which you do because it was emailed to you, just open it up on a window and then you can go back and forth between the Zoom screen and your affidavit.

THE DEPONENT: I will do that. I'm so sorry.

MS. BILDY: That's okay.

THE DEPONENT: I am so sorry for the delay. I am trying hard to find it here as quick as possible.

MS. BILDY: I will email it again to you.

THE DEPONENT: I have it now right in front of me here.

BY MR. HUNTER:

4 Q. I just have a few questions about -- I'll take you to the text, but I just wanted to make sure you had that opportunity.

I'm going to start on paragraph 2 of your affidavit. It's around the first page. I

understand you're the Pastor at the Church of God in Aylmer, Ontario?

A. That is correct, Mr. Hunter.

Q. And is that an ordained ministry? I'm not sure how your church works. Do you have to have any particular qualifications for that position?

A. That is correct, I am ordained.

Q. And did that require university training?

A. It did not.

Q. Do you have a university degree?

A. I do not have university training.

Q. So, therefore, I understand you're not a lawyer?

A. Could you say that question again?

Q. You're not a lawyer?

A. I am not a lawyer.

Q. You're not a physician?

A. I'm sorry, I'm the Pastor of the Church of God.

Q. I just want to clarify for the record about certain other qualifications that you do or do not have. And so I understand you're not a physician?

A. That's correct.

Q. Or any other kind of regulated health professional?

A. I am not.

Q. You don't have any training in epidemiology?

A. No, I don't.

Q. Or in public health?

A. I do not.

Q. Or in statistics?

A. I do not.

Q. So now I'd just like to ask some questions about the Church of God in Aylmer, the building that is. Can you just describe the facility to me?

A. So we have at the west end of it we would call it the auditorium, that's the main building, and then adjacent to that -- well, in between we have the restrooms and the foyer. And then adjacent to that we have the school building where our school is being held, and that is -- it's an L-shaped building. So we have a 10 or 11 classrooms there.

Q. And so is the auditorium where you would normally hold Sunday services?

A. That is correct.

18 Q. And do you know what the capacity of that room is?

A. I am not aware, but I can find out for you.

19 Q. Can we have an undertaking to that effect, please?

U/T MS. BILDY: Yes. I believe that information is available and I will provide that to you.

MR. HUNTER: Thank you.

BY MR. HUNTER:

20 Q. Do you have a floor plan of the building?

A. We do.

21 Q. Can we have a copy of that, please?

A. I'll make sure you get it.

U/T MS. BILDY: Yes, we can provide that to you.

BY MR. HUNTER:

22 Q. So at paragraphs 11 to 15 of your affidavit, this is on pages 3 and 4, you don't need to look at it in detail, but just for your reference, you describe various interactions with

the Aylmer police. And I just want to understand if you understand that the Aylmer police report to the Aylmer Police Services Board and not to the Province of Ontario?

A. I am not familiar how they operate, but it makes sense what you're saying.

Q. And then at paragraph 21 of your affidavit, that's on page 5, you talk about how you have been doing drive-in services which the government did allow in response to some of your efforts and those of others, but then in the summer of 2020 when the Covid situation improved the regulations were changed to allow 30 percent capacity. And you'd agree with me that you were then able to hold services lawfully at that time?

A. Could you ask your question again, please?

Q. So in the summer of 2020 when the Covid situation improved and the gathering restrictions were loosened you were able to hold in-person gatherings lawfully in the Church of God facility, correct?

A. That's correct.

Q. And that occurred again, you know, things were tightened for the second wave in

December or January of 2020/2021, but then they were loosened again when the situation improved in February of 2021?

A. Correct.

26 Q. And then at paragraph 36 of your affidavit, which is on the top of page 9. You see that paragraph?

A. Yes, sir.

27 Q. You state that continuing presently the limit for religious services is 10 people indoors or out. You'd agree with me that's not in fact correct, is it?

A. That is paragraph 36 you said?

28 Q. The second sentence, yes.

A. I do not remember the exact date. Things changed so often I don't know which one was at what time.

29 Q. My point is just that the current limit on religious services is not 10 people indoors or outdoors, correct?

A. You're saying right now?

30 Q. Yes.

A. Right now my understanding is that it is not limited to 10 people.

31 Q. And, in fact, since June 10, 2021,

you may not know the exact date, but you agree with me that it first went up to 15 percent of room capacity? Do you remember that?

A. I'm sorry, I don't remember which date they did what.

32 Q. You don't remember the date, but you remember the fact that it went back up?

A. I believe so. I don't know if it went to 15 or 30 or what. Like I said, it changed so many times, I don't recall which way it went and when it did that.

33 Q. Fair enough. And we obviously have the regulations and we can deal with that as a legal matter.

And do you understand that now there is no limit outdoors?

A. They just changed that last week, right? So I don't know what exactly they have said right now. You're saying there is no limit outside?

34 Q. That's correct. Is that your understanding?

A. It is now. I wasn't sure. I didn't know if they had put a limit on it or not.

35 Q. Not on religious gatherings at

least. And indoors the only limit is the number of people who can maintain a two metre distancing. Were you aware that that's the current limit indoors?

A. I believe so.

36 Q. And, of course, you could actually have no capacity limits if everyone at a particular service is vaccinated.

A. I'm sorry, I don't know what you said about the vaccination. Could you repeat that?

37 Q. Were you aware that religious services -- if everyone present at a particular service, so a particular wedding, funeral, Sunday service, if everyone is vaccinated they can have no capacity limits?

A. I was not aware of that.

38 Q. So I just want to ask you some questions about your religious beliefs and what they do or do not permit you to do.

Do your religious beliefs prohibit you from wearing masks?

A. They do not.

39 Q. Do they prohibit you from having social distance between different households at a service?

A. They do not forbid that.

40 Q. Do they prohibit you from keeping contact information of people attending a service so public health can contact trace if someone tests positive?

A. They do not forbid that.

41 Q. Do they prohibit you from getting vaccinated?

A. That is against our conscience belief, yes.

42 Q. And are you yourself vaccinated?

R/F MS. BILDY: Objection. Irrelevant.

MR. HUNTER: I have your refusal.

BY MR. HUNTER:

43 Q. Do they prohibit you from complying with fire code capacity limits?

A. They do not.

44 Q. Now, your Sunday services they run about an hour usually; is that right?

A. No more than that. So right around an hour and a half to two hours.

45 Q. And generally I think you have an assistant pastor or someone who generally starts off with some singing perhaps with the choir?

A. We would say that it's the song

leader. The song leader starts off with the group, they start singing, yes.

46 Q. And then you'd come in and -- you or someone else who is preaching that week would give the sermon?

A. That's correct.

47 Q. And that's usually about 20, 30 minutes?

A. Around that. I mean we're not set to a certain time, but it's around 30 to 45 minutes.

48 Q. And, you know, you often have -- I think you have a couple different choirs at your church; is that right?

A. It's maybe a children's choir and then the main choir.

49 Q. And the main choir is young adults and also older adults?

A. That's correct.

50 Q. And when you're speaking I think it's fair to say you're a pretty animated speaker?

A. I think so.

51 Q. You speak loudly when you're preaching?

A. Yeah, I do.

52 Q. Maybe even shout a bit?

A. It depends on how it goes. If I really get going I might shout a bit.

53 Q. And I think I've even seen a few times spitting so much you need to wipe your mouth with a napkin?

A. Yeah, that has always been my problem. When I speak there's not a lack of moisture.

54 Q. It's the German background, a lot of fricatives, right, in the speech?

A. (Laughs).

55 Q. So I'm going to ask some questions about some of the services that have been held, just some of the things that were said, and I'm not going to take you to the videos, they're on your YouTube channel, they're in the record, but I'm just going to kind of go through them in chronological order and ask you some questions and, you know, tell me what you can remember.

So do you remember back January 24th, 2021 you were holding a drive-in service in the parking lot of the church, and at the time that was legal as long as people stayed in their cars and stayed distanced from each other. And do you

remember telling the congregation, "If you feel like you can't stay in your vehicle this morning, if you just can't do it, Biblically I cannot forbid you"?

A. That is correct.

56 Q. And then after you said that, you know, probably over 100 people got out of their cars; is that correct?

A. That's correct.

57 Q. And they were standing next to each other. There wasn't any distance really between the occupants of different cars.

A. I mean the distance was there because the parking lot is large. So they were not like just huddled close together, because we have a large parking lot and there's a lot of space.

58 Q. But there wasn't two metres distance between different cars' occupants?

A. You're saying between the cars or the people?

59 Q. So there's people in each car, correct?

A. Yes.

60 Q. They got out of their cars. And there wasn't two metres between them and the people

from the next car?

A. I mean there was probably more than two metres, because like I said, the parking lot is large. So the space was there to -- they would not have to be close together.

61 Q. I'd suggest to you that there was at least 30 people standing pretty much shoulder to shoulder, and I doubt they were all in one car.

A. Well, I don't recall that they were standing shoulder to shoulder, but they were not staying in their car.

62 Q. They weren't two metres apart from each other?

A. Well, like I said, there's probably more space than that, and I would not claim that they were -- I know they were not all close together.

63 Q. Let's talk about you then. You walked around the parking lot hugging and shaking hands with people, right?

A. Correct.

64 Q. And you weren't masked?

A. That's correct. I'm never masked when I preach.

65 Q. And they weren't masked?

A. That's correct, most of them were not.

66 Q. And then you proceeded to give a sermon kind of in the middle of the parking lot. And I think at one point you told the congregation that Joe Biden wants you to get on your knees and wear masks, and you referred to them as muzzles to show that people are peasants. Do you remember saying those things?

A. No, sir.

67 Q. Is it possible you said those things?

A. I don't believe so. I don't recall.

68 Q. But it's possible?

A. I do not believe that I said that.

69 Q. And after you were done preaching you invited everyone to come inside the church for what you called at the time a tour?

A. I did say that.

70 Q. And so probably about a hundred or so people came into the church?

A. I believe that would be correct.

71 Q. And they were all crowded together in the pews?

A. Well, spread out throughout the whole building.

72 Q. But there wasn't two metres between each person, was there?

A. Well, there's a possibility that they were, because the room is there.

73 Q. But there in fact wasn't? At least some of the pews had like 10, 12 people in them?

A. It's possible. I don't recall just how they sat.

74 Q. And then you led the congregation in a prayer?

A. Correct.

75 Q. And then you and everyone else, or at least a large proportion of everyone else sang Joy to the World together?

A. That's correct.

76 Q. No one was wearing masks?

A. I do not recall if they were or not.

77 Q. At least a large proportion of people were not wearing masks?

A. That's correct.

78 Q. And after you sang the hymn you

said, "I forgot to tell you there were masks at the entrance to the church", that's correct?

A. I thought I had said that right at the beginning when we came in, but I don't recall where I said it.

79 Q. But you do recall saying it?

A. I do recall saying it.

80 Q. And do you recall the congregation all laughing when you said that?

A. They do that often. So I don't know in this particular situation they did or not.

81 Q. Let's talk about some of the other services that you held after that. So on January 31st do you recall holding a service that was advertised as a drive-in service but in fact was held indoors?

A. I do not recall that it was -- that it was different than what he had advertised.

82 Q. Do you recall holding it indoors on that date?

A. I do not recall. I don't know the dates when it was, but I do not recall that we would have advertised it as drive-in and had it indoors.

83 Q. So if it was marked on the

church's Facebook group as drive-in but it was in fact indoors, you don't recall that?

A. I do not recall that, because we usually advertise our services as they will be held.

84 Q. So on February 2, 2021 you held another drive-in service. And do you recall a choir -- it was young adults, so I don't know if they're teenagers or 20-somethings -- but standing together? There's a podium set up when you're doing a drive-in service, right?

A. Correct.

85 Q. And so they were standing up by that podium singing to the congregation, do you recall them doing that?

A. That's correct.

86 Q. And they were not two metres apart from each other?

A. Yes, they were. We had it marked with an X on the platform.

87 Q. And they weren't wearing masks?

A. That's correct. Not while they were singing.

88 Q. And on March 28, 2021 -- and now at this point, to be clear, I don't think there was

any gathering restrictions, but there were still other public health restrictions in place. Do you remember having an indoor service with a choir of about 50 people, I'm guessing it was a guest choir of some kind, singing together at the front of the church?

A. No, we never had that many people. Our podium doesn't hold 50 people.

89 Q. Okay. So I have to admit, I'm somewhat confused, because there was a video on your church's Facebook group, and then you were -- it looked like you were in it. So let's just see if we can pull that up then. Give me one moment, please.

Why don't we just go off the record for a minute? It's going to take me a second to find it.

--- Off-the-record discussion.

BY MR. HUNTER:

90 Q. I'm just going to share my screen, Pastor Hildebrandt. Can you see my screen?

A. I believe I do.

91 Q. And so this is a video from Facebook.com/Aylmer Church of God. That's your church's Facebook group, correct?

A. Correct.

92 Q. And it's marked Church of God at Aylmer live March 28th.

A. All right.

93 Q. I'll just let it play for a minute.

So you see there's a choir singing, correct?

A. That is correct.

94 Q. Is this your church?

A. No, sir.

95 Q. So is this a video or something that you were playing?

A. It's a video that we were playing.

96 Q. Very good. My apologies then. Can't tell when it's all on Facebook.

A. Understand.

97 Q. So moving on then. On April 25th, 2021 you held a service indoors where people were not maintaining two-metre distance, and you said, "Now we still have people coming in. Would you feel offended if I asked you just to squeeze together a little bit?" Do you recall saying that?

A. I do not recall the date, but it's possible that I said it.

98 Q. So on May 16, 2021 you held an outdoor service with hundreds of people, do you remember that?

A. Yes, sir.

99 Q. And they were not distancing?

A. We had it set up where there was room for everybody. Because we have a large property here, there was room for everyone. We had the pews set up where everyone could sit distance.

100 Q. They could distance, but it's just that in fact many of them were not distancing; would you agree with that?

A. Families sat together, but the pews were set up where they were able to distance.

101 Q. And, of course, by families you don't necessarily mean members of the same household, do you?

A. Yes, I mean by the same household. But we did not forcefully separate people, no, we didn't.

102 Q. And they weren't wearing masks?

A. That's correct.

103 Q. During that service you asked for any burley men who are not soy boys to come forward; is that correct?

A. Yes, sir.

104 Q. And about 50 to 70 men came up to join you at the front?

A. I believe so.

105 Q. And they were all surrounding you, hugging, cheering, flexing their muscles?

A. I don't know flexing their muscles, but I heard them cheering, yes.

106 Q. And they were quite close to you, correct?

A. That's correct.

107 Q. They weren't physically distanced from each other?

A. No, not that I know of.

108 Q. And they weren't wearing masks?

A. No, sir.

109 Q. And I understand you had similar gatherings with hundreds or maybe more people May 23rd, May 30th and June 13th, do you recall those?

A. Like I said, I don't recall the dates. I don't keep track of the dates like that, but it's possible.

110 Q. You remember having services in May and June of this year, correct?

A. Correct.

111 Q. And there was hundreds of people at each of those services?

A. That's correct.

112 Q. And they weren't masking?

A. Some come masking, but most of them not.

113 Q. And many people were not keeping two metres distance from each other?

A. Like I said, we set up the pews where the distance was there after that, and we told them that that was required, and after that it was up to them what they were going to do.

114 Q. And you had choirs singing at those services?

A. Yes, we did.

115 Q. And the choir members were not socially distanced from each other?

A. That's correct.

116 Q. Now, sometimes you use some fairly inflammatory language in your sermons; would you agree with that?

A. I don't mean to, but sometimes it comes across as that.

117 Q. And sometimes your blood just boils and you use some language that might fire

people up, right?

A. A little passionate.

118 Q. And I think you stated at some times that Covid's a conspiracy made up by Klaus Schwab, Prince Charles and Bill Gates?

A. Well, they definitely had a part in it, but I wouldn't say that it's just them.

119 Q. So there's other people in the conspiracy too in your view?

A. Well, I actually don't have any conspiracy theories left because they used all of them.

120 Q. And in your sermons you've referred to quarantine hotels as concentration camps?

A. I believe I did.

121 Q. You refer to the police as the Gestapo?

A. I don't recall that I said that in a sermon, but it's possible that I said it.

122 Q. Or outside of a sermon?

A. That's right.

123 Q. And, in fact, even in your affidavit you call your fellow townspeople Stasi informants.

A. No, I didn't call them that, but I did say that it was very, very unfortunate that the people in our own town would tell on each other and getting each other in trouble.

124 Q. So can I take you to paragraph 15 of your affidavit? It's on page 4.

A. Sorry, which paragraph did you say?

125 Q. Fifteen. It's the second paragraph on page 4.

A. Yes, got it.

126 Q. And you say:

"Some townspeople, who behave like Stasi informants, as they regularly harassed our church every Sunday." [As read]

Is that what you swore under oath?

A. That's correct.

127 Q. And, of course, the Stasi were the East German Secret Police, correct?

A. That's right.

128 Q. Thank you.

Can we go off the record, please?

--- Off-the-record discussion

--- Recess at 2:27 p.m.

--- On resuming at 2:31 p.m.

MR. HUNTER: Thank you, Pastor Hildebrandt. Those are all my questions.

THE DEPONENT: You're welcome.

MS. BILDY: I have no re-direct.

MR. HUNTER: Let's go off the record then.

--- Off-the-record discussion

---Whereupon the proceedings adjourned at 2:30 p.m.

REPORTER'S CERTIFICATE

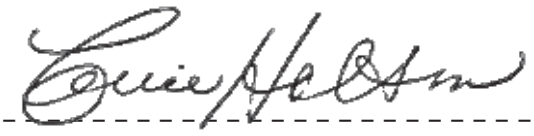
I, CONNIE A. HOLTON, CSR, Certified Shorthand Reporter, certify;

That the foregoing proceedings were taken before me at the time and place therein set forth, at which time the witness was put under oath by me;

That the testimony of the witness and all objections made at the time of the examination were recorded stenographically by me and were thereafter transcribed;

That the foregoing is a true and correct transcript of my shorthand notes so taken.

Dated this 23rd day of December, 2021.



Per: Connie A. Holton, CSR
